Abstract

Objective: This study experimentally investigated whether the effects of three different coping programs designed to reduce test anxiety were due to the predominant component of participants' anxiety. *Design:* The study involved 259 participants, high text anxiety university students, real clinical cases collected and studied during eight years. The experimental sample was finally composed of 94 selected participants with irrational test anxiety. The experimental factors were: *Therapy* (intra-subject factor, pre and post- intervention), *Treatment* (cognitive, physiological and cognitive-physiological), *Worry* (high-low) and *Emotionality* (high-low). *Measures:* Several anxiety questionnaires (TAS, TAI, ITA, CI, STAI) were used as indicators of anxiety. *Results:* Using confidence intervals, we found evidence of changes in the level of measured anxiety in varied degree in the

different Worry and Emotionality groups. *Conclusion:* The three different training programmes reduced test anxiety but did not lead to reductions on the same scale in pre-test anxiety in different groups of emotionality and worry. These results could be decisive in the phase of selection of the most suitable treatment for the patient along the therapeutic process.

Keywords: worry; emotionality; test anxiety; treatment; university students; state-trait anxiety.

Resumen

Objetivo: Este estudio investigó experimentalmente si los efectos de tres programas diferentes de afrontamiento, diseñados para reducir la ansiedad ante los exámenes, se deben al componente predominante de la ansiedad de los participantes. *Diseño:* El estudio incluyó 259 participantes, estudiantes universitarios con alta ansiedad

Resumo

Objetivo: Este estudo pesquisou experimentalmente se os efeitos de três programas diferentes de enfrentamento, desenhados para reduzir a ansiedade ante os exames, devem-se ao componente predominante da ansiedade dos participantes. *Desenho*: O estudo incluiu 259 participantes, estudantes universitários com alta ansiedade ante os exames, casos clínicos reais recolhidos e estudados durante oito anos. A amostra experimental ficou formada por 94 participantes selecionados com ansiedade irracional ante os exames. Os fatores experimentais foram *Terapia* (fator intra-sujeito, pré e pós-intervenção), *Tratamento* (cognitivo, fisiológico e cognitivo-fisiológico), *Preocupação* (alta-baixa) e *Emocionalidade* (alta-baixa). *Medidas*: Vários questionários de ansiedade (TAS, TAI, ITA, IC, STAI) foram utilizados como indicadores de ansiedade. *Resultados*: utilizando intervalos de confiança, encontramos evi-

dência de mudanças no nível de ansiedade medido em um grau variado nos diferentes grupos de Preocupação e Emocionalidade. *Conclusão*: os três programas de treinamento reduzem a ansiedade ante os exames, mas esta redução não se produz na mesma medida nos diferentes grupos de emocionalidade e preocupação. Estes resultados poderiam ser decisivos na fase de seleção do tratamento mais adequado para o paciente ao longo do processo terapêutico.

Many college students need to solve the problem that causes them test anxiety (Cunha & Paiva, 2012; Escalona & Miguel-Tobal, 1996; Lowe & Ang, 2012; Miralles & Hernández, 2012; Orejudo, Herero, Ramos, Turrado & Nuño, 2007). The importance of the negative consequences that this type of anxiety has on students (Amutio & Smith 2008; Bonaccio, Reeve & Winford, 2012; Conley & Lehman, 2012; Gutiérrez-Calvo, 1996; Miralles & Sanz, 2011; Nemati & Habibi, 2012; Polo, Hernández & Pozo, 1996; Szafranski, Barrera & Norton, 2012) makes it necessary to implement treatment programs to control this type of anxiety and develop effective therapeutic methods that are based on studies of their effectiveness (Zeidner, 2007).

Emotion-oriented behavioral interventions are mainly effective in the reduction of the emotional component of test anxiety. Cognitive interventions appear to be more successful than the behavioral interventions in the reduction of the responses of test anxiety, both in emotional and cognitive components. Despite of this fact, by themselves in isolation, these two types of intervention (behavioral and cognitive) do not seem to improve performance. Cognitive-behavioral combination seems to be the most effective intervention in the treatment of test anxiety (Allen, 1980; Ergene, 2003; Erwin-Grabner, Goodill, Hill & Neida, 1999; Escolar & Serrano, 2012; Hembree, 1988; Hernández,

Pozo & Polo, 1994; Paulman & Kennelly, 1984; Serrano & Delgado, 1991; Serrano, Escolar & Delgado, 2002; Sharma, 2002; Spielberger, Gonzalez & Fletcher, 1979; Vagg & Spielberger, 1995).

On the other hand, different studies seem to support the effectiveness of study skills training combined (not implemented in isolation) with cognitive, behavioral or cognitive-behavioral therapy to improve performance and decrease test anxiety response (Ergene, 2003; Erwin-Grabner et al., 1999; Escolar & Serrano, 2012; Furlan, Sanchez-Rosas, Sebastián-Piemontesi & Illbele, 2009; Hernández et al., 1994; Miralles & Hernández, 2012; Miralles & Sanz, 2011; Sapp, 1999; Sharma, 2002; Spielberger et al., 1979; Vagg & Spielberger, 1995).

While many intervention programs have been effective in reducing test anxiety, it is also true that the type of intervention most appropriate for a particular patient type is not yet firmly established. In this respect, Zeidner notes that:

Furthermore, despite earnest efforts by practitioners to individualize treatments to the particular needs and problems of test-anxious students, we still do not have clear evidence to indicate which of the various intervention approaches is most effective for particular types of test-anxious students or for treating different manifestations of test anxiety. (2007, p. 178)

Thus, Can, Debory and Eskin (2012) compared the efficacy of systematic desensitization (behavior therapy) and cognitive restructuring (cognitive therapy) in reducing high scores on test anxiety, guided by the hypothesis that cognitive restructuring would be superior to systematic desensitization in reducing the severity of cognitive symptoms of anxiety, while systematic desensitization would be superior to cognitive restructuring in reducing the severity of the physiological symptoms of anxiety. The results showed that both types of therapy were equally effective in reducing the cognitive and phy-

siological components of test anxiety. Finger and Galassi (1977) obtained similar results. However, other studies have reported that cognitive therapy is more effective than behavioral therapy (Holroyd, 1976; Kaplan, McCordick & Twitchell, 1979).

On these grounds it seems to be necessary to take into account the patient characteristics concerning the different components of test anxiety. In this way, therapy for students who have test anxiety will be optimized.

Our study, responding to this problem, compares the effects of two types of intervention, cognitive and relaxation training, taking into account the levels of worry and emotionality recorded with different instruments for assessing the test anxiety. To this purpose we used the strategy of dismantling a program that includes cognitive training and relaxation. In a previous study (Serrano, Delgado & Escolar, 2010) we presented the results obtained for some of these instruments. Here we present the results obtained with other instruments and we deepen the analytical strategy previously used. We analyze, using different perspectives and methods, part of the general data from previously unpublished research (Escolar, 2007).

Specifically, the objectives of the study were:

1. To test whether different training programs reduce the level of test anxiety as measured on different scales or instruments.
2. If there is a reduction, to prove if it does it occur to the same extent with either of the programs used.
3. If there are differences, to test whether the type of therapeutic intervention has a different impact on the way they face test anxiety depending on the patients main affected variable: worry (cognitive level) and emotionality (physiological level). In accordance with Liebert and Morris (1967), we understand emotionality as the physiological-affective experience generated by autonomic arousal.

4. From the methodological point of view, to re-analyze data more appropriately according to the sample finally obtained.

Conceptualization of test anxiety

In all our research we consider “test anxiety” as a construct based on two facets. The first of these is its nature. We agree with Spielberger and his colleagues (Spielberger, 1972a, 1972b, 1980; Spielberger, Anton & Bedell, 1976; Spielberger et al., 1979; Spielberger, Gonzalez, Taylor, Algaze & Anton, 1978; Spielberger & Vagg, 1995) who state that it is an anxiety trait specific to certain situations. This implies that people with high test anxiety respond to the evaluative threat for most test situations with a greater increase in their state of anxiety than people with low levels (Serrano, Delgado, & Escolar, 2010; Zeidner, 2007). Recently, other authors have shared this definition of test anxiety (Can, Dereboy & Eskin, 2012; Cunha & Paiva, 2012; Nemati & Habibi, 2012; Piemontesi, Heredia, Furlan, Sánchez-Rosas & Martínez, 2012; Putwain & Sysmes, 2012). The second aspect is the differentiation of types of students who may have test anxiety. Like Naveh-Benjamin, McKeachie and Lin (1987) and Naveh-Benjamin (1991) we differentiate between students without study skills and without self-control skills over their study behavior, and students who have these skills in their behavioral repertoire and put them into practice. In the first case, and alluding to the distinction by Wolpe (1958), we are talking about rational anxiety and in the second case about irrational anxiety.

The present study falls in the field of irrational test anxiety. These are, therefore, students who in test situations, although properly prepare, suffer debilitating fear which has as a consequence low academic performance or even avoidance behaviors (Serrano & Delgado, 1990; Serrano et al., 2010; Serrano & Escolar, 2011; Serrano et al., 2002; Serrano, Escolar & Delgado 2011).

Method

Participants

From 1997 to 2004, 259 university students with test anxiety accessed the services offered by the Psychological Services Unit of the University of Salamanca. The age and sex sample composition, obviously, could not be foreseen. We selected those who did not exhibit other types of anxiety and whose study habits were adequate. The final sample was reduced to 94 cases for which complete records were available. Being actual clinical cases, how many would use the Psychological Care Unit each year could not be determined in advance. Therefore, the annual composition of the sample was irregular. After eight years data collection was terminated. The research was done with the knowledge and written consent of each of the participants.

Measures

To rule out students with other anxiety disorders or with “rational test anxiety” problems, according to our conceptualization of the construct, we used the State-Trait Anxiety Inventory (STAI E/R; Spielberger, Gorsuch & Lushene, 1970) and the Inventario de Hábitos de Estudio (Study Habits Inventory) (IHE; Pozar, 1979) which assesses student work and study habits using four scales. The IHE, according to the split-half method, has a reliability index greater than .91.

To evaluate “irrational test anxiety” in its physiological and cognitive components we used:

- The Test Anxiety Inventory (TAI; Spielberger, 1980) measures the physiological and cognitive manifestations of trait test anxiety. It has a Cronbach alpha coefficient reliability index of .92.
- The Test Anxiety Scale (TAS; Sarason, 1978) measures the physiological and cognitive

manifestations of test anxiety. The test-retest reliability index is .87 (Wagaman, Cornier & Cornier, 1975).

- The Inventory of Test Anxiety (ITA; Osterhouse, 1969) measures the physiological and cognitive response to the test anxiety state. Osterhouse developed it specifically to measure the effects of treatments aimed at reducing test anxiety. Reliability obtained by the split-half method was .92 (McMillan & Osterhouse, 1972; Osterhouse, 1972).
- The Cognitive Interference Questionnaire (CIQ; Sarason, 1984) measures the cognitive response to the test anxiety state. Specifically, it measures the frequency of aversive and task irrelevant thoughts.
- Record the Subjective Units of Anxiety (SUA) manifested by participants, using a scale with values that go from zero (completely relaxed) to 100 (extremely tense).
- Self-report by patients about their current state and performance.

In this article we will refer to the data obtained using the TAS inventories and the CIQ score. To see the data obtained from the TAI and ITA inventories see Serrano et al. (2010).

Procedure

The general procedure was carried out in the following stages:

1. Pretreatment evaluation of situational test anxiety. Students were assessed immediately after taking one of the most difficult exams, according to student, in the first quarter.
2. Application of the program. The intervention is based on the stress inoculation paradigm. Participants in the cognitive therapy group were trained in cognitive restructuring and thought stopping. Participants in the physiological treatment group were trained in relaxation. Participants in

the combined treatment group were trained in relaxation and cognitive training.

The assignment of each person to a type of therapy was carried out using an inter-intra factorial design with two factors and six groups as shown in the diagram in the design section. Originally the patients were treated using conventional therapy (combined). Over time the cognitive and physiological components of the therapy (dismantling) were tested trying to balance the sample sizes. It is important to note that, since this was a therapeutic process and not a randomized experiment, equal sample sizes could not take precedence over achieving the therapeutic end:

1. Later, each group of participants, using the specific skills learned, faced, in imagination, the anxiety arousing situations of their respective anxiety hierarchies.
2. Then, all participants faced in vivo situations when they took their exams (final exams usually from June to July).
3. Post treatment evaluation. Participants were assessed immediately after completing one of the most difficult final exams, according to the student.

Design

The factors considered were:

Therapy. Pre-treatment and post-treatment intra-subject factor data were obtained.

Type of treatment. As noted above: (1) cognitive treatment, (2) physiological treatment, and (3) combined therapy: cognitive + physiological.

Worry. Was obtained by dividing the participants into two groups using the “k-means” partitioning procedure into two clusters according to the variability of the subject on the worry scales of the TAI, TAS and ITA inventories. Thus, (1) high worry and (2) low worry groups were defined.

Emotionality. Was obtained by dividing the participants into two groups using the “k-means” partitioning procedure into two clusters according to the variability of the subject on the emotionality scales of the TAI, TAS and ITA inventories and the CIQ scale. Thus (1) high emotionality and (2) low emotionality groups were defined.

All this results in a mixed factorial design scheme with one intra-subjects variable (Therapy) and three inter-subjects variables (Treatment, Preoccupation, and Emotionality). Given its applied nature and the fact that study was conducted with diagnosed clinical cases that needed psychological therapy, it was not possible to predetermine how many participants would predominate a component of high or low emotionality or high or low worry. Thus, randomization or balancing cases on the factors was not possible. And the cell size of the design could not be equal, or even proportional, which posed difficulties in analyzing the results.

Results

Analysis of Variance was performed using the GLM Repeated Measures in SPSS. The objectives of the study were achieved by analyzing third-order interactions (Therapy \times treatment \times Preoccupation \times Emotionality). Due to the small size of some of the cells, the study power was low and did not meet the usual criteria for statistical significance. But a single value (a single F for third-order interaction) can be regarded as an “omnibus” test, not as a focused analytic procedure) (Rosenthal, Rosnow & Rubin, 2000). A process that allows us to decompose the various integrated simple main effects in this interaction consists of the visual inspection (Cumming & Finch, 2005) of the confidence intervals around the means of the 24 cells of the design.

Larger sample sizes would obtain statistical significance, but getting suitable sizes would mean having prolonged the study many more years. The composition of the sample has already been des-

cribed and justified. Under these conditions, statistical tests with dichotomous decisions and power analysis are particularly poorly suited. Therefore, and for the reasons given above (focused analytic procedure) we chose analysis using confidence intervals.

We have chosen to analyze the differences between the scores before treating participants (pre-treatment) and the scores after treatment (post-treatment). Comparison of confidence intervals for correlated data, such as those coming from repeated measures as in this design, cannot be accurately done without taking into account the correlations. The correct choice, in this case, is to assess the confidence intervals of the differences between the pre- and post-treatment means, or gain scores (Cumming & Finch, 2005). Loftus and Masson (1994) propose another method for estimating the confidence intervals in this type of design, but we consider the calculation of gain scores simplest and best adapted to the problem of eventual improved scores after treatment.

Means and standard errors were obtained with the SPSS GLM program with standard errors adjusted for design features using suitable weights (Federer & King, 2007; Fox, 2008; Kirk, 1995) for the design features. With these values the confidence intervals were constructed using programmed routines in R (R Core Team, 2013) with the “gplots” package (R. Warnes. Version 2.11.0.1).

The data are analyzed and interpreted following the recommendations of Meehl (1997), Cumming (2009), Cumming and Maillardet (2006), and Cumming et al. (2007).

The criterion for statistical significance, in addition, can be replaced with advantage by:

1. The replicability of findings. In this case, replication in the same study with different variables, with consistent results among them. Replicability and consistency is decisive evidence (Beyth-Marom, Fidler & Cumming, 2008; Cumming, 2010).

2. The importance of the therapeutic effects, that is, changes from the point of view of therapeutic goals. Over the years, with these samples and others not related to this study, we have obtained consistent reductions in anxiety. As a concurrent criterion of therapeutic efficacy (importance) of which there is documentary evidence, we can add the qualitative evidence that the participants have communicated to us their subjective feelings of improvement. Let us add to these the attainment of the clinical goal: adequate coping in examination contexts without tension, as a fundamental criterion.

Next, we show the analysis of the variables described in the previous section. The rest of the results, as already noted, can be found in Serrano et al. (2010).

Variable: Trait

TAS-T inventory (total score) that assess the test anxiety trait for emotionality and worry variables together (see figure 1).

In the left panel of the figure, for participants of high emotionality, the differences between the before and after scores for each type of treatment are compatible with zero except for the combined treatment; these differences should be considered significantly different from zero. This is true for participants with high and low levels of worry.

In the right panel of Figure 1, for low emotionality subjects, the differences between the scores before and after each type of treatment are consistent with zero except for high-worry participants who improve with combined and physiological therapies (ranges that exclude the zero value). In cognitive therapy treatment groups there are intervals that include zero although very marginally, at the borders of the interval limit. These results considered concurrently with others that will be explained later are worthy of note.

TAS-W inventory (test anxiety trait, worry component). The results are similar to those encountered with TAS-T. In the graph on the left panel of figure 2 we see intervals that do not include the zero value in the combined treatment for high emotionality participants in the high and low worry groups.

Figure 1. Confidence intervals around TAS inventory total score means

For participants with low emotionality (right panel of figure 2), in all treatments we find differences in the groups of people with high worry, although in a borderline or marginal form for cognitive therapy.

TAS-E inventory (test anxiety trait, emotionality component). In the left panel of figure 3, high emotionality participants, we find results consistent with those previously discussed with TAS-T and TAS-W. In contrast, in the right panel of figure 3,

Figure 2. Confidence intervals around TAS inventory Worry Score means

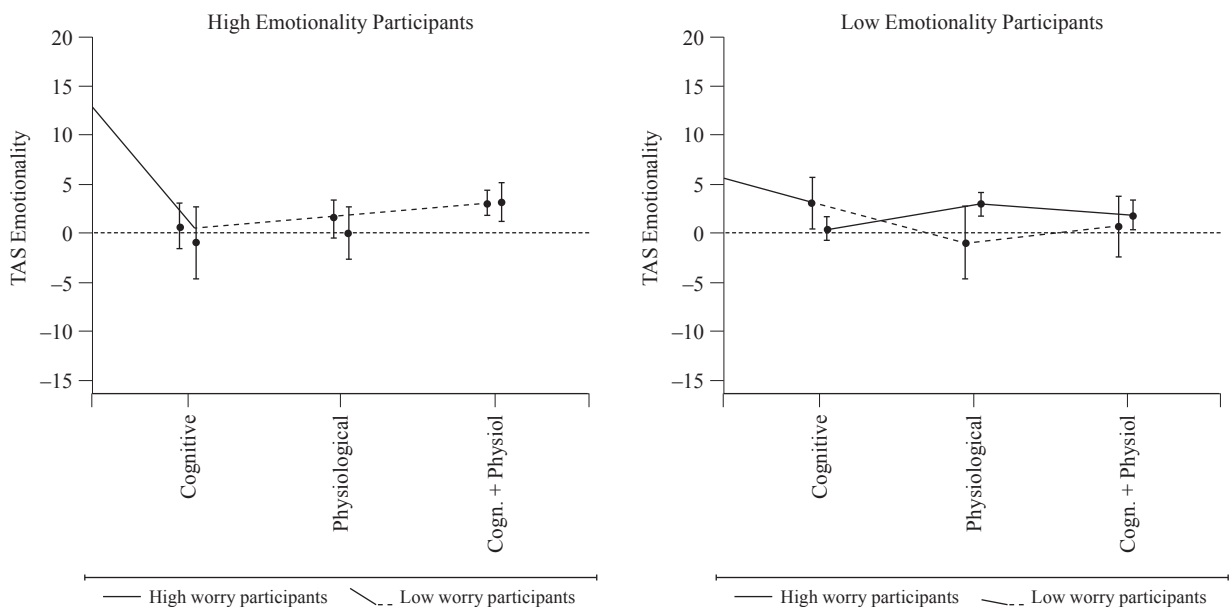

Figure 3. Confidence intervals around TAS inventory Emotionality Score means

for participants with low emotionality, something new is seen: the pre-post-treatment differences for the low worry group are not compatible with the zero value for the cognitive treatment, albeit borderline. They are clearly different from zero in the high worry group with the physiological treatment. They are different from zero, although borderline, for the high worry combined treatment group.

Variable: State

CIQ-T inventory (test anxiety state, cognitive and preoccupation dimension). In the left panel of Figure 4, high emotionality participants, we found the following results: The pre-post-treatment differences do not include the zero value in the high worry combined therapy group. However, in the low worry group, these differences are significantly different from zero with the three therapies although cognitive therapy results are almost bordering on zero, and those of physiological therapy are the most distant from zero.

In the right panel, low emotionality participants, the results are similar but deserve a separate com-

ment. Considering only the means of the interval values, all are greater than zero. The lower variability of the high worry group leaves the confidence interval at the borderline for the high worry combined therapy treatment group. Regarding the low worry groups, once again physiological therapy treatment participants show the greatest pre-post-treatment differences from zero. In those treated with cognitive and combined therapies, incompatible differences are obtained with the zero value but less distant than this one.

Discussion and conclusion

Trait anxiety

Given these results and those reported in Serrano et al. (2010) for inventories assessing worry and emotionality test anxiety traits together, similar results are obtained with different tests and the importance of change is kept. In summary, we found that the combined treatment produces the main improvement in individuals who start out at high levels of worry and emotionality. The

Figure 4. Confidence intervals around CIQ Inventory total score means

same goes for individuals who have high levels of emotionality and low levels of worry. Individuals who initially have low levels of emotionality and high levels of worry improve with physiological and combined therapy but not with cognitive therapy. However, individuals who have low levels of emotionality and worry get slightly more benefit from cognitive therapy than with combined therapy. There is no benefit seen from the physiological treatment.

Analyzing the emotionality and worry dimensions separately, the results are similar. With combinations of high levels of emotionality with high or low levels of worry, combined therapy ensures greater level of improvement. In individuals with low levels of emotionality and high levels of worry the greatest benefit is obtained with physiological and combined therapies. However, individuals with low levels of worry and emotionality seem to benefit most from cognitive treatment, that being said with some caution since the confidence intervals in this group are very broad, probably due to small sample size.

State anxiety

The results, in accordance with Serrano et al. (2010), allow us to conclude for the worry component that in state anxiety before exams, the same interaction appears as in the trait anxiety results although with different nuances. Once again, combined treatment produces only significant improvement for participants with high levels of worry and emotionality. For individuals with low levels of emotionality and high levels of worry combined therapy would also be advisable. That is, whenever we go to treat individuals with high levels of preoccupation we should apply the combined treatment. On the other hand, participants with high levels of emotionality and low levels of preoccupation obtained greater improvement with physiological therapy and slightly less with the combined therapy and lower reduction with cognitive therapy.

Physiological treatment is also more efficient for individuals that start with low levels of emotionality and worry, although cognitive and combined treatments would also be effective although to a lesser extent. These results imply that physiological treatment would be recommended for individuals with high levels of emotionality and low levels of worry as well as for individuals with low levels of emotionality and worry.

Choosing physiological treatment for this type of individual would be supported by those who have shown that people exposed to stressful situations have difficulty executing complex mental operations which deal with stress (Gaudry & Spielberger, 1971). And conversely, relaxation treatment (Hernández et al., 1994; Spielberger & Vagg, 1995) applied during the assessment counteracts the activation state of the individual and reduces subjectively experienced anxiety as well as tension. That is, in these participants, physiological treatment possibly acts positively on the cognitive manifestation of anxiety.

It is true that some studies (Fletcher & Spielberger, 1995; Gonzalez, 1995; Parker, Vagg & Papsdorf, 1995), suggest that cognitively focused treatments have been consistently more successful than emotionally focused treatments in reducing test anxiety and their emotionality and worry components. But it is of great importance to note that none of these studies has considered the prior interindividual variability of these students that we have controlled for.

Therefore, we conclude, in general, that there are differences in efficacy in coping strategies in reducing test anxiety depending on the variable mainly affected. And specifically that:

1. The various training programs do reduce (significantly) the degree of test anxiety.
2. This reduction does not occur to the same extent with the three intervention programs.
3. Proved the existing differences between treatments, participants who present high levels in

any dimension are benefited mainly by combined treatment.

4. However, which treatment should be chosen for individuals with low levels of emotionality and worry depends on if we are more interested in reducing anxiety trait levels or the anxiety state since in the first case we should opt for the cognitive treatment while in the second case we should opt for physiological treatment.

These findings are absolutely relevant and decisive, at the stage of choosing the ideal treatment for the patient throughout the treatment process. In addition, we respond to different authors who such as Martínez-Monteaudo, Inglés, Cano-Vindel and García-Fernández (2012) have concluded, in relation to general anxiety, that the different components of the anxiety response result in differential response profiles, raising the need to evaluate them to determine the precise adjustment of subsequent treatment depending on the response to treatment and the predominant anxiety component in the patient (cognitive, physiological or behavioral). This ultimately, according to these authors, leads to a reduction in the financial and time costs of interventions. In this line, Furlan et al. (2009) note that multidimensional test anxiety assessment would specify the areas in which the symptoms are more pronounced in each student, and adapt intervention strategies accordingly.

Moreover, the conclusions of this study are consistent with other authors such as Miralles and Hernández (2012), Miralles and Sanz (2011), Onwuegbuzie and Daley (1996) and Zeidner (1998) who raise the need to adapt the coping strategy to the type of response mainly affected in each individual, and the possibility of not being successful using the same therapeutic procedures with all students who have test anxiety (Escolar & Serrano, 2012).

Finally, we are aware that every piece or research is merely indicative and barely conclusive (frequently inconclusive). The findings in behavioral research must be replicated, although the repli-

cation rarely is fully (if at all) accomplished (Yong, 2012). In this sense, the present research constitutes a replication of our past research, reasserting what we have previously found with different variables and analytical approaches. This replication is the basis of our confidence on the results presented in this paper. Anyway, we are aware that each result must be taken with caution.

Acknowledgements

The authors thank the Psychological Care Unit at the Faculty of Psychology at the University of Salamanca for starting test anxiety treatment groups and allow us to carry them out. Consequently, we would like to thank the ninety-four students that have been the sample for this research for the trust they have placed in our work as a way to alleviate their fears and anxieties.
