Table 3 - Estimation of a panel World Production Function 2007-2018 by the Fixed Effects Method Dependent variable: l_GDP_pc

As can be seen, the only indices that are significant are those corresponding to Infrastructure and Punctuality. The other four are not significant. The following question arises: Why these results? To answer this question we will carry out an analysis of efficiency in world production using the DEA methodology.

In the production function, from which the efficiency scores are obtained, the specification of the Cobb-Douglas function is used and therefore constant and unit elasticity of substitution between inputs is required.

The question now is to analyse why some countries have high levels of efficiency while others have low levels.

That is, what is the cause of scale efficiency in the countries of the world?

To answer this question we will use the information on logistics and its components provided by the World Bank. As explained above, the model of Simar and Wilson (2007) will be used to study how LPI and its components influence the efficiency of global production.

Table 4 shows the estimated efficiency explained by the LPI synthetic index for 133 countries in the period for which LPI is available, i.e. 2007, 2009 and 2012, 2014, 2016 and 2018.

Variable	Coefficient	Standard deviation	Statistic t	p-value	Sig.

LPI	0.3693917	0.0176201	20.96	0.000	***

Table 4 - Efficiency Estimation with CRS, Simar and Wilson (2007).
Source: Own elaboration based on World Bank data, with STATA.

As can be seen in Table 2 the variable LPI (overallLPI-e) is significant and positive with a value of 0.369. This is when we assume that there are Constant Returns to Scale (CRS).

Table 5 presents an estimate in which the LPI is broken down into its components.

In the following table, the component indices of the LPI are very significant and positive: Infrastructure (LPI1) and Opportunity (LPI4). It can be observed that some component indices of the LPI are not significant such as Customs (LPI2), International Shipping (LPI6) and Tracking (LPI4). In addition the logistics quality index contributes to inefficiency (LPI3).

Table 9 shows that the results for Scale Efficiency are very similar to those obtained in Table 5. The explanation is similar.

Figure 5 presents the Efficiency of Scale results for countries around the world.

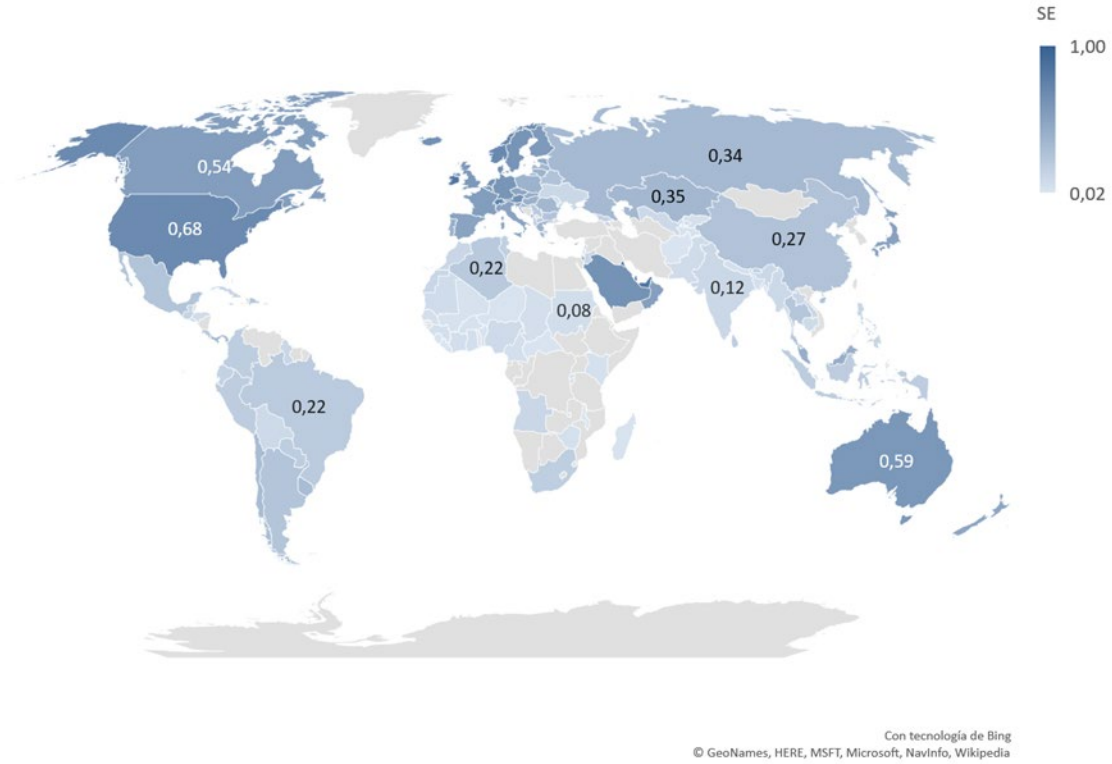

Figure 5 - Efficiency of scale ranking for the world's countries for the year 2018 Source: Own elaboration based on the estimation of a production function of world GDP by country explained by physical capital, human capital and employment.

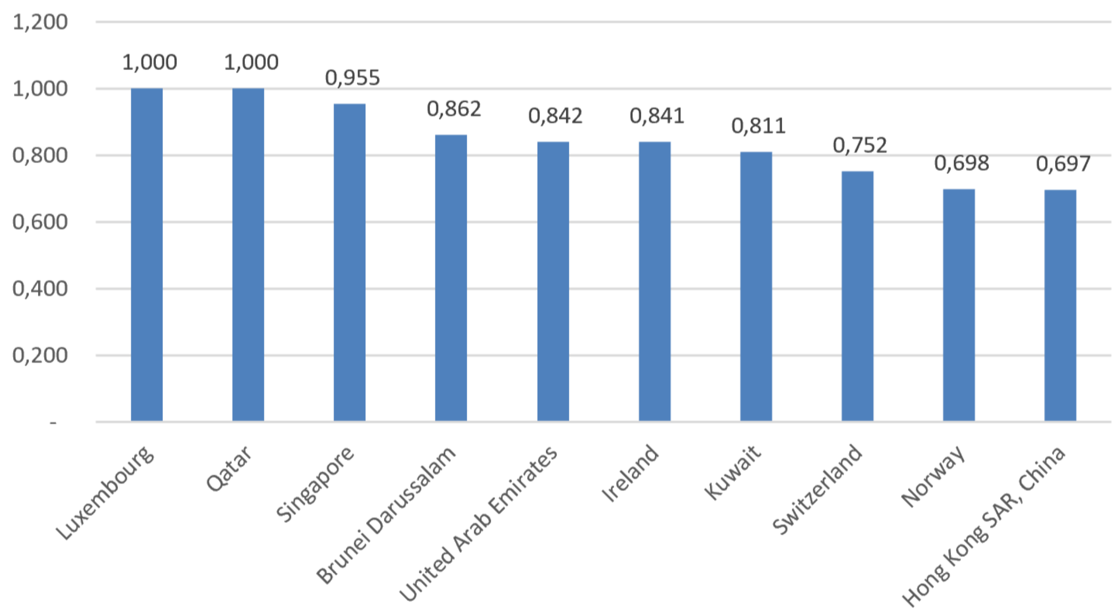

Figure 6 - Top ten countries in the world with the highest Efficiency of Scale in 2018 Source: Own elaboration based on the estimation of a production function of world GDP by country explained by physical capital, human capital and employment.

It can be seen that Qatar, Luxembourg and Singapore are the countries with the highest production scale efficiency (Figure 6), while Congo, Liberia and Gambia have the lowest production scale efficiency levels (Figure 7).

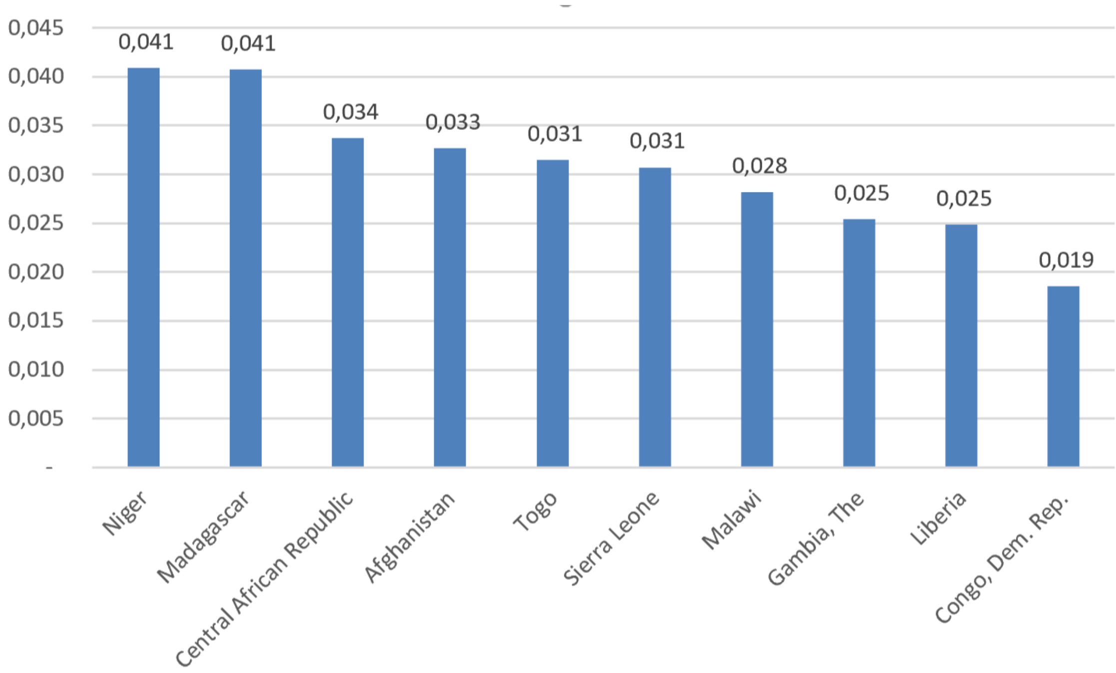

Figure 7 - Top ten countries in the world with the lowest Efficiency of Scale by 2018
Source: Own elaboration based on the estimation of a production function of world GDP by country explained by physical capital, human capital and employment.

Note that Scale Efficiency is defined as the quotient between Efficiency with Constant Returns to Scale and Efficiency with Variable Returns to Scale. As can be seen the results for Scale Efficiency are consistent with those for Efficiency at Constant Returns to Scale.

Logistics (LPI) has a positive sign and is statistically significant at the 1 % level, indicating that its impact on efficiency is positive and helps individual countries to approach their production frontier. Therefore, we find that countries with a high degree of logistical development perform well because of the benefits they gain in terms of scale efficiency.

As for the impact of LPI performance on Global Efficiency of Scale, the estimated LPI coefficient suggests that a 1 % increase in LPI performance increases the efficiency of scale of the world's countries by 0.42 %.

The results confirm that it is the right combination of non-isolated LPI components that causes the growing importance of networks in the evolution of the global economy.

These results also have important policy implications.

Policy makers can use preferential policies to encourage innovation and logistics activities and thus improve their productivity. In addition, governments should facilitate networking activities and develop the necessary infrastructure to encourage the establishment of logistics activities.

As noted by Rollery Waverman (2001), an adequate and reliable supply of infrastructure (e.g. infrastructure associated with communication and transport) facilitates mobility and efficient allocation of inputs as well as final products, reduces transaction costs and improves productivity.

6. CONCLUSIONS

Logistics has allowed the reduction of transport costs, facilitating the growth of the world economy through the use of logistics networks and platforms. Using a production function of the type proposed by Mankiw et al. (1992) the scale efficiency of 133 countries for the period 2007-2018 has been estimated through the DEA method and the application of the Simar and Wilson (2007) model.

This paper contributes to the literature by estimating the contribution of logistics to the scale efficiency of countries around the world. Therefore, to improving the state of knowledge on the impact of logistics in the world. This research is the first to document that logistics performance as measured by LPI (as the sole explanatory variable of efficiency) increases productivity through improved scale efficiency. It also includes as a novelty the breakdown of each of the components of LPI as explanatory factors of scale efficiency.

The results highlight the significant impact of logistics on global scale efficiency. Available data from the World Bank show that a 1 % increase in the logistics performance index increases the current global level of scale efficiency by 0.42 %.

There are substantial variations in the level of efficiency among the countries in the sample. Qatar, Luxembourg and Singapore achieve the highest technical efficiency. Congo, Liberia and The Gambia, on the other hand, have the lowest levels of scale efficiency in production.

In the empirical study, an estimation of the world production function has been carried out first. Here a panel data estimating a Cobb-Douglas type production function has been used.

In this first estimation, only the infrastructure quality index and the punctuality index are significant. The rest of the logistic components are not significant. I then carried out a more detailed non-parametric analysis using linear programming techniques with a DEA.

The results obtained with this second method verify the previous ones and also indicate that the logistic quality index goes from not being significant to being significant and having a negative sign. This means that logistics quality is currently a barrier to global production.

The results are meaningful and useful for policy makers. The different components of the synthetic LPI index show different results, allowing governments to improve the productivity of countries by acting on these components of the LPI.

The results obtained with the DEA methodology in the LPI components reveal glaring inefficiencies in customs processes and formalities, and in the quality and competencies of logistics services, which clearly identify the lack of global logistics. Inefficiencies in international transactions, and in the tracking and tracing of logistics chains could be corrected with blockchain technology, especially in multimodal and intermodal chains.

The results contrasted with DEA analysis indicate that logistics efficiency is positive and significant in its infrastructure and punctuality, significant but negative in logistics quality and not significant in customs, international shipment transactions, and tracking and tracing.

NOTES

1 In this study we use the LPI variable to approximate the level of logistical performance of each country. The World Bank has only published the International LPI for the periods mentioned.
2 See Coelli et al. (2005) for a more comprehensive review of the literature related to efficiency and productivity.
3 Connecting to Compete 2018 Trade Logistics in the Global Economy. The Logistics Performance Index and Its Indicators. World Bank 2018
4 In order to avoid problems of heterogeneity in the sample, only countries considered by the World Bank have been taken into account in the upper middle-income and high-income groups.
5 The capital stock of each country was calculated cumulatively from gross capital formation (in constant 2005 dollars). The methodology of Dhareshwar and Nehru(1994) has been followed.

EUROPEAN MODULAR SYSTEMS PERFORMANCES COMPARISON IN FREIGHT TRANSPORT OPERATIONS

Emilio Larrodé Pellicer
Department of Mechanical Engineering, University of Zaragoza
Victoria Muerza Marín
Department of quantitative methods for business and economy, University of Zaragoza

ABSTRACT

European countries has been working in the last ten years in the implementation of high capacity vehicles in road networks. The EU allowed each member state to use combinations of cargo carriers with a modular concept, the European Modular Systems (EMS). This paper analyses the real behavior in road test of the Euro Modular vehicle of 70 tons of maximum load (called Duotrailer). A route in real conditions is used and comparisons between different vehicle typologies (Trailer, Gigatrailer and Duotrailer) in terms of fuel consumption and emissions are performed. Results in the route tested show that, as expected, the highest consumption correspond to Duotrailers. However, savings with regards to trailers are around 22 % (per ton) and 26 % (per ton and m^3), and savings with regards to Gigatrailers are around 9 % (per ton) and 23 % (per ton and m^3) considering that the charge factor is higher in Duotrailers. Although emissions are higher in Duotrailers, the load capacity is higher.

1. INTRODUCTION

Freight transport is a significant source of CO2 emissions. Hence, to find solutions to reduce the carbon footprint of road freight transport is necessary. The European Modular System (EMS) is a solution that allows combinations of existing loading units (modules) into longer and sometimes heavier vehicle combinations to be used on some parts of the road network. EMS improves road freight transport efficiency and reduces its environmental impact (Acea, s.f.).

The maximum vehicle´s dimensions and combinations, and masses are regulated in the European Council Directive 96/53/ EC revised by European Council Directive 2015/719. The EMS is defined in Article 4, Point 4. (b) of this directive as: "*Member States may allow vehicles or vehicle combinations used for goods transport which carry out certain national transport operations that do not significantly affect international competition in the transport sector to circulate in their territory with dimensions deviating from those laid down in points 1.1 , 1.2, 1.4 to 1.8 , 4.2 and 4.4 of Annex I*". Each country of the European Union have to transpose this directive to its national legislation.

Nevertheless, dimensions, masses and vehicle combinations are not uniform, as each country has taken up this directive with some modifications or different conditions (Jagelčák et al., 2019).

The experience of countries already using high capacity vehicles shows positive results, and CO2 reductions have been confirmed in practice. In the European Union, high-capacity vehicles in the form of combinations of EMS are allowed and used in Belgium, Denmark, Finland, most of the German federal states, the Netherlands, Portugal, Spain and Sweden (Acea, 2019).

The objective of this paper is to test this type of vehicles (70 t) in real conditions within a route in Spain performed by the company “Group Sesé”. Consumption and emissions are analysed in comparison with different vehicle typologies (Trailer, Gigatrailer and Duotrailer).

The rest of the paper is structured as follows. Section 2 presents the background of the study. Section 3 shows the method that has been applied. Section 4 analyses the main results, and finally, Section 5 concludes the main findings.

2. BACKGROUND

In recent years, research in the development and implementation of high capacity vehicles (HCV) has increased considerably in different countries. The “International Transport Forum” in its document “High Capacity Transport. Towards Efficient, Safe and Sustainable Road Freight ”(ITF, 2019) examines the experiences carried out in different countries in this regard, reviews the potential impact on road infrastructure and analyzes the consequences for other modes of transport, industry and society.

Countries such as Australia, Canada, the Netherlands, Finland, Sweden, Germany, the United States, Mexico, Argentina, New Zealand and South Africa have implemented additional regulations (e.g., additional features in vehicle performance, driver qualification, operation under special operations among others). This has allowed the deployment of these vehicles safely, with a positive impact in their public acceptance and by the Administration (Moore et al., 2014).

The precursor countries are Australia and Sweden. Since 2011, they have established different pilot tests in collaboration with the Public Administration. In turn, countries such as Australia, Canada, New Zealand and South Africa are also pioneers in the area, as they have developed Performance Based Standards.

Within the HCV are the so-called EMS. The EMS consists of the longest semi-trailer, with a maximum length of 13.6 m and the longest load support according to class C, with a maximum length of 7.82 m, allowed in the EU. This results in combinations of 25.25 m vehicles. The maximum length in the rest of Europe is 18.75 m. The EU allowed each member state to use combinations of cargo carriers with a modular concept. Sweden and Finland can combine a long and a short module, while in the rest of the EU only transport with two short or one long modules is allowed alternately. When using EMS, the volume of the three EU combinations can be transported by two combinations of EMS (TFK, 2007). See Figure 1 for more detail on this concept.

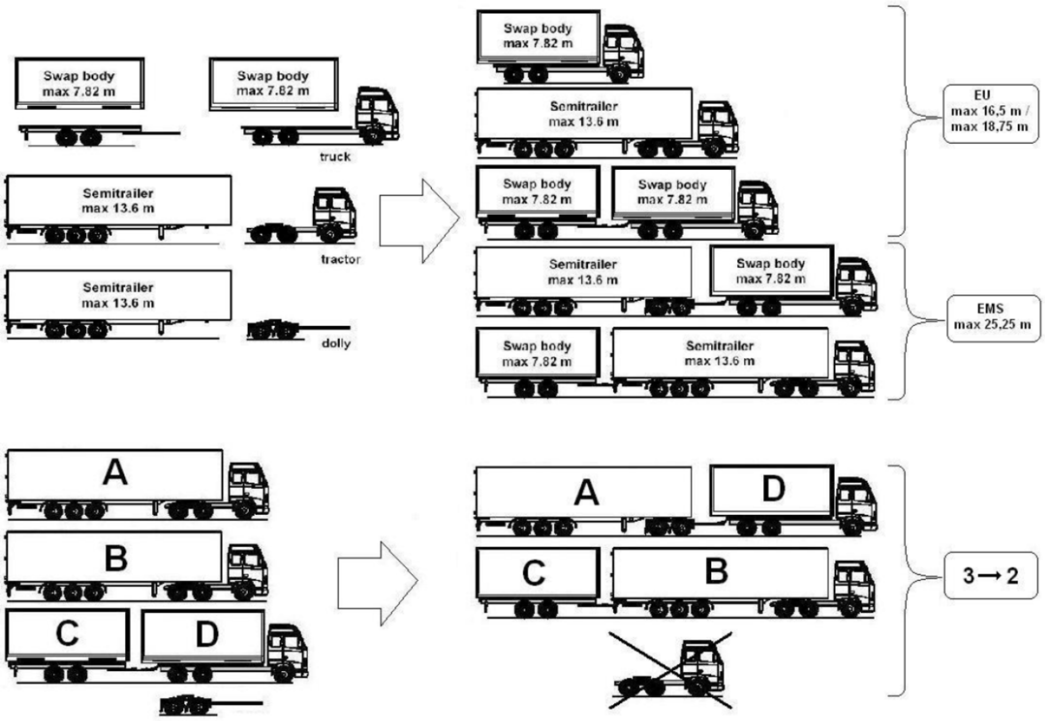

Fig. 1 – EMS configuration. Source (TFK, 2007)

In Finland, the experience in the use of high capacity vehicles nowadays includes 100 million km traveled, more than 300 km of transport annually, mixture of light cargo and food. In 2018, use of vehicles of dimensions 450x25.25 m and 60/ 64t. In 2023, it is expected to use 200x32-34m and 76t A-double vehicles and 120x 28-31m 64-76t vehicles + full trailer/ dolly + semi-trailer. As a result it is expected to obtain 25% less driving, and 15% less emissions (Lahti, 2020).

3. METHOD

The methodology proposed in this research consists of three steps: (1) the selection of the type of vehicles to be used, (2) a set of driving tests in real conditions considering a route and different load configurations, and (3) comparison in terms of consumption and CO_2 emissions.

3.1 Selection of type of vehicle

Different types (T) of vehicles were selected to compare results within a route (see Figure 2):

(1) T1: Trailer (conventional truck) of 16.50 m total length. Free movement on the Spanish road network.
(2) T2: HCV called Gigatrailer of 25.25 m total length. Free movement on the Spanish road network.
(3) T3: HCV called Duotrailer of 31.75 m total length. Subject to strict regulations and circulation under license by the Administration.

Tests were carried out with T3 vehicles (Duotrailer). Two types of Duotrailer were selected for the tests: 9 axle vehicles and 10 axle vehicles. The selection of vehicles tried to consider not only weight restrictions in Spain but also in Finland as a pioneer in the research and use of HCVs from many years. The maximum weight allowed in this country is 75 t. With this weight, a dolly of two axles is needed for the transport operation. On the other hand, tests in Spain are limited to 70 t and a one axle-dolly would be enough for the transport operation.

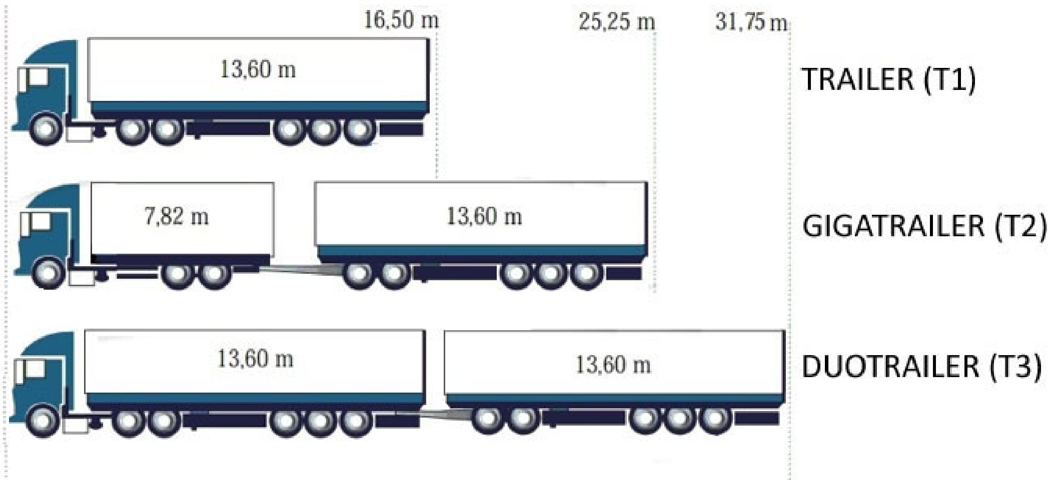

Fig. 1 – Comparison of vehicles within the route used for tests

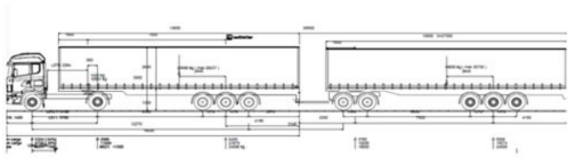
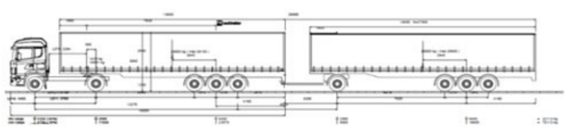
The characteristics of the Duotrailer vehicles in terms of power, maximum authorised mass (MAM), technically permissible maximum masses (TPMM), and total length of the Duotrailer are shown in Figure 3 according to the tractor unit, semitrailer 1, dolly and semitrailer 2.



10 axle Duotrailer set



9 axle Duotrailer set

Typology	Power (kW) Tractor unit (T)	MAM (kg)	TPMM (kg)	MAM (kg) Semitrailer 1 (S1)	MAM (kg) Dolly (D)	MAM (kg) Semitrailer 2 (S2)	Total length (m)	Total number of axles
T3.1	383/427/464	18,000	70,000	35,000	Two axles 18,000	35,000	31.750	10
T3.2	383/427/464	18,000	70,000	35,000	One axle 10,000	35,000	31.750	9

Fig. 2 – Weights and dimensions of the used vehicles (Duotrailer)

Three vehicle configurations (VC) have been used in the tests (see Table 1).

Vehicle Configuration	**T**	**S1**	**D**	**S2**
				
VC1	580 CV (2 axles)	3 axles	2 axles	3 axles
VC2	580 CV (2 axles)	3 axles	1 axle	3 axles
VC3	520 CV (2 axles)	3 axles	1 axle	3 axles

Table 1 – Identification of the vehicles used in the tests

3.2 Driving tests in real conditions

The transport company Group Sesé in Spain performed the tests in real operation. A route was chosen for the use of the Duotrailer vehicle: Azuqueca- Martorell (round trip) with a distance of 552 km (each trip). A load of 13.5 t was transported (30% use of the vehicle). A set of conditions for the vehicles has been stablished:

(1) **Characteristics of the set of vehicles:**

(1a) Tests with 9-axle and 10-axle vehicles.

- Resistance to advance, specific consumption.
- Manoeuvrability, interaction with infrastructure.

(1b) Tests with two available tractor units: 520 CV and 580 CV.

- Optimize energy efficiency.
- Emissions.

(2) **Characteristics of the type of route:**

(2a) Tests with different distances long and short routes.

- Average consumption.
- Energy efficiency.

(2b) Route profile (flat profiles and mountain profiles).

- Energy consumption.

(3) Characteristics of the type of merchandise.

(3a) Type of heavy good.

- Powers, consumption and emissions.

(3b) Type of bulky and light merchandise.

Tests were scheduled along 2018 and 2019. The schedule can be seen in Figure 3. A total number of 150 test were performed.

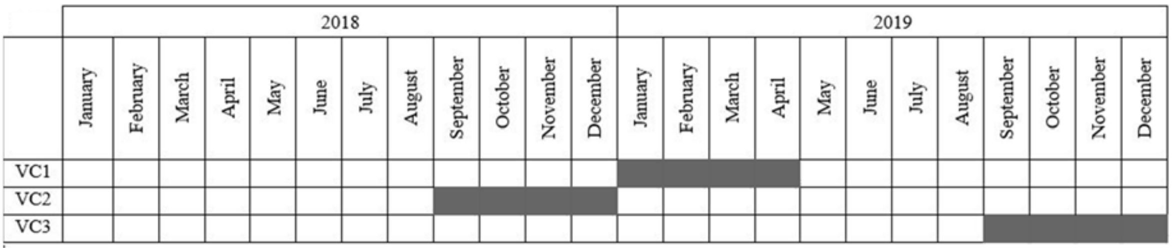


Fig. 3 – Tests schedule

3.3 Comparison of consumptions and CO_2 emissions

A matrix of cases is constructed. The calculation of consumptions has initially considered the following conditions:

- Condition 1: Influence of meteorological conditions:
  - Action of the wind.
  - Consumptions.
  - Ultrasonic wind speed measurement sensors.
- Condition 2: Influence of traffic conditions.
  - Heavy traffic or slow traffic
  - Average consumption.
  - Variation of speed conditions.
  - Considerable increase in braking and acceleration.
- Condition 3: Influence of driving type.
  - Average consumption of vehicles.
  - Short distance routes.
  - Transport of heavy merchandise.

To limit the number of tests to be carried out, the working intervals of each of the factors that were taken into account were established and the following working hypotheses were adopted:

(1) Hypotheses regarding the type of vehicle (HVE):

- Type of connection:
  - HVE1: Dolly of two axles (10-axle Duotrailer).
  - HVE2: Dolly of one axle (9-axle Duotrailer).

- Type of tractor (T):
    - HVET1: 520 CV (383 kW).
    - HVET2: 580 CV (427 kW).

(2) Hypotheses regarding the route (HR):

- Distance (HRD):
    - HRD1: Route of short distance traveled (<600 km).
    - HRD2: Route of long distance traveled (>600 km).
- Profile (HRP):
    - HRP1: Profile of the route with strong ramps accumulated (> 12%).
    - HRP2: Profile of the route with accumulated average ramps (> 5% and <12%).
    - HRP3: Profile of the route with slight accumulated ramps (<5%).

(3) Hypotheses regarding the merchandise (HM):

- Volume transport (HMV): ≤ 33% of maximum payload.
- Load volume (HML): medium load transport (> 33% of maximum payload) and full load transport (> 66% of maximum payload).

(4) Existence of externalities:

- Wind forces.
- Traffic congestion.
- Stressed driving.

The analysis of emissions was performed by using EcoTransIT (https://www.ecotransit.org/calculation.es.html) calculation tool. The tool provides information of emissions in terms of CO_2, CO_2 equivalent, NO_2, non-methane hydrocarbons, particles and distances. In this research, we focus on CO_2 emissions.

4. RESULTS

Table 2 shows the average results in terms of consumption for the route tested using Duotrailers (T3). It can be seen that, on average, consumption is higher for the transport from Martorell to Azuqueca than the road trip even if average payload transported is lower. This is due to the profile of the route.

	Azuqueca-Martorell	Martorell-Azuqueca
Average consumption (l/100km)	39.10	41.47
Average distance traveled (km)	552	552
Average payload transported (t)	14.25	12.75
Average charge factor	2.50	2.60

Table 2 – Average consumption results for T3 in the route tested

Table 3 shows a comparison between T1, T2 and T3 in the same route in terms of consumption savings. However, it has to be highlighted that different charge factors have been considered as the tests have been performed in real operation. The highest consumption correspond to T3 vehicles (Duotrailer). However, savings with regards to T1 vehicles are around 22 % (per ton) and 26 % (per ton and m^3) (mean), and savings with regards to T2 are around 9 % (per ton) and 23 % (per ton and m^3) (mean) considering that the charge factor is higher in T3 vehicles.

		Typologies of vehicles				
	T1(410 CV gas)	T1(450 CV)	T2 (580 CV)	T3 (520 CV)	T3 (580 CV)	T3 (580 CV)
Consumption (l/100km)	24.8	27.1	39.5	38	40.80	41.48
Saving per ton (%)	-	-	13.66	25.1	19.63	20.29
Saving per ton and m^3 (%)	-	-	2.9	29.90	24.87	23.52
Real charge factor	-	-	1.5 (theoretical)	2.53	2.5	2.5

Table 3 – Comparison of consumptions and savings between vehicles

Figure 4 shows a comparison in terms of mass transported and the unladen mass of the vehicles used. Although T3 vehicles (Duotrailer) are heavier, they transport nearly twice load.

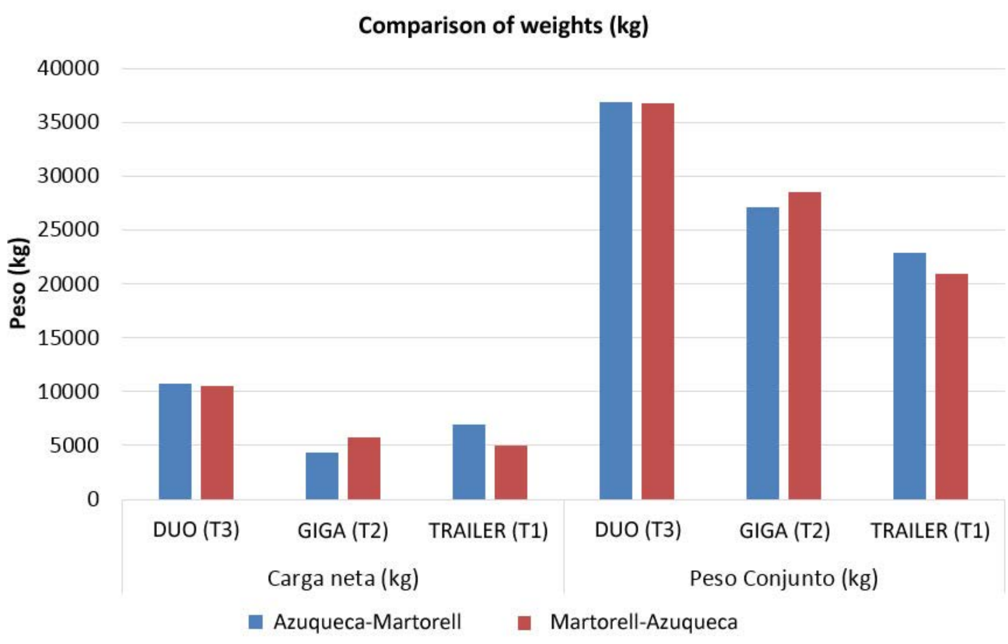

Fig. 4 – Comparison of weights of the vehicles used

Figure 5 shows the differences in total emissions between the three types of vehicles. T3 vehicles (Duotrailer) are the most polluting.

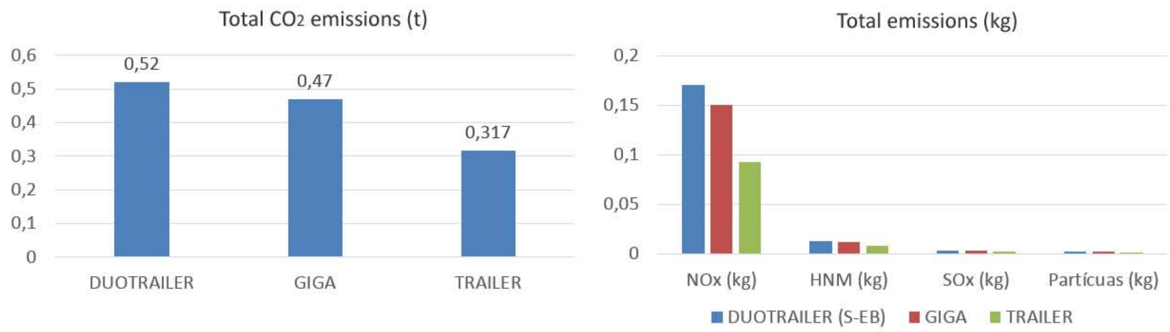

Fig. 5 – Difference of emissions in the vehicles used

Representando las emisiones de CO_2 en función de la masa desplazada y por carga útil.

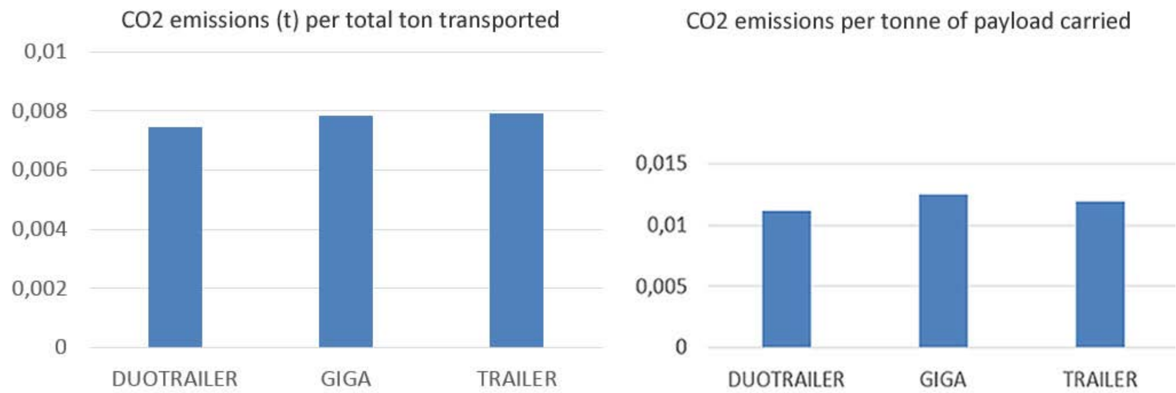

Fig. 6 – CO_2 emissions as a function of the mass displaced by each type of vehicle

5. CONCLUSIONS

In this research, through a set of experimental tests it has been possible to analyze the behavior of EMS vehicles in real road behavior, in this case the Duotrailer vehicles. The data capture and monitoring during the test allows obtaining data from the entire operation and a comparison with other vehicles, both in volume transport and maximum load.

Results are considered positive from the standpoint of the behavior of the vehicle, and the environmental, operational and economic improvement. Other conclusions include:

- The vehicle in terms of dynamics and mechanics behaves properly and its maneuverability is correct in all sections where it has been tested.
- The vehicle has shown safety throughout the test run and no incidents occurred during the tests.

- The vehicle is stable in running behavior and does not show road damage, given its distribution of axle loads.
- The test scenarios performed and their repetition, allows to verify the behavior of the vehicle both in terms of safety, maneuverability and its economic and environmental profitability.

Future research will focus on conducting more tests, in order to assess more possible scenarios, corroborate the results obtained and verify that the vehicle's behavior complies with all safety and effectiveness guarantees in road transport operations.

ACKNOWLEDGEMENTS

This research has been funded by the company Group Sesé through the Sesé Professorship in partnership with the University of Zaragoza.

ABSTRACT

The total amount of kilometres travelled by freight vehicles is expected to triple between 2018 and 2050. Today, 64% of all the trips happen within urban environments. There is, hence, a need for organizing the mobility and the urban freight distribution in a more sustainable way.

E-commerce has taken more relevance in the last years and an important increase of this type of consumption is expected. E-commerce has compelled to modify supply chain strategies and the management of platform distributions. Urban areas, especially old quarters and pedestrian streets are not the best scenarios for deliveries. Streets are narrow and congested, with insufficient space for loading and unloading manoeuvres. The e-commerce is worsening this situation.

One of the possible solutions that have emerged in the last years is the micro consolidation centre, a transhipment point where logistic operators store their goods and transfer them through more environmentally-friendly and smaller vehicles such as cargo bikes, for last mile distribution.

This paper presents the study case of the micro distribution in “Ciutat Vella” quarter (Barcelona) and surroundings. This micro consolidation centre, part of H2020 project, GrowSmarter, is in the oldest and most touristic part of the city, with plenty of narrow streets, and the delivery is made by cargo bikes. During the months from January 2017 to March 2019, where the study case took place, the main key performance indicators of the initiative were tracked and analysed. The results of the analysis showed a reduction of the total number of vehicle kilometres, the amount of CO_2 emissions, energy and noise levels compared to using conventional vans for the last mile distribution.

Besides these direct results, the experience of this case study allows to establish some conclusions and policy recommendations for retailers and city planners in order to implement these types of measures.

1. INTRODUCTION

By 2050, it is estimated that 68% of the world's population will live in urban areas while the global freight demand is expected to triple according to ITF (International Transport Forum) studies (Nations United, 2018).

In the context of freight transport, last mile distribution represents one of the most serious problems in urban areas of large cities. For instance, in Europe, approximately 10-15% of vehicle kilometres (CIVITAS, 2015) are travelled by urban freight vehicles. Moreover, the last mile is considered as one of the most expensive, inefficient and polluting parts of the supply chain. Freight vehicles are responsible for more than 50% of NO_x emissions of the transport sector (Dablanc, 2011). Additionally, the fact that most of the door-to-door deliveries are done by small vans implies that the carbon footprint per kg is higher than that of transport by a bigger truck. This growing number of vehicle and transport needs in urban areas is having a severe impact on cities' quality of life.

In addition to that, today the e-commerce model is fully accepted in almost all societies and is present in all sectors of the economy. The numbers prove it: according to the National Institute of Statistics (INE) and the National Centre of Markets and Competition (CNMC), in Spain the internet sales have grown by 37% from 2014 to 2017. Whereas in the city of Barcelona, in 2017, freight transport represented approximately 21% of total traffic, which in absolute values was about 430.000 daily trips per year (Pimecomerç, 2018).

However, these same figures also indicate that there is still much growth ahead, given that there are other countries that show much higher levels of penetration of e-commerce. In fact, according to Europe last mile data, issued by the European Commission, in the period between 2005 and 2050 the transport of goods will increase by 80% (Commission, 2011).

Undoubtedly, the situation is testing the limits of the infrastructures of our larger cities, which will require the drastic restriction of CO_2 emissions due to the high levels of air pollution as proposed by EEA (European Environment Agency). Consolidation schemes (Janjevic and Ndiaye, 2014) are one of the most popular measures in city logistics. The most common of them being the Urban Consolidation Centres (UCCs).

The key purpose of UCCs is avoiding the need for freight vehicles to deliver part loads into urban areas (Browne, Woodburn and Allen, 2007).

Different cities, mainly in continental Europe, have conducted studies, trials and showed the growing interest in the UCCs (for instance, the UCC case initiatives of Parma in Italy, Huddinge in Sweden and Sheffield in UK) (ProSFeT, 2018).

However, despite their popularity, many researchers have also demonstrated the limits of the Urban Consolidation Centres, the difficulty to implement them in a competitive environment and their limited benefits (Ville, Gonzalez-Feliu and Dablanc, 2013).

Danielis, Rotaris and Marcucci (2010) have demonstrated that in few cases the UCCs survived financially without public subsidies or strong political commitment. Allen (2012) confirms that the success of the UCC is greatly dependant of its type and implementation conditions. The financial considerations are often too complicated and need to be resolved with schemes requiring on-going public subsidies for UCCs that serve part or all of an urban area. UCCs are successful only in specific conditions and most often with structural public subsidies. (Janjevic and Ndiaye, 2014)

Nevertheless, many innovative experiences have been performed in the cities across the globe (for instance, Manchester in UK, Stockholm in Sweden, Helsinki in Finland), offering a large panel of alternative consolidation schemes. In particular, many experiences have focused on downscaling the consolidation effort by grouping goods much closer to the point of reception, whereas UCCs do so outside the boundaries of the urban area.

Generally, these experiences are referred to as “micro consolidation initiatives” where the scale of the consolidation is smaller, and thus the size and weight of transported goods is also smaller.

Micro consolidation initiatives usually involve the urban light freight. In fact, bundling the goods near the reception point requires the setting-up of facilities in the heart of urban areas, making these initiatives unsuitable for heavy loads.

Some of the common characteristics of these micro consolidation initiatives are:

- The aim to reduce the total vehicle trips performed in an urban area (and particularly in most dense areas) by bundling the goods close to the final destination.
- The setting-up of logistical facilities in urban areas.
- Targeting the deliveries of small and light loads (i.e., parcels as opposed to pallets) that can be grouped under the common denomination of “urban light freight”.
- The use of clean vehicles or soft transportation modes (cargo bikes) for the last leg of the delivery.

Using micro consolidation centres located closely to the final destination is a frequent solution for the improvement of last mile delivery and collection. Moreover, there are alternative consolidation schemes. Verlinde, Macharis and Witlox (2012) have provided a first classification of the alternative schemes based on the nature of the measure (behavioural or physical), and a further classification of physical measures that consist of either traditional urban consolidation centres or alternative transhipment points. Whereas, the logistic spaces are classified according to spatial dimension i.e. the size of the urban area that is served, and that can vary from one building or street to a whole city. Some of these measures focus on small urban areas: loading and unloading areas, collection points and smart points.

The objective of this paper is to show the implementation of a pilot case, present the results and draw conclusions for other similar measures. Whereas the overall objective is to demonstrate that, compared to the conventional ways and vehicles used for the distribution of goods in the urban area of the city of Barcelona, the implementation of a new business model such as the micro urban consolidation centre (mUCC) would help reduce emissions as well as vehicle kilometres.

The paper offers a comparison between the deliveries with electric cargo bikes and deliveries with standard vans in urban areas in terms of CO_2 emissions, noise, and energy consumption. Moreover, the paper also presents a description of the business model used for the implementation of the pilot case in the “Ciutat Vella” of Barcelona.

For the purpose of this article, a thorough research has been carried out in order to establish a state of the art and the different types (see Figure 1) of micro consolidation measures currently implemented in the European cities. These types are:

1. Loading and unloading areas consist in setting-up zones where carriers can load and unload the goods destined to the neighbouring receivers. In addition to reducing parking problems and better accommodating trucks, the setting-up of this type of devices also reduces the vehicles-trips to be performed in the delivery area.
2. Collection point (Click and collect) consists in setting-up an urban service where carriers can deliver their goods to a communal delivery point. This service can be used by private or business customers. In addition to providing a new service and allowing off-hours deliveries, these points also aim to reduce the total vehicles-trips in the delivery area by bundling goods at the reception point.
3. The smart points are boxes that bundle the goods at reception and enable the deliveries in the absence of the receivers by setting-up automated lockers. This typology is valid for both business and private customer are currently used in different European cities for the delivery of letters and parcels in absence of the receivers. The lockers can be installed in the streets, residential zones, office

buildings, among others to create new many-to-many hubs between the company and the customers.

4. Micro consolidation centres (platforms) adopt a similar scheme as one of the classical urban consolidation centres - bundling the goods, combined with a fleet of non-polluting vehicles making rationalized rounds. However, as opposed to UCCS, micro consolidation centres are much closer to the delivery area and have a more limited spatial range that is conditioned by the range of vehicles used for the last mile (generally clean vehicles such as such as cargo bikes or light electric vehicles). Furthermore, the bundling of goods usually takes place in a suburban depot from where a consolidated transport is performed towards the micro consolidation centre.
5. Logistic facilities bundle goods and perform consolidated transport to the city centre where a transhipment point (i.e., a loading and unloading area) is used to transfer goods to lighter and more adapted vehicles.
6. Logistic facility in a combination with a mobile micro consolidation centre that is used to perform the consolidated transport of goods towards the urban area and that contains all the necessary equipment and vehicles for the last mile of the delivery.
7. Micro consolidation centres in combination with a Smart Point can be used by different distribution companies at the same time. The purpose of the local distribution station is to reduce the number of delivery vehicles in the city centre and to support carbon neutral logistics. The service is aimed at residents and commuters. Generally, the location of this hub is strategic, in order to make it easy for public transport users and pedestrians to grab a pre-ordered shopping bag from the hub.

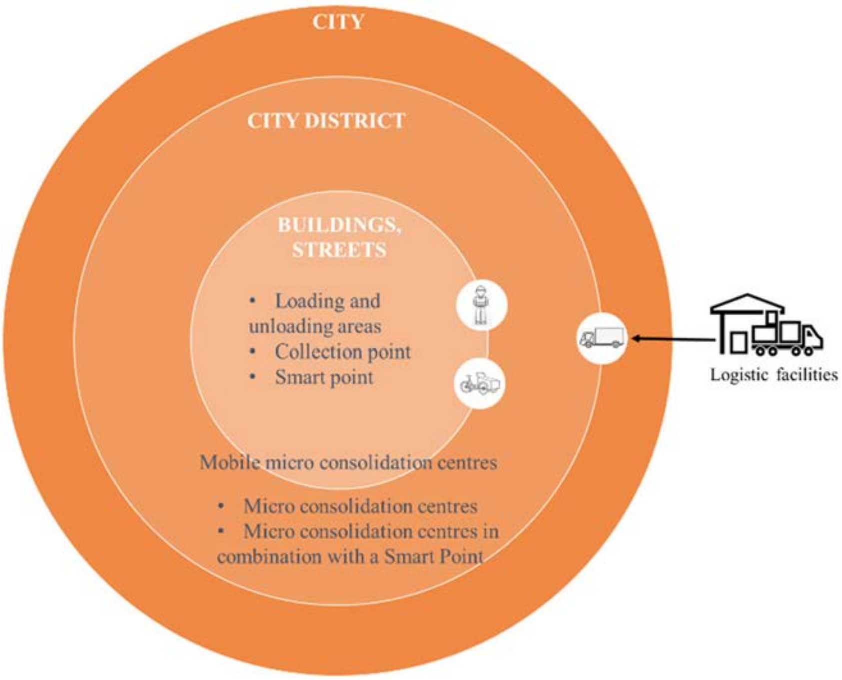

Figure 1: Urban logistic spaces within the city

This paper is based on a study case that analysed a micro urban consolidation centre (mUCC) where transport operators could store their products and transfer them to electric cargo bikes for the last mile urban distribution, covering a high-density area in the old town of Barcelona (narrow streets and stores). The project database was built with data from January 2017 to March 2019.

The remainder of the paper is organized as follows. The second section provides a brief review of the state of the art, giving context to the micro urban consolidation centres. The second section describes the study case in Barcelona. This is followed by the calculations of the key performance indicators, in the fourth section. The fourth section is an assessment of the environmental impacts. Then, the fifth section explains the business model in this study case. The following section offers a discussion of the results and policy recommendations.

2. THE DESCRIPTION OF THE STUDY CASE

Barcelona has opted for micro consolidation centre of goods to incentivize the use of friendlier transport. A consolidation centre was installed next to the "Estació de França" to serve the old town (
Figure **2**). It is an area of 4,49 km2 characterized by narrow streets, high density and an import commercial activity (the majority are small stores and restaurants) with high demand. Moreover, the area is characterized by a lack of parking space. Thus, freight delivery in this area can be critical if carried out by vans. The implementation of the solution was part of the Growsmarter project that ended in 2019.

However, the consolidation centre is still active and running.

The micro consolidation centre operates in the following way:

- The services of the last mile operator (independent operator) can be contracted by any logistics operator.
- The micro consolidation centre, owned by an independent operator, is the place of transhipment of all packages from vans to sustainable vehicles and is also used as a small storage place.
- The last mile distribution is carried out by electric cargo bikes.

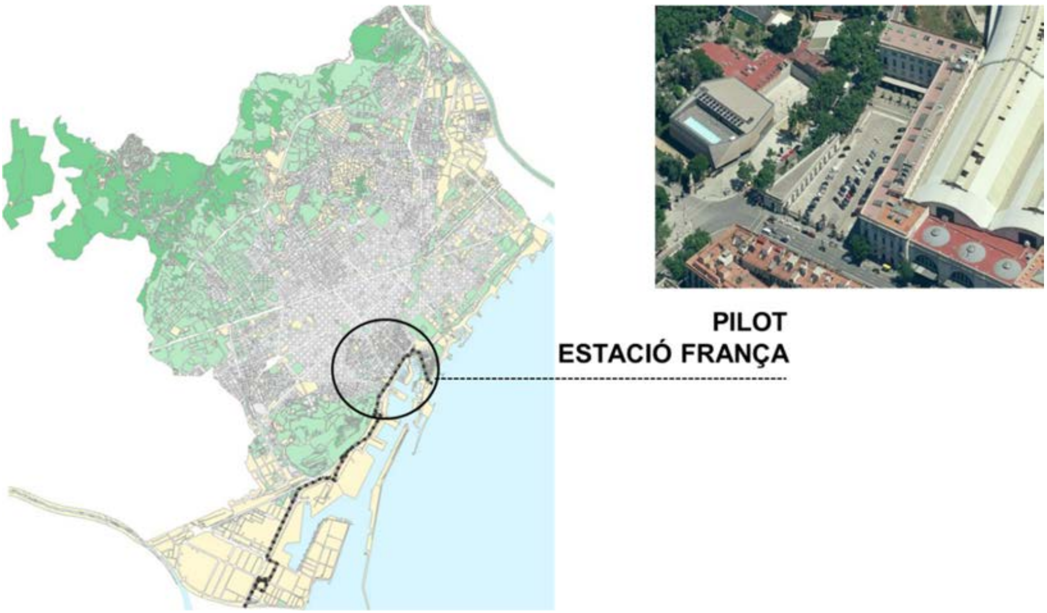

Figure 2: Area of delivery

Carriers bring their packages to the consolidation centre and the last-mile operator handles the delivery of goods to their final destination using electric cargo bikes, thus reducing congestion, diminishing emissions, and lowering delivery times in the highly populated areas as well as reducing costs for conventional carriers. During the implementation of the measure there was an increase in the use of electric cargo bikes, from 3 to 15 vehicles, and a modal shift from vans to electric cargo bikes.

3. CALCULATIONS OF THE KEY PERFORMANCE INDICATORS

The data was collected for a period of 26 months (from January 2017 to March 2019) as part of the Growsmarter project where the last mile deliveries were carried out through the usage of electric cargo bikes.

3.1 Vehicle kilometre reduction

The vehicle-km reduction was calculated as follows:

- It was assumed that, without this last mile delivery service, the deliveries were performed by regular vans. With the new service, last mile delivery was carried out by using cargo bikes, allowing the shortening of the routes, since cargo bikes can run through narrow streets (which do not allow access to regular vehicles).
- From the data collected from the trips, which were provided by the logistic operator involved in the study case, the difference in vehicle-kilometres between the two types of delivery was calculated.
- In Figure 3, it is possible to observe an example of a route in the studied area. As observed, the difference between the two routes (with vans and with cargo bikes) is 1,5 km.

Figure 3: Example route: the route of the van is blue, and the cargo bike route is orange

3.2 CO_2 reduction

An interview with the last mile operator was carried out as part of the study and the information provided by the interviewee was used for the calculations. The interview provided data and information about the number of cargo bikes, number of packages per cargo bikes and type of contract for each logistics company, among others.

In order to calculate the reduction of emissions obtained, a comparison was carried out between the emissions of the electric cargo bikes and the standard delivery vans. These steps were followed:

- The first step consisted of the calculation of the total number of kilometres travelled during the evaluation period (26 months) by cargo bikes taking into account all deliveries. The data on kilometres was provided by the logistic service provider that used GPS to track it. For example, during the Growsmarter project the cargo bikes travelled an amount of 72.183 km.
- The second step consisted in the conversion of the kilometres travelled by electric cargo bikes (calculated in step 1) to the equivalent kilometres that would have been carried out by standard courier services for the same deliveries. The conversion was implemented taking into account the route differences between the vehicles as shown in the example of Figure 3.
- During the third step, the calculation of the energy required by the cargo bikes was carried out. The energy required by the vehicles was represented by the capacity of the electric battery. To carry out the calculations of the energy that the standard services. would have consumed, the Catalan energy mix (Climàtic, 2020) was used.

This mix represents the average value of kg CO_2 emissions that 1kwh of produced energy generates. Two conditions were taken into account for the calculations:

1. The standard courier services (by truck/van) used for distribution produce local emissions.
2. The production of electricity (for cargo bikes) does not generate local emissions (only at the energy production site, if any).

- Finally, the amount of CO_2 emissions by the standard courier services was calculated considering the kilometres travelled as obtained in step 1 and the reference value in kg CO_2/km obtained from EEA (European Environment Agency, 2019) for standard delivery vans.

3.3 Energy saving

To calculate the savings in energy, a comparison between the energy needed for the cargo bikes and the energy needed for standard delivery vans, was carried out.

The energy of the cargo bikes is represented by their capacity. Thus, the total energy needed by the cargo bikes during the evaluation period was obtained by multiplying the capacity by the number of cargo bikes available and the number of working days.

To calculate the energy consumed by standard delivery vans, the total number of kilometres was multiplied by the amount of fuel per km.

Finally, the comparison between the values obtained was carried out. To carry out the calculations, get real values, better understand the practices carried out by logistic operators and cope with the reality of the sector, the interview with the last mile operator was of utmost importance.

3.4 Noise reduction

To calculate noise reduction in the pilot area, a comparison was carried out between the noises emitted by cargo bikes and noise emitted by standard delivery vans.

The number of cargo bikes available for the pilot was 15. Taking into account that approximately 1,5 cargo bikes were needed for each van (information obtained from the interview), the number of vans necessary for the same deliveries would have been 10.

The noise reduction was calculated assessing and comparing the noise a standard van generates in average for each operation (approx. 80 dB) with the noise generated by a cargo bike (approx. 45 dB). Since, decibels are a logarithmic scale, an increase of 10 decibels (dB) is perceived as a doubling of noise volume. The number of decibels from multiple sources cannot simply be added to get the total number of decibels.

If two trucks that produce 80 dB of noise each are passing the same location at the same time, they will produce a total of 83 dB. Table 1shows an approximate scheme for the calculation of the noise from overlapping of multiple sources. The table is accurate within 1 dB of the exact value.

Adding Decibel Amount differ by:	Add this amount to the higher value	Example
0 or 1 dB	3 dB	70 dB + 69 dB = 73 dB
2 or 3 dB	2 dB	74 dB + 71 dB = 76 dB
4 to 9 dB	1 dB	66 dB + 60 dB = 67 dB
10 dB	0 dB	65 dB + 55 dB = 65 dB

Table 1: Example of noise calculation (Rudy Hendriks, Bruce Rymer, David Buehler, 2013)

4. ASSESSMENT OF THE ENVIRONMENTAL IMPACTS

During the study period of 26 months when the data was collected (with the exception of June 2018, because there were contractual changes between the micro consolidation centre company and the different logistics companies), the number of deliveries has undergone large variations as can be observed in Figure 4. Despite the increase experienced during the first 6 months of the year 2017, the summer represented a difficult time for the company.

However, the difficulties encountered were due to the fact that one of the main logistic companies stopped using the micro consolidation centre. This fall was observed only for a few months, and as of October 2017, the number of deliveries carried out raised up again. From this point of inflection, they remained constant for a year. From October 2018 until March 2019, a new company joined and helped double the number of deliveries. During the study period, a total number of 207.000 deliveries was carried out.

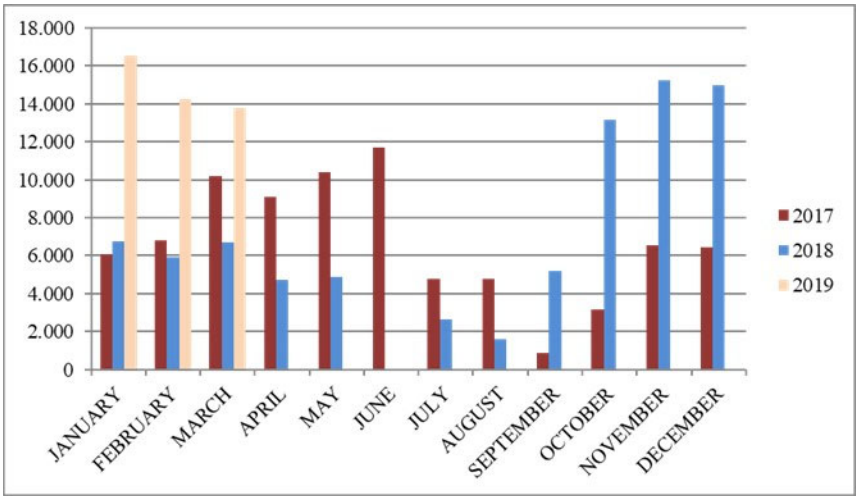

Figure 4: Number of monthly deliveries

Looking the data at a more disaggregated level, the distance between two delivery points is displayed in Figure 5. It can be noted, that with the increase of the number of cargo bikes available, the distance between delivery points decreases. The lower the distance between two delivery points, the more optimized and efficient are the routes, therefore a higher number of packages arrive on the micro consolidation centre for delivery because a higher number of logistic operators employ the service.

The overall average distance between two delivery points during the study period was 427 m.

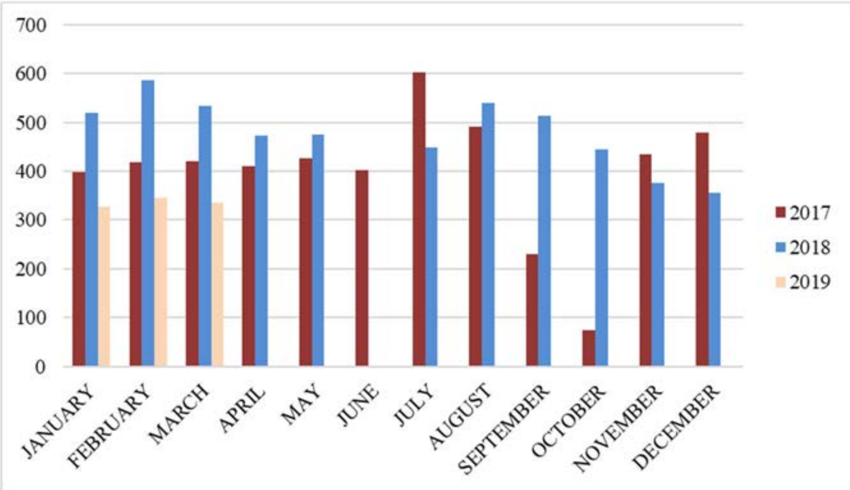

Figure 5: Distance between two delivery points (m)

More in detail, the number of expeditions carried out per hour is plotted in Figure 6. The expected number of hours corresponds to the time needed for the trip, excluding the time required for loading the cargo bicycle, for example, at the beginning of the route or the time used for lunch stops. On average, during the study period, 7,12 deliveries per hour were carried out.

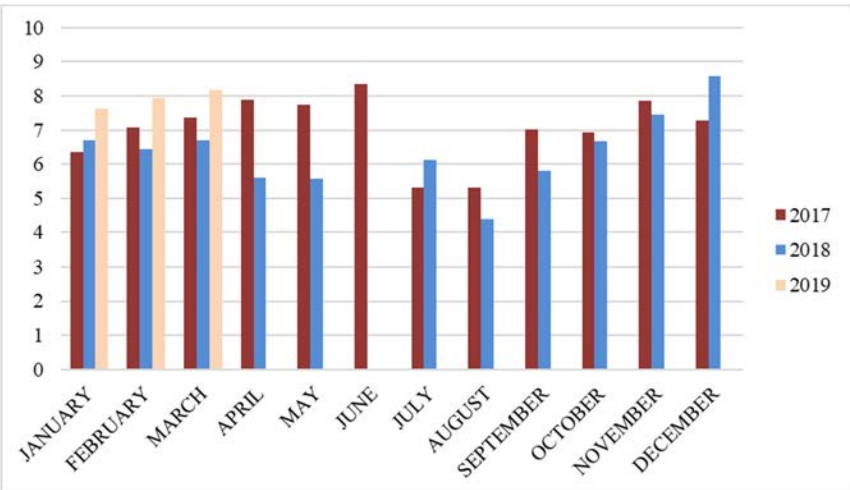

Figure 6: Expedition per hour

Moreover, the number of kilometres travelled by each cargo bike per day is shown in Figure 7, with an average of 19.3km per day. The figure indicates the variations that have occurred over the study period. The variations are lower during the end of the pilot (2019), because the micro consolidation centre has been used by more logistic companies than the ones operating in the study zone.

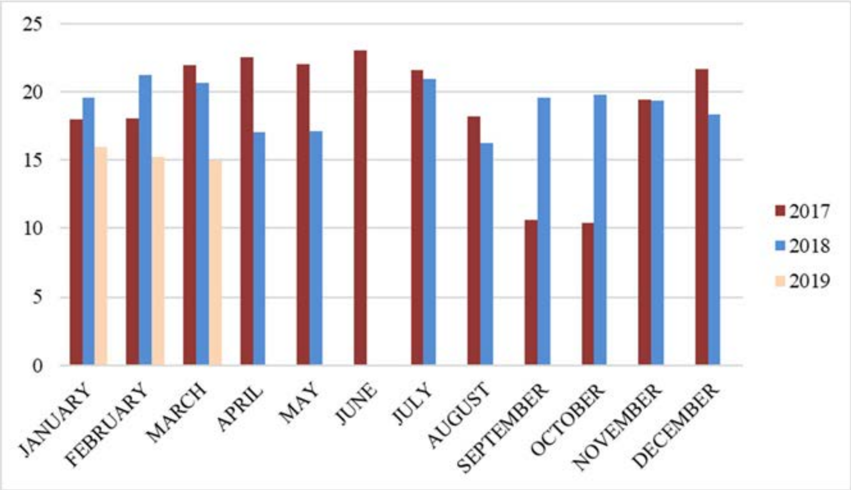

Figure 7: Number of daily kilometres covered per cargo bike

The number of kilometres covered by the cargo bikes during this time period is shown in Figure 8. It can be noted that it follows a similar shape to the curve of the number of deliveries (see Figure 4). Moreover, as can be seen from the figure, October 2018 was the month in which the highest number of kilometres was covered, more than 5.000 km.

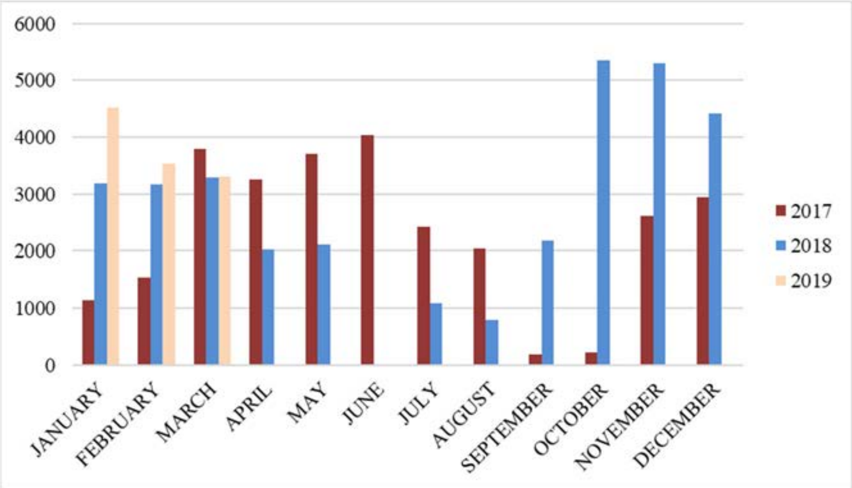

Figure 8: Total distance covered by all vehicles monthly (km)

Table 2 presents the main indicators calculated to check if the modal change in last mile distributions in the old part of Barcelona has helped reducing pollution, energy and noise.

	Average emissions per heavy vehicle kilometre (kg CO_2/km)	Average energy use per heavy vehicle kilometre in the site (kWh/km)	Number of heavy vehicle kilometres shifting to renewable fuels (km)	Number of bicycle/tricycle kilometres needed to perform the same deliveries (km)
Key indicators baseline	0,26	0,79 kwh/km	101.778 km	0
Key indicators 26 months	-	-	0	72.183 km
	Total estimated reduction of emissions (kg CO_2) based on indicators	Total estimated reduction of energy use (% kwh) based on indicators	Total estimated reduction of emissions (% CO_2) compared to baseline	Total estimated reduction of noise (dB) based on indicators
Key indicators baseline	27.084 kg CO_2	80.970 kwh	-	115 dB
Key indicators 26 months	1.085 kg CO_2	97,55% kWh	95,99% CO_2	90 dB

Table 2: KPIs evaluated

The reduction in terms of emissions generated in kg of CO_2 using electric cargo bikes instead of heavy vehicles is 95,9%. Similarly, the energy reduction between these two types of vehicles is about 97,5% and the noise reduction is about 22%.

Finally, the data gathered during the pilot study indicates that the implementation of the micro consolidation centre helped reduce the number of vans circulating in the area as well as pollution, congestion and noise.

5. BUSINESS MODEL

The current study takes into account the business model based on the micro urban consolidation centres. Through the business model, the municipality aimed at making these services economically autonomous with no need for monetary subsidies.

The business model was created following the canvas methodology. The following table summarizes it:

<table>
<tr><th>Key Partners</th><th>Key Activities</th><th>Value Propositions</th><th>Customer relationships</th><th>Customer Segments</th></tr>
<tr><td rowspan="3">1) Carriers / Transportation companies
2) City council / local governments</td><td>1) Reception and consolidation of goods into the consolidation centre
2) Operating the micro distribution centre
3) Delivery to their final destination using cargo bikes
4) The Workshop</td><td rowspan="3">1) Customers / citizen: increased time frame to perform deliveries and extended delivery coverage
2) Traditional carriers: they avoid entering the limited access and pedestrianized areas of the city centre and costs saving. The sensors in the cargo bikes can help optimizing delivery routes, and to make it more competitive for the last mile operator
3) Community: reduced environmental and noise impact
4) City Council: to monitor the noise and pollution levels in that area</td><td>1) Customer support
2) Personal assistance</td><td rowspan="3">1) Users / customers
2) Carriers / Transportation
3) City Councils / Municipalities</td></tr>
<tr><td>Key Resources</td><td>Channels</td></tr>
<tr><td>1) Physical assets (UCC construction and maintenance, electric cargo bikes)
2) Human resources (Delivery staff, operation staff at the consolidation centre)
3) Technology
4) Public Financing</td><td>1) With users/consumers: website and mobile phone apps
2) With City Councils: WLAN communications
3) With carriers: sales force and web sales</td></tr>
<tr><td colspan="2">Cost Structure</td><td colspan="3">Revenue Streams</td></tr>
<tr><td colspan="2">1) Fixed costs (Running costs, Salaries, Cargo bikes)
2) Variable costs (Costs of operating the micro distribution centre)</td><td colspan="3">1) Fee charged from carriers
2) Delivery fee charged from customer</td></tr>
</table>

Table 3: Business model canvas

With regards to Table 3, three main considerations are taken into account: (1) the main revenues are dedicated to delivery parcel (which is very scarce). Additional revenues are provided through maintenance/repairs to other cycle companies or electric cycle owners and by pick-up points (storage services); (2) the rent of offices of the logistics company in this case, is responsibility of the City Council; (3) the more efficiently parcels are delivered, the more profitable can the company be.

The micro consolidation centre is managed by a company which negotiates different conditions with each logistics company. These conditions might include different benefits per package delivered, advertising of the logistics company on the cargo bikes, uniform for distributors etc. The procedure followed for the delivery consists in each logistic company sending their packages to the micro consolidation centre (early in the morning) which are then delivered by the cargo bike operators to their end customer. Nevertheless, the details of the agreement between the last mile company and the logistics companies are confidential and cannot be presented.

During the current study, all logistic companies used a micro consolidation centre which was managed by a company that offered last mile solutions. However, there is a risk that partners (logistics companies) may build their own micro consolidation centres of a high enough parcel delivery density to be profitable. If such thing happened, we would increase the number of micro consolidation centres and thus the number of cargo bikes moving through the city as well as the number of vehicles that distribute parcels in the different micro consolidation centres.

Thus, the best solution would be to use shared micro consolidation centres, in order to reduce the risks and optimize the routes and last mile deliveries. Moreover, a neutral stakeholder/company should operate the micro consolidation centre, otherwise, it would be unlikely to be accepted by all the logistic operators, who should be ensured that they will not lose clients as there is tough competition between them. The city – or another public authority – should take care that the neutral operator stays neutral.

6. CONCLUSIONS

This paper describes the pilot case of a micro consolidation centre located in the oldest part of Barcelona. On-bike sensors were installed to assist with routing and to monitor the service and environmental conditions for research purposes along the routes. Over 207.000 journeys were made by the e-cargo bikes over a 26-month period, reducing CO_2 emissions by approximately 96% compared to delivery by trucks, and also cutting noise and pollution.

The results indicated that the reduction of vehicle kilometres, emissions, energy and noise could be achieved by using micro consolidation centres with cargo bikes for urban last mile distribution.

Last mile delivery is an emerging market segment, and creative support from city administrations is needed to accelerate a transition to sustainable delivery systems. Such support could be given in terms of e.g., designating a zone for deliveries with a dense population and high turnover of parcels; mandating actors to deliver within the zone and monitoring non-compliance; and – in this case – identifying premises and agreeing a tenancy arrangement to enable implementation. Identifying a suitable location for the service, agreeing the terms of operation, and ensuring a suitable installation of the sensor units on the bikes were the main challenges and achievements. It is important to reach a trade-off between robustness, safety and functionality.

The urban freight transport possibilities are generally determined by policies of public authorities, such as the local government, the national government, and for some issues even the European Commission (e.g., setting EURO-standards for truck engines).

However, lessons learned from past experiences in European projects show that success in implementing urban freight logistics measures such as the micro consolidation centres, requires the involvement of multiple stakeholders. Private, public and community stakeholders are all impacted by last mile issues and/or could potentially play a role in developing their solutions.

ACKNOWLEDGEMENTS

This study has been financed by the Growsmarter project, as one of the 12 smart city solutions in energy, infrastructure and transport integrated and demonstrated in the context of the project.

Andrés Monzón de Cáceres
Profesor Catedrático, TRANSyT-Universidad Politécnica de Madrid

RESUMEN

Hoy en día, las ciudades están experimentando un proceso de urbanización, y el transporte urbano de mercancías tiene que hacer frente al actual auge del comercio electrónico, que produce un fuerte aumento de la actividad de transporte de mercancías y complica la logística de las ciudades. A partir de los resultados de un caso de estudio real, este artículo pretende identificar las principales (in)eficiencias de las entregas postales de última milla en condiciones reales de tráfico, tanto en términos de consumo energético como de características operativas. Con esta investigación, se quiere ofrecer una visión más amplia a los planificadores de transporte y a los responsables políticos en cuanto a la gestión, planificación y funcionamiento de la distribución urbana de última milla.

Durante un mes, trece conductores de una misma empresa logística condujeron vehículos ligeros eléctricos y diésel para sus entregas habituales. Mientras tanto, se registraron instantáneamente la posición GPS, la velocidad y otros parámetros de los vehículos: se analizaron 242 rutas de reparto, cada una de las cuales duraba unas 4 horas. Se identificaron 4.479 microviajes de entrega de paquetes individuales, correspondientes a 7.262 km de ruta recorrida en el centro de la ciudad y en la zona periurbana de Madrid.

Los resultados de este análisis subrayan claras ineficiencias en el rendimiento actual de las entregas de última milla, tanto a nivel energético como a nivel operativo. En este contexto, una gran proporción de las entregas de última milla consideradas en el estudio debería pasarse a modos de transporte no motorizados, especialmente en el centro de la ciudad, ya que el 40% de ellas se caracterizan por una velocidad media inferior a 10 km/h. Además, la proximidad de los puntos de entrega entre sí, la falta de espacio de aparcamiento y los frecuentes atascos producen una considerable ineficiencia en términos de consumo energético. A través de este estudio, se pone de manifiesto que la mayoría de las ineficiencias operativas en las entregas de última milla son similares independientemente de la zona de entrega, pero las soluciones deberían variar en función de ellas. Los responsables de las administraciones de las ciudades y los operadores logísticos deberían trabajar de forma proactiva para desarrollar nuevos esquemas logísticos que minimicen los impactos negativos del transporte urbano de mercancías, cambiando las tendencias actuales de altas emisiones que producen.

1. INTRODUCCIÓN

Según el informe social de las Naciones Unidas, a partir de 2020 más del 50% de la población mundial vive en zonas urbanas (Naciones Unidas, 2020), lo que produce, entre otro, un aumento inevitable del movimiento de mercancías dentro de las ciudades. Debido a la antigüedad de las flotas de vehículos y a la frecuencia de sus paradas, el reparto urbano de mercancías es responsable de elevadas emisiones locales y afecta directamente a la salud de los ciudadanos: en las grandes áreas urbanas europeas, los vehículos de carga son responsables de un tercio de las emisiones de NOx relacionadas con el transporte (Macharis y Melo, 2011; Marcucci et al., 2017).

Por otro lado, el reciente crecimiento del comercio electrónico ha dado lugar a un aumento significativo del número de entregas directas al consumidor y a los retos asociados de "última milla", sobre todo en las zonas urbanas (Savelsberg y Woensel, 2016). De hecho, la entrega de última milla suele ser uno de los capítulos más caros, menos eficientes y más contaminantes de la cadena logística (Gevaers, et al., 2011): los problemas de los costes de la entrega de última milla suponen posiblemente entre el 13% y el 75% del coste total de la logística.

En los últimos años, se han investigado y promovido diferentes estrategias e iniciativas para hacer frente a los retos de la entrega de última milla. Para aumentar su eficiencia y mitigar los impactos negativos medioambientales y socioeconómicos, los estudios anteriores se centraron en identificar soluciones estratégicas, administrativas o de planificación urbana específicas para la logística urbana. Entre otras, herramientas relativas a la mejora de las rutas de los vehículos, flotas logísticas “verdes y limpias”, las innovaciones tecnológicas de los vehículos y la cooperación de los competidores (Savelsbergh y Woensel 2016).

A pesar del creciente interés por el tema, hay una escasez de estudios basados en datos reales sobre la entrega de última milla, lo que permitiría comprender en profundidad el problema. De hecho, muchos estudios se basan en simulaciones haciendo que la mayor parte de la investigación actual sea cualitativa y no cuantitativa. Como consecuencia, las soluciones propuestas suelen ser excesivamente amplias y generales, sin diferenciar por contexto geográfico y entorno urbano. Teniendo en cuenta estas limitaciones, esta investigación pretende contribuir a la comprensión de las actividades de transporte urbano de mercancías y a reducir su impacto negativo en la sociedad.

Basándonos en un caso de estudio real, investigamos los principales patrones y características operativas de las entregas postales de última milla en diferentes contextos geográficos dentro de la Comunidad de Madrid, en España.

A través de una campaña de toma de datos reales realizada en colaboración con Correos, obtenemos datos que muestran la eficiencia (o ineficiencia) operativa de los envíos postales de última milla en diferentes entornos, siendo urbanos y periurbanos. El objetivo de la investigación es demostrar cómo las características operativas pueden variar en una misma empresa logística según el contexto geográfico. Además, se pretende poner de manifiesto la inadecuación de la aplicación de determinadas soluciones en algunos entornos urbanos.

2. TENDENCIAS Y ESTADO ACTUAL DE LA DISTRIBUCIÓN URBANA DE ÚLTIMA MILLA

En 2020, el último informe social mundial de las Naciones Unidas afirma que, por primera vez en la historia, hay más gente viviendo en las ciudades que en las zonas rurales (Naciones Unidas, 2020). De hecho, cada vez más, existe una tendencia de desplazamiento de la población del campo a la ciudad. En la actualidad, el 55% de la población mundial vive en zonas urbanas, una proporción que se espera que aumente hasta el 68% en 2050: las proyecciones muestran que la urbanización, combinada con el crecimiento global de la población mundial, podría añadir otros 2.500 millones de personas a las zonas urbanas en 2050 (Naciones Unidas, 2020). En el transcurso de un siglo se habrá producido un cambio de paradigma: el entorno vital menor se ha convertido en el dominante (Monzón y Boggio-Marzet, 2020). Por ello, el sistema de transporte debe seguir el ritmo de esta tendencia a la urbanización; debe adaptarse y tratar de avanzar hacia la aplicación de estrategias de movilidad sostenible.

En este contexto, un transporte de mercancías eficiente y bien planificado puede mejorar el funcionamiento de una ciudad y aumentar su competitividad. De hecho, es necesario considerar la movilidad de las mercancías en las zonas urbanas no solo como una cuestión de tráfico o medioambiente, sino también como un problema concreto de gestión de un sistema socioeconómico complejo, ya que afecta a las funciones de uso de todo el "sistema" de la ciudad. Es necesario encontrar soluciones que permitan alcanzar un equilibrio entre un sistema logístico urbano eficaz y un nivel sostenible de externalidades producidas, con especial atención a la congestión del tráfico, las emisiones contaminantes y la seguridad.

Según el Programa de las Naciones Unidas para el Desarrollo, las ciudades representan entre el 60% y el 80% del consumo de energía y al menos el 70% de las emisiones de carbono, a pesar de que sólo ocupan el 3% de la superficie terrestre (PNUD 2019). Otra vez, la evolución de la movilidad urbana resulta ser una clave fundamental para cambiar la realidad actual de un entorno poco propicio para una adecuada calidad ambiental.

Estudios anteriores estiman que el transporte urbano de mercancías representa hasta el 30% de las emisiones totales del tráfico, dependiendo del contexto local (Marcucci et al., 2017).

Dentro de la movilidad urbana, la entrega de última milla es el último tramo de la cadena logística directa al consumidor, y suele ser uno de los capítulos logísticos más caros, menos eficientes y más contaminantes (Gevaers, et al., 2011). La entrega de última milla se define como el movimiento de mercancías desde un centro de transporte hasta el destino final. Así, además de las externalidades reconocidas en la mayor parte de la literatura (como el tráfico, la ocupación del suelo urbano, las emisiones de GEI y el ruido), los problemas de LMD también están relacionados con la recogida de mercancías y correos, y con aquellos paquetes que son objeto de reclamaciones o entregados a un cliente final equivocado. Todo ello, puede suponer entre el 13% y el 75% del coste logístico total de una empresa.

Además del fenómeno de la urbanización, el sistema de transporte urbano de mercancías tiene que hacer frente al actual auge del comercio electrónico, que ha producido un aumento drástico del número de paquetes entregados cada día y ha incrementado las expectativas de los clientes, que ahora incluyen no solo la entrega rápida sino también la gratuita. Solo en España, el comercio electrónico superó los 48.800 millones de euros en 2019, lo que supone un aumento de casi el 25% desde el año anterior, con un incremento interanual constante (Comisión Nacional de los Mercados y la Competencia, 2020). Según Ragás Prat (2018), el "Boom" del comercio electrónico conlleva dos consecuencias principales: primero, el número de entregas y, la movilidad de los vehículos de mercancías que circulan por la ciudad que se multiplica.

En segundo lugar, cualquier dirección se convierte en un potencial punto de entrega. En otras palabras, la distribución urbana de mercancías se lleva a cabo en zonas residenciales no diseñadas para acoger este tipo de operaciones a escala masiva. En este contexto, que la distribución urbana de mercancías se está transformando rápidamente y requiere respuestas urgentes por parte de los operadores y las administraciones.

Varios autores han identificado tendencias y avances tecnológicos que conducen a un nuevo paradigma de la logística urbana. Según Sevelsbergh y Woansel (2016), las tendencias de crecimiento de la población y la urbanización, junto con el aumento del comercio electrónico, el deseo de rapidez y la economía colaborativa, aumentan la complejidad de la logística de la ciudad y agravan sus impactos negativos en la congestión, la seguridad y el medio ambiente. Por otro lado, las nuevas y emergentes tecnologías, como la conectividad digital, el big data y la tecnología del automóvil, podrían impulsar la innovación en la logística de las ciudades y disminuir potencialmente estos efectos.

Para aumentar la eficiencia energética, mitigar sus impactos negativos sobre el medioambiente y hacer frente a los retos de la entrega de última milla, se promueven varias estrategias e iniciativas, como las mejoras en las rutas de los vehículos a través de la instalación de sistemas de Green navigation, la elictrificación de la flota, las innovaciones tecnológicas de los vehículos y la cooperación de los competidores (Schliwa et al., 2015;

Savelsbergh y Woensel 2016; de Mello Bandeira, et al., 2018; Alho et al., 2018; Giordano et al., 2018; Lafkihi et al., 2019; Simoni et al., 2019). Sin embargo, estas iniciativas encuentran en la práctica varias dificultades de aplicación, como la falta de información en tiempo real para ofrecer un servicio dinámico de rutas de vehículos; los costes de inversión que son muy elevados para los transportistas; y los competidores del sector del transporte de mercancías que no están dispuestos a compartir información valiosa para cooperar, ya que la misma información forma parte de su negocio. Se necesitan estrategias o soluciones factibles y rentables.

Ranieri et al. (2018) agruparon diferentes soluciones de última milla para el transporte de mercancías según cuatro aspectos principales: innovación en los vehículos, estaciones o puntos de proximidad, soluciones colaborativas y cooperativas e innovación en políticas e infraestructuras públicas. En la misma línea, Lafkihi et al. (2019) y Mangiaracina et al. (2019) llevaron a cabo una exhaustiva y extensa revisión bibliográfica sobre los retos y oportunidades del transporte de última milla e identificaron varias soluciones efectivas, entre las que se encuentran por ejemplo las entregas nocturnas, que pueden desplazar el tráfico a las horas valle, reduciendo así la congestión diurna y, por tanto, las emisiones de GEI relacionadas. Según Olsson et al. (2019), para optimizar las operaciones de última milla, las empresas pueden optar por diferentes niveles de actuación: (1) nivel estratégico, como la ubicación de los centros de distribución, (2) nivel táctico, como el tamaño de la flota y las entregas nocturnas, y (3) nivel operativo, como el enrutamiento de los vehículos.

La literatura señaló la importancia de darse cuenta de que las circunstancias geográficas, económicas, sociales y culturales afectan a la logística de la ciudad y a la percepción de la gente sobre los temas críticos relacionados con la logística urbana. Dependiendo del área de aplicación y de la intensidad, las mismas iniciativas pueden dar lugar a resultados diferentes en cuanto a la reducción de los impactos sociales y medioambientales del transporte de mercancías. Además, la mayoría de las publicaciones científicas sobre el tema abordan la política de transporte con un enfoque teórico sin presentar datos reales; otras simulan las soluciones en un área específica, sin tener en cuenta los diferentes entornos a aplicar. Faltan datos reales sobre las características operativas de las empresas logísticas, y la falta de datos reales complica la investigación de soluciones sostenibles para la logística urbana.

Resulta esencial caracterizar adecuadamente los viajes urbanos de mercancías tanto en las zonas urbanas como en las periurbanas, en las que hay una mayor demanda de movimientos de mercancías, teniendo en cuenta que todavía falta una comprensión completa del tema. Hasta donde sabemos, hay una verdadera escasez de estudios que presenten un análisis de las ineficiencias de las entregas de última milla basado en datos reales de pruebas de campo. A partir de aquí, el objetivo de esta investigación.

Tras introducir el contexto de la investigación, la motivación del trabajo y el estado del arte, la sección 3 presenta la metodología utilizada para llevar a cabo la investigación, incluyendo la definición del caso de estudio, la campaña de toma de datos y el procesamiento de los mismos. El análisis de los resultados y la discusión se presentan en la Sección 4. Por último, en la sección 5 se describen las principales conclusiones y recomendaciones futuras.

3. METODOLOGÍA

Para este trabajo se ha desarrollado una metodología sistemática. En primer lugar, se ha definido el estado del arte mediante la realización de una profunda y exhaustiva revisión bibliográfica de investigaciones y artículos anteriores (Sección 2). Esto ayuda a centrarse en las lagunas de investigación más urgentes en el transporte urbano de mercancías, proporcionando problemas y desafíos, así como comparando los impactos de las estrategias actuales ya implementadas en la entrega de última milla. Este trabajo, quiere analizar las pautas operativas de la distribución urbana de última milla, con el objetivo de identificar sus principales ineficiencias, tanto operativas como energéticas, y poder actuar sobre las mismas. Para ello, contamos con una campaña de toma de datos reales en colaboración con la empresa logística de Correos.

CORREOS es el servicio público postal de España (100% estatal) con 51.000 empleados, que distribuye más de 3.600 millones de envíos al año. Con el apoyo de la empresa, fue posible realizar la campaña de toma de datos simultáneamente en la zona de reparto urbana y peri-urbana de Madrid, gracias a la colaboración de 13 conductores profesionales de dos centros de distribución urbana (CDU) de CORREOS en la misma área metropolitana de Madrid. Además, la ventaja de colaborar con una empresa pública estatal es facilitar la homogeneidad de la muestra. De hecho, la flota de vehículos está compuesta para ambos casos por vehículos ligeros diesel y eléctricos del mismo fabricante y modelo. Además, el hecho de considerar una zona de reparto urbana y otra peri-urbana dentro de la misma área metropolitana de Madrid, hace que las circunstancias económicas de ambas zonas sean mayoritariamente homogéneas.

La campaña de toma de datos tuvo lugar en septiembre y octubre de 2018 en zonas de reparto tanto urbanas como peri-urbanas de Madrid. 13 conductores de la misma empresa condujeron a lo largo de su normal ruta de trabajo vehículos diésel o eléctricos de carga ligera mientras entregaban paquetes en el área Metropolitana de Madrid. En todos los vehículos diésel que participaron en la prueba de campo había una llave OBD preinstalada, que registraba segundo a segundo la posición GPS del vehículo, así como la velocidad, el tiempo de viaje y otras variables. Para los vehículos eléctricos, las mismas variables fueron monitorizadas y registradas segundo a segundo a través de un teléfono móvil en el que estaba preinstalada la App Mytracks.

Además de las variables registradas, a través de la programación con el software R -un entorno de software libre para la computación estadística y los gráficos- y la ayuda de ArcGis, se calcularon otras variables instantáneas relativas al comportamiento de conducción, al consumo de energía y a las condiciones de la carretera. Tras la toma de datos y el cálculo de las variables, se crea finalmente el conjunto de datos y se valida a través de su procesamiento. Así, como conjunto de datos se almacenan dos tipologías de datos: datos relacionados con el viaje y datos relacionados con el patrón de conducción.

El último paso de la metodología es el análisis de los datos. El análisis de datos tiene como objetivo caracterizar la entrega de última milla en términos de distancia, velocidad, tiempo de parada, etc., en diferentes contextos geográficos, ya sean urbanos o peri-urbanos. Para caracterizar el rendimiento operativo de la entrega de última milla y presentar en qué medida varían las operaciones de distribución para una misma empresa en dos zonas de entrega estudiadas, urbana o peri-urbana, adoptamos el método estadístico. Los resultados obtenidos, deberían proyectarse a las empresas de distribución de mercancías, para mejorar su impacto ambiental y económico.

3.1 El caso de estudio

El caso de estudio se desarrolla en el área metropolitana de Madrid, capital de España. Madrid es la principal ciudad de España, capital del país y de la misma Comunidad de Madrid. El área metropolitana asociada a la ciudad tiene una población de 6,6 millones de habitantes, lo que la convierte en una de las más pobladas de la Unión Europea; la mitad de los habitantes se concentran en la misma ciudad de Madrid (Monzón et al., 2017).
El Área Metropolitana de Madrid tiene una extensión de 8.030 km2, con una proporción de superficie urbanizada del 11%. Tres autopistas orbitales rodean la ciudad (la M-30, M-40 y M-50) a las que se accede desde siete autopistas radiales. Por lo general, el terreno que rodea la ciudad es relativamente llano, salvo la cordillera, que es relativamente remota y fronteriza, situada en el noroeste de la provincia.

Los datos en los que se basa el estudio, derivan de una campaña de toma de datos reales realizada en 2018 en colaboración con Correos, que es el servicio postal nacional español (de titularidad 100% estatal). Cuenta con 51.000 empleados y distribuye más de 3.600 millones de envíos al año. Dentro de la Comunidad de Madrid, Correos cuenta con 27 CDU que realizan la distribución en vehículo ligero: 15 están ubicados dentro de la ciudad de Madrid y 12 fuera de la ciudad. Dos de ellos, uno situado en el centro de la ciudad y el otro en la zona periurbana de Madrid, participaron en la prueba de campo, lo que hace que nuestro experimento sea bastante representativo de la realidad.

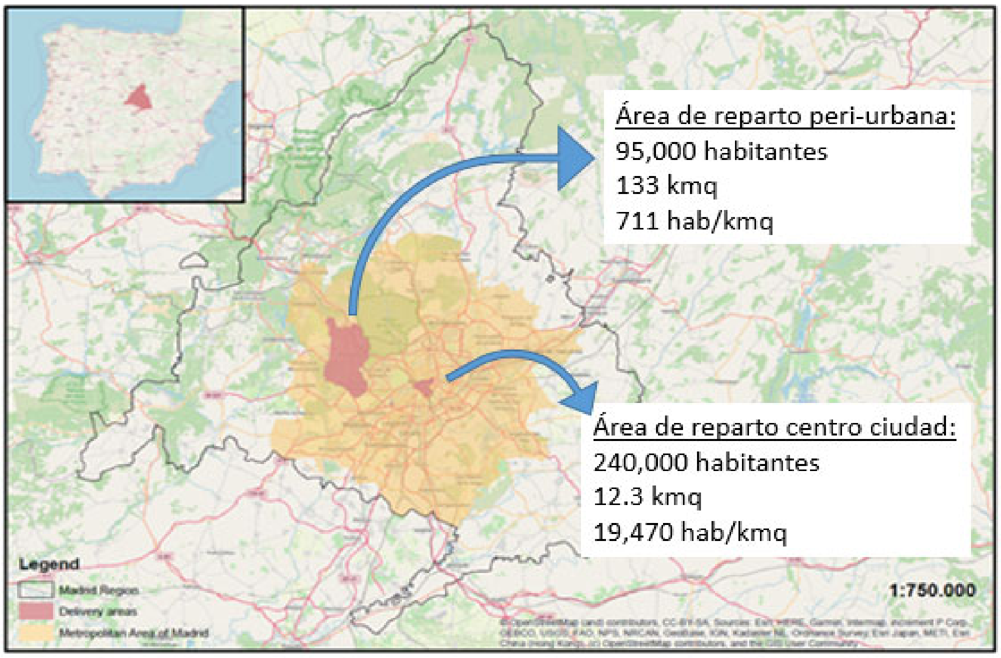

Figura 1- La Región de Madrid y las áreas de reparto del experimento

La figura 1 muestra las dos áreas de reparto involucradas en el experimento, que son un punto clave para entender las características operativas de la distribución urbana de última milla. Uno de los dos depósitos de Correos se encuentra en el municipio de Las Rozas, situado en la franja noroeste del Área Metropolitana de Madrid, y cubre un área de entrega periurbana de más de 130 km2. El otro depósito está situado en el centro de la ciudad de Madrid, y da servicio a un área de entrega diez veces menor, de unos 12 km2, pero 27 veces más densa que la de Las Rozas.

Como se ha mencionado anteriormente, el objetivo de esta investigación es determinar las principales ineficiencias operativas y energéticas de las actividades de distribución urbana de última milla. Los datos en los que se basa nuestro análisis proceden de un experimento realizado en condiciones reales de tráfico para estudiar la cuestión a partir de datos y circunstancias muy reales.

La campaña de toma de datos tuvo lugar durante cuatro semanas. Durante un mes, 13 conductores profesionales participaron en la prueba de campo, siendo 11 hombres y 2 mujeres, con edades comprendidas entre los 33 y los 62 años. Ellos condujeron vehículos de reparto eléctricos y diésel a lo largo de sus rutas de trabajo habituales, mientras que la posición GPS, la velocidad y otros parámetros se recogían instantáneamente cada segundo.

En total, se registraron 242 turnos de trabajo de reparto válidos (cada uno de ellos correspondiente a una ruta de reparto) de unas cuatro horas cada uno; así, se analizaron 1.050 horas de conducción, que cubrieron 7.262 km de recorrido.

Las rutas no estaban predefinidas, sino que el conductor las definía cada día de forma diferente para optimizar todas las entregas durante su jornada laboral. Por lo tanto, los conductores se enfrentaron a diferentes situaciones de tráfico, lo que afectó a las variables de la investigación, como la velocidad y los tiempos de espera debidos a la congestión del tráfico. No obstante, este aspecto refleja su trabajo real.

Por último, después de cada ruta de entrega, recogimos la opinión de cada conductor a través de un breve cuestionario en el que, entre otros puntos, podían informar de cualquier incidencia encontrada, como la congestión del tráfico o la falta de aparcamiento. Esta información fue muy útil para entender los problemas reales relacionados con la distribución de paquetería según las diferentes zonas de entrega.

3.2 Definición del Dataset

Para llevar a cabo el siguiente análisis y alcanzar los objetivos de la investigación, fue necesario definir el conjunto de datos en dos dimensiones diferentes: las rutas de entrega diarias – ruta de reparto - y los microviajes de entrega de cada paquete – microviaje. Cada ruta de reparto contiene un cierto número de entregas de paquetes (microviajes) cuyas características varían en función de las distintas condiciones de tráfico y entorno. Así, hemos creado dos bases de datos diferentes: la primera adopta la forma de rutas de reparto y describe los principales aspectos del reparto postal de última milla en términos de características generales de funcionamiento; la segunda permite caracterizar los patrones de conducción propios de los microviajes de reparto de paquetes individuales y comprender la ineficiencia energética durante el reparto.

Para ello, utilizamos todos los datos registrados para definir manualmente los microviajes de entrega dentro de cada ruta de reparto, basándonos en los registros instantáneos.

Seleccionamos aquellos segundos en los que la velocidad era nula, y si el tiempo consecutivo con velocidad nula era superior a 2 minutos (± 30 segundos dependiendo del posicionamiento GPS) lo considerábamos como una parada de entrega entre dos microviajes consecutivos. No obstante, este no era un criterio absoluto, y teníamos que comprobarlo manualmente con los datos del GPS. Así, creamos dos conjuntos de datos diseñados como base para el análisis mediante la programación en R, un conocido entorno de software libre para la computación estadística y los gráficos. La primera base de datos (Ruta de entrega) cuenta con 242 rutas de entrega, cada una de las cuales incluye unas cuatro horas de conducción. La segunda base de datos (microviajes) consta de 4.479 microviajes de entrega de paquetes individuales. Así, se han analizado 1.050 horas de conducción, correspondientes a 7.262 km de recorrido: 1.965 km en el centro de Madrid y 5.297 km en la zona periurbana de Madrid.

Como se ha mencionado anteriormente, nuestro objetivo es identificar las principales ineficiencias de la entrega de última milla tanto en términos operativos como de consumo energético.

En el caso de las ineficiencias operativas, nos basamos en el análisis estadístico basado en las dos bases de datos creadas, y en las opiniones de los conductores. Para el caso del análisis de la ineficiencia energética del vehículo, hemos considerado la base de datos compuesta por microviajes de entrega de paquetes individuales, considerando varios parámetros de conducción que han demostrado tener una influencia significativa en el consumo de energía del vehículo (Ericsson, 2001; Lois et al., 2019; García-Castro et al., 2018).

4. ASPECTOS PRINCIPALES DE LA DISTRIBUCIÓN DE ÚLTIMA MILLA

Una vez completado el procesamiento de los datos, desarrollamos un método de análisis de los mismos, es decir, la correcta manipulación de los elementos, para generar y abordar resultados significativos en relación con los objetivos de investigación fijados. Adoptamos métodos estadísticos para caracterizar el rendimiento operativo de la entrega de última milla, y para presentar el grado de variación de las operaciones de distribución para una misma empresa en dos zonas de entrega estudiadas (urbana y periurbana), así como sus ineficiencias. Así, en primer lugar, definimos las principales características operativas de las entregas de última milla para mejorar el conocimiento de la actividad de reparto en las dos zonas consideradas. A continuación, identificamos sus principales ineficiencias: tanto en términos de energía como de características operativas, tanto en la zona de reparto urbana como en la periurbana.

4.1 Ineficiencias energéticas en la distribución de última milla

Para tener una idea concreta de los principales aspectos de las actividades de reparto, se presenta la siguiente tabla. Distinguiendo entre zona de reparto periurbana o urbana, la Tabla 1 muestra los valores medios, así como el mínimo y el máximo, de las principales características operativas según la zona de reparto

	Área Peri-Urbana (Las Rozas)			Área urbana Centro ciudad (Madrid)		
Parámetros	Min	Max	Media	Min	Max	Media
Longitud ruta de reparto [km]	17.38	93.67	50.93	5.64	55.44	14.34
Tiempo de ruta de reparto [hh:mm]	02:27	06:22	04:24	02:02	05:58	03:57
Longitud microviaje [km]	0.02	19.22	2.25	0.01	6.82	0.77
Velocidad microviaje [km/h]	0	94.9	24.8	0	44.02	12.8
% Tiempo de microviaje con velocidad < 3km/h	0%	70%	9%	0%	87%	21%

Tabla 1- Características operativa de las rutas de reparto

A pesar de que el tiempo total para cumplir la ruta de reparto de ambos CDU implicados en la prueba de campo es similar (una media de 4 horas), en la zona de entrega urbana, la distancia media recorrida durante una ruta de entrega es de 14,3 km, que es 3,5 veces menor que en la periurbana. En el caso urbano, durante el 21% del tiempo de viaje la velocidad es inferior a 3 km/h. Además, el 50% de los microviajes en la zona es inferior a 477 metros de longitud y se realiza con una velocidad media inferior a 13 km/h.

El caso periurbano es bastante diferente en términos de características operativas. La distancia media recorrida por cada conductor durante la ruta de reparto es de 50,9 km, y la distancia media para entregar un solo paquete es de 2,25 km (SD: 3,24), lo que implica una zona bastante dispersa. Allí, el 50% de los microviajes tiene una longitud superior a 1,1 km. La velocidad media es de 25 km/h y el porcentaje de tiempo a velocidades operativas inferiores a 3 km/h es del 9%, menos de la mitad del porcentaje propio del centro ciudad.

Además, la velocidad instantánea del vehículo es un factor decisivo a la hora de definir la eficiencia energética de la entrega de última milla. La imagen siguiente (Figura 2) muestra la velocidad instantánea de un vehículo durante su ruta de reparto, tanto en zona urbana como periurbana.

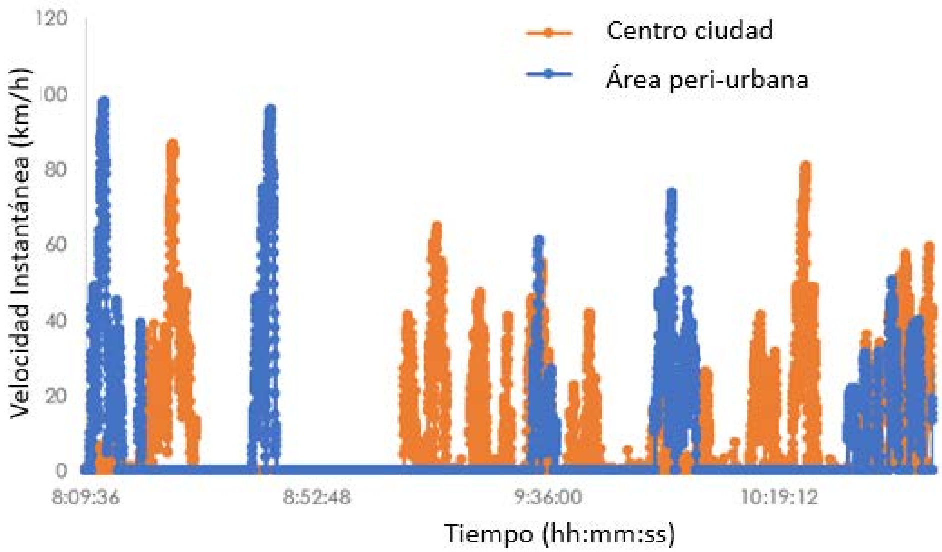

Figura 2- Velocidad instantánea del vehículo durante una ruta de reparto en centro ciudad y en área peri-urbana

En el centro ciudad, los conductores conducen casi tres veces más despacio que en área periurbana, y el 20% del tiempo en el centro ciudad el vehículo está parado debido a la congestión de la carretera, o al semáforo o al hecho de entregar el paquete en sí. De hecho, la baja velocidad de circulación puede deberse a varios factores. Según nuestros datos, en el centro de la ciudad, entre el 16% y el 27% del tiempo de viaje se pasa con velocidades operativas inferiores a 3 km/h. En concreto, el 35% de los microviajes en el centro de la ciudad tiene una velocidad media de 7 km/h, y las velocidades superiores a 19 km/h sólo se alcanzan en el 5% del tiempo de viaje. Por lo tanto, estas entregas podrían realizarse con otros medios de transporte distintos de los vehículos ligeros, ya que la distancia media de las entregas individuales es inferior a 500 m, una longitud que puede cubrirse fácilmente a pie o en bicicleta, por ejemplo. Además, la covarianza de la velocidad (es decir, la variabilidad de la velocidad durante la conducción) durante estas entregas es la más alta registrada, hasta 0,8 en la mayoría de los casos, lo que pone de manifiesto un estilo de conducción caracterizado por altas aceleraciones y desaceleraciones que, en parte debido a la red de carreteras y los flujos de tráfico, aumentan el consumo de combustible y las emisiones resultantes (Lois et al., 2019). Allí, aunque se mantenga la velocidad reducida, el alto nivel de covarianza hace que el consumo energético aumente notablemente, y en consecuencia el consumo de combustible y las emisiones.

Para aclarar el concepto, la siguiente imagen (Figura 3) muestra el posicionamiento instantáneo y la velocidad de un vehículo en zona urbana durante una ruta de reparto. Los colores se corresponden con la velocidad operativa del vehículo: rojo para la velocidad inferior a 10 km/h, amarillo para la velocidad entre 10 km/h y 30 km/h y verde para la velocidad superior a 30 km/h.

Figura 3-Posicionamiento y velocidad instantánea de un vehículo durante una ruta de reparto en el centro ciudad (Boggio-Marzet y Monzón, 2021)

En el 40% de los casos, en el centro de la ciudad, la velocidad media de un micro viaje es inferior a 10 km/h. Este aspecto debería hacernos reflexionar sobre la necesidad real de transferir las operaciones de entrega de última milla de los vehículos a medios no motorizados, especialmente en las zonas del centro de la ciudad. Además, como se muestra en la figura 3, hay algunas calles que se recorren varias veces durante la misma ruta de reparto, debido a las calles de un solo sentido típicas del centro ciudad, así como a la falta de plazas de aparcamiento. Este aspecto puede justificar en parte la bajísima velocidad de funcionamiento propia de la muestra. De hecho, el conductor se ve obligado a pasar por la misma calle varias veces durante diferentes micro viajes de la misma ruta de reparto, debido a la conformación de la red vial de la zona.

En cuanto al tema de la eficiencia energética de los vehículos, ya se ha demostrado en la literatura que las aceleraciones y desaceleraciones fuertes provocan un aumento considerable del consumo energético del vehículo (Ericsson, 2001; ECOWILL, 2013; García-Castro et al., 2018; Wang & Boggio-Marzet, 2018). Así, queremos analizar la proximidad de las paradas que el conductor realiza durante su viaje. Aparte de aquellas paradas provocadas por el tráfico, los semáforos y los pasos de peatones, el conductor, durante las entregas de última milla, debe adaptar su conducción a una especie de intermitencia de situaciones caracterizada por frecuentes arranques y paradas y, en consecuencia, por producir altas emisiones de GEI y contaminantes. Además, las entregas son prácticamente las mismas de un día a otro. De hecho, la ruta de entrega de un conductor concreto es bastante homogénea cada día, ya que cada conductor es responsable de una “microzona” determinada dentro del área de entrega del CDU.

Las variaciones menores se deben a un único cliente final situado en una carretera cercana, en un edificio concreto o en un edificio cercano, pero en la misma "microzona" de la que es responsable cada conductor.

En este contexto, sería útil realizar un análisis profundo de la geolocalización de los puntos de entrega y determinar la ubicación óptima para instalar un conjunto de “Taquillas inteligentes”. Asimismo, el 18% de las entregas en la zona periurbana se realizaron en menos de un minuto y medio, a unas decenas de metros de distancia. Estas entregas se refieren a las realizadas a lo largo de amplias vías flanqueadas por grandes casas, una al lado de la otra, con poco tráfico, donde el mensajero puede detener el vehículo justo delante de la puerta, y entregar el paquete al conserje, para luego repetir el proceso a lo largo de toda la avenida. Este proceso produce entregas con un impacto medioambiental muy elevado. Dado que los vehículos contaminan mucho durante su arranque, en aceleración y en frenado, sería aconsejable en este contexto vial implantar otro sistema de entrega.

4.2 Ineficiencias operativas en la distribución de última milla

Para este análisis, además de considerar los datos instantáneos de los vehículos implicados, hemos tenido en cuenta las entrevistas que hemos realizado a los conductores después de cada ruta de reparto. Así pues, los principales aspectos relativos a la ineficacia operativa de distribución de mercancía en las entregas de última milla se han ahondado tanto a partir del análisis estadístico como, en su mayor parte, de las entrevistas a los conductores.

La primera ineficiencia identificada en ambas áreas de reparto es el largo tiempo de espera necesario para realizar determinadas entregas. Aunque el tiempo medio de entrega es de 5 minutos, hay algunas entregas que requieren un tiempo de espera de más de una hora. En el centro de la ciudad, la entrega se realiza en una media de 04:17 minutos, con una desviación estándar de 06:14, lo que significa que alrededor del 70% de las entregas se realizan en menos de 10 minutos. En la zona periurbana, la entrega se realiza en una media de 07:25 minutos con una desviación estándar igual a 09:41, lo que significa que alrededor del 70% de las entregas se realizan en menos de 15 minutos. Sin embargo, el tiempo máximo de entrega registrado durante la campaña de toma de datos es respectivamente de 52 minutos en el centro de la ciudad y de 96 en el entorno periurbano, independientemente del conductor. Esto se debe a que, el cliente final puede ser un polígono industrial o una gran empresa con amplias instalaciones, por lo que el mensajero debe ser identificado y pasar varios controles de seguridad antes de realizar la entrega, y luego entregar en varios edificios del polígono. Desgraciadamente, no hay un único conductor responsable de todo este tipo de entregas, y por tanto no hay una ruta fija que cubra estos puntos de entrega; así, se pierde eficiencia operativa, aumentando el porcentaje de largos tiempos de espera para todos los conductores que participan en la logística de última milla.

Otro aspecto interesante es el de las entregas que fracasan, por ejemplo porque el cliente no está en casa cuando llega el mensajero o porque la dirección del punto de entrega es errónea. Si el mensajero no encuentra al cliente en casa, debe volver una segunda vez, al final de su ruta de entrega. Si el cliente sigue ausente, el mensajero transfiere el paquete al conductor responsable de la siguiente ruta de entrega, que tendrá que cambiar su ruta a propósito. Evidentemente, esto implica una pérdida de tiempo y reduce la eficacia operativa de LMD, pero también genera un gasto de consumo de energía para el vehículo, además de que se recorren más kilómetros, lo que implica que se crea más tráfico, se emiten más contaminantes, etc. El porcentaje de entregas fallidas en el primer intento ronda el 25% en ambas zonas de reparto, y se reduce al 11% en el caso de las entregas periurbanas y al 8% en el centro de la ciudad mediante las entregas posteriores. Este fenómeno tiene un extraordinario efecto negativo en el medio ambiente de nuestras ciudades, ya sea en términos de congestión, contaminación, ruido, etc. Por ello, sería interesante crear un sistema de geolocalización instantánea, aunque, en este caso, nos enfrentaríamos sin duda a problemas de privacidad entre otros.

Por último, según los informes de los conductores al rellenar la breve encuesta después de cada ruta de reparto, hay dos preocupaciones principales en sus comentarios: la falta de espacio para aparcar y los problemas relacionados con la congestión. La falta de espacio para aparcar es una de las principales razones que provocan una mayor distancia de viaje y una baja velocidad de circulación (en busca de una parcela de aparcamiento libre), lo que aumenta el uso de energía y produce mayores emisiones y contaminantes atmosféricos. En este caso, se requiere información sobre el estacionamiento en tiempo real y debería considerarse la posibilidad de utilizar otros modos, como la moto o bici eléctrica, para sustituir al vehículo motorizado en el futuro.

Cabe destacar que la falta de espacio para aparcar representa el 29% de los problemas detectados durante el reparto en el centro de la ciudad, pero, según la opinión de los conductores, no es relevante en el caso periurbano.

El otro problema clave revelado por los conductores es la congestión de las carreteras. Alrededor del 40% de las rutas de reparto realizadas informan de situaciones de atasco, independientemente de la zona de reparto considerada. Este aspecto debería ser tenido en cuenta por los responsables políticos, ya que la naturaleza profunda de los LMD se caracteriza por su corta duración, por lo que los atascos pueden tener una influencia mucho mayor en la eficiencia operativa de las entregas de última milla comparado con las entregas de larga distancia. De acuerdo con los resultados, la distribución urbana de última milla debería realizarse durante las horas valles, de menor afluencia en carretera, adoptando la información de tráfico en tiempo real para seleccionar las rutas menos congestionadas.

5. CONCLUSIONES Y RECOMENDACIONES

En los últimos años, las ciudades están experimentando un considerable proceso de urbanización, y el sistema de transporte urbano de mercancías tiene que hacer frente al actual auge del comercio electrónico, que produce un fuerte aumento de la actividad y complica aún más la logística de la ciudad. A través de esta investigación, caracterizamos las pautas clave de las entregas de última milla urbanas y periurbanas. Con el fin de cambiar las tendencias actuales de las emisiones producidas por la entrega de última milla sobre las ciudades y los ciudadanos, nos propusimos estudiar en términos cuantitativos, cuáles son las ineficiencias más evidentes en términos operativos y energéticos, en diferentes áreas de entrega de la misma región de Madrid.

Tras realizar una campaña de toma de datos reales, se analizaron 242 rutas de reparto, correspondientes a 4.479 microviajes de entrega de paquetes individuales realizados durante 1.050 horas de conducción, cubriendo un total de 7.262 km de ruta: 1.965 km en el centro ciudad y 5.297 km en la zona periurbana de Madrid. Las principales conclusiones se presentan a continuación.

De nuestros resultados se desprende que existen claras ineficiencias operativas en el desempeño actual de las entregas, tanto en términos de consumo energético como de eficiencia operativa: una gran proporción de las entregas que actualmente se realizan en vehículos ligeros deberían pasar a modos de transporte no motorizados, especialmente en el centro de la ciudad. De hecho, el 40% de las entregas en el centro de la ciudad se caracterizan por una velocidad media inferior a 10 km/h, y al ser inferiores a 400 m de longitud, estas entregas podrían cubrirse fácilmente a pie o en bicicleta cargo.

Desde el punto de vista del consumo energético, sería útil realizar un análisis profundo de la geolocalización de los puntos de entrega y determinar la ubicación óptima para instalar un conjunto de taquillas inteligentes para paquetes, ya que la mayoría de las veces los puntos de entrega a los que llegan los conductores son casi los mismos, día tras día.

Además, la proximidad de los puntos de entrega entre sí supone un gasto adicional de combustible debido a las frecuentes paradas de inicio y final de viaje que se suman a las producidas por el contexto vial, es decir, por los atascos, los semáforos o los pasos de peatones.

Desde el punto de vista operativo, nuestros resultados muestran una clara falta de homogeneidad en cuanto al tiempo necesario para la entrega. Aunque por término medio se tarda 5 minutos en hacer una entrega, se puede llegar a tardar una hora. Podría ser útil definir una ruta fija que cubra las entregas a las grandes empresas, evitando que todos los conductores tengan que experimentar los mismos tiempos de espera.

La falta de espacio para aparcar, así como las entregas fallidas y los frecuentes atascos encontrados, implican una pérdida de tiempo para el mensajero y reducen la eficacia operativa de la LMD; también generan un gasto extra de consumo energético para el vehículo, así como hace sí que se recorran más kilómetros, y, en consecuencia, se emiten más contaminantes. La distribución urbana de última milla debería realizarse durante las horas de menor afluencia y adoptando la información del tráfico en tiempo real para seleccionar las rutas menos congestionadas. A través de esta investigación, señalamos que la mayoría de las ineficiencias operativas de las entregas de última milla son similares independientemente de la zona de entrega, pero las soluciones deberían variar según el contexto geográfico.

Debido a la gran cantidad de datos analizados, esta investigación ofrece una visión más amplia a los planificadores de transporte y a los responsables políticos en cuanto a la gestión, el funcionamiento y el uso de la distribución de última milla en áreas urbanas. La misma, puede ayudar a diseñar estrategias de reducción de emisiones para que las empresas de transporte urbano de mercancías mejoren su impacto medioambiental entre otros.

Los responsables de las ciudades deberían trabajar de forma proactiva con las partes interesadas para desarrollar nuevos esquemas logísticos que minimicen los impactos negativos del transporte urbano de mercancías, cambiando las tendencias actuales de las emisiones que producen.

Las investigaciones futuras deberían ampliar el área de estudio y centrarse en medir y cuantificar el impacto de las diferentes soluciones de última milla según las circunstancias sociodemográficas.

LOGÍSTICA URBANA FERROVIARIA Y E-COMMERCE: ANÁLISIS DE COSTES EXTERNOS DEL MODELO M4G (METRO FOR GOODS)

Rafael Villa Martínez
Profesor Asociado. Universidad Camilo José Cela
Andrés Monzón de Cáceres
Catedrático Universidad. Universidad Politécnica de Madrid

ABSTRACT

Las ciudades están en el centro de la vida humana y están viviendo un intenso proceso de transformación en distintos ámbitos (económicos, sociales, medioambientales) donde la distribución urbana de mercancías aparece como uno de los grandes retos para el sector del transporte y la logística, afectando directamente a este proceso de transformación de la ciudad.

La aparición de la covid-19 ha tenido especial relevancia e impacto en la movilidad de la ciudad y en el comercio electrónico. El B2C, o negocio de empresa a consumidor, ha crecido notablemente en los últimos años y se ha acelerado a raíz de la pandemia, aumentando el acceso de la población a Internet y produciendo cambios en los hábitos de comportamiento de los consumidores. En las áreas metropolitanas, el "efecto Amazon" (amplia selección de minoristas online, envío rápido, devoluciones gratuitas y precios bajos) ha llevado a un mayor uso de vehículos ligeros en el reparto del comercio electrónico en las ciudades. Este hecho está afectando el funcionamiento racional del sistema de transporte urbano de mercancías, incluyendo un alto grado de fragmentación, baja optimización de carga y, entre otras externalidades, mayor congestión del tráfico.

Este articulo expone las principales soluciones sostenibles dentro del ámbito de la logística de la ciudad y pone el foco en los sistemas de transporte ferroviarios urbano como una posible solución a considerar. De forma práctica, investiga el potencial uso de la red de metro, en una gran ciudad como Madrid, para proporcionar servicios de entrega de paquetes de e-commerce aprovechando su actual capacidad de transporte disponible y utilizando las estaciones para la entrega de los paquetes. Se definen las características de un nuevo modelo de distribución mixto (M4G: Metro for Goods).

Los resultados muestran las externalidades sociales y los costes medioambientales derivados del nuevo modelo M4G son significativamente menores que los costes actuales de reparto a través de furgonetas.

1. INTRODUCCIÓN

La población urbana está en continuo crecimiento, el 55 % de las personas del mundo ya vive en ciudades y el porcentaje de urbanización crecerá hasta el 68 % en el año 2050 (Naciones Unidas, 2018), lo que trae consigo un aumento de la demanda de bienes y servicios concentrados principalmente en áreas urbanas, que a su vez presentan cada vez más restricciones de acceso. Este hecho, inevitablemente, está llevando a las ciudades de todo el mundo a enfrentarse a mayores desafíos en términos de transporte eficiente de personas y mercancías, al tiempo que tratan de minimizar sus impactos negativos en la calidad de vida de sus ciudadanos.

Este aumento de bienes y servicios tiene su máximo exponente en el comercio electrónico, donde el incremento de las compras online se espera que, en 2024, sea 5 veces superior al que se realizaba en 2014. El efecto pandemia ha obligado a muchos consumidores a buscar opciones de compra en los canales online, modificando sus hábitos de compra no solo durante el periodo de la covid-19, sino en el periodo pospandemia. En España, los sectores como los supermercados o la compra de electrodomésticos, en 2020, casi doblaron su facturación online respecto al tercer trimestre de 2019 (CNMC, 2020).

Más personas viviendo en las ciudades y más personas realizando transacciones online se traduce en mayor número de demanda de entregas en la ciudad, sobre todo tras la aparición del q-commerce (Delivery Hero, 2020) o comercio rápido, que aparece como un nuevo modelo dentro del comercio electrónico donde prima la velocidad, la conveniencia y la atención al cliente. La entrega de última milla representa el 53 % del coste total de envío y el 41 % de los costes totales de la cadena de suministro (World Economic Forum, 2020).

Este mayor número de entregas ha hecho que todos los agentes implicados en el reparto urbano teman un colapso en la última milla y se planteen medidas que permitan aumentar su capacidad de entrega y, a su vez, reducir el impacto medioambiental que tiene su actividad en las grandes ciudades. Si no se producen intervenciones de los grupos de interés, se espera un aumento del 32 % en las emisiones de car-bono del tráfico de reparto urbano para 2030 (World Economic Forum, 2020).

Las medidas propuestas tienen dos vertientes diferenciadas. Por parte de las autoridades públicas, tratan de minimizar los impactos derivados de la logística urbana para mejorar la calidad de vida de sus ciudadanos y restringir el uso de los vehículos en las ciudades (Civitas, 2015). Por parte de los actores que intervienen en la distribución urbana (Macharis y Kin, 2017), se plantean iniciativas que aumenten su productividad de entrega y minimicen sus costes, teniendo cada vez más presentes los impactos medioambientales.

1.1 Medidas regulatorias y soluciones para la mejora de la logística urbana

Diferentes autores han organizado las numerosas medidas para la mejora de la logística de la ciudad en distintas categorías. Sobre la base de los resultados de los proyectos europeos, Russo y Comi (2011) proponen cuatro categorías de medidas, que están relacionadas con: (i) la infraestructura material, (ii) los sistemas de transporte inteligentes o telemáticos, (iii) los equipos de carga y unidades de transporte, y (iv) la gestión de la red de tráfico. Los autores proponen esta categorización de medidas como una herramienta para ser utilizada por las autoridades de la ciudad, al diseñar elementos de regulación para las actividades de logística y transporte de mercancías en las ciudades.

Browne et al. (2012) parten de la relación existente entre cinco características del transporte urbano de mercancías y sus externalidades. Estas características son: (i) niveles de ruido causados por cada transporte de mercancías, (ii) emisiones de contaminantes atmosféricos, (iii) consumo de combustible fósil, (iv) kilómetros totales recorridos por el vehículo, y (v) riesgo de accidente por kilómetro recorrido por el vehículo. Para cada una de estas características, los autores combinan iniciativas específicas que pueden reducir los impactos. Estas pueden agruparse en tres categorías: (a) compartir espacio y tiempo, (b) fomentar la cooperación (también entre el sector público y el privado), y (c) cambiar el comportamiento de los usuarios.

Por otro lado, Stathopoulos et al. (2012) definen seis clases de medidas para reducir los problemas de transporte: (i) medidas basadas en el mercado, (ii) medidas regulatorias, (iii) planificación del uso del suelo, (iv) medidas de infraestructura, (v) nuevas tecnologías y (vi) medidas de gestión. En esta misma línea, el proyecto Civitas (2015) enumera una serie de iniciativas para ciudades de entre 50 000 y 250 000 habitantes, tanto desde un punto de vista estratégico como desde la propuesta de medidas de pequeño impacto que podrían implementarse con mayor facilidad. Las citadas medidas pueden resumirse en las siguientes: (i) compromiso de los grupos de interés, (ii) medidas regulatorias, (iii) medidas basadas en el mercado, (iv) planificación del uso del suelo y medidas de infraestructura, (v) nuevas tecnologías y (vi) concienciación ecologística.

Esta breve descripción general de las distintas categorizaciones demuestra la gran variedad de medidas con relación a la logística urbana que se han introducido, probado y (o) implementado en las ciudades. Sin embargo, la literatura se ha centrado principalmente en la perspectiva de las autoridades locales y los responsables políticos, a pesar del papel clave del sector privado en muchas de estas medidas. En respuesta a esto, Macharis y Kin (2017) se centran en las medidas de logística urbana que incluyen explícitamente a los grupos de interés que son responsables y actúan en la logística en las ciudades. Las clasifican según las llamadas «cuatro aes» (inglés): (i) concienciar (awareness), (ii) evitar (avoidance), (iii) actuar y cambiar (act), y (iv) anticipación de nuevas tecnologías (anticipation). Dentro de las soluciones en logística urbana que “desplazan” al coche de la ciudad, los grupos de interés públicos tratan de restringir el acceso de vehículos con medidas reguladoras (restricciones de acceso a zonas sensibles, regulación de estacionamiento, etc.), medidas basadas en el mercado (peajes, impuestos, tarifas de estacionamiento, etc.) o medidas relacionadas con las infraestructuras (zonas de carga/descarga, área de entregas cercanas).

Por parte de los grupos de interés que son responsables y actúan en la logística de la ciudad, las medidas innovadoras tratan de buscar la eficiencia en las operaciones de reparto la entrega de la última milla. Con relación a los medios de reparto, se estudian iniciativas para sustituir los vehículos comerciales por vehículos no tripulados (drones o vehículos terrestres) que permitan, a su vez, hacer entregas minimizando el uso de las calles de la ciudad. Estas soluciones presentan, en la actualidad, numerosas barreras que es necesario solventar para que el reparto urbano con drones o con vehículos terrestres no tripulados pueda ser una realidad en muchas urbes. En la figura 1 se recopilan las diferentes iniciativas o medidas relacionadas con la logística urbana y afectan a la distribución urbana de mercancías.

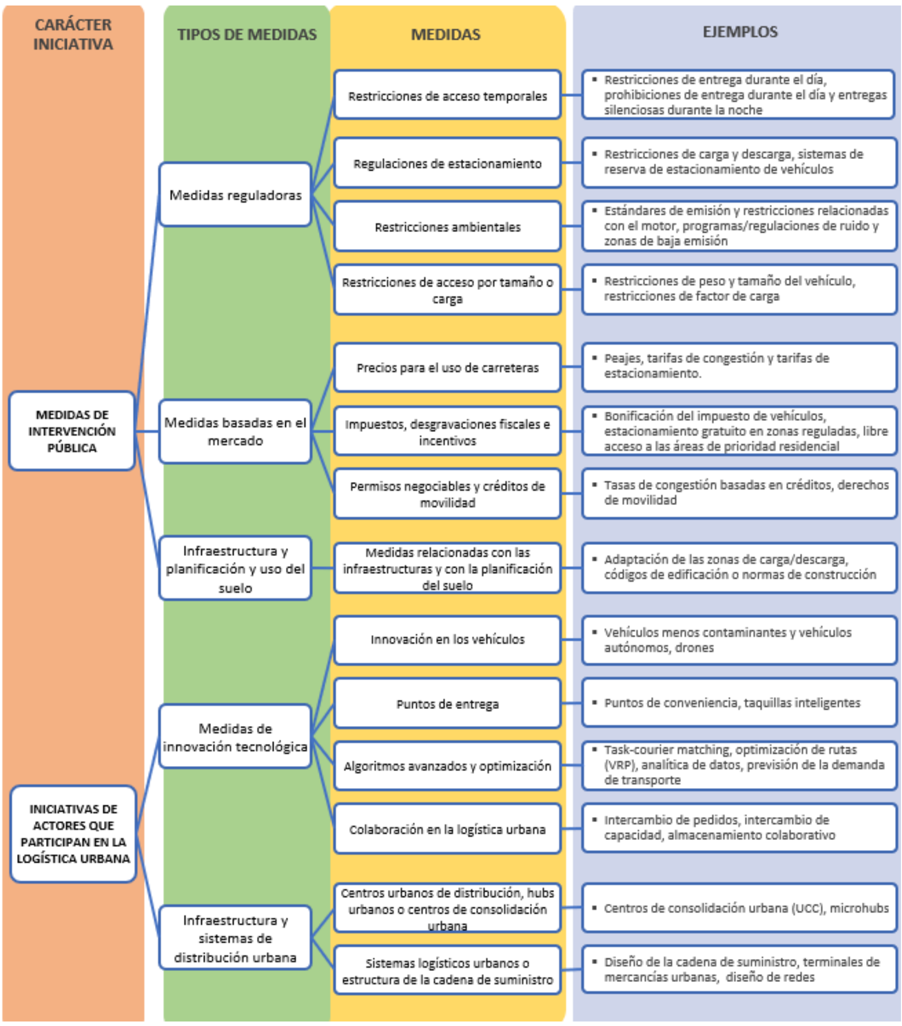

Figura 1: Medidas e iniciativas relacionadas con la logística urbana. Fuente: elaboración propia a partir de Stathopoulos et al. (2012); Civitas (2015); Macharis y Kin (2017).

1.2 Sistemas logísticos urbanos a través de metro o tranvía (M-ULS)

El transporte de mercancías por carretera es el modo que generalmente domina en las operaciones de entrega urbana. En un intento por mejorar la eficiencia de la distribución de mercancías en las ciudades y lograr y mejorar la sostenibilidad ambiental, las autoridades locales buscan políticas específicamente dirigidas a la logística urbana. Por lo general, estas políticas consisten en modelos de restricción de acceso que evitan que ciertas categorías de vehículos ingresen a áreas sensibles. Estos son, típicamente, los centros de las ciudades, donde se enfrentan varios desafíos simultáneos: la falta de espacio, la protección de la salud de los ciudadanos y la protección del patrimonio (Alessandrini et al., 2012). Existen, de forma adicional, diferentes ineficiencias y costes asociados a la distribución urbana de mercancías: edad media de los vehículos, dificultades de acceso y estacionamiento, restricciones de velocidad, congestión, etc. que favorecen el uso de modelos alternativos (Sładkowski et al., 2014)

Con relación al transporte ferroviario, se han producido una serie de estudios y pruebas en los últimos años con el propósito de utilizar este medio de transporte de mercancías en diversas ciudades. Las razones para utilizar el ferrocarril para llevar a cabo la distribución urbana se definen como consecuencia de intentar minimizar el transporte por carretera en la logística de la ciudad. El transporte por carretera es uno de los medios más utilizados, pero también resulta más contaminante y menos sostenible, reforzando así la necesidad de entregar bienes de forma innovadora.

Muchas ciudades europeas disponen de una extensa infraestructura ferroviaria para cumplir con las funciones principales de transporte público, ya sea a través de un sistema de metro, trenes o una red de tranvías, existiendo cada vez más posibilidades de utilizar estos sistemas para el transporte de mercancías en el centro de las ciudades. A diferencia de la industria del transporte de mercancías por ferrocarril pesado, que necesitaría una considerable inversión, el transporte de mercancías a través del metro o tranvía utilizaría la infraestructura existente. No es necesario cambiar las infraestructuras del material rodante ni de las estaciones, aunque deben realizarse modificaciones y adaptaciones (Dampier y Marinov, 2015).

Los estudios sobre sistemas logísticos subterráneos (ULS o UFT) llevan desarrollándose durante casi 50 años, pero no es abundante la literatura científica que aborda la distribución urbana a través de sistemas ferroviarios. Robinson y Mortimer (2004) señalaron el potencial de estos sistemas y su posible contribución a reducir la congestión del tráfico urbano al proporcionar una alternativa a la distribución por carretera. Para su posible implantación, es necesario que los costes operativos sean equiparables a los del transporte por carretera, se minimicen los conflictos entre el viajero y los trenes de carga, y se produzcan mejoras en las infraestructuras y la organización. Dampier y Marinov (2015) propusieron una nueva concepción de ULS, integrando el transporte subterráneo de mercancías en el sistema de metro de pasajeros (denominado M-ULS o sistema logístico subterráneo por metro), que ofrece una solución viable con un presupuesto limitado. Su ventaja no solo radica en los beneficios tradicionales de ULS para aliviar la congestión del tráfico, mejorar el entorno urbano y la eficiencia del transporte de mercancías, sino que también contribuye a un gran ahorro del espacio subterráneo, reduciendo los costes y el periodo de construcción.

En los últimos años, los sistemas de intercambio de pasajeros y carga, que son diferentes de los tradicionales vehículos de carga dedicados, han recibido una atención cada vez mayor. De este modo, se introducen conceptos como pooling logístico (reutilización de recursos), flete en tránsito, entrega multimodal, uso del transporte público urbano para entregas, cargo hitching (transporte mixto de pasajeros y mercancías), integración de sistemas de transporte de pasajeros y de carga, etc. La combinación de los flujos de pasajeros y mercancías brinda la oportunidad de promover aún más las ganancias de eficiencia. Las estrategias de intercambio actuales para los servicios de carga se basan en modos de transporte público como el metro o autobuses (Cochrane et al., 2017).

Otros estudios recientes han analizado la viabilidad y la eficiencia de utilizar el transporte público, como el metro y los tranvías, para la entrega urgente. Kikuta et al. (2012) estudiaron la integración del sistema de metro en Sapporo, Japón, con el sistema tradicional de transporte por camión para facilitar la distribución de mercancías entre los barrios del centro de la ciudad. Diziain et al. (2014) compararon los sistemas urbanos de transporte intermodal de mercancías entre Francia y Japón. Estos sistemas son prometedores pero difíciles de implantar en la última milla ya que los servicios ferroviarios requieren de gran volumen, suponen altos costes y conllevan dificultades organizativas. Dampier y Marinov (2015) estudiaron la viabilidad del sistema de metro, en Tyne y Wear (Reino Unido), para entregar mercancías directamente en el centro de la ciudad. Arvidsson et al. (2016) revisaron el éxito y el fracaso de los sistemas de tranvía para el transporte urbano de mercancías y propusieron una solución de transporte multimodal de bajas emisiones utilizando este medio de transporte. El proyecto Cargo hitching (van Duin et al., 2019) comenzó con el objetivo de utilizar la capacidad excedente del transporte público para el transporte de paquetes, y su viabilidad depende de poder incluir y valorar conceptos sociales como aportación a los clientes y a la sociedad. Por su parte, Jiang et al. (2020) concluyen que el metro es adecuado para la distribución en ciudades con una gran rotación de mercancías, mientras que los autobuses y los tranvías resultan más adecuados para la distribución en áreas con baja rotación de mercancías. En la sociedad actual, donde la eficiencia energética es cada vez más importante, el transporte urbano de mercancías basado en el metro es más competitivo que los autobuses y tranvías. La distribución de mercancías a través del metro puede aprovechar su alta capacidad de transporte, la alta velocidad de operación, su puntualidad y fiabilidad en los horarios y la baja contaminación ambiental producida.

Partiendo de una falta de estudios que cuantifiquen el efecto socioeconómico-medioambiental de estos sistemas dentro del sector logístico, el planteamiento del problema en este estudio es el siguiente: dentro del ámbito de las grandes ciudades, ¿puede considerarse un sistema de transporte público como el metro una alternativa eficiente y sostenible para la logística urbana en la era del comercio electrónico? A continuación, se muestran una serie de objetivos que pretenden ayudar a dar respuesta a la pregunta de la investigación:

- ¿Qué nivel de demanda de paquetería justificaría el uso de la red de metro como operador logístico urbano?
- ¿Cómo se pueden utilizar las infraestructuras y los trenes para implementar este modelo?
- ¿Cuáles son los beneficios sociales y medioambientales derivados del uso de metro para distribuir paquetes en el centro de la ciudad?

El resto de este documento está estructurado de la siguiente manera: La Sección 2 describe la metodología empleada para evaluar los costos externos del modelo propuesto. Las secciones 3 y 4 presentan el caso de estudio y la aplicación de la metodología para la ciudad de Madrid. La sección 5 analiza los resultados y, por último, la sección 6 presenta las conclusiones y posibles áreas de investigación.

2. METODOLOGÍA

2.1. Propuesta metodológica

La Figura 1 muestra el marco metodológico utilizado, donde se describen los pasos, procedimientos y fuentes de datos empleadas para resolver las preguntas planteadas. Es importante señalar que las fuentes de información empleadas se corresponden con datos de organismos oficiales.

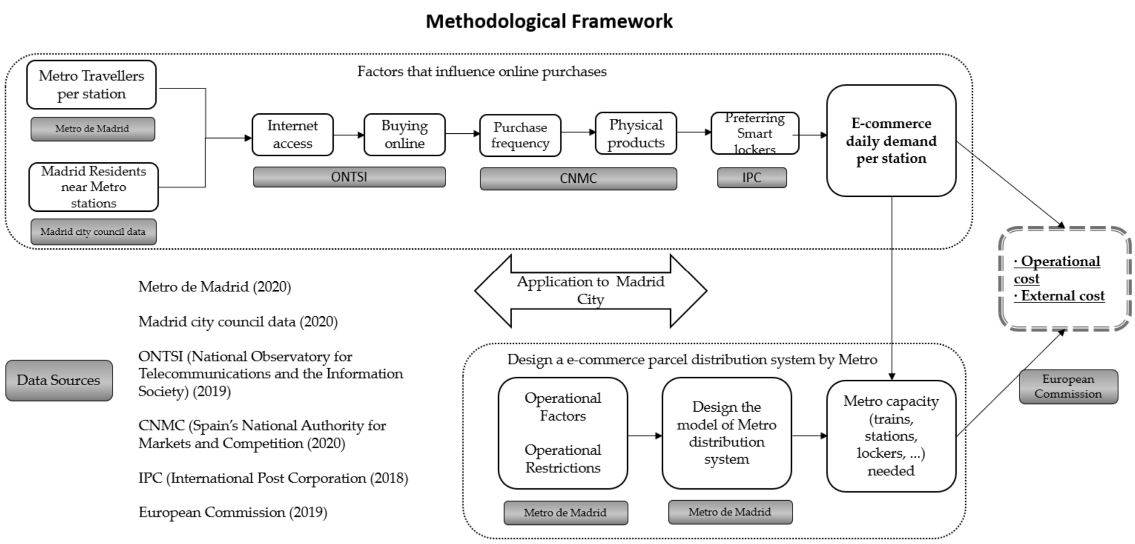

Figura 1: Marco metodológico. Fuente: elaboración propia

2.2. Definición del modelo de reparto en la última milla: modelo M4G

Antes de describir el modelo M4G, se representa en la Figura 2 un diagrama de procesos del modelo actual de reparto e-commerce B2C con entrega a domicilio, donde se explican las principales actividades realizadas:

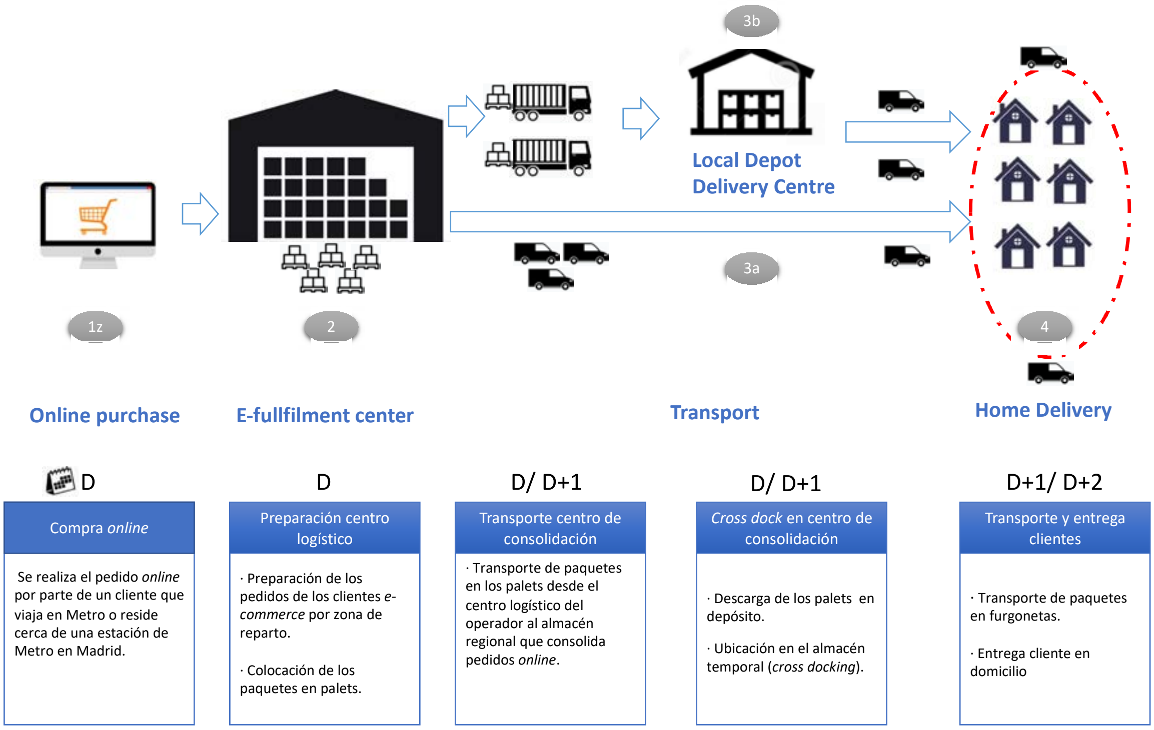

Figura 2. Modelo actual de reparto de e-commerce. Fuente: elaboración propia

1. Se realiza el pedido *online* por un residente y selecciona entrega en su domicilio.
2. Se procesa el pedido en el *e-fulfillment center* (centro logístico o centro de consolidación del minorista o del operador logístico, situado en las afueras de la ciudad). En el *e-fulfillment center* se prepara el paquete y está listo para el transporte.
3. Transporte desde el centro logístico hasta el domicilio del cliente. Dos opciones:
   i. Un camión pesado desde el centro logístico hasta un almacén local o centro de consolidación más cercano al centro de la ciudad (*local depot*). Posteriormente se clasifica el pedido y se envía al domicilio del cliente mediante furgonetas (LCV, *light comercial vehicle*).
   ii. El LCV tiene su origen en el centro logístico (*e-fulfillment*) y envía directamente al domicilio del cliente. Esta es la opción que se considera en la comparativa de este estudio.
4. Se entrega el pedido de *e-commerce* en el domicilio del cliente.

El modelo M4G, el diagrama de los procesos del modelo M4G de reparto de *e-commerce* se muestra a continuación en la Figura 3 y se describen a continuación.

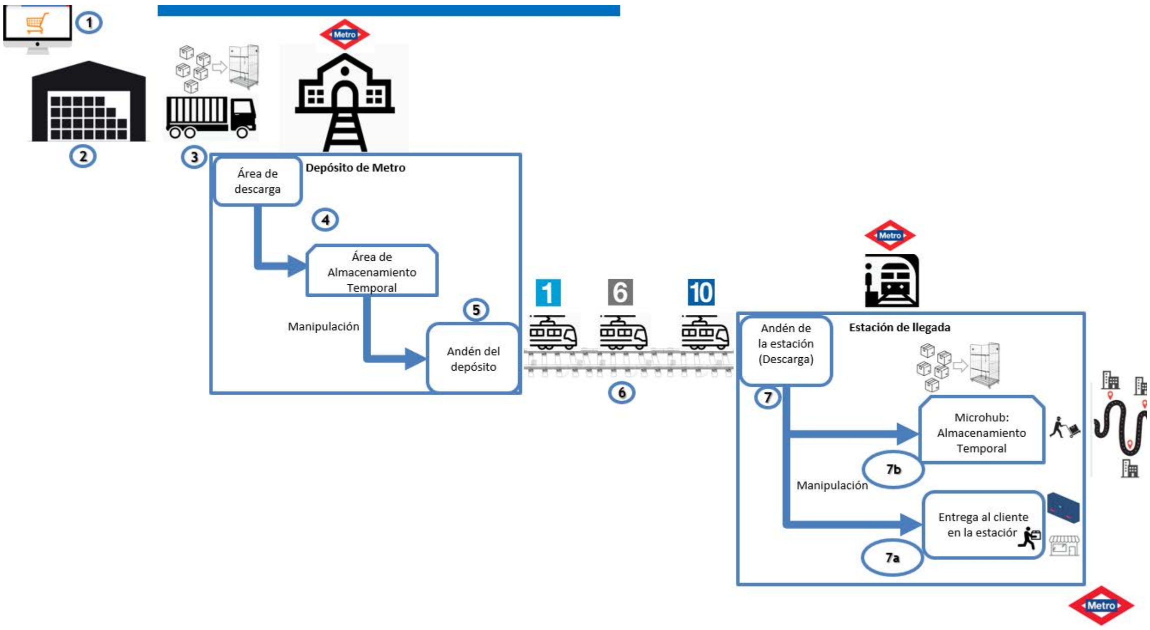

Figura 3. Modelo M4G. Fuente: elaboración propia

Para llevar a cabo la distribución urbana propuesta, a través de la red metropolitana, se detallan las 7 grandes actividades a realizar, y que serían las siguientes:

1. Se realiza el pedido *online* por un viajero de metro o por un residente de algún barrio cercano a una estación de metro. El cliente selecciona un método de entrega concreto (taquilla, centro de recogida, entrega a domicilio, etc.).
2. Se procesa y se prepara el pedido en el centro logístico/centro de consolidación del minorista o del operador logístico. Los paquetes correspondientes a pedidos *online* se preparan y colocan en los contenedores rodantes (*rollers containers*, ver Figura 4) por estación. Los contenedores rodantes son sistemas para el transporte de forma ágil de paquetes y otros productos. Son ligeros y permiten cargas de 500-800 kg. Pueden tener diferentes tamaños para adaptarse a las características interiores de cada tren. La utilización de contenedores rodantes, en la preparación de pedidos, minimiza la ruptura de la carga en todo el proceso (descomposición total o parcial del contenedor al proceder al almacenaje o transporte al receptor de la carga).

Figura 4. Ejemplo de roll container. Fuente: Todo Contenedor (https://cutt.ly/6bVKy0n)

Llegados a este punto el pedido estaría listo para el transporte.

3. Transporte hasta el depósito de metro: con un camión pesado (HGV) se transportan, mediante contenedores rodantes, los paquetes agrupados por destinos, desde el centro logístico hasta el depósito o cochera de metro seleccionado.
4. Descarga y almacenamiento temporal en las instalaciones de metro: los contenedores que contienen paquetes con pedidos de *e-commerce* se ubican, de forma temporal (*cross dock*), en el depósito a la espera de ser cargados en los trenes para su distribución posterior.
5. Carga de los paquetes en los trenes: antes del inicio del trayecto del tren, que va a circular por toda la línea, se cargan los coches/vagones necesarios con los contenedores que llevan la mercancía.
6. Transporte desde el depósito de metro hasta cada estación: el tren se carga con los contenedores rodantes en el depósito de metro y se utiliza el tren para transportar los pedidos hasta las estaciones.

Dentro de este punto, hay un aspecto fundamental a tener en cuenta en el reparto de mercancías a través de trenes en redes metropolitanas. Se trata del empleo de trenes compartidos o trenes exclusivos para transportar los contenedores rodantes. A saber:

- Trenes compartidos: en este caso, el mismo tren es compartido por viajeros y paquetes, pero no están mezclados ya que cada coche que compone el tren transporta o viajeros o paquetes. Se puede utilizar un coche de la composición de ese tren para el transporte de paquetes, y el resto transporta viajeros (ver Figura 5). Con esta alternativa se utilizan los mismos horarios de paso de los trenes en esa línea. Para que no afecte a las ratios viajeros/m^2, es recomendable utilizar esta opción durante los periodos valle.

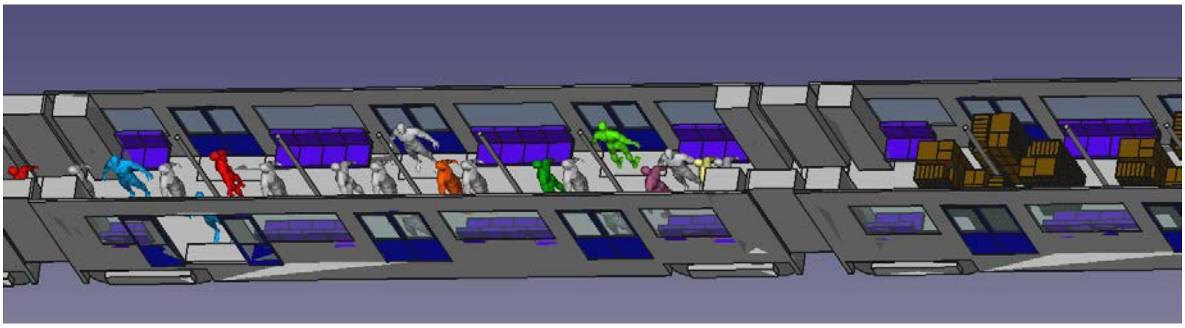

Figura 5. Ejemplo de trenes compartiendo viajeros y paquetes. Fuente: elaboración propia

- Trenes exclusivos: para esta opción, el tren que recorre las diferentes estaciones de la red de metro solo transporta paquetes. En este caso, no se modifica la estructura ni el diseño interior del tren, cada coche se carga con los contenedores rodantes que, a su vez, están llenos de paquetes. La composición del tren (número de coches que lo componen) puede variar y los horarios no coinciden con la tabla de trenes definida para los viajeros, con el fin de no interferir con ellos.

En cada estación se descargan los paquetes correspondientes. Dentro del modelo M4G y teniendo en cuenta las características descritas en el cuadro anterior, se pueden considerar dos grandes categorías en la entrega final de la mercancía al cliente que realiza el pedido de e-commerce: 7a) Entregas dentro de la estación (centros de recogida o taquillas inteligentes) y 7b) Entregas fuera de la estación (domicilio/oficinas).

2.3. Cuantificación de la demanda de paquetes de *e-commerce*

Los compradores online disponen de numerosas alternativas para elegir qué productos comprar, dónde pueden comprarlos y cuándo pueden comprarlos.
De igual forma, cuando hablamos de la entrega de paquetes en el comercio electrónico, los clientes esperan poder elegir diferentes alternativas. Una empresa que ofrezca (o el cliente perciba) un alto valor del servicio para una entrega de comercio electrónico, generalmente producirá la satisfacción del cliente dentro del proceso de compra y, además, tendrá un efecto directo en su lealtad y permanencia, lo que finalmente generará mayor consumo y, por extensión, aumentará los beneficios de las empresas (Copenhagen Economics, 2013).

Por lo tanto, la forma en que se materializa la entrega física también condiciona la demanda del comercio electrónico.

La demanda diaria de pedidos de comercio electrónico del modelo M4G tiene dos componentes, la demanda de viajeros y la demanda de residentes:

2.3.1 Demanda diaria de viajeros (DDV)

Una de las principales sinergias entre el transporte urbano ferroviario de personas y el transporte urbano de mercancías en las grandes ciudades se produce cuando un viajero de metro puede, a su vez, ser un cliente de comercio electrónico y recoger los pedidos cuando entra o sale de una estación.

El cálculo de esta demanda diaria potencial de pedidos de e-commerce de los viajeros de metro se construye aplicando el método de proporciones en cadena propuesto por Kotler y Keller (2012), que consiste en multiplicar un número base por una serie de porcentajes hasta llegar a la demanda objetivo.
La formulación sería la siguiente:

$$DDV=A\times P1\times P2\times P3\times P4\times P5\times P6\times P7 \qquad (1)$$

donde:

- A = viajes diarios en metro por estación
- P1 = % promedio de viajeros distintos en metro por estación
- P2 = % promedio de personas que viajan en metro > x años por estación
- P3 = % promedio de personas > x años que usan Internet
- P4 = % promedio de personas > x años que usan Internet y compran online
- P5 = % promedio de personas > x años que usan Internet y compran online de forma diaria
- P6 = % promedio de personas > x años que usan Internet y compran online de forma diaria bienes y productos físicos que pueden entrar en un paquete de tamaño estándar
- P7 = % promedio de personas > x años que usan Internet y compran online de forma diaria bienes y productos físicos que pueden entrar en un paquete de tamaño estándar y muestran preferencia por un método de entrega concreto (taquillas o recogida en centro o domicilio)

2.3.2 Demanda de residentes (DDR)

La privilegiada ubicación de todas las estaciones de metro en las grandes urbes (en distancia y en accesibilidad) les otorga una ventaja competitiva a la hora de determinar los posibles puntos de entrega de pedidos de comercio electrónico para los residentes de estas ciudades.

De forma análoga al método anterior, se calcula la demanda potencial diaria de pedidos de e-commerce para las personas que residen dentro del área de influencia de una estación de metro (se considera área de influencia de una estación el área que ocupa el barrio donde vive el residente).

Para este caso, la formulación sería:

$$DDR = Y \times P3 \times P4 \times P5 \times P6 \times P7 \qquad (2)$$

donde:

Y = personas residentes que viven en un área de influencia de una estación de metro > x años y no viajan en metro de forma regular.

La demanda diaria total de pedidos de e-commerce por estación DDT(i) será la suma de ambos conceptos:

$$Demanda\ diaria\ de\ pedidos\ e - commerce\ de\ la\ estación\ DDT(i) = DDV(i) + DDV(i) \qquad (3)$$

(i) = estaciones de metro

2.4. Análisis de costes externos

Según la Comisión Europea (European Commission, 2019), «Los costes externos, también conocidos como externalidades, surgen cuando las actividades sociales o económicas de una persona (o un grupo) tienen un impacto en otra persona (o grupo) y cuando ese impacto no se contabiliza por completo o no se compensa por la primera persona (o grupo)».

Estos costes, generalmente, no son asumidos por el usuario de transporte y no se tienen en cuenta a la hora de decidir qué medio de transporte utilizar. La Tabla 1 muestra las dos grandes categorías de costes externos y el tipo externalidad que la componen, donde:

Costes externos	Tipo de coste externo	Variables que influyen en el tipo de coste	Definición
I: Social (CS)	Costes de congestión C(c)	$Cc = f(D, T, M, P)$	Pérdida de tiempo que sufre un individuo y que aparece cuando un vehículo adicional reduce la velocidad de otros vehículos dentro de un flujo de tráfico, aumentando el tiempo de viaje.
	Costes de accidentes C(a)	$Ca = f(D, M, P)$	Tiene en cuenta, no solo los costes materiales (costes administrativos, daños materiales en otros vehículos e infraestructuras, etc.), sino también los costes inmateriales
II: Medioambiental (CM)	Costes de ruido C(r)	$Cr = f(D, M, T, P, H)$	El ruido se puede definir como sonidos no deseados de diferente duración, intensidad u otra calidad que causan daño físico o psicológico a los seres humanos. Los sistemas de transporte son fuentes de ruido.
	Costes por polución de aire C(pa)	$Cpa = f(D, M, P, F, S, E)$	Los motores de transporte emiten ciertos contaminantes (por ejemplo, SO_2, NO_x, PM_{10}, CO) a la atmósfera. Tienen en cuenta tanto los efectos sobre la salud como otro tipo de daños
	Coste de cambio climático C(cc)	$Ccc = f(D, M, P, F, S, E)$	Los costes del cambio climático se definen como los costes asociados a todos los efectos del calentamiento global, como el aumento del nivel del mar, la pérdida de biodiversidad, los problemas de gestión del agua,etc.

donde: D (km): distancia recorrida para entregar los paquetes de comercio electrónico por un determinado modo de transporte. M: modo de transporte (LCV, HGV, Metro). T situación del tráfico (sobrecapacidad, congestionado, cerca de la capacidad, por debajo de la capacidad, denso, fluido, etc.) P: área de actuación en el transporte de paquetes (área urbana, área interurbana, etc.) H: momento del día. F: tipo de combustible. S: tamaño del vehículo. E: tipo de emisión.

Tabla 1- Costes externos y variables que influyen en el tipo de coste

La cuantificación monetaria de las externalidades del modelo de distribución de paquetes de comercio electrónico a través del sistema M4G considera los siguientes costes agregados totales (CT):

$$CT = CS + CM \tag{4}$$

donde:

$$CS = C(c) + C(a)$$
$$CM = C(r) + C(pa) + C(cc)$$

2.5. Capacidad de la red de metro y factores operativos

El cálculo de la oferta de servicios logísticos de comercio electrónico por estaciones de metro (para residentes y viajeros) estará condicionado tanto por aspectos vinculados a la demanda de entregas en cada una de esas estaciones, como por factores logísticos operativos. Como se muestra en la Tabla 2, los siguientes factores operativos condicionarán el coste de envío por paquete a través del modelo M4G.

Factor operativo	Definición	Característica
Tipo de tren 	En función de las líneas con mayor demanda de paquetes, el tipo de tren (serie) que circula por ellas es diferente. Cada uno de estos trenes puede presentar un diseño interior en cada coche que lo compone y por lo tanto tiene una capacidad de transporte de paquetes distinta.	Capacidad interior +++ (por coche) Capacidad interior + (por coche)
Tamaño del contenedor 	Debido a su facilidad de manejo y su capacidad, se utiliza el *roll container* como medio para transportar paquetes en los trenes. En función de la capacidad interior del tren, se selecciona el tamaño de *roll* más adecuado.	*Roll container* grande *Roll container* mediano
Operativa de trenes	Trenes compartidos: los trenes no modifican su frecuencia actual para el transporte de viajeros y se utiliza parte de un tren para dar servicios logísticos. Trenes específicos: se utiliza un tren para transportar paquetes. Este tren no está disponible para los viajeros y tiene un horario diferente.	Tren compartido Tren específico
Tiempo de descarga de contenedores en estación 	Tiempo para la descarga de *rollers containers* en cada estación.	Trenes compartidos = al de tiempo de parada de transporte de viajeros Trenes específicos = en función del número de *rollers containers*
Tamaño paquetes 	Se consideran diferentes tamaños de paquetes. Esto permite 1 pedido = 1 paquete, así es posible incluir varios productos en un mismo paquete o considerar varias combinaciones en función de los m^3 necesarios.	Paquete pequeño Paquete mediano Paquete grande Paquete especial
Tamaño de las taquillas, de los centros de recogida y  del *microhub*	En función de la demanda de paquetes diaria de cada estación, el tamaño de las taquillas inteligentes puede ser diferente. Para el caso de los centros de recogida y del almacén urbano situado en la estación (*microhub*), se determinará la superficie necesaria en función de la demanda diaria de paquetes en esa estación.	Estaciones con alta demanda de taquillas ++++ Estaciones con menor demanda Taquillas ++ La superficie de los centros de recogida y los *microhubs* de estaciones están condicionados por la demanda de paquetes de esa estación A mayor demanda mayor superficie de almacenaje

Tabla 2- Factores operativos del modelo M4G

3. CASO DE ESTUDIO

El siguiente apartado describe la aplicación del sistema de reparto mixto de última milla propuesto para mercancías de comercio electrónico en la ciudad de Madrid. A continuación, se define el modelo M4G para la distribución de los paquetes originados por el e-commerce, considerando el caso de la ciudad de Madrid. Esta nueva distribución urbana se realiza a través del sistema de transporte público ferroviario Metro de Madrid (Metro). El objetivo es poder comparar las externalidades de este nuevo modelo con el modelo actual de reparto urbano de paquetes en la ciudad de Madrid.

3.1 Background

La distribución urbana es fundamental para la actividad y el desarrollo de cualquier ciudad, y Madrid no es una excepción. Por su relieve y la evolución histórica de su estructura urbana, la distribución dentro de la ciudad de Madrid es una de las más complicadas entre las grandes ciudades europeas. La ciudad, motor esencial de la economía española que representa el 12% del PIB nacional, está dividida en 21 distritos con una población total de 3,3 millones (INE, 2020) y tiene una superficie total de 60.436,7 hectáreas, con una densidad de población media de 54 habitantes por hectárea.
En la actualidad, existen dos tipos principales de problemas asociados a la distribución urbana en la ciudad de Madrid (Área de Gobierno de medioambiente y Movilidad, 2019):

- Infraestructura urbana:
  · No hay planificación urbana de puntos de distribución.
  · Problemas con el uso de áreas de estacionamiento y carga / descarga.
  · Crecimiento significativo de viviendas particulares como puntos de entrega de comercio electrónico.
- Gestión:
  · No existe un modelo de gestión de la logística de distribución que identifique y organice adecuadamente los numerosos agentes y operaciones para cada canal de distribución urbana.
  · Crecimiento del comercio electrónico y nuevos modelos de entrega.
  · Mal uso de las actividades de carga / descarga.

En Madrid el problema se agrava ya que, siguiendo las directrices europeas, se están tomando medidas para expulsar (o desplazar) al coche que más contamina del centro de la ciudad (por ejemplo, Madrid Central o Madrid 360) y lograr una mejor calidad del aire. Esta prohibición de acceso de los vehículos a determinadas zonas plantea los siguientes inconvenientes:

- Si no se sustituyen los vehículos actuales de reparto por otros menos contaminantes, un porcentaje considerable de la flota de estos vehículos (84 321 LCV distintos accedieron a Madrid Central de enero a junio de 2019) no podrán hacer la distribución en el centro de la ciudad en el futuro a corto plazo.

- Si se produce una sustitución de los vehículos actuales de reparto por otros menos contaminantes (por ejemplo, eléctricos), no se habrá logrado el objetivo de «expulsar» al vehículo de la ciudad y seguirán existiendo problemas de congestión.

En Madrid, el transporte por carretera supuso el 34,1% del total de emisiones de gases de efecto invernadero, según el Inventario de Emisiones de Gases Contaminantes a la Atmósfera 2016. La flota de coches de Madrid destaca por su elevado porcentaje de vehículos diésel y la edad media ronda los 9,3 años. (Área de Gobierno de medioambiente y Movilidad, 2019). El porcentaje de vehículos comerciales e industriales con más de 10 años rondaba el 73,2% a finales de 2018 (Anfac, 2018). Según datos del Ayuntamiento, durante los meses de enero y junio de 2019, entre 13.000-16.000 vehículos LCV accedieron (en días laborables) a la zona de bajas emisiones establecida en 2018 como Centro de Madrid (una superficie de 472 hectáreas).

Por otro lado, Metro de Madrid es el mayor operador de metro de España y un referente internacional por su red, calidad de servicio e innovación y capacidad tecnológica. Con más de 100 años de experiencia, es el medio de transporte público más utilizado en la Comunidad de Madrid. La red, compuesta por doce líneas y un ramal especial, presenta una extensión total de 294 kilómetros y conecta 12 municipios. Durante la temporada de invierno, más de 2,3 millones de viajeros (periodo pre-covid) utilizan el metro cada día laborable. El desplazamiento diario por motivos de trabajo o estudio representa el 70% del volumen total (https://www.metromadrid.es/es).

3.2. Descripción del modelo M4G en la ciudad de Madrid

La Figura 6 describe el modelo para el reparto de paquetes de e-commerce B2C para los residentes y viajeros de Metro de Madrid, a través del suburbano. Este modelo, M4G, presenta las operaciones involucradas desde que se realiza el pedido online por un cliente hasta que llega a las estaciones de Metro.

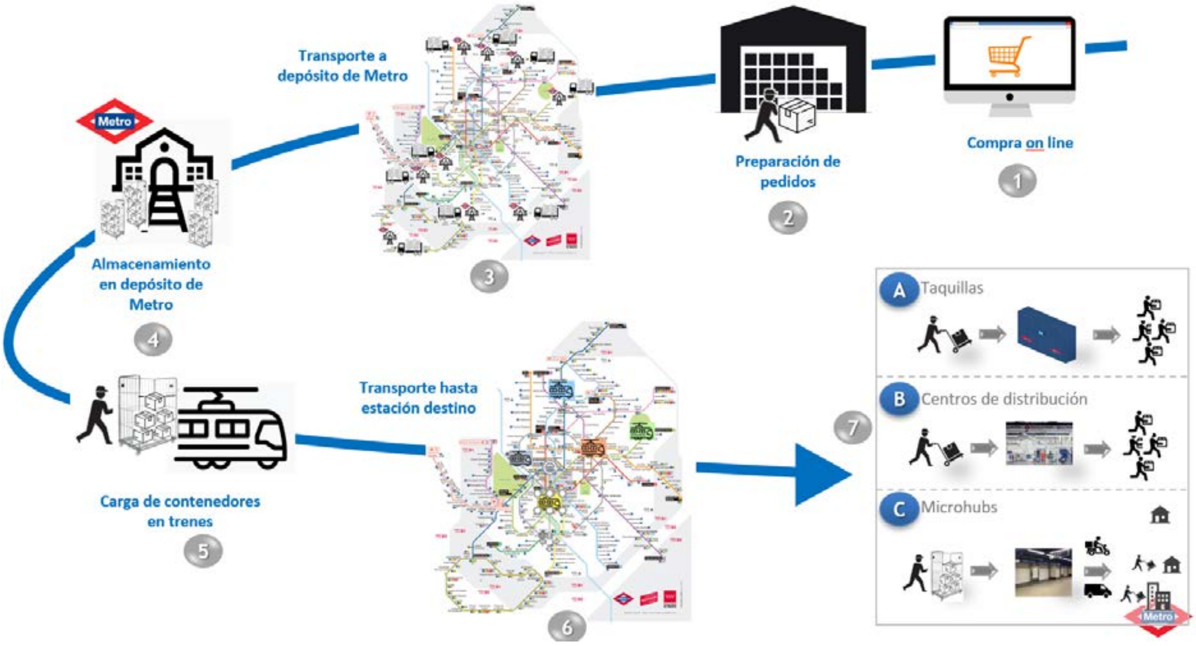

Figura 6. Flujograma de actividad del modelo M4G para la ciudad de Madrid. Fuente: elaboración propia

Las actividades descritas en la Figura 6 son:

1. Se realiza el pedido *online* por un viajero de Metro de Madrid o por un residente de la ciudad de Madrid. En ese momento el cliente selecciona un método de entrega.
2. Se procesa y se preparan los pedidos *online* en el centro logístico (del minorista o del operador, según el caso). En una ciudad como Madrid, estos centros de almacenaje y preparación de pedidos se ubican en las afueras de la ciudad (corredor del Henares, Alcobendas, Getafe, Pinto, etc.). En ellos, se preparan los paquetes y se señalan los contenedores rodantes que los transportan (ver Figura 6), quedando listos para el transporte y diferenciándose por estación.

Figura 7. Contenedor rodante cargado con paquetes. Fuente: elaboración propia

3. Transporte de paquetes B2C hasta un depósito de Metro: los paquetes se trasladan desde el centro logístico situado a las afueras de Madrid hasta el depósito de Metro seleccionado. El transporte se realiza con un camión pesado cargado de contenedores rodantes llenos de paquetes B2C y la mercancía se descarga en un espacio habilitado en el depósito.
4. Almacenamiento temporal en el depósito de Metro de Madrid: los contenedores rodantes se almacenan en una carpa o almacén de Metro durante un breve periodo de tiempo (horas o días, según el caso).
5. Traslado y carga de contenedores rodantes en trenes: antes de iniciar el reparto de los pedidos de *e-commerce*, se trasladan los contenedores desde el almacén temporal hasta las vías donde se sitúan los trenes que inician su recorrido desde el depósito.

   Se colocan los contenedores rodantes en los coches que componen un tren. Dependiendo de la alternativa seleccionada, los trenes tienen una composición de coches con viajeros más coche con paquetes o el tren se compone solo de coches con paquetes.

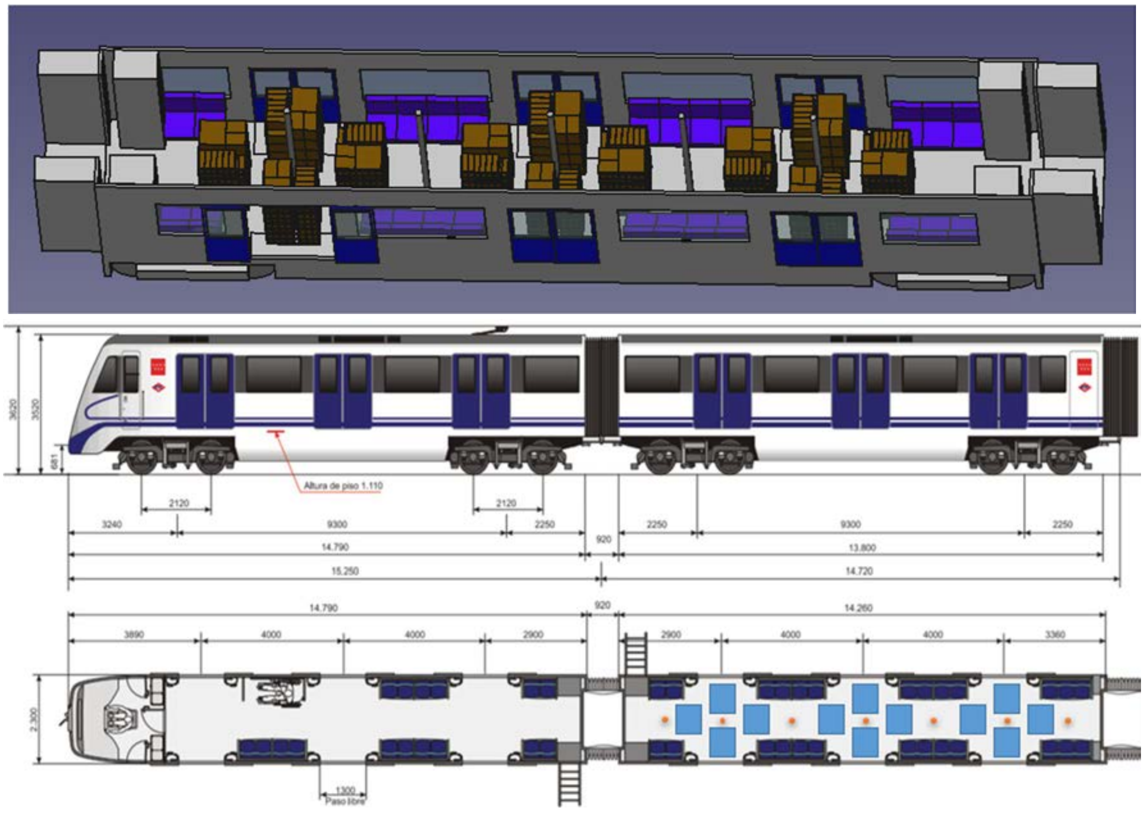

Figura 8. Coche serie 3000 de Metro de Madrid cargado con contenedores rodantes. Fuente: elaboración propia a partir de Metro de Madrid
(https://www.metromadrid.es/es)

6. Transporte desde el depósito de Metro hasta la estación de destino: se transportan los pedidos de *e-commerce* en trenes desde el depósito de Metro (inicio de la ruta) hasta cada una de las estaciones destino donde se descargan los contenedores rodantes con paquetes.
7. Entrega al cliente final en un centro de recogida: la entrega se realiza dentro de la estación en un centro de recogida de paquetes que funciona similar a una tienda de conveniencia o punto de recogida. El operador logístico lleva directamente los paquetes desde el tren hasta el centro de recogida que está dentro de la estación de Metro. Hay una persona que entrega el paquete al cliente.

4. APLICACIÓN DE LA METODOLOGÍA AL CASO DE ESTUDIO

4.1. Diferentes alternativas de aplicación del modelo M4G

Se distinguen dos alternativas del modelo M4G teniendo en cuenta la forma de transportar paquetes dentro de los trenes: trenes compartidos (paquetes + viajeros) o trenes específicos para el transporte de paquetes e-commerce. Se muestran en la Tabla 3:

Alternativa	Características de la entrega	Modo de transporte desde el centro logístico al cliente	Demanda de paquetes
Alternativa 1 (A1)	Entrega de paquetes de *e-commerce* en centros de recogida en la estación	HDV + trenes compartidos	DT1
Alternativa 2 (A2)	Entrega de paquetes de *e-commerce* en centros de recogida en la estación	HDV + trenes específicos	DT1

Tabla 3- Alternativas y características del modelo M4G

Cada una de las alternativas del modelo M4G se compara con el modelo actual de reparto de paquetes de *e-commerce* a través de LCV, que es el denominado escenario de referencia.

Alternativa	Características de la entrega	Modo de transporte desde el centro logístico al cliente	Demanda de paquetes
Escenario de referencia para la alternativa 1 (A0)	Entrega de paquetes de *e-commerce* con LCV en el domicilio del cliente	HDV + LCV	DT1

Tabla 4- Escenario de referencia para las alternativas del modelo

4.2. Cálculo de la demanda de paquetes por Línea

Siguiendo lo explicado en el apartado 2.3. se cuantifica la demanda de paquetes diaria para las alternativas del modelo M4G.

La demanda es igual para ambos casos, ya que las alternativas se diferencian en función del uso de trenes en el transporte (específicos o compartidos). Además, en la Tabla 5 se detallan el número de contenedores rodantes necesarios para el transporte de esos paquetes. Para el cálculo de la demanda, se tienen en cuenta aquellas estaciones que están dentro de la ciudad de Madrid, excluyendo las estaciones de Metro de Madrid que están en ciudades colindantes. De igual forma, se excluyen las líneas 8 y 11 por tener muy poco alcance.

Alternativa A1&A2			
Línea	Paquetes	Contenedores utilizados	Estaciones con centro de recogida
Línea 1	2147	57	Plaza de Castilla, Cuatro Caminos, Sol, Pacífico, Villa de Vallecas
Línea 2	1645	72	-
Línea 3	2086	89	Villaverde Bajo-Cruce, Legazpi, Embajadores, P. España, Moncloa
Línea 4	1319	58	-
Línea 5	1271	34	-
Línea 6	2421	64	Carpetana, Plaza Elíptica, Conde de Casal, Nuevos Ministerios, P. Pío
Línea 7	1416	38	-
Línea 9	1438	39	-
Línea 10	1485	40	-
Total best 3	6654	210	-

Tabla 5- Number of parcels, roll containers and parcel lockers (daily per Line)

La columna Paquetes de la Tabla 5 se corresponde con la suma de las 5 estaciones (donde se situarían los centros de recogida) con mayor demanda de pedidos por cada línea. De estas, se seleccionan las tres líneas de mayor demanda (Total best 3). La estimación de paquetes diarios entregados es de 6654 en 15 estaciones diferentes. Los trenes inician el recorrido en los depósitos de las líneas 1, 3 y 6 y entregan paquetes en los centros de recogida, donde se almacenan hasta que el cliente final retira su paquete. Estos centros de recogida pueden ser también centros que presten servicios alternativos al viajero, como atención al cliente u oficina de objetos perdidos.

Se considera que no hay límite de envío de paquetes por estación (el máximo de entrega diario lo presenta la estación de Sol con 673 paquetes) y la demanda potencial está formada por la suma de pedidos de *e-commerce* que realizan viajeros de Metro y de los residentes de barrios en los que está la estación donde se encuentra el centro de recogida

4.3. Datos de la modelización

Para realizar el cálculo de los principales indicadores del modelo y sus alternativas, se utilizan datos de partida basados en la literatura estudiada y teniendo en cuenta la opinión de los expertos de las principales empresas del sector de paquetería e-commerce en Madrid. Diversos estudios realizados para ciudades distintas (Edwards et al., 2009; Lemke et al., 2016; de Maere, 2018) nos muestran que la productividad de la entrega varía considerablemente según el área donde se realiza. Existen algunas características comunes en toda gran ciudad: a mayor densidad de población, mayor productividad de entrega en la distribución urbana, y existen zonas de alta congestión o críticas, que concentran importantes niveles de actividad económica. Este tipo de zonas, que incluyen sectores como los centros históricos, los distritos comerciales, los de entretenimiento, entre otros, albergan un elevado número de establecimientos comerciales y, por tanto, atraen continuamente una alta intensidad de flujos logísticos (Merchán et al., 2015).

En el presente caso de estudio, se considera el funcionamiento actual de la logística de última milla en Madrid que responde al esquema tradicional, con grandes centros de clasificación y reparto situados en el extrarradio. Se trata de centros logísticos con grandes capacidades y volúmenes. Desde estos centros, y siempre mediante furgonetas ligeras, se accede a los diferentes núcleos urbanos en largos periodos de reparto.

<u>Validación de datos del escenario actual:</u> con objeto de corroborar la fiabilidad de estos datos y particularizarlos a la ciudad de Madrid, durante los meses de enero y febrero de 2020 se llevó a cabo una consulta individual con cuatro expertos de los de los principales operadores logísticos de comercio electrónico que operan en Madrid. A partir de esta información, se estableció en 60-100 paquetes transportados por un mensajero estándar. En cuanto al peso transportado, el grupo de expertos consultados consideró un peso medio de entre 1,5 y 3 kg por bulto. El modelo considera un valor de 2 kg, siguiendo los datos de una encuesta de International Post Corporation (2020).

Con base en la literatura y las opiniones de los expertos, se consideran los siguientes valores con relación al reparto de paquetes de e-commerce en la ciudad de Madrid:

- T (jornada laboral) = 8 horas
- Km (kilómetros recorridos) = 90 km
- Pr (paquetes en ruta) = 80
- FTHR (tasa de acierto a la primera) = 25 %
- Pd (paquetes entregados) = 60
- Peso del paquete = 2 kg
- Distancia del centro de cumplimiento electrónico al depósito = 25 km
- Peso del contenedor rodante = 15 kg

- Logística inversa depósito Metro-Centro de consolidación = 5 % paquetes
- Optimización de la carga de camiones desde el centro de cumplimiento electrónico hasta la estación de Metro: >80 % (≥ 22 contenedores grandes o ≥ 35 contenedores rodantes medianos).

4.4. Calculo de costes externos y principales indicadores

Tomando como base el Manual de costes externos de la Comisión Europea (European Commission, 2019), la Tabla 6 muestra la valoración de los costes diarios medioambientales y sociales (€) que supone cada una de las diferentes alternativas de entrega de paquetes de e-commerce. En su segunda columna, se indica el modo de transporte de paquetes que genera la externalidad (furgoneta LDV, camión HDV o Metro).

Coste externo		Modo	*DT1*		
			Courier (A0)	*Shared trains* (A1)	*Dedicated trains* (A2)
Medioambiental	Ruido Cr	LDV	169,67		
		HDV Rigid 20-26 t EIV		65,89	65,89
		Metro			
	Costes por polución de aire Cpa	LDV Euro 4 Diesel	418,19		
		HDV Rigid 20-26 t EIV		88,69	88,69
		Metro			23,87
	Coste de cambio climático Ccc	LDV Euro 4 Diesel	257,50		
		HDV Rigid 20-26 t EIV		55,75	55,75
		Metro			21,06
	Total medioambiental (€/día)		845,36	210,33	255,27
Social	Costes de accidentes Ca	LDV Euro 4 Diesel	75,85		
		HDV Rigid 20-26 t EIV		5,07	5,07
		Metro			6,28
	Costes de congestión Cc	LDV Near capacity	2604,93		
		HDV Near capacity		174,5	174,50
	Total social (€/día)		2680,79	179,57	185,85

Tabla 6- Costes externos para las diferentes alternativas (A0, A1 y A2)

A continuación, la Tabla 7 compara los principales indicadores para cada una de las alternativas analizadas del modelo M4G (A1 y A2) y del escenario de referencia de reparto a través de furgonetas (A0).

	DT1 (Centros de recogida)		
	Courier (A0)	*Shared trains* (A1)	*Dedicated trains* (A2)
Paquetes de *e-commerce* entregados por día		6654	
Estaciones de Metro utilizadas	-	15	15
Emisiones de CO_2 LDV/HDV (toneladas/año)	418,25	87,52	87,52
Kilómetros en carretera LDV/HDV (km/día)	9981	500	500
Consumo diésel (litros/año)	144 140	28 635	28 635
Costes medioambientales por paquete	0,127	0,032	0,038
Costes sociales por paquete	0,403	0,027	0,028
Total coste externo por paquete	0,530	0,059	0,066

Tabla 7- Principales indicadores de las alternativas analizadas

5. ANALISIS DE RESULTADOS

Los costes totales estimados para las alternativas propuestas indican que el uso del sistema ferroviario metropolitano para entregar paquetes de comercio electrónico puede ser una alternativa prometedora desde un punto de vista social y ambiental.

Esta sección analiza los resultados desde varias perspectivas:

1) Coste externo por paquete:

Para poder comparar la eficiencia social y ambiental de cada alternativa, es necesario asociar el coste externo total por cada paquete entregado y para cada una de las alternativas, como se muestra en la Figura 9.

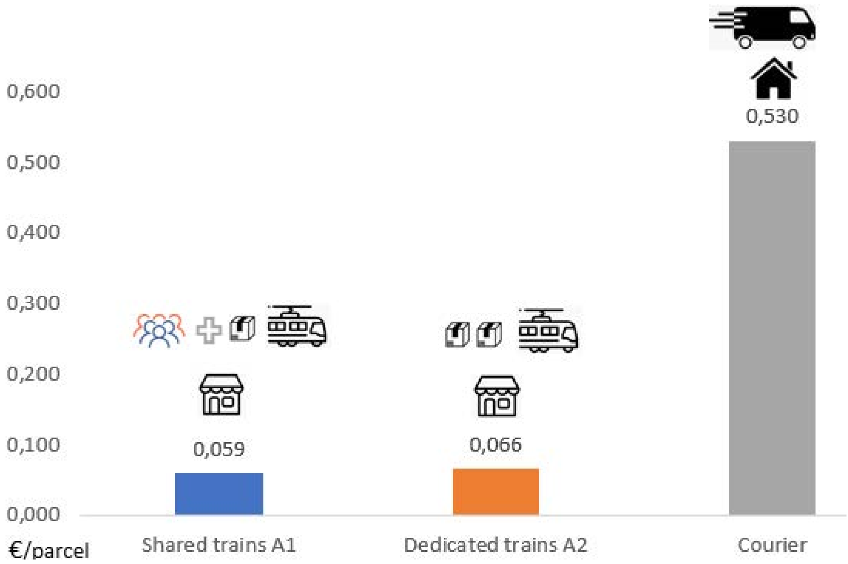

Figura 9. Coste externo (€) por paquete para las alternativas analizadas (A1, A2, A0).

Como se puede observar en la Figura 9, las dos alternativas del modelo M4G presentan unos costes externos notablemente inferiores a la situación de reparto actual mediante furgonetas. En concreto, los costes medioambientales y sociales suponen entre un 88,87 % y un 87,63 % menos que los mismos costes externos del modelo actual de reparto.

Dentro de las alternativas del M4G, los valores son similares y las externalidades provocadas por los trenes específicos son poco relevantes. Como puede verse en el desglose de cálculos de los costes externos de las alternativas con la misma demanda de paquetes, los costes externos de los camiones pesados que viajan a los depósitos de Metro suponen un impacto significativamente mayor que las externalidades de los trenes dedicados que transportan paquetes. Para las alternativas que involucran trenes, la diferencia en los costes externos radica en optimizar el número de camiones pesados que transportan contenedores empleados en el transporte a depósitos de Metro

2) Coste por tipo de externalidad:

Dentro de todos los costes externos, los costes de congestión son los que producen mayor impacto en cualquiera de los escenarios analizados. Dentro del modelo M4G, la congestión media de las dos alternativas (42,0 %) es producida por los camiones que transportan paquetes desde el centro logístico a los depósitos de Metro, y en el caso del escenario actual, la congestión (73,9 %) es producida por el número de furgonetas que reparten desde el centro logístico al domicilio de cada cliente.

Con relación al medioambiente, la polución del aire es el principal causante de los costes debido a la participación dominante que ostenta el transporte como medio por carretera (24,2 % en el caso de M4G y 11,9 % en courier). La externalidad con menor relevancia es el coste que se produce por accidentes con, aproximadamente, un 2 % de los costes externos.

La Figura 10 muestra la media de los costes externos de las alternativas del modelo M4G (A1-A2) y el coste externo del modelo actual de reparto (courier).

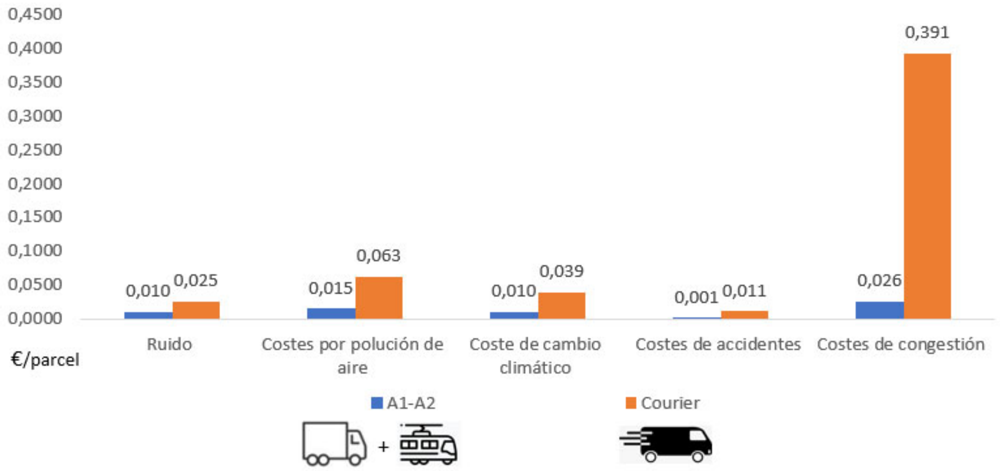

Figura 10: Coste externo promedio por paquete para las diferentes externalidades.

3) Analisis de sensibilidad:

Se considera en este estudio la variación de la demanda de paquetes como consecuencia del incremento o disminución del potencial número de compradores online, es decir, para el caso de estudio: (i) el número de viajeros de Metro, y (o) (ii) el número de residentes en los barrios donde hay una estación de Metro para recoger el pedido online.

Potencial número de compradores online: el porcentaje total de paquetes solicitados por viajeros es del 39,6 % y por residentes del 60,4 %. A priori, estos porcentajes se pueden considerar valores estables con pequeños crecimientos o decrecimientos a lo largo de los años, pero la aparición de la covid-19, si bien no ha tenido incidencia significativa en el número de residentes de los barrios de Madrid, sí que ha supuesto una modificación sustancial en el número de viajeros que utilizan el transporte público metropolitano. En la Figura 11 se muestra la evolución de los residentes en la ciudad de Madrid y la evolución de los viajes en Metro en el periodo 2000-2020.

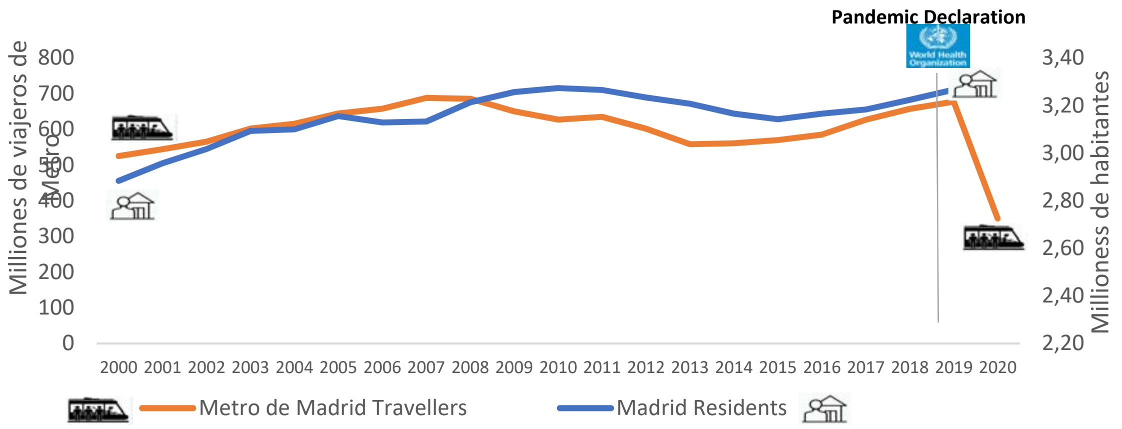

Figura 11: Evolución del número de residentes y del número de viajeros de Metro de Madrid (2000-2020).

Las dos curvas presentan evoluciones similares hasta el año 2020. En ese año, mientras los residentes de la ciudad de Madrid siguen creciendo, la demanda de Metro de Madrid cae drásticamente. En 2019, Metro de Madrid realizaba una media de 2,3 millones de viajes al día, de lunes a viernes. Durante la pandemia, excluyendo los periodos de máxima restricción (marzo-junio de 2020), la demanda de viajeros se mantuvo estable en el 50 % del periodo precovid-19. Desde la Comunidad de Madrid (https://cms.uitp.org/wp/wp-content/uploads/2020/12/201221-NP-TRANSPORTES-Balance-y-campa%C3%B1a-transporte-p%C3%BAblico.pdf), se prevé que se pueda recuperar las cifras previas a la crisis en 2023. Parece factible una recuperación progresiva de la demanda de viajeros, lo que parece más complicado es alcanzar los niveles de demanda de viajeros precovid-19, debido a los cambios sociales y de movilidad que ha experimentado la sociedad.

En el caso de una variación de la demanda de viajeros de Metro (manteniendo la misma estructura de la matriz origen-destino y el resto de variables constantes), la variación de la demanda diaria de paquetes de e-commerce influye solo en los pedidos que realizan los viajeros de Metro.

Ante estos cambios en la demanda de paquetes, las alternativas analizadas presentan costes externos muy estables (Figura 12 y Figura 13). El volumen máximo de paquetes (9981) no requiere trenes adicionales para el caso de la alternativa de trenes específicos y, como se explicó anteriormente, las externalidades provienen principalmente de los camiones que realizan el transporte desde el centro logístico al depósito de Metro. Si no cambian estos parámetros, la variación es casi nula en ambos casos. En términos sociales y medioambientales (costes externos), la opción de reparto a través de M4G es mucho más eficiente que el reparto actual ante cualquier variación de la demanda de paquetes.

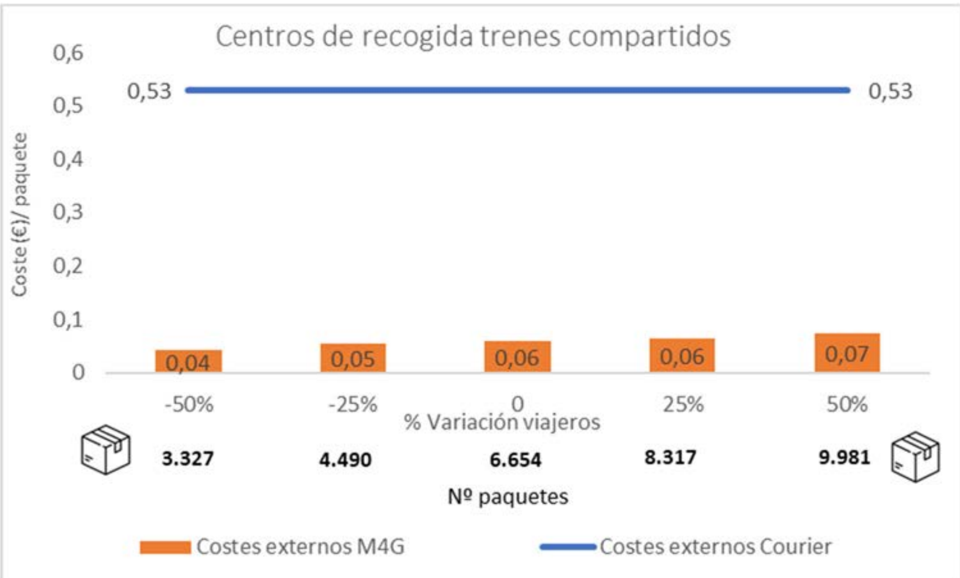

Figura 12. Costes externos (€/paquete) ante variaciones en el número de paquetes para centros de recogida y trenes compartidos

Figura 13. Costes operativos (€/paquete) ante variaciones en el número de paquetes para centros de recogida y trenes compartidos

Una limitación operativa de esta alternativa se produce cuando el número de paquetes que se concentran en un centro es muy elevado. Por ejemplo, en el caso de un incremento de viajeros en un 50 %, el número de paquetes diarios que se entregarían en la estación de Sol es de 1010, lo que supondría disponer de unas infraestructuras suficientes para almacenar y entregar este volumen de paquetes diarios.

6. CONCLUSIONES Y FUTURAS LÍNEAS DE INVESTIGACIÓN

Este estudio plantea la cuantificación de los costes externos de un nuevo modelo de entrega de paquetería de comercio electrónico a través de la red de transporte público ferroviario urbano de una gran ciudad.

Los resultados, aplicados a una ciudad como Madrid, buscan dar respuesta a las preguntas planteadas en la introducción. En primer lugar, la demanda de compras por comercio electrónico por parte de viajeros y residentes que viven cerca de las estaciones alcanza un volumen suficiente para justificar el uso de trenes para su entrega. Cabe destacar que las perspectivas de crecimiento del comercio electrónico contemplan mayores volúmenes en el futuro. En segundo lugar, en relación al uso de las infraestructuras y medios necesarios para implementar el modelo, debemos considerar: (i) la capacidad de transporte de paquetería en cada tren, (ii) la posibilidad de emplear trenes dedicados o compartidos, (iii) el horario y carga / descarga de mercancías de los trenes, (iv) la interacción con los viajeros, y (v) el uso de centros de recogida para completar las entregas.

Por último, los costes sociales y ambientales asociados con el modelo de entrega propuesto son considerablemente más bajos que los del sistema actual basado en LCV.

En la actualidad, el coste externo promedio por paquete entregado se sitúa entre 8,0 y 8,98 veces mayor que las alternativas del modelo propuesto. En el caso de los trenes compartidos, las externalidades son generadas por camiones pesados que viajan desde el centro de cumplimiento electrónico hasta la estación de Metro, mientras que en el caso de los trenes dedicados, los costes externos son muy similares a los de los trenes compartidos. Por lo tanto, se deben considerar otras variables para seleccionar entre ambas opciones.

Inevitablemente, surgen varias limitaciones en el estudio, que representan direcciones valiosas para futuras investigaciones. Por un lado, sería valioso cuantificar con precisión todos los costes (económicos, sociales y ambientales), para poder realizar un análisis de costo-beneficio social (SCBA) y así contemplar las necesidades de cada grupo de interés.

Por otro lado, este estudio podría ampliarse considerando otras formas de entrega (taquillas inteligentes, entregas a domicilio, etc.) y evaluando los impactos sociales y ambientales de las principales alternativas existentes actualmente en el comercio electrónico.

Por último, sería interesante conocer la posición de los usuarios de Metro en cuanto a compartir infraestructuras (trenes, ascensores, etc.) en sus desplazamientos fuera de las horas punta.

ANALYSIS OF THE TECHNICAL AND OPERATIONAL CAPACITY OF A COMBINED SEMI-TRAILER RAIL TRANSPORT SERVICE BETWEEN THE PORT OF ALGECIRAS AND ZARAGOZA.

Jaime Escobar de la Iglesia
Director of strategy and intermodal development, Aragón Plataforma Logística
Emilio Larrodé Pellicer
Professor, Mechanical Engineering Department, University of Zaragoza

ABSTRACT

The aim of this study is to evaluate the feasibility to run an Autopista Ferroviaria with Iberian width from a technical and operational point of view in order to analyse the business model in the short term.

A.F. (Autopista Ferroviaria) is defined by the Spanish Public Works Department as a combined transport in which semitrailers are transported by train in a shuttle service using specific wagons and terminals conditioning for this service according with the chosen operational typology. According to this definition, Spain, for the moment, still has not a service that could be called A.F. in Iberian width.

This study is based on the current Iberian railway line between the Port of Algeciras and Plaza (Logistic Platform of Zaragoza) and its focus is to determine whether from a technical and operational point of view, this rail line provides enough features to be used as A.F. To reach this goal, a European Ten-T corridor, the Atlantic one, and two important connections which are included in the Core Networks: Algeciras and Zaragoza are considered.

1. COMBINED FREIGHT RAIL TRANSPORT IN SPAIN

How is it possible that a country with an incredible technologic railway level, a good GDP level and a large railway net in three different gauge has one of the worst Europe figures in terms of freight rail? And the last but not the least question: Why Spain still has not an Iberian track rail motorway with the target of increasing rail freight transportation? Is it a technical issue due to the current infrastructure? Operational or Economic trouble? Or perhaps, could it be due to the past and present of the public policies in matters of rail freight transportation?

Nowadays, in Spain, the freight transport by rail compared to the total freight in all the transportation modes, inside the country, is around 1,4%.

The percentage of the freight transportation between the two terrestrial modes (road versus rail) indicates that the 95% of the terrestrial frights are moved on the roads. Only 5% are transported by train. The percentage of Spain in comparison with the European average and with several countries with similar characteristics is pretty small. The graphic bellow describes the curve of the historical evolution of the freight via road versus rail in Spain.

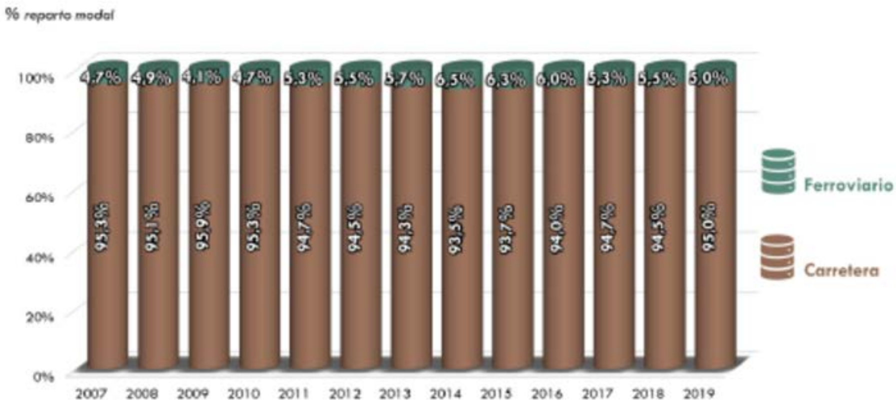

Fig. 1 – Percentage of modal split Spanish terrestrial transport. Source: Informe OTLE 2020

The question is easy: What makes these numbers possible? The answer is not so easy to respond. In the past, the freight operations were running by a state company in a monopoly market that oriented the Spanish railway sector just on passengers, not freights. The strategy was based always on passenger transport because the returns in economics and in politics terms are higher. Also, Spain has a very good highway net with large public inversions year to year. The result of the combination of these two public strategies through time is already mentioned percentage between road and train freight transportation.

In the year 2005 (Ministerio de transportes, movilidad y ayuda urbana), the market was opened for private capital, as a result, other companies entered to play the game. However, although the theory says that the market should be more competitive, and the cake should be distributed, the reality is completely different.

In Spain, freight railway transport can be competitive comparing to road transport when a minimum distance is overcome and the supply chain is fed with the necessary load. Also, the goods to be transported must meet certain characteristics. Otherwise, there will not exist an opportunity for railway transportation.

Consequently, to be sustainable in terms of the supply chain of the companies, freight railway transport has to adapt to the rules of the current logistic markets. Nowadays, the freight rail sector is not flexible enough to compete with the road one with the “market rules” of the logistic supply chain.

Definitively, the challenge to succeed is that the freight rail transportation would be competitive in order to reliability, cost and supply chain adaptation.

2. OPERATIONAL FEATURES

Freight railway transport needs a minimum distance to be competitive versus road transport. Moreover, the efficiency of the AF will depend on a daily minimum quantity of freight to be transported. Hence, in order to ensure the sustainability of the AF, a minimum distance, a big quantity of goods and a perfect adaption to the current supply chain are important and necessary features.

The selection of nodes of Algeciras and Zaragoza, as a part of the AF, is born out of these necessities. The distance is optimal for rail transportation and the freight to move via semi-trailers is daily and large enough. Furthermore, Algeciras and Zaragoza belong to the Ten-T Core Network and Atlantic and Mediterranean corridors are involved between both cores.

Fig. 2 – Ten-T core network corridors. Source: European Commission's Ten-T portal

Therefore, for the complete analysis of the technical and operational capacity of the AF between the nodes of Port of Algeciras and the Intermodal terminal of Plaza-Zaragoza) several critical issues have to be analysed.

The infrastructure of the railway (slopes, electricity, …), the infrastructure nodes (terminals), the technical system for loading semi-trailers, typology of wagons, selection of the railway traction, characteristics of the supply chain of the goods to be transported, etc.

2.1 Infrastructure

2.1.1 Railway Infrastructure

The railway infrastructure that joins Algeciras with Zaragoza consist of 1.074 km with Iberian width. Currently, all the line has got energy (catenary) except the path between Algeciras and Bobadilla which is planned to be ready in the short term (this issue is in ADIF´s planning department).

One of the singularities of the infrastructure is that the maximum slope of the line is 24´´.

This fact is very relevant in terms of traction or maximum load to be transported and it will have a significant importance in terms of operational profitability. Besides, the maximum length of the composition (traction and wagons) is, for the moment, 550 meters. It is because of the maximum length of the railway sidings.

The table below reflects the characteristics of the railway infrastructure.

Length	1.074 km
Width	1.668 mm
Catenary	3 Kv (except Algeciras – Bobadilla. It will be 25 Kv)
Maximum length	550 m (railway sidings)
Maximum slope	24´´ Bobadilla - Algeciras
Rail gauge	Analysing by Technical department of ADIF

Table 1 – Main characteristics of the railway infrastructure. Source: Compilation based on the public information from ADIF

The main problem to make available the infrastructure for the combination of wagon and semi-trailer (P400 or more) is the tunnel gauge for the rolling stock. The nature of this problem is because of two aspects. The first one is that, currently, there does not exist regulation for this type of rail gauge in terms of safety. The responsible for this regulation is the State Agency for Railway Safety (Department of Transport, Mobility and Urban

Agenda of the Spain Government). And the second aspect is the need to analyse whether physically the current tunnels permit or not the traffic of the combinations of wagons and semi-trailer. If not, it will be necessary to study the investments needed for improving the infrastructure (tunnels, platforms, etc) in order to permit the pass of the "new" railway set (extra low wagons and semi-trailers P-400 or more).

2.1.2 Terminals Infrastructure

The multimodal (road-train) terminals based on Zaragoza (Plaza) and Algeciras (Port of Algeciras) are already in service. The maximum length of the railway is 750 m in both cases, and these have all the characteristics to house the rail service system for providing "trailer on flatcar".

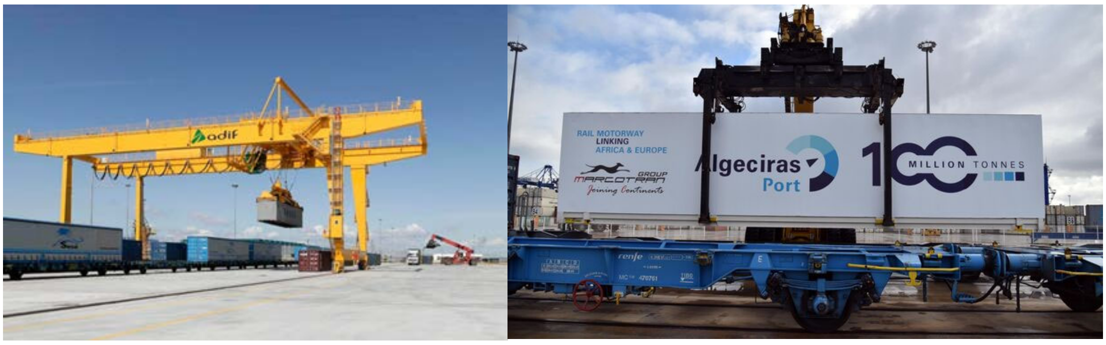

Fig. 3 - Left: Rail terminal of Plaza. Right: Rail terminal of Port of Algeciras

On the other hand, it will be necessary to adequate the terminals for the singularities of the operations of the AF. For instance, access to a big number of semitrailers, new digital systems, space for the "trailer on flatcar" system, etc.

2.2 "Trailer on flatcar" system

In Europe, there exist several systems operating combined transport, which objective is to load semi-trailers on wagons. The most common systems are: Modalohr, CargoSpeed System, Load-unload semi-trailer systems through cranes, bimodal bogies, … All of them have benefits and disadvantages in comparison with the others.

For the present study, the system which has been chosen is Load-unload semi-trailer system through cranes because of its flexibility, initial investment (the lowest), space necessary in terms of demanded surface and reutilization in case of other possible projects.

2.2.1 Wagon

Wagon must be special in terms of height in order to fulfil the requirements of tunnel gauge. For this reason, wagon must be low-floor. Currently, there are no Iberian gauge low-floor wagons. They must be designed, produced, and certificated for Spanish rail-tracks. Besides, it is important that these wagons could be compatible with different uses. Although, the AF has been thought for loading P-400 (or more) semi-trailers, it is important that other types of load could be carried (maritime containers, etc).

2.2.2 Platform to load semi-trailers

Generally, road transport companies do not use crane trailers. This fact make necessary a special platform in order to load the semi-trailer on the wagons. This piece will travel with each semi-trailer from terminal to terminal.

This platform must fit with the wagon.There are different alternatives in the market.

2.3 Composition of the train

The maximum slope of the railway track (24”), the maximum length permitted (around 550 m) and the maximum load (TBR; gross tons towed) are the technical variables that have an influence in the decision of the selection of the rail traction. The following table shows the information of the different alternatives.

	SLOPE & TONS		
RAIL TRACTION	16´´	17´´	24´´
253	1.180	1.130	860
253 DT (hight resistance hooks)	2.130	2.040	1.550
EURO 4000 (335) Diesel	1.490	1.410	1.060
EURO 4000 (335) Diesel (DT)	2.680	2.540	1.910

Table 2 – Different rail traction alternatives. Source: Compilation based on the public information from ADIF, Bombardier and Vossloh

In addition, in order to select the rail traction and respecting the maximum length that is permitted on the rail infrastructure (550 m) the factors to be analysed are: mix of container (semitrailer vs maritime container) and average load of each container. There are many different combinations as a result and all of these have different consequences in the economic part of the analysis. (The hypothesis considered for the analysis are 22 tons of average load for semi-trailers, the low-floor wagon is the standard gauge T-3000 and the platform is the Krona).

COMPOSITION	NUMBER OF WAGONS	LENGTH (m)	WEIGHT (Tons)
Simple traction + 8 wagons (SR) + 4 wagons (UTI)	12	430	1.230
Simple traction + 10 wagons (SR) + 3 wagons (UTI)	13	467	1.448
Double traction + 10 wagons (SR) + 3 wagons (UTI)	13	491	1.571
Simple traction + 11 wagons (SR) + 3 wagons (UTI)	14	502	1.550
Double traction + 11 wagons (SR) + 3 wagons (UTI)	14	525	1.673

Table 3 – Examples of different possible combinations of train compositions. Source: Compilation based on the public information

2.4 Availability of Traffic (Railway Capacity of the infrastructure)

To fulfil parameters defined for being an AF, certain capacity (railway operation of trains) on the infrastructure is needed. This capacity must permit to enhance the needs of the current supply chain. Otherwise, the success of the AFAZ will fail. One relevant aspect of the supply chain between these points are schedules agreed of the freights.

3. TRADE FLOWS

The AF makes economic sense if the trade between Africa; through Tanger Med Port of Morocco; and Spain and Europe; via Zaragoza; is economically sustainable, enhance the current supply chain and can be transported via rail.

3.1 Trade Flows

With the flows studied in the point 3.1, it will be considered that the trade flows are optimal in terms of this project.

Besides, the main flows that could be captured will be coming from RO-RO. The table below describe the forecasting for these flows.

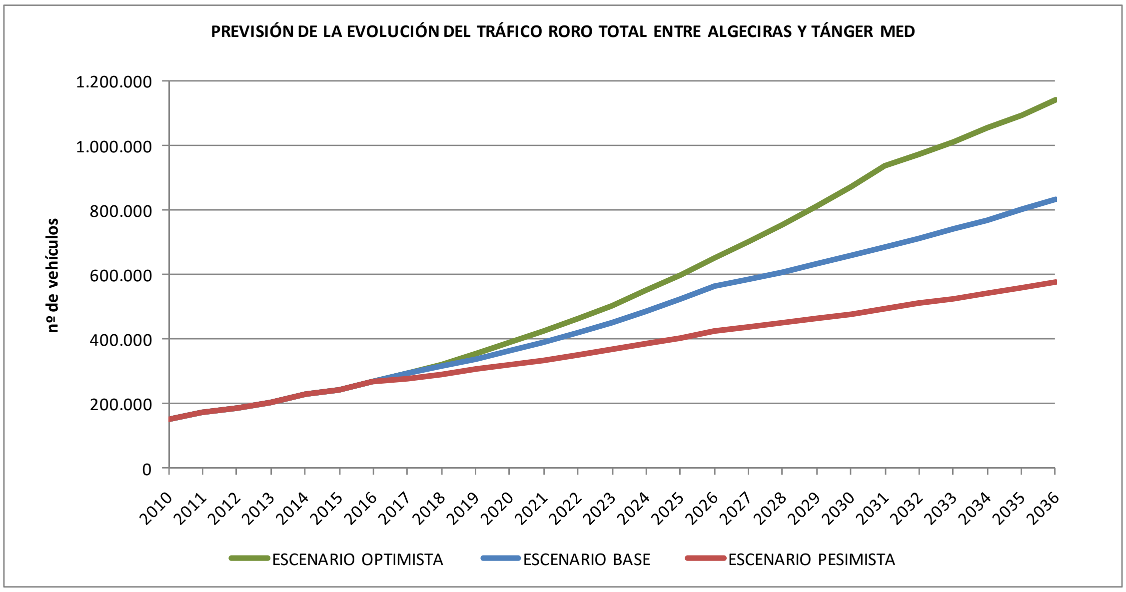

Fig. 4 – Evolution forecast of RO-RO traffic between Algeciras and Tanger Med. Source: Autoridad Portuaria Bahía Algeciras

With this scenario it is logical stablish that the freight to be transported is big enough. It will be necessary an exhaustive analysis in order to know which kind of loads (sectors) are more interesting to be carried by train.

3.2 Supply Chain

After several meetings with important road transportation companies that operate currently between Algeciras and Zaragoza (both directions), there is one variable that is repeated constantly:

The most important feature of the supply chain is the concerted time for the freight, principally in the area of Zaragoza, in the direction Algeciras-Zaragoza. Therefore, Adif has to offer the possibility to use the infrastructure with these requirements.

4. COST EFFECTIVINESS

4.1. Economics

Although a precise model is being realized in this moment as a part of a PhD in the Mechanical Engineering (Transports) of the University of Zaragoza, an example of a Profit and Loss forecast results is expressed in the next table. The main inputs, for the moment, are simple. The combination of the rail traction and wagons are the same in all path. So the mix of the freight is formed by traction, 17 wagons and Nikrasa platforms. The averaged for the load is 24 ton. It is a non-stop in Madrid or other place in order to load or unload goods. The considered occupation is a 70%,80%,100% of the total wagons in the first, second and third year respectively. The costs are based in the cost publications and consultants and the sales are based on the different scenarios.

	ECONOMIC RESULTS (millions of euro)								
TRACCION	Euro 4000 DT -> Euro 4000 (524.84/501.82 m)			253 DT -> 4000 (550.8/536.02 m)			253DT->253DT (550.8 m)		
YEARS	Y1	Y2	Y3	Y1	Y2	Y3	Y1	Y2	Y3
SALES	10,6	11,3	12,0	11,4	12,2	12,9	11,4	12,2	12,9
COSTS	11,5	11,6	11,7	12,1	12,3	12,4	12,7	12,8	13,0
INCOMES B.T.	-0,9	-0,3	0,3	-0,7	-0,1	0,5	-1,3	-0,6	-0,1

Table 4 – Forecast P&L (years 1 to 3)

With these inputs, it is possible to find combinations that permit an economic sustainability operations model.

4.2 External cost

Nowadays, it is very important for different reasons, such as environmental, safety, etc., to keep in mind that rail transport is more ecological than road transportation. With a unique frequency (Algeciras-Zaragoza and Zaragoza-Algeciras) and considering the short train of the analysis (8 wagons for semitrailers and 4 wagons for maritime containers) the train transport will absorb 48 trucks per day. The number of annual kilometers (just for this composition) would be 14.396.429.

5. CONCLUSIONS

On one hand, considering all technical aspects, AF (with Iberian gauge) in Spain between Algeciras and Plaza is possible. The limitations in the infrastructural aspects such as slopes, static, cinematic and dynamic gauges, catenary and terminals do not limit the possibility to run the AF services between Algeciras and Zaragoza.

At the same time, the main operational features (wagons, traction, and systems to load and unload semitrailers) are running in the European market. Therefore, from the perspective of the operations, the AF between Algeciras and Zaragoza is feasible.

On the other hand,currently, there is a big amount of semitrailers in both directions and it will be increased in the short time. And make sense, if the supply chain of the principal players is not altered, that the logistic market accepts a new channel with attractive attributes.

Finally, it has to be mentioned that AF between Algeciras and Zaragoza is a sustainable economic model for private equity with the previous compromise of the public sector.

ABSTRACT

Operational problems in agri-food supply chains usually show characteristics that are scarcely addressed by traditional academic approaches. These characteristics make an already NP-hard problem even more challenging; hence, this problem requires the use of tailor-made algorithms in order to solve it efficiently. This work addresses a rich vehicle routing problem in a real-world agri-food supply chain. Different types of animal food products are distributed to raising-pig farms. These products are incompatible, i.e., multi-compartment heterogeneous vehicles must be employed to perform the distribution activities. The problem considers constraints regarding visit priorities among farms, and not-allowed access of large vehicles to a subset of farms. Finally, a set of flat tariffs are employed to formulate the cost function. This problem is solved employing a reactive savings-based biased-randomized heuristic, which does not require any time-costly parameter fine-tuning process. Our results show savings in both cost and traveled distance when compared with the real supply chain performance.

1. INTRODUCTION

Feeding pigs in the pork production industry is a highly relevant activity to achieve successfully the supply chain goals (Rodríguez, 2014). Such activity requires a precise logistics from the production plant to the farms where the pigs are raised. Hence, our work consists in designing a set of vehicle routes that meet the feed demand of a set of pig farms, considering the real case of a pork production company in Spain. From an academic point of view, the analyzed problem can be considered as a rich vehicle routing problem (RVRP) (Caceres-Cruz et al., 2014), since: *(i)* vehicles are heterogeneous and have multiple compartments to separate different types of incompatible products that must be distributed to a set of farms; *(ii)* each farm may require multiple products; *(iii)* some farms admit only that a small-medium vehicle deliver the feed; *(iv)* a visit priority must be met, which indicates that some farms must be visited as soon as possible, whereas other farms must be the last to be served; and *(v)* the cost function considers a set of flat tariffs, which depend on both the location of the farm and the number of farms visited in the same route.

A flexible and enriched heuristic is then proposed to address this problem. Apart from the multi-product and multi-compartment RVRP, this heuristic must be able to deal with an objective function that relies on a flat-rate policy instead of the traditional distance-based minimization. Then, this enriched savings-based heuristic is extended into a biased-randomized algorithm (BRA), which is able to provide multiple solution configurations in short computational times. As described in Grasas et al. (2017), biased-randomized techniques are based on the introduction of an oriented (non-uniform) randomization process inside the constructive stage of a given heuristic. By doing so, a deterministic heuristic is transformed into a randomized algorithm that can be run multiple times (either in sequential or in parallel) without losing the logic behind the heuristic. Hence, the main contributions of our paper can be stated as follows: *(i)* the consideration of a flat-rate cost function, together with multi-product and multi-compartment characteristics; *(ii)* the design of a flexible and agile heuristic, which enriches the traditional savings heuristic, to solve a rich and real-life problem in the agri-food distribution industry; *(iii)* the extension of the former heuristic into a biased-randomized algorithm capable of providing, in short computational times, a set of alternative solution configurations to the problem, each of these including different dimensions; and *(iv)* the introduction of a reactive (automatic) fine-tuning process for the main parameter of the biased-randomization process.

Rich vehicle routing problems have been increasingly addressed by the academic community, since they incorporate highly realistic constraints, especially when these are considered simultaneously (Azadeh and Farrokhi-Asl, 2019). Characteristics regarding input data, decision management components, vehicles, time constraints, among others, turns a classical VRP into a rich VRP (Lahyani et al., 2015b). For instance, Alemany et al. (2016) combine the well-known savings heuristic (Clarke and Wright, 1964) with Monte Carlo simulation to solve a heterogeneous-fleet, multi-depot, multi-compartment, multi-product, and multi-trip VRP. In general, vehicles can be classified according to their physical characteristics, e.g., they can be homogeneous or heterogeneous, or compartmentalized or not. The relevance of considering compartmentalized vehicles emerges whenever different types of products are demanded and they are incompatible, i.e., products must be carried separately into the same vehicle and not be mixed. Despite the practical applications of this strategy for addressing real-world problems, the multi-compartment VRP has been scarcely studied (Derigs et al., 2011). Both theoretical and real-world cases can be found in the multi-compartment VRP literature. Silvestrin and Ritt (2017) and Muyldermans and Pang (2010) show examples of the former.

These works propose metaheuristic approaches given the combinatorial nature of this problem. Regarding real-world cases, products as diverse as apparel, fuel, food, and waste require the use of compartmentalized vehicles for performing an appropriate transport (Wang et al., 2014; Reed et al., 2014; Vidovic et al., 2014; Coelho and Laporte, 2015).

Agri-food supply chains represent also a field where the multi-compartment VRP has been addressed. These chains have special characteristics that should be taken into account in its modelling, such as products perishability (Tordecilla-Madera et al., 2018) or supply and demand seasonality (Vlajic et al., 2012). For instance, Lahyani et al. (2015a) propose a branch-and-cut algorithm to solve a multi-period and multi-compartment VRP with heterogeneous vehicles. A real case from the olive-oil collection process in Tunisia is considered, where compartments cleaning activities are considered. Oppen et al. (2010) address also cleaning activities in a multi-compartment VRP where inventory constraints are considered. Different types of animals are transported in this case, as well as a heterogeneous fleet and multiple trips. An exact method based on column generation is used as solving approach. Alternatively, employing approximate methods is a usual approach in agri-food multi-compartment VRPs. For instance, Caramia and Guerriero (2010) propose a hybrid approach combining mathematical programming and local search techniques to solve a real-life case regarding the collection of different types of milk in Italy. Finally, the number and capacity of compartments can also be a variable to consider, i.e., compartments are flexible. For instance, a large neighborhood search algorithm is proposed by Hübner and Ostermeier (2019) to solve this variant of the multi-compartment VRP. A relevant contribution of this paper is the consideration of loading and unloading costs, which are a function of the number of compartments.

The remainder of this paper is structured as follows: Section 2 shows the main characteristics of our addressed problem, and Section 3 describes the algorithm employed to solve it. Section 4 shows our main found results based on a real case study, and Section 5 shows the concluding remarks and future work.

2. PROBLEM DESCRIPTION

The part of the supply chain addressed in this paper is that in charge of distributing the animal food from central depots to the farms, as displayed in Figure 1. We consider each day as an independent instance, where the subset of farms requiring service can be different. Each farm generates an order, and each order may be composed of different types of feed, e.g., Figure 1 displays circles, hexagons and triangles representing three different products. In general, products can be classified in medicated and non-medicated.

Also, the characteristics of each type of product depend on the growth stage of each herd, i.e., the required diet mix is different according to the age (in weeks) of each individual.

The demand of each product in each farm is deterministic. The feed distribution is carried out from a depot through a set of compartmentalized heterogeneous vehicles. For instance, Figure 1 shows two types of vehicles with three and four compartments, respectively.

Compartments are also heterogeneous, i.e., each compartment has a different known capacity. The demanded quantity per product and farm is at most the capacity of a vehicle.

Hence, each vehicle can visit multiple farms in the same route, as long as the aggregate demand does not exceed the vehicle's capacity. Split deliveries are not allowed, i.e., a single farm must be served by a single vehicle. The objective of using compartmentalized vehicles is to separate each type of feed, since they cannot be mixed during a trip. In addition, if the demand of a product is higher than the capacity of a single compartment, it can be split into two or more compartments in the same vehicle. Nevertheless, in general, medicated feed cannot be transported in the same route as non-medicated feed. Not all types of vehicles can visit all customers, since some farms have access constraints. That is, a subset of farms can be served by all types of vehicles, whereas another subset cannot be served by large vehicles. An additional constraint assigns a sanitary priority indicator, which determines a specific order in which a subset of farms must be visited in case they are in the same route. The company classifies the farms into 3 types according to this sanitary priority: *(i)* a subset of farms with an assigned priority according to a consecutive natural number. These farms must always be served in ascending order whenever they are in the same route, e.g., a farm with a priority of 2 must always be visited before a farm with a priority of 5; *(ii)* a subset of farms with no priority; and *(iii)* a subset of farms with a "negative" priority, which indicates that they must be the last to be served in any route.

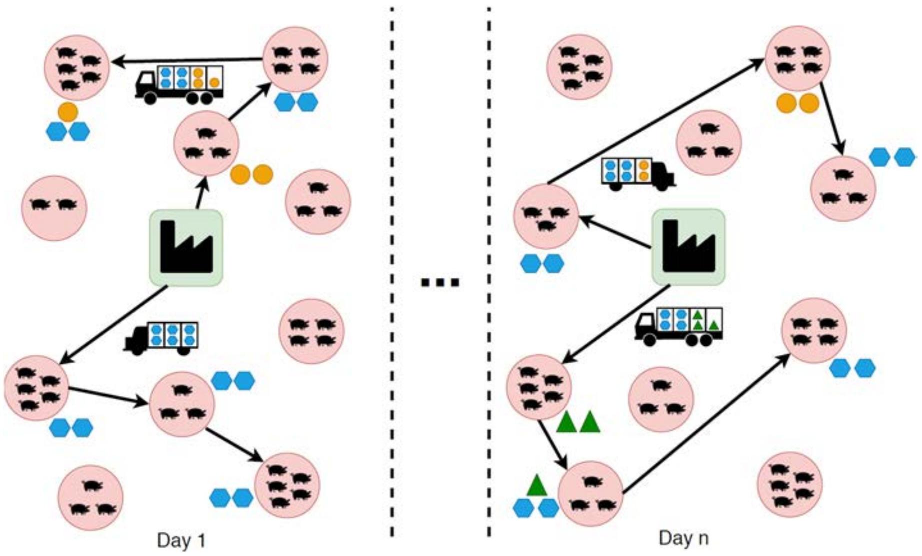

Fig. 1 – Representation of our real-life problem.

Our main objective is to minimize the total distribution cost.

As the company outsources the feed transportation, the distribution cost calculation has been settled in a distribution agreement. This cost is computed as the product of the delivered quantity and a pre-established tariff. The whole distribution region is clustered in zones, so that the tariff $c(n,z)$ depends on both the zone z where the customer is located and the number of farms n visited in the same route. Each customer has three different tariffs according to n (Equation 1), where $c_1(z) < c_2(z) < c_3(z)$.

$$c(n,z) = \begin{cases} c_1(z), & \text{if } n = 1 \\ c_2(z), & \text{if } n = 2 \\ c_3(z), & \text{if } n \geq 3 \end{cases} \tag{1}$$

Figure 2 displays a few examples of tariffs (expressed in €/t) employed by the company.

Figure 2a shows the case in which each farm is the only one visited in its route. Hence, the tariff of all customers in the Zone 1 is $c_1(1) = 7.74$ and the tariff of the customer 4, located in the Zone 2, is $c_1(2) = 8.98$. Figure 2b shows the case in which all customers in the Zone 1 form a single route, therefore, the employed tariff is $c_3(1) = 8.76$. The customer 4's tariff remains the same as in the former case. Finally, Figure 2c shows the case in which customers of different zones form a unique route. Under these circumstances, the distribution agreement indicates that the employed tariff must be the greatest one. Hence, as $c_3(1) = 8.76$ and $c_3(2) = 9.24$, the final distribution tariff for the route in this instance is 9.24 €/t. Since the total satisfied demand is the same in the 3 cases of Figure 2, and the total variable cost depends on the supplied food-load in tonnes, the case in Figure 2b incurs a higher variable cost than the instance in Figure 2a, and the case in Figure 2c incurs the highest variable cost in the example. This means that merging routes increases the variable cost in our problem, which is the opposite of merging routes in traditional routing problems. This behavior is caused by the flat tariffs indicated in the distribution agreement.

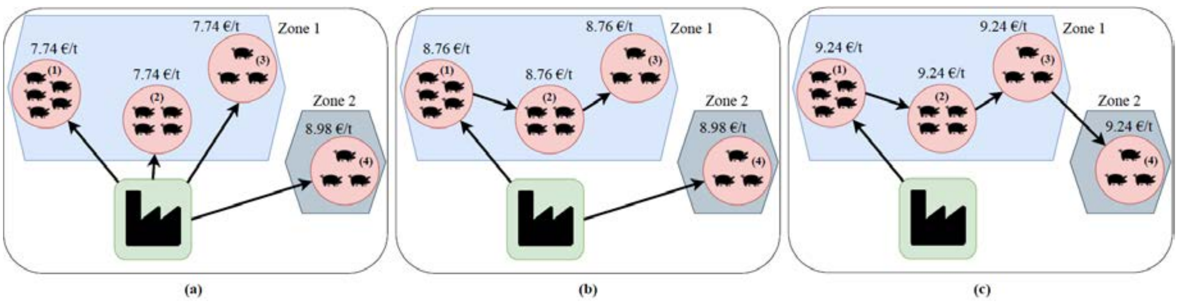

Fig. 2 – Examples of tariffs used by the company.

The considered problem requires that the total delivery cost is not the only key performance indicator (KPI), i.e., the approach used to solve this problem must show enough flexibility to consider additional KPIs, such as the number of designed routes and the total traveled distance.

Despite its non-typical objective function and unique constraints, the problem can be classified as a rich variant of a multi-product and multi-compartment open VRP (RVRP). Hence, it is an *NP-hard* problem and, as such, the use of heuristic-based approaches (Londoño et al., 2020) is justified whenever the size of the problem goes beyond a certain level.

3. FROM A FLEXIBLE AND FAST HEURISTIC TO A REACTIVE BIASED-RANDOMIZED ALGORITHM

This section shows our approach for dealing with the described RVRP. This approach is based on both multi-start (Martí et al., 2013) and biased-randomized algorithms (BR) (Grasas et al., 2017). Algorithm 1 provides a general view of the proposed heuristic to solve the RVRP. The core of our approach is a flexible and fast two-stage heuristic, which includes all problem characteristics considering multiple KPIs. In the stage 1, a first initial solution is generated, in which each customer is assigned to a vehicle in a single round-trip, meeting all the considered constraints. Once this initial solution is generated, the algorithm merges routes in stage 2 as much as possible, reducing the number of used vehicles. Algorithm 2 outlines the stage 2, which consists of the following steps: firstly, it computes the *savings* associated with potential route merges. These savings are computed for every edge and are based on both the distance between farms and the tariff per zone.

Then, a list of edges associated with the savings values is created and sorted in decreasing order. The main loop iterates on the sorted savings list, where each edge is selected to be part of the solution only if it meets the following merging conditions: *(i)* both customers in the origin and the end of the edge belong to different routes; and *(ii)* these customers are adjacent to the depot. Unlike the traditional savings method, we do not consider the total vehicle capacity. Instead, it is evaluated whether the demand of each product fits in the available compartments, considering both their capacity and a feasible layout. When a feasible assignment is found, the algorithm merges the routes and updates the solution; otherwise, the current edge is rejected and the algorithm proceeds to the next iteration with a new alternative. The current solution is updated by removing the routes at both extremes of the selected edge and adding the resulting new merged route. All KPIs are then updated, including the cost, which considers the flat-rate delivery tariffs (Figure 2). Again, notice that this approach is different to the distance-based cost computation employed in most articles on the VRP, which do not consider a flat-rate tariff. Finally, the current edge is removed from the list, and the whole process is repeated until the savings list is empty, returning a complete new solution *sol*.

Algorithm 1 Multi-Start R-BR

```
Require: inputParameters
  sol ← Stage_1(inputParameters)
  β_1, β_2 ← T(0, 0.5, 1)
  newsol_1 ← Stage_2(sol, β_1)
  newsol_2 ← Stage_2(sol, β_2)
  sol, m* ← best(newsol_1, newsol_2), best(β_1, β_2)
  while time not reaches the limit do
      β_s ← T(0, m*, 1)
      newsol ← Stage_1(inputParameters)
      newsol ← Stage_2(newsol, β_s)
      sol, m* ← best(sol, newsol), best(m*, β_s)
      if sol ∉ S* then
          S* ← add(S*, sol)
      end if
  end while
Ensure: S*
```

Algorithm 2 Stage_2

```
Require: sol, β
  savings ← computeSavingsSorted(sol)
  while savings ≠ ∅ do
      edge ← selectNextArc(savings, β)
      savings ← remove(savings, edge)
      if isMergePossible(edge) then
          sol ← updateSolution(sol, edge)
      end if
  end while
Ensure: sol
```

The previous heuristic is extended into a reactive BR algorithm (R-BR). This procedure allows not only to diversify the search for good solutions, but also to generate alternative solutions assessed in terms of multiple KPIs. Our proposed methodology in Algorithm 1 uses both stages 1 and 2 (Algorithm 2) as the base for the R-BR. Previously described steps are followed the same, except for the selection of the next edge in the savings list.

This selection is now performed by considering a skewed probability distribution, which introduces a sort of randomness into this process. In our case, the selection of the next element is performed according to a geometric distribution with parameter $0 < \beta < 1$.

Employing this distribution introduces diversification to explore other regions of the solution space, preserving at the same time the savings heuristic original purpose. Unlike previous works, our algorithm is *reactive*, since the parameter β is automatically fine-tuned. The R-BR implementation procedure is described next: firstly, initialize parameters β_1 and β_2 using a symmetric Triangular probability distribution with mode $m = 0.5$. Secondly, generate two complete solutions using β_1 and β_2, respectively.

Then, compare the yielded costs (or any other KPI) to obtain the best-found mode m^* and the best-found solution *sol* so far. Then, the algorithm iterates while the time limit is not reached. For each iteration, a new β_s is computed using a Triangular distribution with mode equal to m^*.

Later, generate a new complete solution *newsol* using β_s. Again, obtain the best-found mode m^* and solution *sol*. Finally, introduce the new solution *sol* in the pool of solutions S^*.

4. CASE STUDY

Real-world instances representing multiple products demands from 44 workdays have been provided by the company. They represent daily deliveries made to 214 farms. Currently, the company performs a delivery only when the customer generates an order. Hence, only a subset of farms is served each day. Furthermore, the delivered product mix also changes every day, and each customer may require multiple types of food at the same day. The feed shelf life is greater than one day; therefore, perishability is not included in our case study.

The number of vehicle types are 3: a vehicle type with 6 compartments and a total capacity of 26 t, a vehicle type with 6 compartments and a total capacity of 21 t, and a vehicle type with 5 compartments and a total capacity of 21 t. A single product demand can vary between 1 t and 26 t. Our approach yields 4 KPIs: *(i)* total distance, computed as an approximation by employing the Euclidean distance between two farms, considering their real Cartesian coordinates; *(ii)* total cost, computed employing the flat tariffs described in Section 2; *(iii)* total number of routes; and *(iv)* average utilization of vehicles, computed considering the utilization percentage of every vehicle used in every route of a complete solution. The algorithm is implemented in Python 3 and executed in a personal computer with 16 GB RAM and a 2.8 GHz Intel Core i7-1165G7 processor.

Table 1 shows the average results after running our biased-randomized algorithm employing 44 instances. This table compares the results obtained when considering a non-reactive and a reactive biased-randomized (BR) heuristic. The latter refers to the procedure described in Section 3. The former refers to the case already described in the literature, in which the parameter β of the geometric probability distribution must be fine-tuned by hand. In our experiments, our manual fine-tuning process found the best results when β follows a uniform probability distribution between 0.01 and 0.40. Both BR procedures employ a time limit of 60 seconds. Table 1 also shows the results obtained by the company in its real daily operations. Obviously, these results are independent of our both BR procedures. Four types of solutions are generated, where each one is the best-found solution assessed in terms of each aforementioned KPI. For instance, the *Best-distance* solution is the one that achieves the minimum distance. Hence, the reached value of the KPI *Distance* is underlined for this solution.

The reasoning in this example can be extended for the rest of the KPIs. The greater the utilization, the better. The other KPIs have an opposite interpretation. Values obtained by the non-reactive BR are only slightly better than the ones yielded by the reactive BR, i.e., differences are minimal. Nevertheless, the non-reactive BR requires a few work hours for performing the fine-tuning process, whereas the reactive BR is automatic and does not require any fine-tuning.

The average percentage difference between our solution and the company solution is shown in the columns *Gap* of Table 1. This indicator is computed considering the gap between each KPI obtained for each instance. A negative gap indicates that our solution outperforms the company's. If the gap is positive, then the smaller the gap, the better.

Hence, a few results can be highlighted. Firstly, our heuristic always reaches a smaller cost than the company, regardless of the type of solution. Secondly, savings in distance provided by our heuristic are high when considering the *Best-distance* solution. Thirdly, the company slightly outperforms our algorithm when considering the number of routes and the vehicle utilization. Finally, the cost is a KPI whose behavior is opposite to the rest of the indicators', i.e., when the cost improves, the other KPIs worsen. This behavior is a result of considering the flat tariffs explained in Section 2.

Type of solution	Non-reactive BR				Reactive BR			
	KPI				KPI			
	Distance	Cost	#Routes	Utilization	Distance	Cost	#Routes	Utilization
Real company	1153.6	5555.5	23.9	95.8%	1153.6	5555.5	23.9	95.8%
Best-distance	<u>1104.0</u>	5541.7	24.7	92.5%	<u>1106.6</u>	5540.6	24.8	92.3%
Best-cost	1201.3	<u>5495.7</u>	26.7	86.2%	1196.9	<u>5497.5</u>	26.8	86.1%
Best-#routes	1178.8	5544.3	<u>24.2</u>	94.1%	1173.3	5542.4	<u>24.3</u>	93.8%
Best-utilization	1168.5	5549.6	24.2	<u>94.8%</u>	1174.7	5548.6	24.3	<u>94.6%</u>
	Gap				Gap			
Best-distance	<u>-4.4%</u>	-0.2%	3.5%	3.3%	<u>-4.1%</u>	-0.3%	3.7%	3.5%
Best-cost	4.3%	<u>-1.1%</u>	12.3%	9.6%	4.0%	<u>-1.1%</u>	12.6%	9.6%
Best-#routes	2.0%	-0.2%	<u>1.4%</u>	1.7%	1.5%	-0.2%	<u>1.7%</u>	2.0%
Best-utilization	1.1%	-0.1%	1.4%	<u>1.0%</u>	1.7%	-0.1%	1.7%	<u>1.2%</u>

Table 1 – Average results considering different KPIs.

The best-found distance and best-found cost gaps between our solution and the company solution for the 44 instances are displayed in Figure 3. This figure also shows a comparison between our both tested heuristics, i.e., non-reactive BR (NR-BR) and reactive BR (R-BR). Regarding the distance, only a few instances exceed the 0% limit, i.e., our agile approach is able to outperform the company’s distance results for the vast majority of instances. Furthermore, our approach always reaches a negative gap in costs, which is a great result considering the tough restriction imposed by the flat tariffs. Finally, Figure 3 also shows that our reactive BR is able to yield solutions highly similar to the ones achieved by the non-reactive BR.

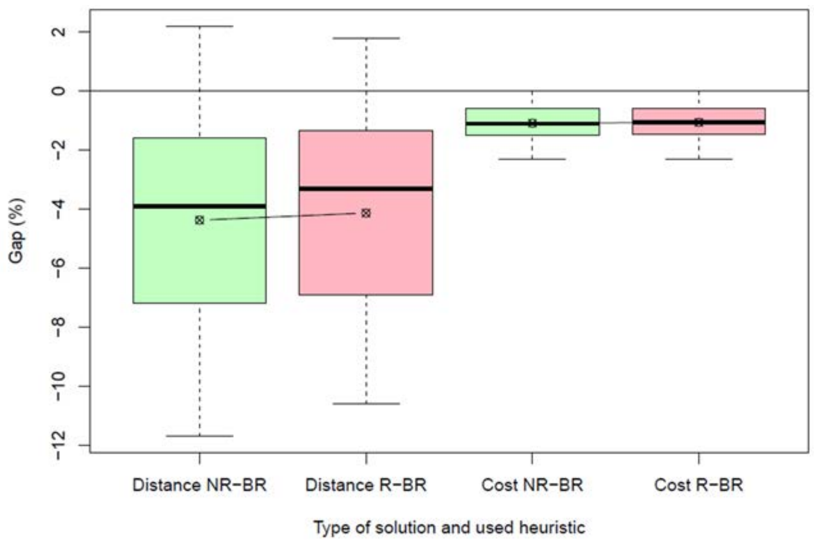

Fig. 3 – Distance and cost gaps of our best-found solutions with respect to the company’s.

4. CONCLUSIONS

This work has proposed a reactive biased-randomized heuristic to solve a real-world rich vehicle routing problem for the distribution of animal food. A set of complex constraints have been considered, such as multi-compartment heterogeneous vehicles, flat tariffs, visit priorities, among others. Four KPIs have been proposed to assess the solutions quality.

Advantages of employing our agile approach are mainly twofold. Firstly, our yielded results outperform the real company's outcomes in terms of traveled distance and distribution cost. These results are obtained in only a few seconds, whereas designing these routes by the company takes a few work hours. Secondly, results yielded by our reactive biased-randomized algorithm are highly competitive when compared with a non-reactive one. However, the latter requires a time-costly fine-tuning process, whereas our proposed heuristic does not require to perform this procedure. Future work includes considering inventory planning jointly with the vehicle routing. In this case, both food perishability conditions and a multi-period planning can be included.

ABSTRACT

The growth of e-commerce and the on-demand economy in urban and metropolitan areas has been accelerated by the recent COVID-19 pandemic. As a consequence, logistics and transportation operators are subject to a noticeable pressure to develop efficient delivery systems. These systems are also influenced by the global trend towards more sustainable transportation and mobility, which implies changes in urban policies and technological innovations --$e.g.$, the substitution of traditional diesel petrol-drive vehicles by electric ones. This paper analyzes the current and predicted needs of logistics operators in the Barcelona metropolitan area. To do so, urban regulations are analyzed and key shareholders are interviewed. The analysis of these interviews promote a discussion on how the use of new `agile' optimization algorithms --which are based on the combination of biased-randomized heuristics, computer parallelization techniques, and IoT / 5G technologies-- can contribute to enhance urban distribution practices. Finally, we present a case study in which the effect of different configurations of working/resting times and parking areas availability on routing solutions is studied. Our research aims to provide comprehensive knowledge to managers and policy-makers, and to offer them with powerful tools capable of generating real-time solutions to complex last-mile delivery challenges under dynamic conditions.

1. INTRODUCTION

Currently, more than 50% of the world's population lives in urban areas and this figure will increase up to 68% by the year 2050 (United Nations, 2019). As the world population increases, the demand for goods and commodities will increase. The transportation and mobility sectors have become indispensable for meeting these demands.

However, these sectors emit alarming amounts of carbon dioxide (CO_2) into the Earth's atmosphere. The emitted CO_2 accounts for most transformed climate conditions in regions where climate patterns were once consistent. Respiratory and cardiovascular complications, as well as increased mortality rates have been associated with air contamination.

To alleviate this concern, an innovative paradigm for mobilizing people within urban areas, as well as for developing and sustaining healthier cities while decarbonizing and minimizing the emission of CO_2 is urgently needed. Although preventing the complete mobilization of people would be impractical, exploring environmentally sustainable alternatives such as employing zero-emission electric and unmanned vehicles, and adopting ride-sharing ordinances to reduce idle capacity could have promising results. Nevertheless, adopting technological advances for mobilizing people entails complex operations challenges that need to be properly addressed as well.

As with the mobility of people, the supply of goods is crucial to meeting the United Nations' sustainable development goals. More population implies greater flows, but it also occurs at a time of transformation of the urban business model and related supply chains.

With the emergence of e-commerce, an increasing number of consumers are switching to the online channel, and most are opting for home delivery. This means that the packaging sector is constantly booming, with more vehicles and more companies operating day after day in cities. Thus, the Urban Freight Distribution (UFD) has important implications in terms of both traffic and parking. On the one hand, it significantly contributes to congestion and the emission of polluting particles in urban environments. On the other hand, it strains the demand for parking, filling the reserved spaces and making it difficult to drive through irregular parking practices.

This work aims to investigate the problems emanating from the UFD, and in particular on the public policies imposed at the municipal level to regulate it. Each municipality has a certain infrastructure and dictates its conditions, leaving an extremely fragmented scenario that needs to be taken into account by operators.

The first contribution of this work is an analysis of the logistics conditions in the Barcelona (Spain) metropolitan area. This analysis is based on interviews to key shareholders from different sectors, which allows us to claim the need for agile optimization algorithms (Martins et al., 2021a).

These algorithms constitute an intelligent approach that relies on the combination of biased-randomized heuristics, computer parallelization techniques, and IoT/5G technologies in order to deal with the requirements of large-scale, dynamic, and complex last-mile distribution problems.

A second contribution of the paper is the inclusion of a numerical case study, which allows us to study in more detail the economic and environmental impact that a non-harmonized regulation might have on logistics and transportation operations.

The rest of the paper is structured as follows: Section 2 provides a brief review on related work. Section 3 summarizes a study in which several managers of transportation companies have been interviewed to identify their needs. Section 4 discusses how 'agile' optimization algorithms can contribute to fulfil some of the identified needs.

Section 5 describes a case study regarding the density of parking spots in the city of Barcelona. Section 6 performs a series of computational experiments over the previously described case study. Section 7 analyzes the obtained results and incorporates some managerial insights to be considered. Finally, Section 8 summarizes the main contributions of this study.

2. RELATED WORK

In recent years there has been a huge expansion in e-commerce, with high growth rates of up to two digits in most developed countries. Added to this gradual increase over time are the knock-on effects of the COVID-19 pandemic. Aside from any short-term impacts of the self-isolation and lockdown periods imposed in many countries, the very structure of the market may be undergoing a deep transformation and accelerating the digitization process (Kim, 2020). Thus, for example, in the region of Catalonia (Spain) the online purchases have grown by 27.7% compared to before the pandemic, and 44.6% more than in 2018 (Generalitat de Catalunya, 2020). This increase in e-commerce, in turn, will magnify externalities associated with urban freight logistics and transportation, i.e.: pollution, noise, traffic congestion, as well as the management of parking space.

2.1 UFD Management

Urban freight logistics are made up of the flow of goods circulating throughout a city. In general, an urban transportation system can be defined as the set of transportation elements –both public and private– that involve the mobility of people and goods within the metropolitan area: infrastructure, management, means of transport, entities, service providers, and users (Gonzalez-Feliu et al., 2018). The goal of urban freight distribution is to supply specific items on time and in the right way, guaranteeing low costs and offering good customer service. The recent boom in e-commerce has led to a sizable increase in home delivery packages, with a huge surge in the number of orders shipped and, hence, in urban freight traffic.

In addition, UFD (and especially last-mile delivery) lay bare the conflicting interests of the different stakeholders involved (Rai et al., 2017; Gatta and Marcucci, 2016; Bjerkan et al., 2014). These stakeholders can be classified into three categories: private enterprises (haulage and shipping companies, small retailers, large retailers, and logistics operators), public administrations, and citizens. Public administrations need to take on a leading role in this matter. Local authorities are the ones who have competences for city mobility.

They must have a comprehensive understanding of the complexity of city logistics to identify and implement measures, as well as to create packages of policy tools that facilitate, limit, or manage the distribution of e-goods on different levels of regulation, hence promoting a stronger link between transport planning and land use (Bjørgen et al., 2019; Kiba-Janiak, 2019). Dialogue between all the stakeholders is crucial.
Public policies should be drafted on a consensual basis, especially when logistics operators are the ones that are directly affected by them. Trying to impose specific unilateral measures tends to have unexpected and, more importantly, undesired outcomes (Viu-Roig and Alvarez-Palau, 2020).

Therefore, the goal of the city council is to regulate the use of public space in order to minimize the conflicts that might result from freight transportation in a town, and make this more sustainable (Anderson et al., 2005). The local authorities combat these negative impacts of UFD with different actions, e.g.: by preventing carriers from parking illegally, thus reducing the traffic congestion factor (Cherrett et al., 2012); by enabling enough areas for loading and unloading, thus minimizing the impact on the delivery of goods (Roca-Riu et al., 2017); by imposing vehicle size restrictions in some areas; by creating goods consolidation points or establishing distribution time windows (Rushtonet al., 2014); or by invigorating pollution restriction policies using license plate recognition to avoid the circulation of some vehicles, especially in historic quarters of the city (Liu et al., 2018).

2.2 Loading and Unloading areas

One of the main problems that council cities have to face is the dimensioning of their loading and unloading(L/U) areas, as well as the size of urban land allocated for this purpose (Muñuzuri et al., 2017). Recent researches come to the conclusion that the absence of L/U areas or their poor management causes double parking (Figliozzi and Tipagornwong, 2017).

This mismanagement can sometimes be related to non-commercial use of the L/U zones, such as the use of these by individuals. Something that required greater control for the optimization of the L/U zones (Alhoet al., 2018). In their research, the authors studied the reduction of double parking of cargo vehicles by changing the spatial configuration of the L/U areas and the level of compliance with the parking rule of non-cargo vehicles. Its conclusions show the impact that this mismanagement has on delivery delays and on slow urban traffic. Therefore, the efficiency and effectiveness in the UFD is related, among other things, to the spaces available in the towns for L/U operations (McLeod and Cherrett, 2011; Jaller et al., 2013).

2.3 Time Windows

One of the options used by the council cities to optimize the L/U areas is the implementation of time windows, thus restricting the interval in which delivery vehicles can circulate in various parts of the city (Muñuzuri et al.,2005).

As the time window pressure increases, the number of store deliveries that can be combined in one round-trip decreases, i.e.: the retail chain (who stores and sells the goods) is forced to use extra trucks and cover longer distances to accomplish the store deliveries, which results in an increase of the retailer’s cost.

Furthermore, time windows change over time, and for a retailer it is difficult and costly to accommodate to all these changes. For this reason, many retailers consider time window policies as one of the major problems in urban freight logistics (Quak, 2008). The city council determines their time windows individually, they hardly cooperate and generally copy each others’ municipalities’ regulations regardless of their characteristics (Muñuzuri and Van Duin, 2014).

Another issue that arises in vehicle routing problems or VRPs (Vidal et al., 2019) is the appearance of electric vehicles that require areas to charge the batteries (Juan et al., 2016).

The literature shows some routing examples that would minimize this problem, such as Hiermann et al. (2016) or Keskin and C ̧ atay (2016). The former propose a mixed routing/location problem in which some charging stations are available to allow recharging the vehicle’s batteries during its journey. The latter present a model in which partial recharging of the batteries is assumed to save route times. More recently, Reyes-Rubiano et al. (2019) propose a model for routing electric vehicles that considers limited driving ranges and stochastic travel times.

2.4 Urban Vehicle Access Restrictions

There are many city councils that have limited the entry and circulation of large trucks or polluting vehicles in their cities, since these vehicles have a greater impact on the environment. Several studies show how these policies reduce the environmental impact (Muñuzuri et al., 2005; Anderson et al., 2005).

However, these decisions do not take into account that many more smaller vehicles will be required to transport the same amount of goods or, in the case of license plate recognition, it will force logistics companies to always have to maintain the same fleet entrance into the city, something that will difficult the management of routes (Browne et al., 2008). This will most likely increase the number of vehicles required, as well as the total number of trips (Quak and De Koster, 2005).

Major cities, such as Barcelona, face multiple problems caused by delivery operations in UFD. The urban freight distribution problem in Barcelona has been studied in some works. Thus, for example, Roca-Riu et al. (2015) used mathematical programming optimization models for solving the parking slot assignment problem in the city, while Fernandez-Barcelo and Campos-Cacheda (2012) tried to quantify the social cost (emissions, congestion, and noise)of the urban freight distribution.

As a first goal of this work, we want to analyze the needs of private and public stakeholders in the metropolitan area of Barcelona. To achieve this goal, key actors of urban freight logistics were interviewed, as discussed in the next section.

3. THE VIEW OF THE LOGISTICS SECTOR

According to Taniguchi et al. (2010), decision support tools are needed to help public decision makers and practitioners to deal with city logistics externalities (mainly traffic congestion, greenhouse gas emissions, as well as air and soil pollution). These tools can take the form of decision support systems. These systems are mainly based on modeling, optimization, simulation, and evaluation procedures. In order to devise the optimization model that we present in this research, we first need to know the opinion of the main logistics agents, as well as of the public administrations, that operate in the metropolitan area of Barcelona. Through their opinion and experience, we could know the main concerns that should be taken into account when designing the illustrative case study that considers the different urban restrictions that logistics agents face in their daily activity.

Thus, we interviewed 16 entities that intervene in the UFD in the metropolitan area of Barcelona, bringing together both private companies and public administrations. In our interviews we contemplate different sectors, including: food distribution (Condis), construction (Laymet), transportation (Transcalit), hospitality sector (ADISCAT), and the public administrations (Generalitat, AMB, ATM, or Diputació de Barcelona). We did the interviews by video-conference to comply with the restrictions derived from the health crisis caused by COVID-19. At the end, we accumulated a total of 815 minutes of recordings, with an average duration of about 51 minutes per interview. The following notes summarize the main conclusions of the interviewing process:

- The current loading and unloading areas of the towns do not contemplate the complexity and the different casuistry of each sector. For example, the time required for a parcel delivery door-to-door ranges between 20and 25 minutes, while the time required for the hospitality sector delivery person ranges between 60 and 90minutes.
- e-Commerce growth has altered UFD operations, multiplying the number of destinations and reducing the average size of the parcels.
- The lack of parking availability and its restrictions are leading to increasing illegal parking practices.
- Time windows restrictions for entering the city and for loading and unloading of goods make it difficult for the routes to be efficient.
- The lack of a criteria consensus when considering ordinances among the different towns limits the efficiency of routing plans.
- The restriction of the tonnage of goods delivery vehicles force an increase in the number of trips to make the same route.
- The public administrations recognize the above problems, but they do not have the powers to act on them. They derive this responsibility to each city council. In this sense, if each city council legislates without considering the rest, the inequality of criteria is promoted, thus entering an infinite loop.

4. AGILE OPTIMIZATION ALGORITHMS

Agile optimization (AO) algorithms allow us to process large amounts of data while supporting real-time decision making (Martins et al., 2021b). These algorithms permit a coordinated and effective use of electric autonomous vehicles in modern cities, as well as the development of concepts and solutions which contribute to transform smart cities into sustainable ones (Juan et al., 2020). Using technologies as 5G, data is gathered in real-time via electronic devices mounted onto vehicles and structures, transmitted over the Internet, and analyzed through intelligent algorithms. These algorithms predict the evolution of traffic conditions and allow for making pre-analyzed decisions. The incorporation of low-emission vehicles in last-mile delivery activities raises additional challenges from a planning, operational, and environmental perspective (Juan et al., 2016). For instance, cities are required to provide charge stations for electric vehicles. Thus, investment decisions regarding station numbers, location, and capacity must be addressed. Similarly, the limited driving range and load capacity of most electric vehicles impose additional constraints when designing distribution and collection routes (Londoño et al., 2020). Significant reductions of CO_2 emissions could be reached if carriers embrace the benefits of carefully designed strategy and mobility concepts.

Traditional optimization algorithms are widely applied for coping with optimization problems that assume a fixed time horizon and non-dynamic inputs and constraints. These particular optimization methods might sometimes be insufficient when dealing with real-time transportation problems in modern cities. With the emergence of the Internet of

Things, large amounts of data are generated in smart cities. These cities have continuously evolving conditions, such as: traffic, vehicle location, accidents, and disruptions. The lack of real-time optimization methods raises challenges on the integration of smart mobility innovations, such as unmanned and electric vehicles.

To address these problems, the AO paradigm aligns biased-randomized heuristic algorithms (Estrada-Moreno et al., 2019), which are extremely responsive, parallelizable, flexible, parameterless, effective, and accessible online. As new streams of data are provided, the AO paradigm will embrace the dynamism of real world large-scale scenarios, while offering real-time solutions which re-optimize every few milliseconds. AO algorithms will support environmentally applicable decision making, thus leading the way towards zero-emission transportation activities.

This, in turn, will generate environmental, economic, and social progress via the emergence of new business models like car-sharing and ride-sharing (Martins et al., 2021a), while improving citizen's quality of life (Beneicke et al., 2019). Moreover, the AO paradigm will support current European strategies for low-emission mobility.

5. AN ILLUSTRATIVE CASE STUDY

In order to illustrate the concepts introduced in the previous sections, we have designed a realistic case study based on the city of Barcelona. In this example, two different carriers have to visit a series of customers scattered across the city. Each carrier has its own set of customers and no horizontal cooperation practices (Serrano-Hernández et al., 2017) –or other strategies that can speed up the distribution tasks– are considered at this time.

Therefore, vehicles from different carriers might compete for the available parking spaces in the city. Regarding the availability of these unloading areas, three scenarios are considered: low availability, medium availability, and high availability. For our numerical experiments, we have assumed that this availability level is negatively correlated with the average service time, i.e.: the more parking spaces available in the city, the shorter the average times requested to complete the delivery, and vice versa.

In particular: a low availability scenario assumes that the average service time is 15 minutes, a medium availability scenario is associated with an average service time of 10 minutes, and a high availability scenario implies an average service time of 5 minutes. For each carrier, the associated distribution process is modeled as a VRP.

Vehicle routing problems are very popular in the transportation literature, since they allow to model many different distribution activities (Faulin et al., 2008; Juan et al., 2009). Typically, the goal is to minimize total distribution costs while satisfying all customers' demands and additional capacity constraints. In this case, loading capacity of vehicles is not a constraint –i.e., the transported goods are small in size and, if necessary, they can be piled up inside the vehicles, so loading capacity is not a hard constraint. However, there is a time-capacity constraint for each route, i.e.: no route should exceed a time threshold, t_{max}, given by the carrier. In our experiments, this time threshold is a design parameter that can take different values: $t_{max} \in \{6,7\}$. Figure 1 shows a map of Barcelona together with the depots associated with both carriers and their customers. In Figure 2, a potential solution (set of routes) is drawn.

The aforementioned setting of the VRP is based on the real-life case oriented to deal with the collection of sanitary items – produced using personal 3D printers – from individual houses in Barcelona during the first months of theCOVID-19 pandemics.

The computational experiment will allow us to investigate how different levels of loading/unloading areas in the city will affect the number of trucks needed to complete all visits and, as consequence, the total time that these vehicles are circulating around the city –which is a direct cause of CO2emissions and traffic congestion, apart from being the main factor in the cost function of the carriers.

Our solving approach is based on the algorithm proposed in Tordecilla et al. (2020). This algorithm has been implemented in Python 3.7, and a maximum computational time of 60 seconds has been set for executing each instance of the problem. The experiments were run on a Windows 10 operating system using a computer with the following characteristics: an Intel(R) Core (TM) i7-8750H CPU at 2.20GHz and 16 GB of RAM.

6. COMPUTATIONAL EXPERIMENTS

The results of the case study described in the previous section are shown in Table 1. The first four columns identify the company (1 or 2), the configuration of the time threshold in hours (6+2 or 7+1), as well as the parking areas availability and the service time in minutes: high (5), medium (10, or low 15). The next six columns describe the performance of the best solution found for each case: number of routes (where each route requires one vehicle and driver), time of the longest route, distance of the longest route, total time and total distance (considering all routes), and CO_2 emissions. These emissions have been estimated using the calculator of *myclimate* (https://www.myclimate.org/), which depends on the distance, the fuel type (petrol in our case), and fuel consumption or vehicle type (van). *myclimate* is a non-profit organization and one of the world's quality leaders in voluntary CO2compensation measures. It has a large number of partners, such as *energiapro* or *WWF Switzerland*. The last row of the table shows the average measures.

Based on this data, Figure 3 displays a parallel coordinates plot of the main performance indicators. The data has been added up for each scenario (that is, for each configuration of working/resting times and parking areas availability). It can be concluded that the level of parking area availability has a great effect on the number of routes (which range around 15).

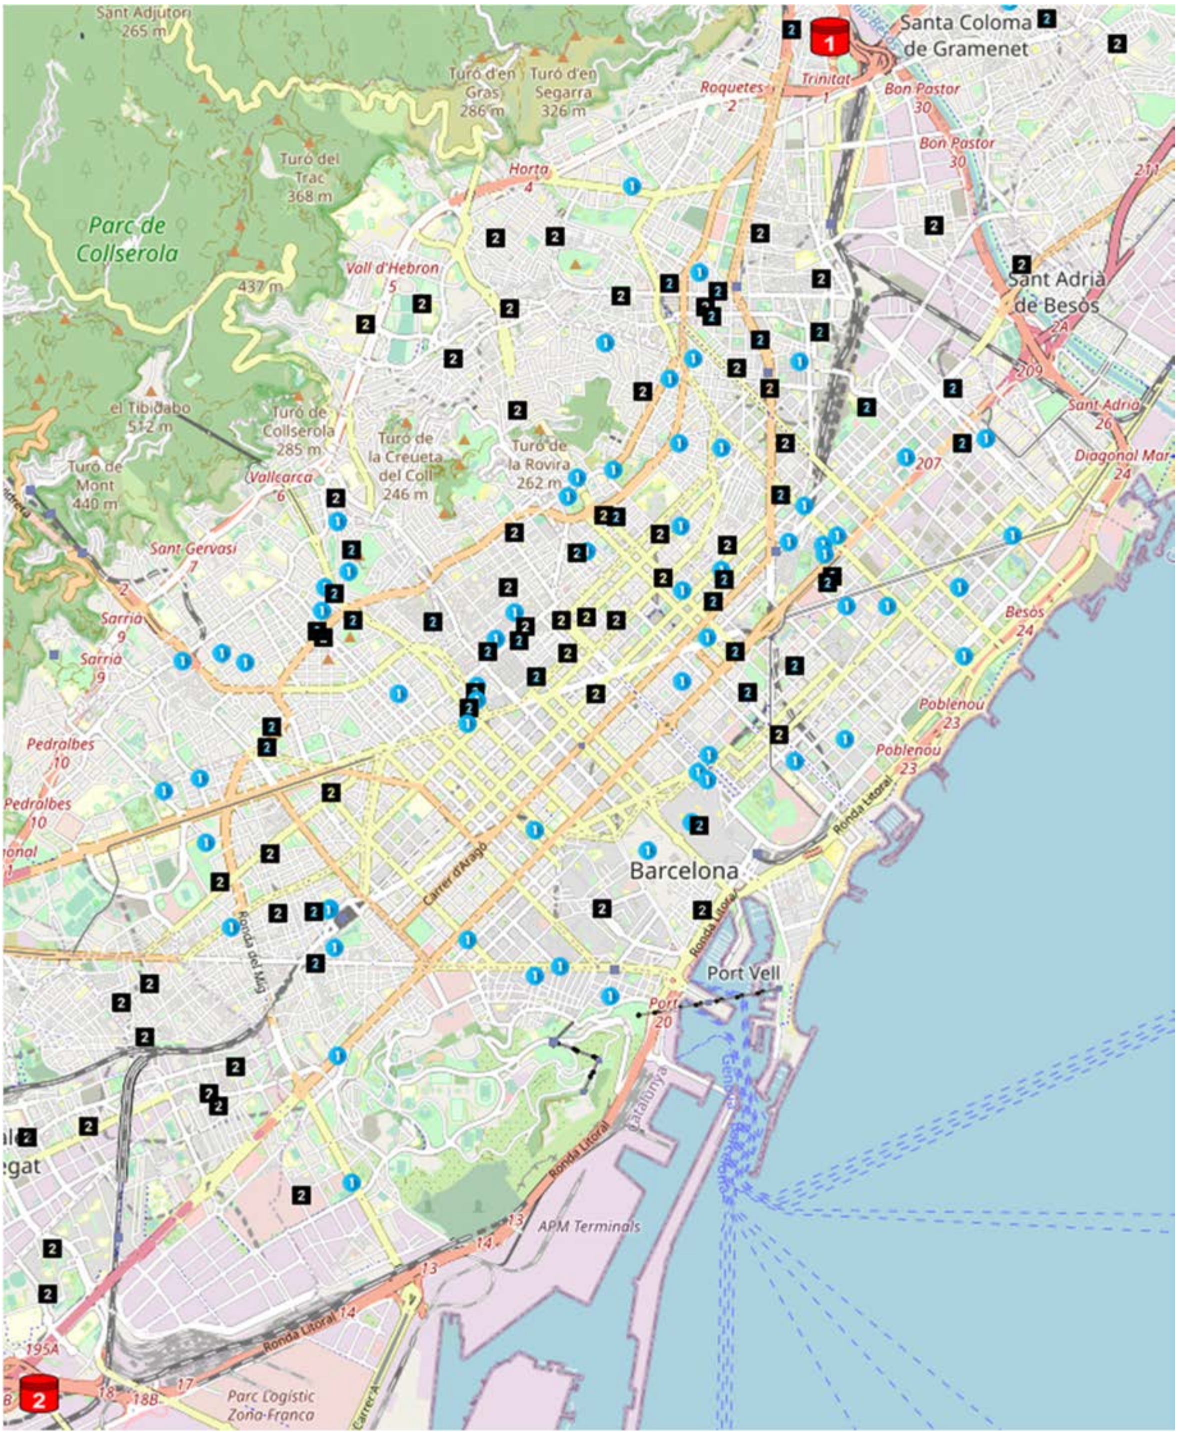

Fig. 1 – Illustrative example in the city of Barcelona. There are two depots corresponding to different carriers (represented by cylinders) and a set of customers for each carrier (represented by circles and squares).

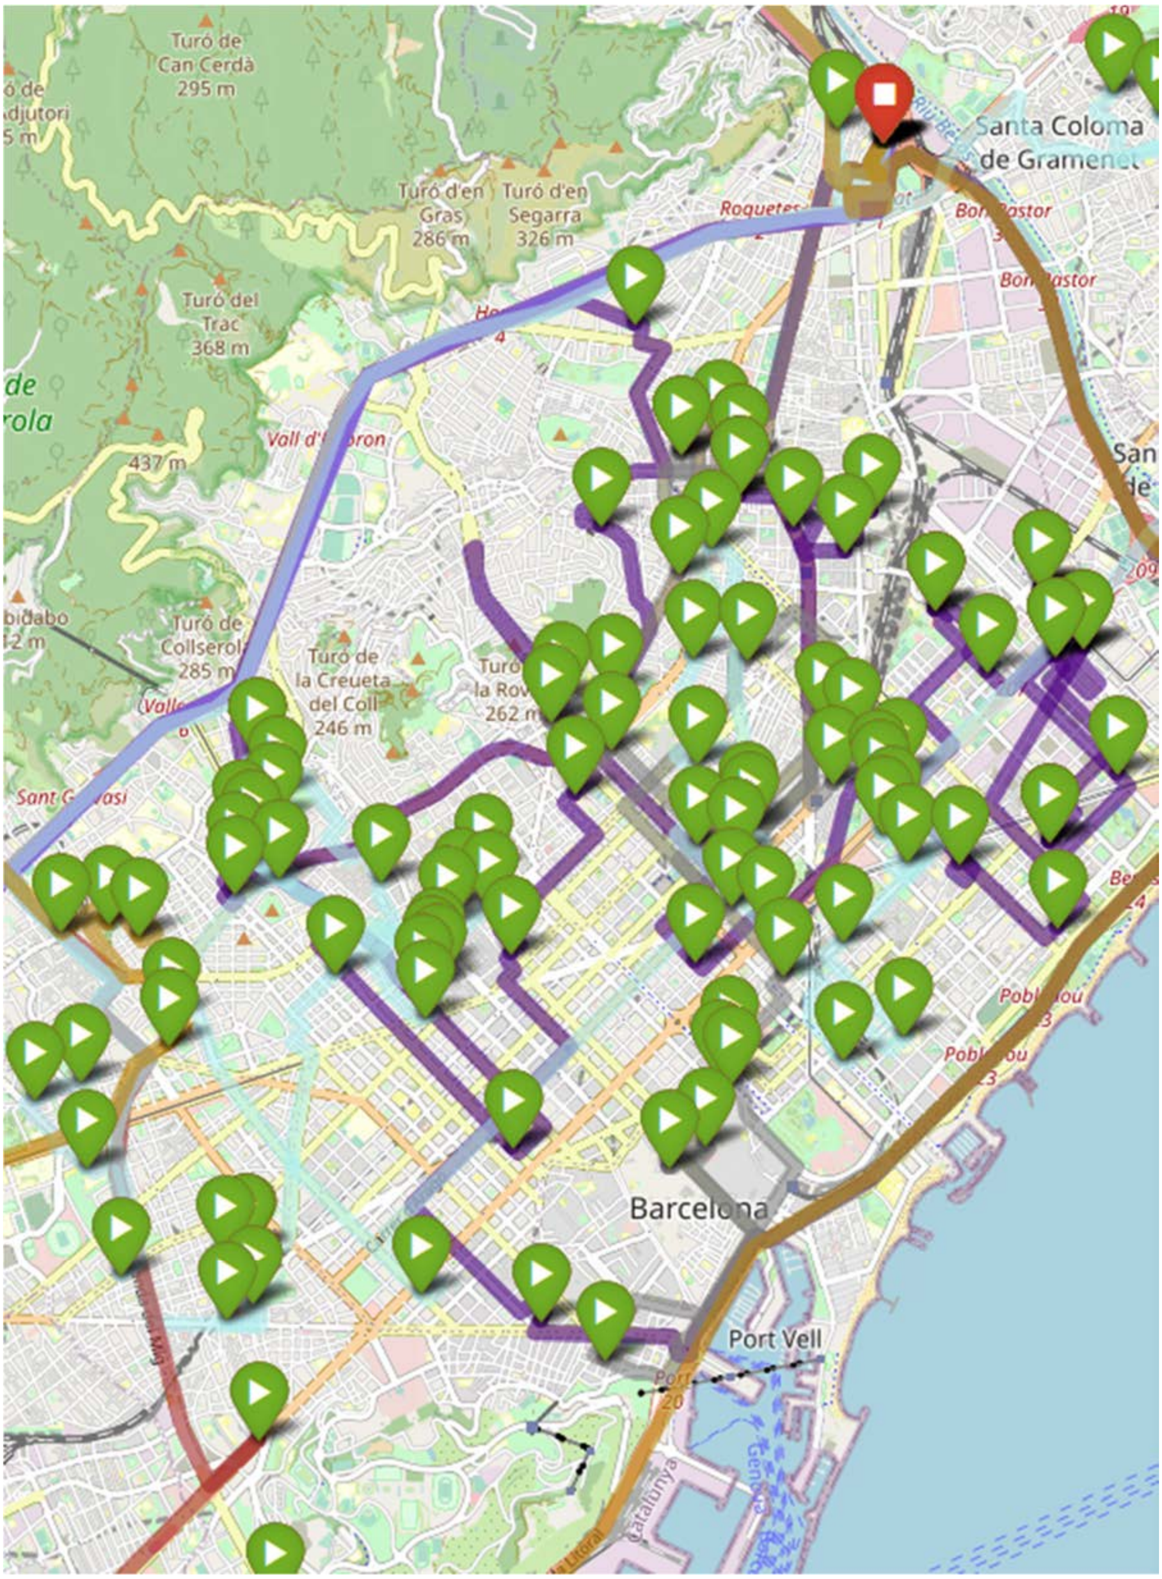

Fig. 2 – Design of routes for an illustrative case study.

Company	Timetable (h)	Parking Areas Availability	Service Time (min)	# Routes	Time Max Route (h:m)	Distance Max Route (km)	Total Time (h:m:s)	Total Distance (km)	CO_2 Emissions (t)

Table 3 – Linear regression models (codes for the significance tests: 0 '*' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1).**

37), the total time (from 5,399 minutes to 11,304), the total distance (from 1,400 to 2,213 kilometers), and the amount of CO_2 emissions (from 0.57 to 0.90). The effect of the maximum time per route is also relevant. From this figure, it is clear that there is a positive correlation between these performance indicators. The correlation matrix is displayed in

Table 2. A linear regression analysis is carried out to quantify the effect of the availability on the routing solutions. A summary of the results is displayed in Table 3. Three models have been estimated and, in all of them, the availability constitutes the independent variable (being 'low' the baseline). Each model has a different dependent variable: total time, total distance, and CO2emissions, respectively. The table includes the coefficient estimates, whether they are statistically significant, and the adjusted coefficient of determination. It can be concluded that the parking areas availability explains a high percentage of the variability of the dependent variable in the three models. Moreover, almost all the coefficients are statistically significant (for a standard significance level, i.e., $\alpha=0.05$).

7. ANALYSIS OF RESULTS AND MANAGERIAL INSIGHTS

The analysis of this case study has revealed the important effect that the ordinances may have on the routing solutions and the performance indicators. Regarding parking areas, a medium or low availability level has a noticeable impact on the economic profitability of the companies (since they require the use of longer routes in terms of both time and distance), the environment (more pollution), and the social welfare (congestion, risk of accidents, etc.).

In addition, we have quantified the effect of varying the maximum time per route (that is, the maximum number of hours that a driver is allowed to drive). While reducing this maximum time may have a positive effect on the drivers' welfare, it also has a great impact on the sustainability of the routes. For that reason, a policy based on the reduction of the maximum time should be compensated with other measures. All in all, it has been shown that, when combined with optimization algorithms, visualization techniques and statistical analyses may be a powerful tool to assess/quantify the effects of changes in the ordinances.

8. CONCLUSIONS

Logistics and transportation operators are subject to an increasing pressure to design efficient delivery systems as a consequence of: *(i)* the growth of e-commerce (goods) and the on-demand economy (services) in urban, peri-urban, and metropolitan areas; and *(ii)* a global trend towards more sustainable transportation and mobility. In this context, we have analyzed the needs of logistics operators in the Barcelona metropolitan area by interviewing 16 key shareholders from different sectors. It is concluded that the next factors significantly affect the efficiency of deliveries: *(i)* current loading and unloading spaces; *(ii)* time windows restrictions for entering the city and for loading and unloading; *(iii)* restriction of the tonnage of goods delivery vehicles; and *(iv)* the lack of a unified criterion for the ordinances. Based on the insights, especially *(i)* and *(ii)*, we discuss the need for agile optimization algorithms. An illustrative case study is carried out, which allows us to quantitatively compare several scenarios with different configurations of working/resting times and parking areas availability. The results support, with numerical evidence, the capability of the proposed methodology to measure the impact of different logistics policies and strategies. Several lines of future research stem from this work. We have explored the problems emanating from the UFD, but an extension of this study could help to assess whether the needs and views differ between private companies and public administrations, or among different sectors (food distribution, construction, etc). It could also be possible to specify and prioritize policies that allow us to boost the efficiency of delivery systems. Regarding the illustrative case study, an enriched approach could consider not only economic and environmental dimensions, but also the social one with indicators such as traffic, accident risks, driving near schools, etc. Likewise, a richer approach could consider the incorporation of fleets of electric vehicles –which might generate additional constraints regarding driving ranges–, or autonomous vehicles, which might allow distribution during the night hours.

ACKNOWLEDGEMENTS

This work has been partially supported by the Spanish Ministry of Science (PID2019-111100RB-C21/AEI/10.13039/501100011033, RED2018-102642-T), and the Erasmus+ Program (2019-I-ES01-KA103-062602). We also thank the entities that accepted to be interviewed during the development of this study.

A PARALLEL PROGRAMMING APPROACH TO THE SOLUTION OF THE LOCATION-INVENTORY AND MULTI-ECHELON ROUTING PROBLEM IN THE HUMANITARIAN SUPPLY CHAIN

Andrés Guillermo Angarita Monroy
Industrial University of Santander, Colombia
Henry Lamos Díaz
Industrial University of Santander, Colombia

ABSTRACT

Disasters around the world are becoming more frequent, diverse, complex and extremely challenging, causing millions of casualties and affecting both human development and available resources. Consequently, the present study addresses a multi-objective location, inventory and multi-scale routing (2E-LIRP) problem, which supports comprehensive decision making, so that the logistics network designer and manager can obtain adequate strategic planning in the face of uncertainty and the negative impact that an adverse event can generate.

Moreover, the problem is formulated as an integer linear programming model, having as main objectives to minimize private logistics costs and maximize the welfare of the affected areas, considering dynamic demand, multiple products and heterogeneous fleet.

Due to the computational complexity associated with the model, a new solution approach is proposed, based on the design of evolutionary metaheuristic algorithms; the first one, known as Non-dominated Sorting Genetic Algorithm version II (NSGA-II), the second one, Strength Pareto Evolutionary Algorithm version II (SPEA-II) and the third one, called Genetic Algorithm (GA), programmed in parallel and executed individually under a cooperative environment. Finally, the experimentation carried out on a test set, composed of twenty instances of varying complexity, allows inferring that the parallel-cooperative and purely parallel approach applied to NSGA-II, substantially improves the processing times and the number of non-dominated solutions, if compared to the results obtained by SPEA-II, designed under identical conditions. Moreover, by building a GA with these same characteristics, it improves up to 50% of the solutions, in terms of social costs (logistic and humanitarian costs), with computation times similar to its sequential counterpart.

1. INTRODUCTION

The occurrence of natural disasters and their devastating consequences are a reality experienced year after year around the world. Approximately 75% of the world's population lives in regions affected at least once between 1980 and 2017 by an earthquake, tropical cyclone, flood or drought. As a consequence of these phenomena, more than 184 people die every day in different parts of the world and they result in a toll that includes the destruction of fixed assets, physical capital, the interruption of production, trade and the decrease in public and private savings and investments, which wipe out progress in economic development (Nagurney et al., 2019). This problematic has generated a deep interest in seeking and establishing the most efficient mechanisms, which allow improving the response to emergency situations, thus giving rise to the emergence of humanitarian logistics as a means to cope with the negative effects of adverse events that put at risk the integrity or the very life of the human being.

Despite research and technological progress, it is still not possible to predict when and where a natural disaster will occur in advance; therefore, activities or actions before, during and after its occurrence are important to reduce the associated losses. Moreover, when a disaster occurs in a certain part of the world, many organizations come forward to provide the required relief items, e.g., food, water, medicine, among others, to the affected people. In these situations, coordination between the different members is crucial and it becomes difficult for a single organization to carry out all the necessary activities, such as repairing damaged infrastructure and delivering relief items.

Moreover, humanitarian logistics becomes a complex network with different actors, including, non-governmental organizations (NGOs) of local or international origin, donors, armed forces, corporations and private companies; each of them with different and sometimes, conflicting interests, obligations, capabilities, budget allocation structure and logistical skills (Nikkhoo et al., 2018).

For this reason, the design and management necessary in the logistics network during the pre- and post-disaster phases cannot be improvised; they must be the result of a correct and rigorous planning, in which very important aspects can be identified and established in advance, such as, the location of facilities, the availability and quality of resources through proper inventory management, flexibility in route plans according to the established budget, among others, which ultimately allow guaranteeing an optimal response when the deployment of humanitarian operations is carried out.

1.1 Justification

Currently, disasters, regardless of their origin (whether natural or human), are considered social phenomena whose damages could be prevented and mitigated to reduce or at least control their effects (Cecchini et al., 2017).

The difficulty in predicting the place where it will occur, the time and magnitude with which it will occur, in addition to the uncertainty associated with the characteristics of the population, the existing infrastructure conditions and the demand required to meet the emergency situation, give rise to one of the greatest challenges in humanitarian logistics, such as unpredictability, defined as the occurrence of unexpected events (Balcik et al., 2010). L'Hermitte et al. (2016) state that unpredictability creates barriers and affects efficiency in the supply chain.

Thus, the proper management of the logistics supply chain for disaster relief and humanitarian support becomes a very important challenge worldwide, since it is responsible for estimating, providing, storing, storing, transporting and distributing personnel, resources and services required to the affected areas (Talebian Sharif & Salari, 2015), through a set of activities carried out in different instances of time, which are intended to assist the survivors after a disaster, reduce its impact and maintain social stability (Aghajani et al., 2020; Vahdani et al., 2018).

For this reason, the need arises to develop a model capable of providing sufficient information to the logistics network manager to make the best decisions related to the location, distribution and inventory management, which ultimately guarantee a timely delivery of goods (products or services) to the stakeholders (affected areas), thus minimizing the negative economic and social impacts caused by the occurrence of adverse events. This model is associated with the 2E-LIRP, which integrates three types of very important decisions within the comprehensive planning of humanitarian logistics, as stated by Rafie-Majd et al. (2018), i.e., strategic decisions: with long-term effects (location and allocation of facilities); tactical decisions: medium-term (inventory control and transportation) and operational decisions: daily or weekly (scheduling and routing), which ultimately determine the responsiveness, flexibility, efficiency and effectiveness of the supply chain.

2. LITERATURE REVIEW

By way of summary, the most common solution techniques used to solve multi-echelon location, inventory and routing problems are presented below; in parallel, some characteristics (see Table 1-2) considered to be of great relevance in the different studies found to date are described.

Convention	**Interpretation**
1	Mathematical formulation
2a	Mono-objective
2b	Multi-objective
3a	Multi-period
3b	Multi-product
4a	Deterministic parameters
4b	Stochastic parameters
4c	Fuzzy parameters
5	Method / Solution algorithm
6a	Parallel programming techniques
6b	Paradigm of cooperation between metaheuristics
7	Deprivation costs in the model

3. PROBLEM DESCRIPTION AND MATHEMATICAL FORMULATION

The following is a schematic representation, with the purpose of facilitating the interpretation and understanding of the problem addressed (see Figure 1).

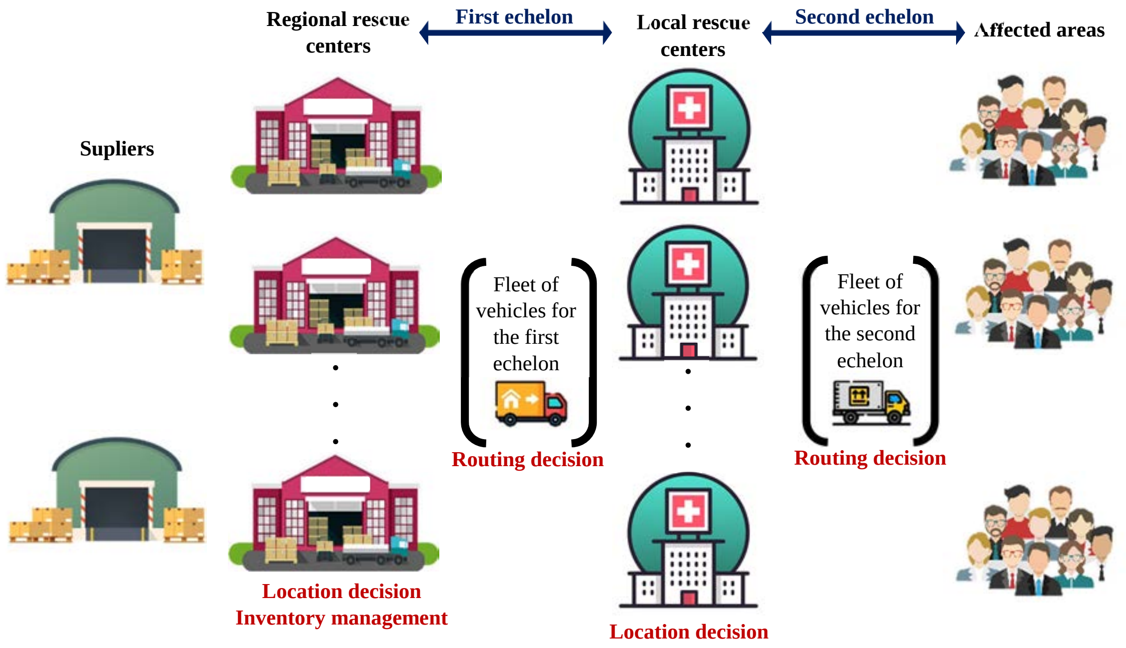

Fig 1 - Graphical illustration of 2E-LIRP

Taking as a reference the research developed by Pérez-Rodríguez & Holguín-Veras (2016), Tavana et al. (2018), Cotes & Cantillo (2019) and Dai et al. (2019), in addition to taking into account the considerations established by the researcher, the mathematical model is formulated as presented below.

3.1 Sets

R = Set of possible regional rescue centers
L = Set of possible local rescue centers
C = Set of areas affected (AA) by a disaster
V = Set of vehicles for first level routes
W = Set of vehicles for second level routes
P = Set of products required in the AA
T = Humanitarian deployment time periods

3.2 Indexes

r = Index for possible regional rescue centers
l = Index for possible local rescue centers
c = Index for areas affected (AA) by a disaster
v = Index for first level vehicles

w = Index for second level vehicles
p = Index for products required in the AA
t = Index for time periods

3.3 Parameters

K_{ip} = Facility capacity $i \in R \cup L$, for product $p \in P$
H_{ip} = Vehicle capacity $i \in W \cup V$, for product $p \in P$
F_i = Cost of opening the facility $i \in R \cup L$
G_i = Cost of using the vehicle $i \in W \cup V$
D_{cp}^{t} = Customer demand $c \in C$, for product $p \in P$, in period $t \in T$
S_{ij} = Cost of traveling between node i and node j for the first echelon
E_{ij} = Cost of traveling between node i and node j for the second echelon
CS_{p}^{t} = Cost of buying the product $p \in P$ in period $t \in T$
CT_{pr}^{t} = Unit cost of transporting the product $p \in P$ from the supplier to the regional rescue center $r \in R$ during the period $t \in T$
CMI_{pr} = Unit cost of keeping the product $p \in P$, in inventory at the regional rescue center $r \in R$
I_{pr}^{0} = Initial inventory of product $p \in P$, at the regional rescue center $r \in R$
F_{jt} = Deprivation time presented by the affected area $j \in C$ in the period $t \in T$
TV_{ij} = Travel time between node i and node j, for $i \wedge j \in L \cup C$
P_j = Number of individuals at the point of demand (affected area) $j \in C$
VP_{j}^{t} = Average economic value of well-being perceived by an individual in the affected region $j \in C$ (it is possible to take as a base value, the GDP per capita of the last year) for the period $t \in T$
$(VP_{j}^{t} * F_{jt}^{-1} * P_j)$ = Deprivation function (DF)
$(VP_{j}^{t} * TV_{ij}^{-1} * P_j)$ = Impact function on distribution (IFD)

3.4 Decision variables

$$y_i = \begin{cases} 1 & \text{If the facility } i \in R \cup L \text{ is open} \\ 0 & \text{Otherwise} \end{cases}$$

$$m_{ijt}^{v} = \begin{cases} 1 & \text{If the vehicle } v \in V, \text{travels from node } i \in R \cup L, \text{to node } j \in R \cup L, \text{on the first level route, during the period } t \in T \\ 0 & \text{Otherwise} \end{cases}$$

$$n_{ijt}^{w} = \begin{cases} 1 & \text{If the vehicle } w \in W, \text{travels from node } i \in L \cup C, \text{to node } j \in L \cup C, \text{on the second level route, during the period } t \in T \\ 0 & \text{Otherwise} \end{cases}$$

$$L_{rl}^{t} = \begin{cases} 1 & \text{If the local rescue center } l \in L, \text{is assigned to the regional rescue center } r \in R, \text{in the period } t \in T \\ 0 & \text{Otherwise} \end{cases}$$

$$P_{rc}^{t} = \begin{cases} 1 & \text{If the affected area } c \in C, \text{ is assigned to the local rescue center } l \in L, \text{ in the period } t \in T \\ 0 & \text{Otherwise} \end{cases}$$

$$q_{i}^{t} = \begin{cases} 1 & \text{If the vehicle } i \in W \cup V, \text{ is used on a route, in the period } t \in T \\ 0 & \text{Otherwise} \end{cases}$$

FN_{prlv}^{t} = Product flow $p \in P$ to be transported, from the regional rescue center $r \in R$ to the local rescue center $l \in L$ in vehicle $v \in V$, for period $t \in T$

Q_{pr}^{t} = Quantity of product $p \in P$ to be purchased at regional rescue center $r \in R$, in period $t \in T$

I_{pr}^{t} = Units of product $p \in P$ in inventory, for regional rescue center $r \in R$, during period $t \in T$

Z_1 = Total logistics cost (Private Costs)

Z_2 = Total wellness of the areas ($-Z_2$ = External Costs/ Human suffering)

3.5 Objective function

$$Minimize\{Z_1\} = Minimize\left\{\sum_{r\in R} F_r * y_r + \sum_{l\in L} F_l * y_l + \sum_{t\in T}\sum_{v\in V} G_v * q_v^t + \sum_{t\in T}\sum_{v\in V} G_w * q_w^t + \sum_{t\in T}\sum_{(i,j)\in R\cup L}\sum_{v\in V} S_{ij} * m_{i\ jt}^{v} + \sum_{t\in T}\sum_{(i,j)\in L\cup C}\sum_{w\in W} E_{ij} * n_{i\ jt}^{w} + \sum_{p\in P}\sum_{r\in R}\sum_{t\in T} CS_p^t * Q_{pr}^t + \sum_{p\in P}\sum_{r\in R}\sum_{t\in T} CT_{pr}^t * Q_{pr}^t + \sum_{p\in P}\sum_{r\in R}\sum_{t\in T} CMI_{pr} * I_{pr}^t \right\} \quad (1)$$

$$Maximize\{Z_2\} = Maximize\left\{\sum_{w\in W}\sum_{t\in T}\sum_{(i,j)\in L\cup C}\left[VP_j^t * p_j * \left(F_{jt}^{-1} + TV_{ij}^{-1}\right)\right] * n_{ijt}^{w}\right\} \quad (2)$$

3.6 Constraints

3.6.1 Second echelon constraints

$$\sum_{l\in L} P_{lc}^t = 1; \quad \forall c \in C \wedge \forall t \in T \quad (3)$$

$$\sum_{c\in C} D_{cp}^t * P_{lc}^t \le k_{lp} * y_l; \quad \forall l \in L, \forall p \in P \wedge \forall t \in T \quad (4)$$

$$\sum_{w\in W}\sum_{j\in L\cup C} n_{jct}^{w} = 1; \quad \forall c \in C, \forall t \in T \wedge j \ne c \quad (5)$$

$$\sum_{h\in L\cup C} n_{hjt}^{w} - \sum_{h\in L\cup C} n_{jht}^{w} = 0; \quad \forall j \in L \cup C, \forall w \in W, \forall t \in T \wedge h \ne j \quad (6)$$

$$\sum_{i\in A'}\sum_{j\in A'} n_{ijt}^{w} \le |A'| - 1; \quad \forall w \in W, \forall t \in T, A' \subseteq A, |A'| \ge 2 \wedge i \ne j \quad (7)$$

$$\sum_{i\in L}\sum_{j\in C} n_{ijt}^{w} \le 1; \quad \forall w \in W \wedge \forall t \in T \quad (8)$$

$$\sum_{b\in L\cup C} n_{cbt}^{w} + \sum_{b\in L\cup C} n_{lbt}^{w} - P_{lc}^t \le 1; \quad \forall l \in L, \forall c \in C, \forall w \in W, \forall t \in T, c \ne b \wedge l \ne b \quad (9)$$

$$I_{pr}^{t} \in \mathbf{Z}^{+} \cup \{0\}; \quad \forall p \in P, \forall r \in R, \wedge \forall t \in T \tag{34}$$

$$Q_{pr}^{t} \in \mathbf{Z}^{+} \cup \{0\}; \quad \forall p \in P, \forall r \in R, \wedge \forall t \in T \tag{24}$$

3.7 Optimization model interpretation

Equation (1) minimizes the private costs, related to the opening of regional rescue centers (first term) and local rescue centers (second term), the use of vehicles at the first and second level (third and fourth terms), the routing at each echelon (fifth and sixth terms) and, in addition, the costs caused by managing the inventory at the first level facilities (regional centers), composed of the quantity purchased (seventh term), transported (eighth term) and in inventory (ninth term).

Moreover, equation (2) maximizes the total welfare of the demand points, which for convenience, is translated into a deprivation cost function (DCF), understood as the welfare that can be foregone by an affected area, given a deprivation time (F_{jt}) and a time required to supply humanitarian goods (TV_{ij}) to that area; thus obtaining two very important components: the deprivation function (first sub-terms, $VP_j^t * P_j * F_{jt}^{-1}$) and the distribution impact function (second sub-terms, $VP_j^t * P_j * TV_{ij}^{-1}$), which together represent the DCF, when the route plan is defined at the second echelon (third sub-terms, n_{ijt}^{w}).

On the other hand, equation (3) guarantees the assignment of each affected area to a single local rescue center; equation (4) ensures that the demand of the regions assigned to the same local rescue center does not exceed the capacity of that facility; equation (5) imposes that each affected area must be visited by exactly one second echelon vehicle; equation (6) allows each vehicle in use to return to the same local center from which it departed.

Furthermore, equation (7) prevents the formation of sub-tours or illegal routes in the second echelon; equation (8) ensures the unique assignment of a vehicle to a specific local rescue center, if it is enabled; equation (9) ensures that the local rescue center r serves the affected region c, if and only if there is a vehicle w leaving r and arriving at c and equation (10) allows that the demand satisfied by a vehicle in the second echelon does not exceed its capacity, if it is used in a facility during period t.

Continuing with the interpretation of the model, equation (11) allows the assignment of each enabled local rescue center to a single regional rescue center; equation (12) refers to the capacity restriction in the regional centers, since, as can be seen, the capacity of an enabled regional center must be greater or equal to the capacity of the local centers assigned to it; equation (13) guarantees the return to the same regional rescue center, the vehicle v assigned. Equation (14) avoids the formation of sub-tours or illegal routes in the first echelon; equation (15) allows a vehicle to be assigned to at most one regional rescue center, if it is used; equation (16) ensures that regional center r serves local center l, if there is a vehicle v leaving r and arriving at l; equation (17) is associated with the conservation of the flow in the local rescue center l, taking into account that the amount of product p entering it must be equal to the total demand of the assigned areas/regions.

Equations (18) and (19) guarantee that the amount of flow in a vehicle v from a regional rescue center r to a local rescue center l is positive if and only if both the regional center and the local rescue center are visited by the same vehicle v; equation (20) is related to the capacity limitation for a vehicle v (the flow or amount of product p transported in a vehicle v from a regional center r to a local center l must be less than or equal to the capacity of that vehicle). Equation (21) allows to include an initial inventory level for each of the products, in the regional centers r enabled; equation (22) represents the inventory balance, which in other words, means that the amount of inventory for a period t, is equal to the units stored in the previous period, plus the purchases made in t, minus the amount transported to each point of demand; Equation (23) prevents the units in inventory for each of the humanitarian products from exceeding the capacity tied to the first level facilities, and equation (24) imposes a zero inventory level for the last period of humanitarian aid in the different facilities (regional rescue centers).

Finally, equations (25)-(35) establish the nature of the decision variables considered in the mathematical model, which as can be seen are mostly binary (25-32) and a small portion take values in the set of positive integers (32-35), thus allowing to address an Integer Linear Programming (ILP) problem.

4. CONSTRUCTION OF EVOLUTIONARY ALGORITHMS

Taking as a reference the logical procedure of each of the chosen algorithms, in addition to the proposed scheme to generate and represent an individual or solution k, it is possible to build a parallel and cooperative version of each technique, using the paradigm of *"distributed systems or islands"* (see Figure 2), which basically consists of the use of a coordinator or collector C (*multi-processing variable*), which fulfills a mediating function in the exchange of information generated by each of the islands. In order to understand its role in the algorithmic process, a summary of its structure is presented below, taking into account the applied technique.

4.1 Parallel-cooperative algorithms

1. **Coordinator *p*-GA_V1**

1.1. Module for the reception and transfer of information generated in island 1

1.2. Module for the reception and transfer of information generated in island 2

1.3. Storage module (starts operation once the stop criterion is met)

1.3.1. Sub-module that stores the set of best individuals obtained in island 1 during each generation $[S^1(T)]$

1.3.2. Sub-module containing the set of best individuals obtained in island 2 during each generation $[S^2(T)]$

2. Coordinator *p*-NSGA-II_V1

2.1. Module for the reception and transfer of information generated on island 1

2.2. Module for the reception and transfer of information generated on island 2

2.3. Storage module (It is activated once the iterative process is finished)

2.3.1. Sub-module that stores the final population $[P_T^1(N/2)]$ of island 1

2.3.2. Sub-module containing the final population $[P_T^2(N/2)]$ of island 2

3. Coordinator *p*-SPEA-II_V1

3.1. Module for reception and transfer of information generated in island 1

3.2. Module for the reception and transfer of information generated in island 2

3.3. Storage module (Executed once the iterative process is finished)

3.3.1. Sub-module storing the final external population $\left[P_{E_1}^T\right]$ of island 1

3.3.2. Sub-module containing the final external population $\left[P_{E_2}^T\right]$ of island 2

4.2 Pure parallel algorithms

4. *p*-NSGA-II _V2

4.1. Module in charge of storing the final population $[P_T^1(N/2)]$ obtained in island 1

4.2. Module in charge of storing the final population $[P_T^2(N/2)]$ obtained in island 2

5. *p*-GA_V2

5.1. Module that stores the set of best individuals obtained in island 1 during each generation $[S^1(T)]$

5.2. Module that stores the set of best individuals obtained in island 2 during each generation $[S^2(T)]$

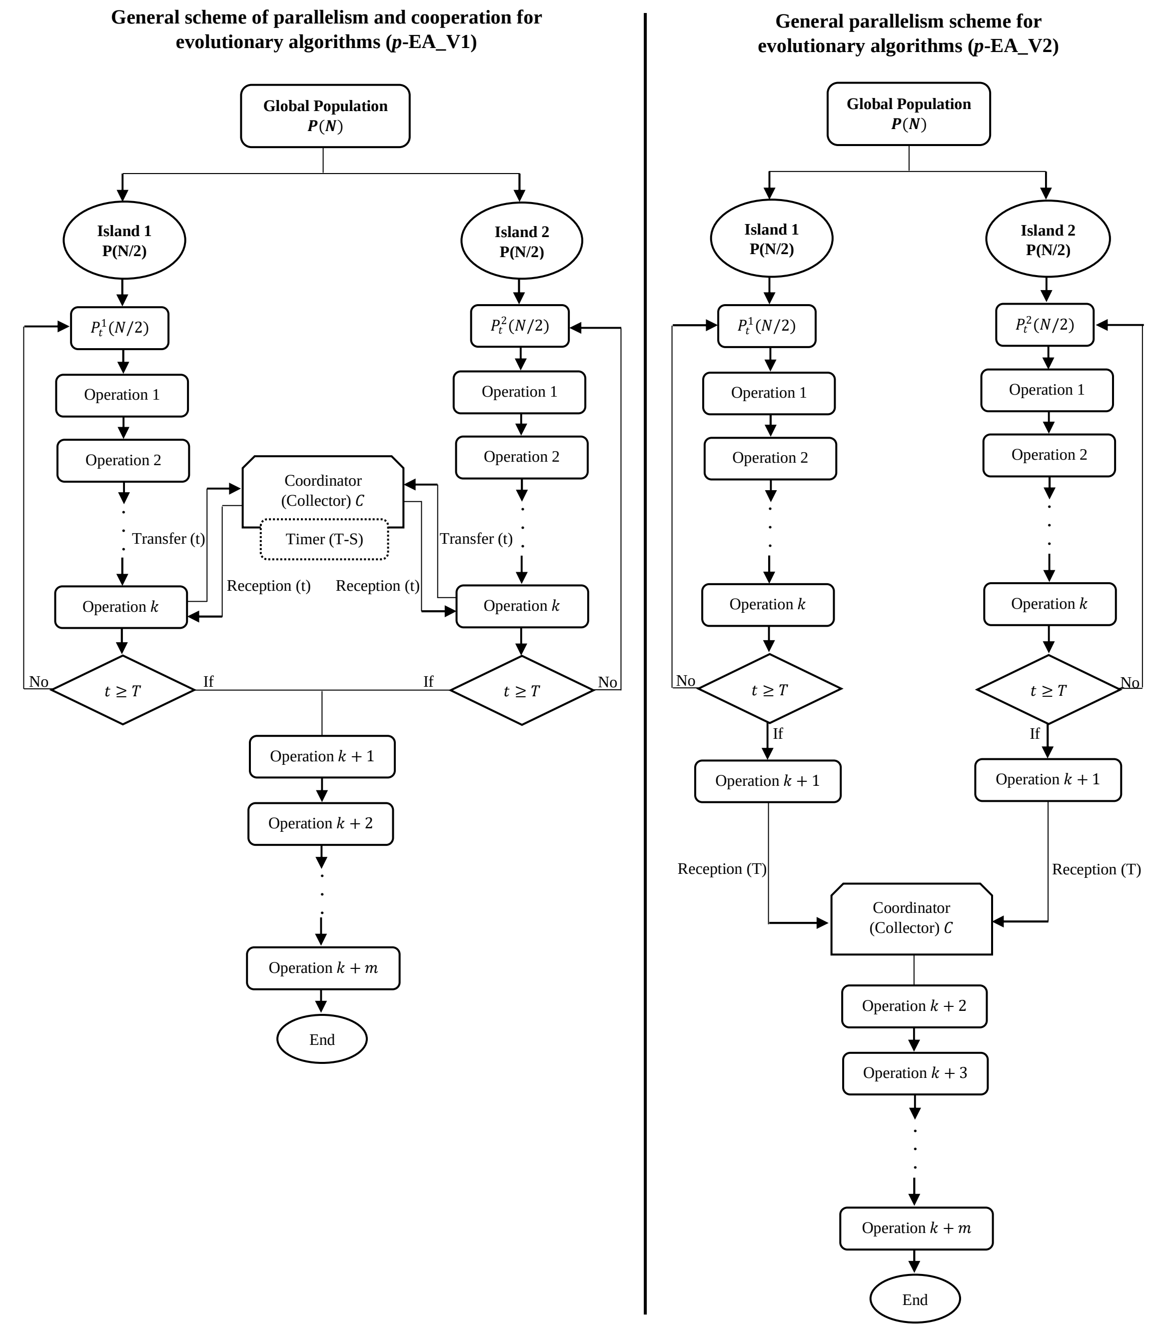

Fig 2 - General operation of parallel-cooperative and purely parallel evolutionary algorithms

5. EXPERIMENTATION

Once the solution techniques have been coded in the Python programming language, it is essential to validate them, in order to verify consistent outputs, depending on the problem addressed and the assumptions established.

To carry out this procedure, it was necessary to create a set of test instances (testbed), taking into account those designed by Albareda-Sambola et al. (2005) and Prodhon (2006), since there are currently no easily adaptable scenarios in the literature; these instances are consolidated under the nomenclature presented in Table 3.

Type of Instance	Nomenclature							Reference
	C	L	R	W	V	P	T	
1	30	10	7	11	6	8	7	I1_30C-10L-7R-11W-6V-8P-7T

Table 3 - Set of instances for validation of AEs

Note. C= Number of clients, L= Potential local centers, R= Potential regional centers, W= Second tier vehicles, V= First tier vehicles, P= Products and T= Relief periods.

Once the errors have been corrected and the codes debugged, it is possible to move on to the calibration process, which consists of identifying the main variables influencing the performance (solution quality and computational time) of the algorithms (GA, *p*-GA_V1/V2 *p*-NSGA-II_V1/V2 and *p*-SPEA-II_V1);

Therefore, it is decided to use a 2^k factorial design (DOE), composed of the parameters of the evolutionary algorithms (factors), i.e., population size (PS), number of generations (NG) and mutation probability (MP); taking into account as response variables, the best solution found (BS), if the methodology is of the single-objective type, the number of non-dominated solutions (NDS), for multi-objective approaches and a variable common to both techniques, the computational time (CT) required. On the other hand, the configurations established for this experiment are shown in Table 4 and Table 5, where the levels or treatments were chosen based on the experimentation and the review of previous studies.

Factors	Levels	
	Low (-)	**High (+)**
PS	100	200
NG	150	300
MP	0,05	0,10

Table 4 - Factorial design for the single-objective techniques

Factors	Levels	
	Low (-)	**High (+)**
PS	240	480
NG	50	100
MP	0,05	0,10

Table 5. Factorial design for the multi-objective techniques

It is important to mention that the tests were performed on a laptop computer with a Core i5-1035G4 processor, 8 GB RAM memory and solid-state hard disk, using a total of 5 replicates for each of the possible combinations of the levels of the main factors; in addition, the hypotheses of significance for the BS and NDS variables were contrasted under a confidence level equivalent to 80% and for the case of CT, a level equal to 95% was taken into account.}

In order to choose the best configuration of levels for the evolutionary factors (initialization parameters) and to allow adequate outputs, taking into account the set of instances tested on each technique, it was decided to use the response optimizer that Minitab 19 has in the section: "DOE>Factorial>Optimizer". Once this tool has been executed, under the same level of importance between test scenarios, the structure shown in Table 6 is obtained, which will serve as a starting point when executing any test instance.

Algoritmo	Best combination of treatments associated with the response variable (Optimizer)					
	BS/NDS			**CT**		
	PS	**NG**	**MP**	**PS**	**NG**	**MP**
GA	200	300	0,05	100	150	0,10
p-GA_V1	200	300	0,05	100	150	0,10
p-NSGA-II_V1	480	50	0,10	240	50	0,10
p-SPEA-II_V1	480	50	0,10	240	50	0,10
p-NSGA-II_V2	480	50	0,10	240	50	0,10
p-GA_V2	200	300	0,05	100	150	0,10

Table 6 - Optimal combination of factors associated with AEs

Taking as reference the configuration of the evolutionary parameters obtained previously by means of the factorial design, the testbed is executed on each algorithm, with the purpose of obtaining sufficient data to verify the preliminary statements, associated to the performance; which is represented in the case of the mono-objective techniques, by the variable: best solution found (BS) and for the multi-objective approaches, the variable defined as: number of non-nominated solutions (NDS), taking into account in turn, the computational time (CT). To carry out this procedure, it was necessary to use a sample size equivalent to thirty (30) per instance tested and to apply the t-test statistic with joint equality of variances, for differences between two means. The results of each technique are presented in Table 7-10, using an algorithmic contrast or GAP.

Table 10 - GAP between algorithms *p*-GA_V2 and GA (n = 30)

Note. The results correspond to an average and the computational time (CT) is given in seconds.

6. DISCUSSION

The experimentation carried out points to the algorithms *p*-NSGA-II_V1 and *p*-NSGA-II_V2 as the best alternatives to solve the multi-objective 2E-LIRP problem applied to the humanitarian supply chain, because they obtain the highest average number of non-dominated solutions (NDS), allowing the decision maker to have a prudent set of possible solutions and also, the execution times (CT) are statistically lower than *p*-SPEA_V1.

Despite an approximately equal performance in terms of computational time (CT) or solution quality (BS), by genetic algorithms (GA) programmed in parallel under a cooperative environment or simply with a parallel approach, compared to their sequential counterpart, it is important to mention that there are some considerable improvements for the variable BS, using the *p*-GA_V1 and *p*-GA_V2 techniques, which are valued at 45% and 50% respectively, taking as a reference the testbed, i.e., the *p*-GA_V1 algorithm improves the solutions for 45% of the tested instances, while the *p*-GA_V2 allows to obtain a global improvement, equivalent to 50%.

On the other hand, the algorithms designed under the mono-objective and multi-objective approaches, taking into account sequential, parallel and cooperative characteristics, generally present a reasonable processing time (5 to 10 minutes approximately), thus becoming valid and efficient tools that support integral decision making for the management of the humanitarian supply chain, whose main objective is to attend the areas affected by a disaster in the shortest possible time, thus saving as many lives as possible.

Finally, the results obtained in each of the solution approaches indicate that the present study has fulfilled the general purpose, related to the development of a multi-objective optimization model for the two-echelon location, routing and inventory problem (2E-LIRP) and, consequently, to the design of a set of computational tools (Python code), which allow solving specific instances, providing relevant information to the decision-maker and designing the humanitarian logistics network.

7. CONCLUSIONS

One of the most significant contributions provided by this research is the development of a multi-objective model for the problem of location, inventory and multi-echelon routing, considering dynamic demand, heterogeneous fleet, multiple periods and products, which takes into account the optimization of social costs, due to its humanitarian context and the new approaches in the area of disasters that seek to mediate between private and humanitarian costs, despised so far in much of the existing literature, because they use adaptations of commercial logistics; in other words, the objectives of the mathematical model constructed are to minimize traditional logistics costs (location, inventory and routing) and, at the same time, to maximize the welfare of the affected areas, using a function that represents the impact on the distribution strategy and the time of deprivation experienced.

The parallel-cooperative or purely parallel scheme, acts favorably when constructing solution techniques that follow the methodology proposed by NSGA-II, thus allowing a higher performance, if compared to the SPEA-II algorithm, designed under identical conditions, using as metrics, the computational time (CT) and the number of non-dominated solutions (NDS). Moreover, it is important to mention how the *p*-NSGA-II_V1 and *p*-NSGA-II_V2 algorithms have strictly lower computational times for 100% of the executed instances and at the same time, the number of non-dominated solutions are at least equal or higher than those of *p*-SPEA-II_V1.

The experimentation carried out showed that using parallel programming under the cooperative paradigm or simply the parallel approach, in the design of a single-objective genetic algorithm (*p*-GA_V1 or *p*-GA_V2), for the solution of the 2E-LIRP, allows obtaining at the inferential level solution methods approximately equal, in terms of the variable, best solution found (MS), than its sequential counterpart, the genetic algorithm

(GA). However, it is important to mention that for a set of replicates (sample level), the *p*-GA_V1 and *p*-GA_V2 algorithms significantly improve the solutions obtained by the GA technique, finding approximately 45% (parallel-cooperative algorithm) and 50% (parallel algorithm) of the best global solutions in the testbed executed.

In spite of the effort made to build a parallel-cooperative genetic algorithm that would present an improvement in terms of computational time (CT), the experimentation allows inferring that under the scheme used (distributed system or islands), this purpose is impossible to achieve, since in most of the instances used, the performance obtained was inferior with respect to its sequential counterpart, This is due to two very important aspects, the first, the need to synchronize the two threads (islands) at the time of the transfer of genetic information and the second, the additional operations that it needs to perform in the collector (communication mechanism), to finally obtain a solution (better individual).

The evolutionary techniques used in the present study offered excellent performance (global range between 5 and 10 minutes) when solving the problem addressed, given the computational complexity that demanded the use of adequate tools to obtain good solutions in reasonable computational times. Each proposed technique was validated by applying a testbed, composed of twenty test instances, where the consistency and validity of the outputs were two very important aspects that were evaluated, with the purpose of offering the decision-maker useful tools to support the management of the humanitarian supply chain, taking into account the needs (location, inventory and routing) from an integral viewpoint, the multi-objective approach, which provides a set of possible solutions, which according to some criteria or specific technique, lead to the selection of an alternative, and the mono-objective approach, which allows to mediate or combine the interests under conflict, by applying a level of importance or weight, in order to obtain a single answer.

ABSTRACT

This article presents a fuzzy process for operational decision-making on the freight pick-up and delivery. It allows assessing the impact of uncertainty conditions presented in urban context variables such as time windows, service time, reacting available time, on the distribution routes. We use the fuzzy decision process to assess customers' requirements on a daily urban freight. The process supports the decision-making for accepting or rejecting the requests. It considers a notable key index, the impact level on the route. This index assesses the current values of the input variables. The changes are accepted when the impact level on the route is lower than 0.25.

1. INTRODUCTION

In urban freight transport (UFT) processes, there are constant changes in customer demand, travel times, and service times, among others (Gómez-Marín, 2020). It is necessary to consider methods that assess the feasibility of reacting quickly to these online changes in terms of additional costs incurred by changing pre-established routes and the impact on the scheduled routes to visit on time for all customers.

The fuzzy inference has been implemented in distribution logistics processes to mitigate the uncertainty and risks that arise in today's business and the constant search to improve the service levels expected by customers (Adarme-Jaimes, Arango-Serna, & Cogollo-Flórez, 2012; Brito, 2011; Lin et al., 2014), to minimize cost and risk on route planning (Pamučar et al., 2016), and to reduce environmental impact of network design (Cirovic, Pamucar, & Bozanic, 2014; Soleimani et al., 2017). It can be used integrating data analysis to assess the UFT system efficiency (Bray et al., 2014; Koohathongsumrit & Meethom, 2021). By using fuzzy inference, stakeholders can make decisions and react to the dynamic context changes and improve the performance of freight transportation systems (Bray et al., 2014; Kuo, Wibowo, & Zulvia, 2016). It allows flexible behaviors or replies to each change. According to Villeta et al., (2012) it is possible to use this tool to model the attitudes and behavior of actors in different scenarios.

Simic & Simic (2011) classify the application of fuzzy inference in UFT into four types: 1) application of expert systems, 2) multi-criteria decision-making processes under uncertainty, 3) routing problems mixed with transportation modes, and 4) process actor selection process. We present an application for a multi-criteria decision-making process to assess the possibility of accepting or rejecting changes based on reached impact level on the distribution plan (route).

This paper proposes a decisional framework to assess a notable key index, the impact level on the route. It considers events of time windows changes and service time changes during the operation day. It also takes into account the moment of the day when the event occurs and the relative customer importance on the route. The paper is organized as follow: at section two, we present the fuzzy decision-making process. In section three, we discuss the results of the fuzzy inference process. Hereafter we present conclusion and propose future works.

2. FUZZY DECISION-MAKING PROCESS

We define four input variables for the fuzzy inference system. These variables represent some possible changes in customer demand conditions and the changes characteristics. The customer sends a request informing the desired changes in time windows and in the service times to the vehicles at loading or unloading activity.

The input variables are defined based on change features and customer order importance.

The output variable is the result of the fuzzy inference process that explores quantifying the impact level on the route considering the changes events to the current route. Figure 1 presents the proposed fuzzy operational decision-making process.

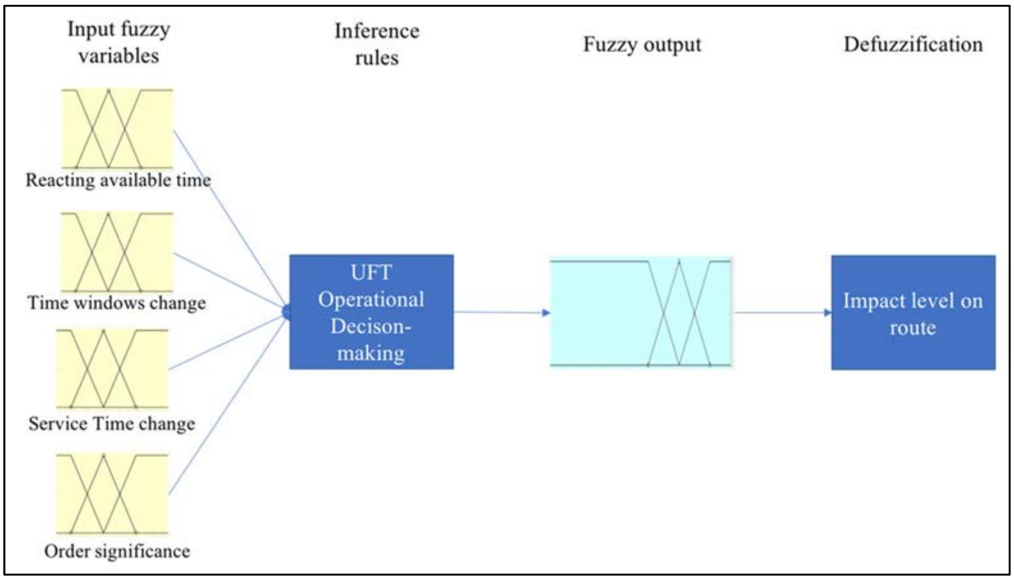

Fig. 1 – Fuzzy operational decision-making process

The selected variables in this fuzzy inference process are used to make decision-making more flexible and promptly and assess the possibility of reprogramming the initial distribution plan. These variables are:

2.1 Input variables

Reacting available time: This variable measures the time availability to react considering the moment when the customer requests the change. The available route time is the difference between the total time for the working day and the moment when the request arrives. Equation (1) shows how to calculate this variable:

$$Reacting\ available\ time = \left(\frac{Available\ route\ time\ (t)}{Total\ time\ for\ the\ working\ day}\right) \quad (1)$$

In the fuzzy parameterization process of the reacting available time, there are three fuzzy sets. Low if the reacting available time is between 0.00 and 0.25; medium, if reacting available time is between 0.125 and 0.375, and high if the reacting available time is greater than and 0.25.

Time windows change: this variable defines the time window increase or decrease, i.e., the new window size requested by the customer measured as a ratio between the change and the initial time window. We do not consider a translation of time window in a different operation time period. The fuzzy sets for the variable parameterization are three: low, when the ratio is lower than 0.25; medium, when this ratio is between 0.125 and 0.375; and high for ratios greater than 0.25. Equation (2) shows how to calculate this variable.

$$Time\ windows\ change = \left(\frac{New\ time\ window\ size}{Initial\ time\ window\ size}\right) \quad (2)$$

Service time change: We consider service time as the waiting time for be served plus the loading/unloading time**.** This variable defines the numerical value of the change in service time location with respect to an established service time, i.e., this variation just can occur when vehicle arrive to customer's location. The pre-established value for service time is 10 minutes. The fuzzy sets for the parameterization of the variable are three: low when the change in service time is negative, that is, the vehicle is served earlier than expected, and can vary between -10 minutes and 5; medium when the additional time that vehicle must wait is between 0 and 10 minutes; and high for changes greater than 5 minutes.

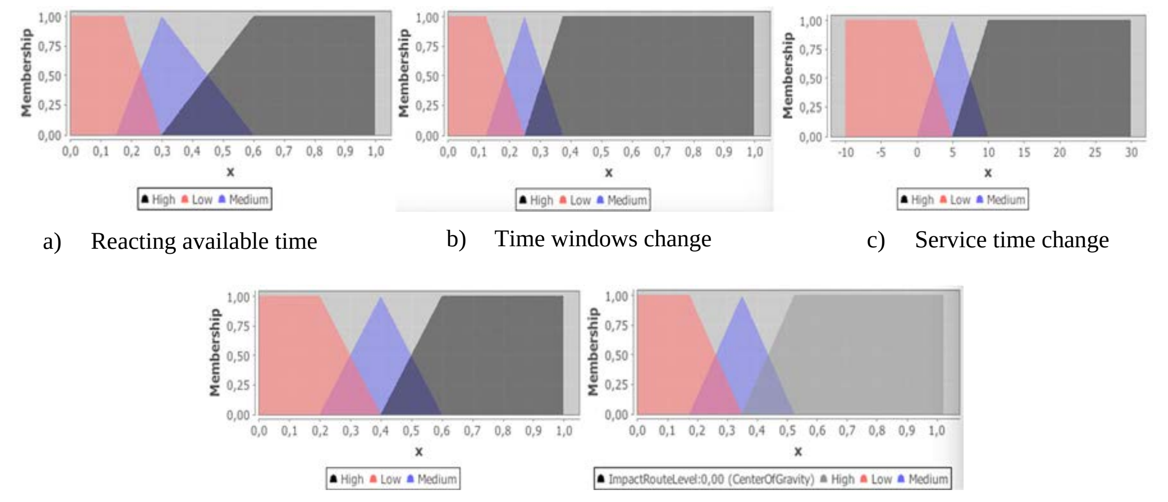
Order significance: This variable measures the ratio between the load quantity for the customer order that requires the change over the total vehicle load. Equation (3) presents the normalization for this variable.

$$Order\ significance\ (i) = \left(\frac{Load\ quantity\ for\ order\ (i)}{Total\ load\ quantity\ at\ vehicle}\right) \quad (3)$$

Order significance variable is bounded by three fuzzy sets. Low, when order significance takes values between 0 and 0.4; medium for significance values between 0.2 and 0.6; and high when the customer has a significance greater than 0.4.

2.2 Output variable:

Impact level on route: this variable measures the impact degree for a set of changes from a customer in the distribution route. This variable has an output range from 0 to 1 in which three fuzzy sets are determined: low, for impact route level values between 0 and 0.35; medium for values between 0.175 and 0.525; and high for impact route level values greater than 0.35. It is expected for values lower than 0.25 the changes can be accepted. Fig.2 presents the membership functions and fuzzy sets for the treatment of the variables.



a) Reacting available time
b) Time windows change
c) Service time change
d) Order significance
e) Impact level on route

Fig. 2 – Membership functions

2.3 Inference rules.

Impact level on route was evaluated on three input variables, which have three fuzzy categories. Therefore, there are $3^4 = 81$ IF-THEN rules in the fuzzy inference system. Table 1, for illustrative purpose, presents the first nine inference rules.

Rule	Service time change	Time window change	Urgency	Customer Significance	Impact level on route
1	High	High	High	High	Low
2	High	High	High	Medium	Low
3	High	High	High	Low	Low
4	High	High	Medium	High	Medium
5	High	High	Medium	Medium	Medium
6	High	High	Medium	Low	Low
7	High	High	Low	High	High
8	High	High	Low	Medium	Medium
9	High	High	Low	Low	Medium

Table 1 – First inference rules

2.4 Deffuzification method.

Since the objective of the work is to make decisions in urban freight transport to react to operational changes in the input variables, it is necessary to defuzzify the output of this inference system. For this purpose, the centroid method was used.

3. RESULTS AND DISCUSSION

The previously described fuzzy operational decision-making process allows to obtain response surface 3D graphs for modeling the relation between the input and output variables in urban freight transport (Figs. 3, 4 and 5). Figure 3 shows that the reacting available time has a greater impact level on route than the order significance. It is possible to obtain low impacts level on route and accept the changes when the reacting available time is below 0.6, regardless of the order significance values. Nevertheless, the impact level on route begins to increase when the available time to react to changes is lower than the approximately half of the total time for the working day.

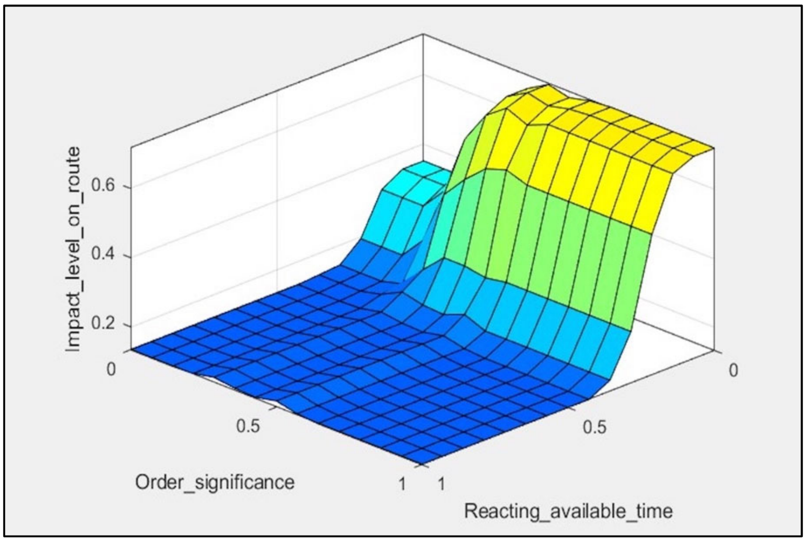


Fig. 3 – The 3D relation between order significance, reacting available time and 3.1 3.1 Impact level on route.

The reacting available time and service time change variables have a greater impact level on distribution route (Figure 4). With reacting available time values above 0.38 and service time change above 17 minutes, impact level on route is higher than 0.25 and the changes should be rejected. When the service time change is below 16 minutes and the reacting available time is more than 0.39, a significant decrease in impact level on route and the changes should be accepted.

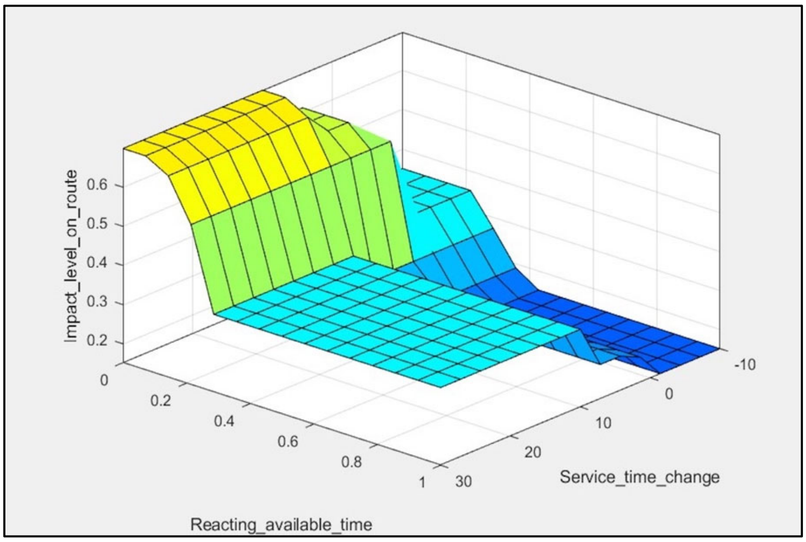

Fig. 4 – The 3D relation between reacting available time, service time change and Impact level on route

Regarding the relationship between order significance and service time change and their impact level on route (Fig. 5), it is possible to obtain high impacts level on route and reject the changes when the service time change is above + 8 minutes, regardless of the order significance values. Additionally, the impact level on route begins to decrease when the service time change is lower than the approximately +7 minutes and the change should be accepted.

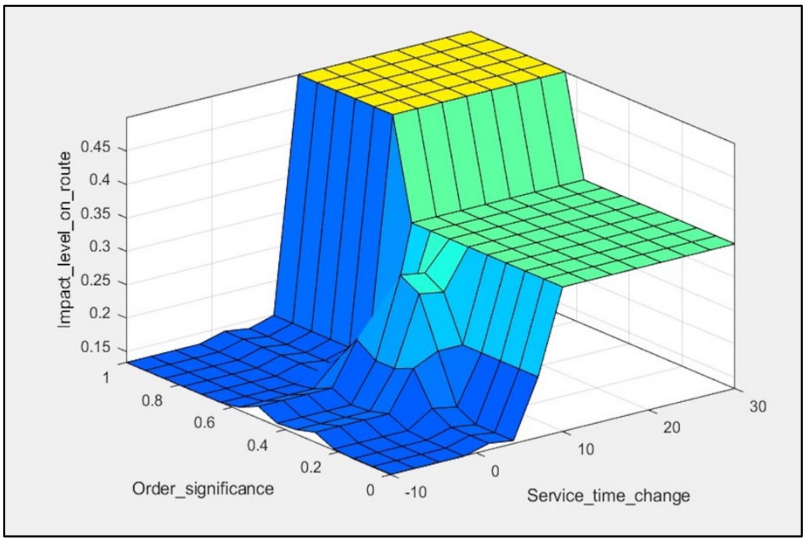

Fig. 5 – The 3D relation between order significance, service time change and impact level on route

4. CONCLUSIONS

The developed system shows that the fuzzy operational decision process is congruent with the reality of the UFT context. When there is more time to react to different changes in the operational context, it is possible to modify the distribution plan and accept the changes obtaining low impacts on routes. When the time to react to changes is relatively short, the change acceptance is affected by the low flexibility to respond to this change.

Additionally, if service times increase, it directly affects the remaining time to visit the customers and produces a higher impact level on the route, decreasing its acceptance. The variables that have a higher impact on the decision process are the reacting available time and the service time change. This work is a product of ongoing research whose objective is a model formulation for planning and evaluating urban freight distribution strategies under uncertain conditions. A future research line is the combination of this decision process integrated with the design of distribution routes and the dynamic vehicle routing problem. Also include some additional variables such as travel times and changes in demand.

MODELIZACIÓN Y SIMULACIÓN
MODELLING AND SIMULATION

A FINITE ELEMENT APPROACH FOR THE TRAFFIC ASSIGNMENT PROBLEM

ABSTRACT

Traffic assignment problem (TAP) in static equilibrium conditions is based on the Wardrop´s first principle. The mathematical solution of this problem involves significant computation times for the analysis of large transportation networks, especially in the context of design. Thus, the development of efficient computational methodologies is of the greatest concern.

In this article, a reduced order model for TAP, based on a Finite Element Approach (FEA), is proposed. Such methodology involves four main ideas: a) the TAP formulation including as variables the travel times from any node of the network to the corresponding destination points, b) the solution of the governing algebraic equation system by means of an efficient iterative approach, known as "Physarum", that takes the travel times as the main unknowns, c) the interpolation of travel times in certain urban subdomains, denominated "finite elements", in terms of the values corresponding to some main nodes previously selected (reduced unknowns), d) the use of the Galerkin's method to express the TAP in terms of the reduced unknowns. The model formulation is presented and a numerical example is given to show its efficiency.

1. INTRODUCTION

Estimation of users' choice of routes and the resulting traffic flow on every arc of the transportation network, known as TAP, is a very important task in studies of urban planning. In static equilibrium conditions, this problem is based on the Wardrop´s first principle (Sheffi, 1984). One of the most used approaches for this problem corresponds to the Beckmann's formulation that constitutes a convex optimization problem having the link flows as the main unknowns. The TAP Beckmann's formulation may be appropriately solved by means of the Frank-Wolfe method (FW).

The computational burden to solve this problem increases with the number of network nodes. Accordingly, involved calculation times for large networks are significant, especially in the context of transportation optimal design because the TAP must be solved many times.

For this reason, remarkable research efforts have been directed to the development of efficient methodologies to solve the TAP.

Some investigations were directed to improve the efficiency of the FW, thus originating the conjugated FW and the bi-conjugated FW (Hearn et al., 1985; Mitradjieva and Lindberg, 2013). Also, efficient algorithms based on trajectories were proposed showing faster convergence with respect to arc-based methods but with higher requirements of computational memory (Florian et al., 2009). On the other hand, Xu et al. (2008) presented an improved origin-based algorithm for assignment and distribution problems.

A strategy to improve the efficiency for solving the TAP is the use of parallel computation.

For example, Lotito (2006) proposed an approach to parallelize, by origin-destination pairs, the disaggregated simplicial decomposition algorithm previously developed by Larsson and Patricksson (1992). Another interesting parallelization method for TAP was recently developed by Jafari et al. (2017) consisting in the partition of the transportation network in small sub-networks. The algorithm alternates between the equilibrium of every sub-network and the equilibrium of a simplified version of the whole network.

In the last years, a new model denominated "Physarum" for solving different optimization problems of scientific and technological interest has been proposed (Tero et al., 2007).

This biologically-inspired algorithm is based on an analogy with the foraging behaviour of the slime mould Physarum Polycephalum that consists in generating protoplasmic tubes following the shortest route to the food sources. The mathematical modelling of such behaviour has been conveniently applied to the determination of the shortest path in networks, the reduction of costs in transportation and communication networks, etc. Very recently, the Physarum approach has been extended to the TAP in user equilibrium conditions following the Beckmann´s formulation (Zang, 2018; Xu et al., 2018). As shown in these articles, the Physarum approach may be more efficient than classical methods based on the FW. On the other hand, Cortínez and Dominguez (2018) have demonstrated that Physarum model, when applied to TAP, may be considered as an iterative strategy for solving an alternative TAP formulation based on travel times (Cortínez y Dominguez, 2017).

This interpretation allows the application of the Physarum approach to the generalized traffic assignment problems (including variable demand, multiple user classes, etc.).

Despite these efforts, the computational burden is still very important in the case of optimal design of large transportation networks. Consequently, several methods have been directed to reduce the number of unknowns. Some of these ones consist in eliminating arcs with low vehicular flow, and other techniques consist in aggregating several arcs in another fictitious equivalent link (Raadsen et al., 2020).

Many of these approaches present certain arbitrariness in the selection of the reduced network topology that can lead to inaccuracies in the calculated flows.

Another kind of models conceives the traffic network as an equivalent two-dimensional continuum medium. To solve these models, discretization methodologies, such as finite differences or finite elements, could be applied with a number of unknowns lesser than that of the original network (Sasaki et al., 1990; Ho et al., 2006, Dominguez, 2013, Cortínez and Dominguez, 2013, 2017).

In the present paper, in order to reduce the number of necessary variables to define the TAP, a finite element approach is proposed. This methodology involves four main ideas: a) the TAP formulation including, as variables, the travel times from any node of the network to the corresponding destination points, b) the solution of the governing algebraic equation system by means of an efficient iterative approach known as “Physarum” that takes the travel times as the main unknowns, c) the interpolation of travel times in certain urban subdomains, denominated “finite elements”, in terms of the values corresponding to some main nodes previously selected (reduced unknowns), d) the use of the Galerkin’s method to express the TAP in terms of the reduced unknowns.

The model formulation is presented and a numerical example is given to show its efficiency.

2. TRAFFIC ASSIGNMENT PROBLEM IN TERMS OF TRAVEL TIMES

A traffic urban network during the rush hour, when users travel from their homes distributed over the city to certain destination points d (d=1,2,...Nd), is considered.

The network topology, assumed as a set of nodes i (i=1,2,…Nn) connected by directed arcs a (a=1,2,…Na), and the properties of every arc (capacity, length, maximum speed, etc.) are known. Moreover, trip generation rates q_i^d (veh/h), at every node i of the network to the different destinations d, are known. TAP consists in obtaining the link flows $\bar{g}_a$ (veh/h) and the travel times u_i^d (h), from each node i to the corresponding destinations d, according to the users route choices in equilibrium condition.

In the following, the TAP is formulated incorporating the travel times u_i^d as variables (Dominguez, 2013; Cortínez y Dominguez, 2017).

2.1 Congestion function

Urban traffic congestion may be defined as the increment of the link travel time t_a caused by the increment of the link flow $\overline{g}_a$ (veh/h).

From a mathematical point of view, congestion may be defined by means of the following analytical expression:

$$t_a = t_a(\overline{g}_a) \tag{1}$$

This strictly increasing function (Figure 1a) is known in the literature as cost function. Several empirical functions have been developed for expressing (1) explicitly, such as the well-known BPR formula (Sheffi, 1984).

The total flow $\overline{g}_a$ on a link *a* may be expressed as the sum of the flow directed to a certain particular destination *d*, g_a^d, and the flows going to the rest of destinations, g_{aR}^d. This last one may be denominated residual flow with respect to the destination *d*:

$$g_{aR}^d = \sum_{dd} g_a^{dd} \qquad \forall dd \neq d \tag{2}$$

From (1) and (2), the flow on the link *a* going to *d* may be expressed as:

$$g_a^d = \overline{g}_a\left(t_a\right) - g_{aR}^d \tag{3}$$

where $\overline{g}_a(t_a)$ is the inverse function of (1).

2.2 Wardrop's first principle

Wardrop's first principle (Sheffi, 1984) for user's equilibrium (UE) states that the used paths travel times, between every origin-destination pair, are less than, or equal to, the travel times of the other paths. According to this sentence, the travel time between a given point of the network to the destination point is unique (and the minimum) for all the paths really used.

Then, such principle may also be formulated by postulating that the travel time between a given point (*x*,*y*) of the transportation network until the destination *d* is only a function of (*x*,*y*) and not of the employed trajectory (it is a potential function):

$$u^d = u^d(x, y) \tag{4}$$

being by definition $u^d(x_d, y_d) = 0$, where x_d and y_d correspond to the coordinates of the destination *d*. Then, travel time from node *i* to destination *d* may be written as:

$$u_i^d = u^d(x_i, y_i) \quad (5)$$

Using this potential function, the link travel time can be expressed as:

$$t_a = t_a^d = \left| u_i^d - u_j^d \right| \quad (6)$$

It is important to observe that, in equilibrium conditions, the link travel time t_a is the same for every user circulating on the link independently of its destination.

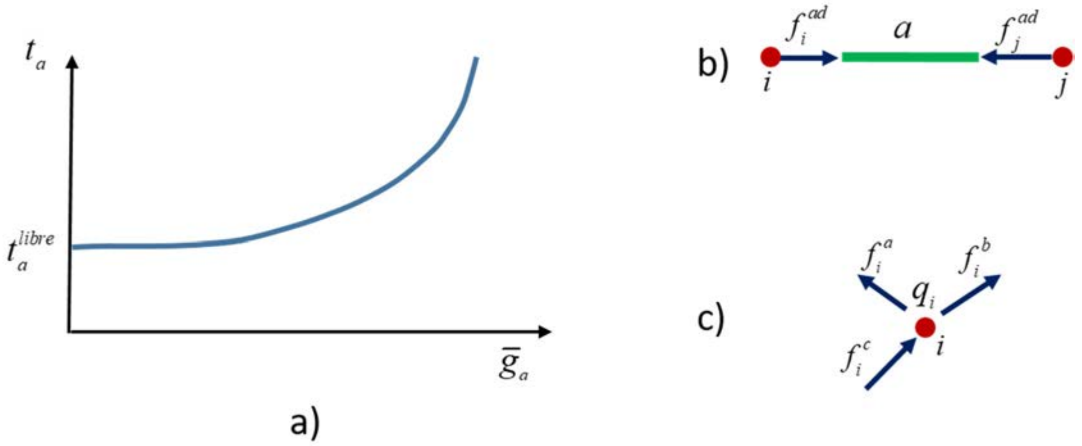

Fig. 1 – Basic definition of UE: a) Cost function, b) flow on link *a*, c) nodal flows at *i*.

2.3 Conservation of vehicles

To formulate the TAP, the conservation of vehicles law at a node must be considered (the number of vehicles entering and exiting a node is a conservative quantity). In order to express such a law, it is convenient to write, making use of (6), the following identity:

$$g_a^d = \frac{g_a^d \left| u_i^d - u_j^d \right|}{t_a} \quad (7)$$

Then, the nodal flows, corresponding to a link *a* (Figure 1b), are defined in the following form:

$$f_i^{ad} = \frac{g_a^d \left(u_i^d - u_j^d \right)}{t_a} = -f_j^{ad} \quad (8)$$

In (8) such flows have been defined positive when they enter the node and negative when they exit. In fact, in (8) $\left(u_i^d - u_j^d\right)$ is positive when the flow is directed from *i* to *j* (in the direction of decreasing *u*). Expression (8) is then useful for non-directed arcs, that is to say those links in which flows can be directed from *i* to *j* or from *j* to *i* according to the sign of $\left(u_i^d - u_j^d\right)$. However, TAP involves directed arcs (one-way links). To define the correct direction of a link *a*, the indicator λ_{ij}^a is introduced:

$$\lambda_{ij}^a = \begin{cases} 1 & i \to j \\ -1 & j \to i \end{cases} \qquad \lambda_{ij}^a = -\lambda_{ij}^a \tag{9}$$

Therefore, the expression for nodal flows corresponding to directed arcs should be re-written, generalizing (8), in the following form:

$$f_i^{ad} = \frac{g_a^d}{t_a} \xi_e^d \left(u_i^d - u_j^d\right) \tag{10}$$

where:

$$\xi_a^d = \begin{cases} 1 & \lambda_{ij}^a \left(u_i^d - u_j^d\right) \geq 0 \\ 0 & \lambda_{ij}^a \left(u_i^d - u_j^d\right) < 0 \end{cases} \tag{11}$$

As can be observed, ξ_a^d has a unit value when the travel time decreases in the allowed link direction and is null in the other case (vehicles cannot flow in a not allowed direction). One can observe that:

$$g_a^d = \left| f_i^{ad} \right| \tag{12}$$

According to expressions (8) and (10), the nodal flows on link *a* going to *d*, may be re-written as:

$$\begin{cases} f_i^{ad} = k_{ii}^{ad} u_i^d + k_{ij}^{ad} u_j^d \\ f_j^{ad} = k_{ij}^{ad} u_i^d + k_{jj}^{ad} u_j^d \end{cases} \tag{13}$$

where the link conductivity matrix has been introduced:

$$k_{ii}^{ad} = k_{jj}^{ad} = \frac{g_a^d \xi_a^d}{t_a^d}; \quad k_{ij}^{ad} = k_{ji}^{ad} = -\frac{g_a^d \xi_a^d}{t_a^d} \tag{14}$$

This matrix depends on $g_a^d(t_a)$ and t_a, and then, according to (6), depends on the potential functions u_i. Expressions (13) involve the travel time corresponding to the considered link *a*. However, it is possible to generalize expressions (13) involving all the nodes of the network by defining in an enlarged form the conductivity matrix. This definition can be performed by adding zeros in those elements connecting two nodes *m*, *n* not belonging to the considered link *a*:

$$k_{mn}^{ad} = 0, \quad m,n \neq i, j \tag{15}$$

In this way, nodal flow to destination *d*, at node *i* of link *a*, can be written as:

$$f_i^{ad} = \sum_{j=1}^{NN} k_{ij}^{ad} u_j^d \tag{16}$$

Therefore, the conservation of vehicles, at generic node *i*, may be expressed by the following equation (Figure 1c):

$$q_i^d - \sum_a f_i^{ad} = 0 \tag{17}$$

In (17), the sum involves all the arcs, although, obviously, the nodal flows are null for the links not connected with node *i* (in agreement with expression 15):

$$f_i^{ad} = 0 \qquad i \notin a \tag{18}$$

Substituting (16) into (17), the vehicle conservation equation may be written in the following form:

$$\sum_j \left(\sum_a k_{ij}^{ad} \right) u_j^d = q_i^d \tag{19}$$

Or, using a matrix notation:

$$\mathbf{K}^d \mathbf{u}^d = \mathbf{q}^d \qquad d = 1, 2, \ldots, Nd \tag{20}$$

In (20), the elements of the global conductivity matrix for vehicles going to *d* have been defined in the form:

$$K_{ij}^{d} = \sum_{a} k_{ij}^{ad} \tag{21}$$

Such system must be complemented with the expressions (corresponding to the definition of travel times):

$$u_{d}^{d} = 0 \qquad d = 1, 2, \ldots, Nd \tag{22}$$

As can be seen in (14), conductivity matrices $\mathbf{K}^{d}$ depend on t_a and g_a^d and, accordingly, expressions (1), (2), (3), (6), (20) and (22), constitute a non-linear algebraic equation system whose unknowns are given by u_i^d, g_a^d, $\bar{g}_a$ and t_a. Cortínez and Dominguez (2017) have shown that this system can be iteratively solved by means a sequence of problems whose unknowns are given by u_i^d. It can be demonstrated that the system (1), (2), (3), (6), (20) and (22) is equivalent to Beckmann's variational formulation (Dominguez, 2013; Cortínez y Dominguez, 2017).

3. NUMERICAL SOLUTION BY USING PHYSARUM APPROACH

The previous system can be iteratively solved by means of a Newton-Raphson technique (Cortínez and Dominguez, 2017). One of the difficulties found with this methodology is due the fact that if some links are decongested, g_a^d tends to zero and then, according to (14), also the conductivity matrix tends to zero.

Therefore, the system becomes indeterminate. This methodology makes use of the Physarum iterative approach (Zhang and Mahadevan, 2018; Xu et al., 2018; Cortínez and Dominguez, 2018), based on an analogy with a biological process, that works appropriately even in presence of decongested links.

The methodology starts with the approximation of the numerator and the denominator of the conductivity matrix elements (see expressions 14 and 15):

$$\begin{aligned} g_a^d \xi_a^d &\to D_a^d \\ t_a &\to L_a \end{aligned} \tag{23}$$

Consequently, expression (10) is approximated as:

$$f_i^{*ad} = \frac{D_a^d}{L_a}\left(u_i^d - u_j^d\right) \tag{24}$$

where f_i^{*ad} is an approximation to f_i^{ad}. Therefore, following (14), matrix k_{ij}^{ad} may be approximated by k_{ij}^{*ad} defined as:

$$k_{ij}^{*ad} = \begin{cases} D_a^d / L_a & i = j \\ -D_a^d / L_a & i \neq j \in a \\ 0 & i, j \notin a \end{cases} \tag{25}$$

Thus, considering (21), system (20) is approximated by the following linear system with unknowns $\mathbf{u}^d$:

$$\mathbf{K}^{*d}\mathbf{u}^d = \mathbf{q}^d \tag{26}$$

Before solving (26), it is necessary to take into account conditions (22). This may be performed easily modifying $\mathbf{K}^{*d}$ by means of a penalization approach (summing very large values to the diagonal elements corresponding to the unknowns u_d^d, Chandrupatla and Belegundu, 2012). One can observe that (26) (modified by 22) constitutes a decoupled system of linear equations for every destination. Formally, the solution may be expressed as:

$$\mathbf{u}^d = \left(\mathbf{K}^{*d}\right)^{-1}\mathbf{q}^d \tag{27}$$

Once determined $\mathbf{u}^d$, better approximations for link flows g_a^{*d} are obtained by means of (12) and (24):

$$g_a^{*d} = \frac{D_a^d}{L_a}\left|u_i^d - u_j^d\right| \tag{28}$$

Then, new approximations for ξ_a^{*d} are calculated using (11). Now, it is possible to obtain updated values for coefficients D:

$$D_a^{d(new)} = \frac{D_a^d + g_a^{*d}\xi_a^{*d}}{2} \tag{29}$$

The new approximation for total flow on the link *a* is obtained as:

$$\bar{g}_a^* = \sum_d g_a^{*d} \xi_a^{*d} \tag{30}$$

Finally, using expression (1), a new approximation for the link travel time t_a^* is achieved and then, the updated coefficient *L* is expressed as:

$$L_a^{(new)} = \frac{L_a + t_a^*\left(\bar{g}_a^*\right)}{2} \tag{31}$$

With the updated values, matrix conductivity $\mathbf{K}^{*d(new)}$ is re-calculated and the procedure is iterated. When convergence is achieved, D_a^d and L_a converge to $g_a^d \xi_a^d$ and t_a, respectively. The fact that, in each iteration, the systems (26) should be solved separately for every destination *d*, allows the application of this methodology in a context of parallel computing.

4. REDUCED MODEL: FINITE ELEMENT METHOD

System (26) for every *d* is often very large for urban or regional networks and, accordingly, very demanding from the computational point of view, because it should be solved many times up to convergence. This is especially true in the context of optimal design. For this reason, it is of interest to develop a model with lesser unknowns being approximately equivalent to system (26). In this section, an approach for reducing unknowns is developed by taking ideas from the Finite Element Method (FEM) commonly used in the field of continuum mechanics (Chandrupatla y Belegundu, 2012).

The methodology starts with the subdivision of the transportation network in subdomains, denominated finite elements (FE), each one containing a part of the network, as shown in Figure 2. The geometrical shapes of such elements may be relatively simple: rectangles, triangles, irregular quadrilaterals, etc.

Over these elements certain nodes are identified corresponding to the main unknowns U_K^d that represent the travel times from each point *K* to the corresponding destination *d*. Inside each FE, travel time from a generic point, with (*x*,*y*) coordinates, to destination *d*, is approximated by means of an interpolation in terms of travel times corresponding to the main nodes U_K^d:

$$u^d(x,y) = \sum_K N_K^e(x,y) U_K^d \tag{32}$$

For a consistency reason, the interpolation functions $N_K^e(x,y)$, must adopt the values $N_K^e = 1$ if $(x,y) = (x_K, y_K)$ and $N_K^e = 0$ if (x,y) correspond to any of the other main element nodes. Moreover, such functions are null outside the considered *e* element: $N_K^e = 0$ if $(x,y) \notin e$. There are many ways to select the interpolation functions (Chandrupatla y Belegundu, 2012). One of them will be presented in the numerical example given below. According to (32), travel time from *i*-node to destination *d* may be approximated as:

$$u_i^d = \sum_K \sum_e N_{iK}^e U_K^d \tag{33}$$

where $N_{iK}^e = N_K^e(x_i, y_i)$. On the other hand, if one defines:

$$N_{iK} = \sum_e N_{iK}^e \tag{34}$$

expression (33) could be written as:

$$u_i^d = \sum_K N_{iK} U_K^d \tag{35}$$

Or, in matrix form:

$$\mathbf{u}^d = \mathbf{N}\mathbf{U}^d \tag{36}$$

That is to say, the travel time u_i^d may be expressed in terms of travel times corresponding to the main nodes U_K^d. It should be observed that, using (36), the number of unknowns are significantly reduced with respect to the original network.

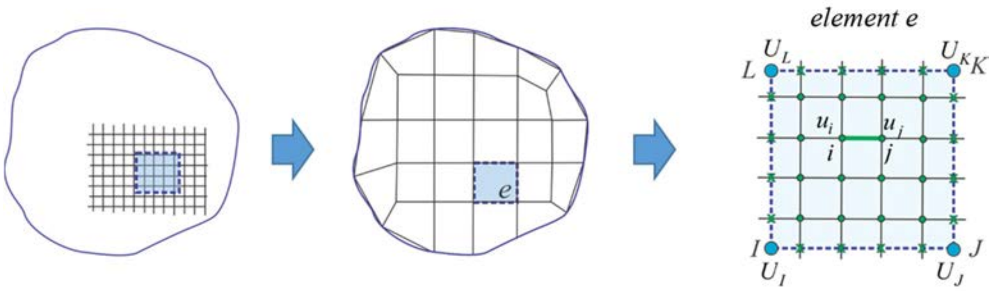

Fig. 2 – Scheme of the finite element reduced model

To obtain the reduced equation system with unknowns $\mathbf{U}^d$, the Galerkin's method is employed (Chandrupatla y Belegundu, 2012; Cortínez y Dominguez, 2017). Accordingly, a virtual vector $\delta\mathbf{u}$ is defined, with arbitrary values at all nodes excepting at those corresponding to destinations *d* where takes zero value. Now, pre-multiplying expression (26) by the transposed of $\delta\mathbf{u}$ one arrives at:

$$\delta\mathbf{u}^T\left(\mathbf{K}^{*d}\mathbf{u}^d - \mathbf{q}^d\right) = 0 \tag{37}$$

Interpolating $\delta\mathbf{u}$ in a form similar to (36), that is to say:

$$\delta\mathbf{u}^d = \mathbf{N}^T\delta\mathbf{U}^d \tag{38}$$

expression (37) can be re-written in the form:

$$\delta\mathbf{U}^T\mathbf{N}^T\left(\mathbf{K}^{*d}\mathbf{N}\mathbf{U}^d - \mathbf{q}^d\right) = 0 \tag{39}$$

Then, taking into account that $\delta\mathbf{U}^d$ is an arbitrary vector, equation (39) is true if:

$$\left(\mathbf{N}^T\mathbf{K}^{*d}\mathbf{N}\right)\mathbf{U}^d = \mathbf{N}^T\mathbf{q}^d \tag{40}$$

This expression may be conveniently re-written as:

$$\mathbf{\Psi}^d\mathbf{U}^d = \mathbf{Q}^d \tag{41}$$

considering the following definitions:

$$\mathbf{\Psi}^d = \mathbf{N}^T\mathbf{K}^{*d}\mathbf{N}, \quad \mathbf{Q}^d = \mathbf{N}^T\mathbf{q}^d \tag{42 a, b}$$

$\mathbf{\Psi}^d$ is a reduced conductivity matrix and $\mathbf{Q}^d$ is a reduced trip demand vector. One should observe that for representing appropriately the network in a reduced form, the destinations *d* must be included among the main nodes. On the other hand, the rest of the main nodes do not need to match with the real nodes. Before solving (41) matrix $\mathbf{\Psi}^d$ should be modified using the conditions (22) by means of the penalization approach described in the previous section.

5. COMPUTATIONAL PROCEDURE

According to the methodology explained in the above sections, the present algorithm to solve TAP is the following:

I) Definition of FE model (reduced model).
   a. Choice of main nodes K.
   b. Definition of nodes and links in each element.

II) Initialization of the iterative process.
   a. Adoption of initial values for g_a^d, ξ_a^d and t_a $\forall(d,a)$.
   b. Determination of the initial values for D_a^d and L_a $\forall(d,a)$ → Expression (23)

III) Iterative calculation up to convergence
   a. Determination of the conductivity matrix for each link k_{ij}^{*ad} $\forall(d,a,i,j)$ → Expression (25).
   b. Determination of the global conductivity matrices K_{ij}^{*d} $\forall(d,i,j)$ → Expression (21).
   c. Determination of the reduced FR conductivity matrices ψ_{IJ}^{*d} $\forall(d,I,J)$ → Expression (42a).
   d. Determination of the reduced EF trip demand vector Q_I^{*d} $\forall(d,I)$ → Expression (42b).
   e. Determination of travel time from main nodes to destinations *d*: U_I^{*d} $\forall(d,I)$. → Solution of system (41) for every destination *d*.
   f. Recovery travel times for the transportation network nodes u_i^{*d} → Expression (35).
   g. Updating of g_a^{*d}, ξ_a^{*d} $\forall(d,a)$ → Expressions (28) and (11).
   h. Updating of $\bar{g}_a^*$ and t_a^* $\forall a$ → Expressions (30) and (1).
   i. Updating of D_a^d and L_a $\forall(d,a)$ → Expressions (29) and (31).
   j. Verification of convergence. If $\max\left|u_i^{*d} - \left(u_i^{*d}\right)_{previous}\right| < Tolerance$ → end of iterative calculation.

6. NUMERICAL EXAMPLE

A fictitious transportation network of 2.9x2.9 km^2 consisting in 1740 one-way links of 100m length and 900 nodes (Figure 3) is analysed. The links, normal one each other, have a BPR cost function given by $t_a = 0.1\left(1+0.15\left(g_a/600\right)^2\right)$, corresponding to a link capacity of 600 vehicles/h and a maximum allowable speed of 60 km/h. Trip demand is assumed to be 6308 trips/h uniformly distributed among all the nodes with an only one destination.

In Figure 3, three paths from different origins to the destination, with arrows showing the circulation direction, are depicted. The nodes and links identified with numbers and letters, respectively, correspond to those used in the following figures to show the numerical results.

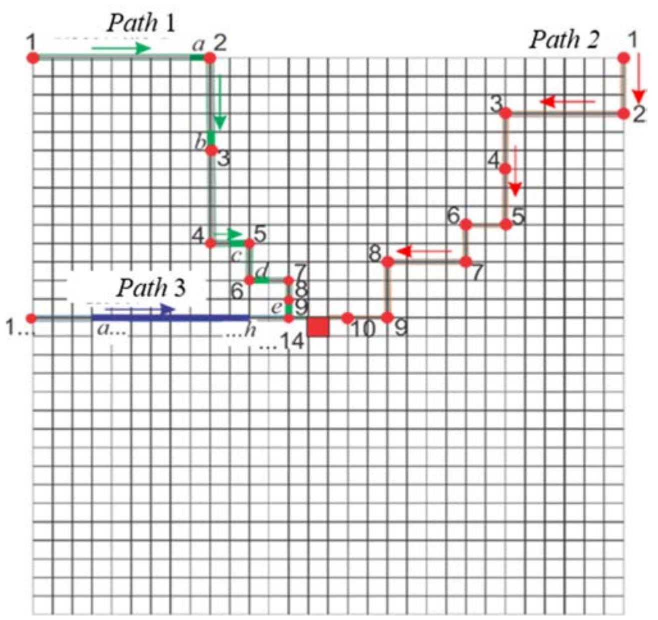

Fig. 3 – Scheme of the transportation network under analysis.

To solve the TAP corresponding to the described network, the explained methodology is applied using two different meshes, one of 16 elements (shown in Figure 4) and the other of 64 elements.

Each element has been assumed to be rectangular, with four main nodes (one per vertex). Bi-linear interpolation functions have been adopted. That is to say, they have the generic form $a_K(b_K - x)(c_K - y)$, where constants a_K, b_K, c_K are determined in such a way the following conditions are verified: $N_K^e = 1$ if $(x,y) = \left(x_K, y_K\right)$, and $N_K^e = 0$ if (x,y) correspond to any other main node.

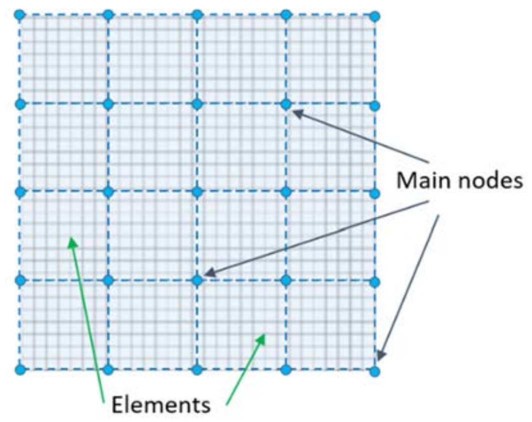

Fig. 4 – Scheme of the reduced model (considering 16 finite elements).

In order to perform a numerical study on the accuracy of the present methodology, TAP has also been solved: a) using the classical Beckmann's formulation along with Frank-Wolfe method (FW) and b) with the iterative Physarum method (Physarum) for the full network. The results of these two methods are considered to be exact.

Observe that Beckmann's formulation involves 1740 link flows as basic unknowns, Physarum solution to the full network involves 900 travel times (one for each node) while the FE reduced models of 16 and 64 finite elements involve only 25 and 81 main unknowns, respectively.

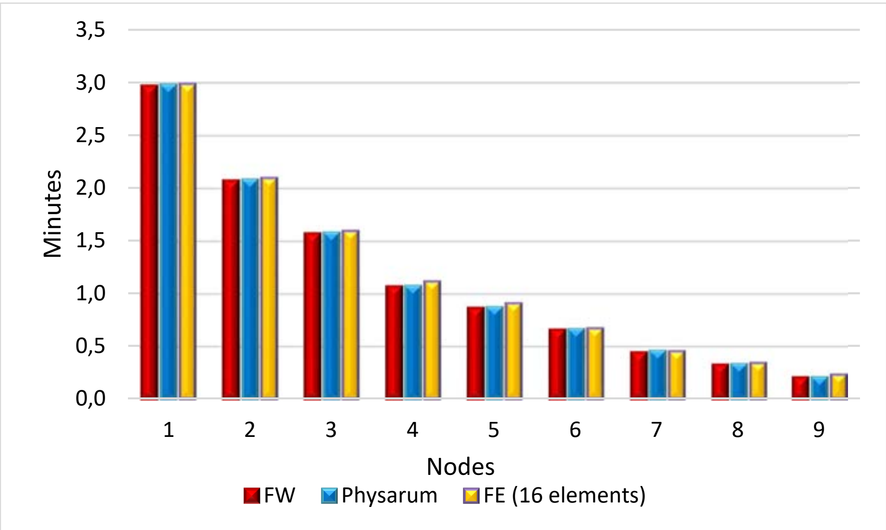

Fig. 5 – Travel times u_i from nodes corresponding to Path 1.

In Figure 5 a comparison of travel times obtained with FW, Physarum and FE (16 elements) for the nodes of Path 1 is shown. A very good agreement between the values obtained with all the models is observed. The same observation is valid for the nodes corresponding to Path 2 (Figure 6).

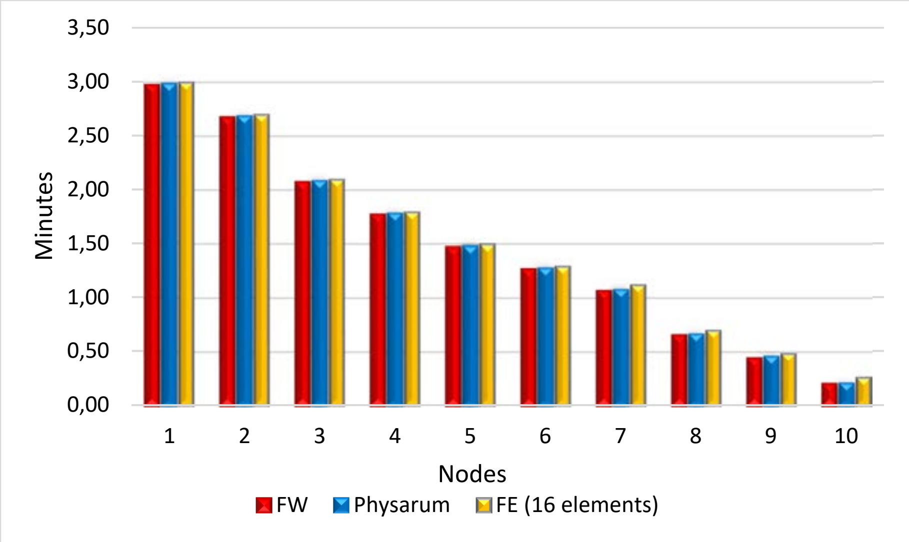

Fig. 6 – Travel times u_i from nodes corresponding to Path 2.

In Figure 7, a comparison for link travel times (expressed as the ratio between link travel time and free link travel time) determined by Physarum and the reduced FE (16 and 64 finite elements) for different links of Path 1, is shown. As observed, the results are almost identical except for link *e*, where the FE reduced model with 16 elements presents an error of approximately 10%, and the FE reduced model, with 64 elements, an error less than 5%.

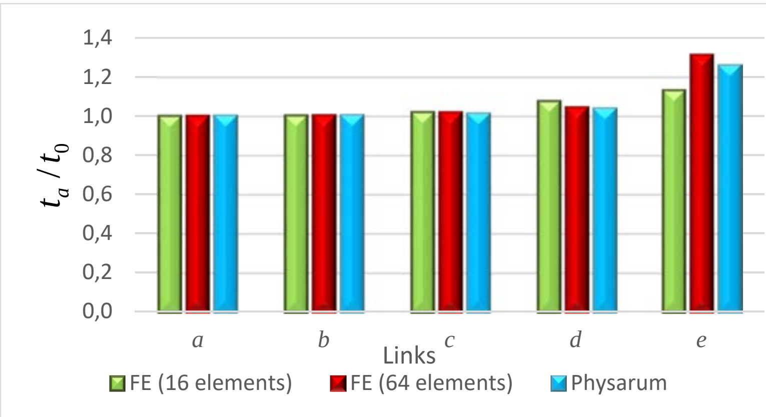

Fig. 7– Ratio between link travel time and free link travel time t_a / t_0 on links of Path 1

On the other hand, in Figure 8, a comparison for the link flows corresponding to Path 1, obtained by means of Physarum and the FE reduced model (64 elements), is shown. The maximum error of the reduced model is of 8% approximately.

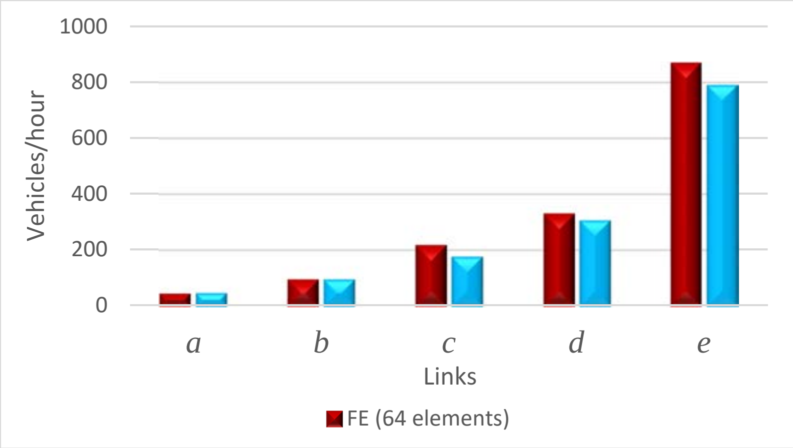

Fig. 8 – Link flows ($\bar{g}_a$) for Path 1.

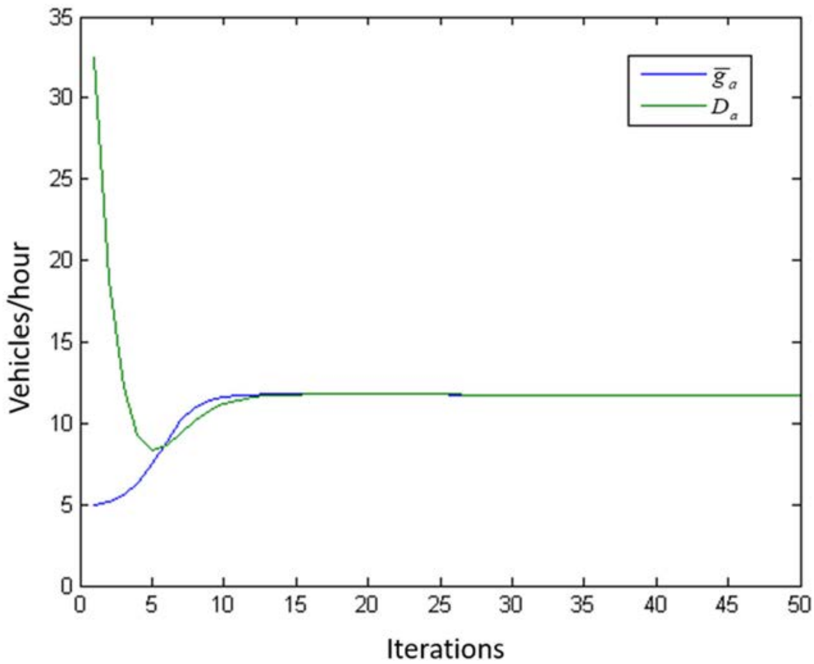

Fig. 9 – Convergence of the methodology in terms of traffic flow on the first link of Path 1 using the 64 FE reduced model.

The iterative procedure converges quickly, as can be observed in Figures 9 and 10. Figure 9 shows the convergence of D_a^d and $\bar{g}_a$ for the first link of Path 1. Convergence is achieved in less than 15 iterations. It is interesting to note that this convergence is reached even when the link is practically decongested. Figure 10 shows a similar information for the last link (*e*) of the same path. Although this link is congested, the convergence is also achieved in the same number of iterations.

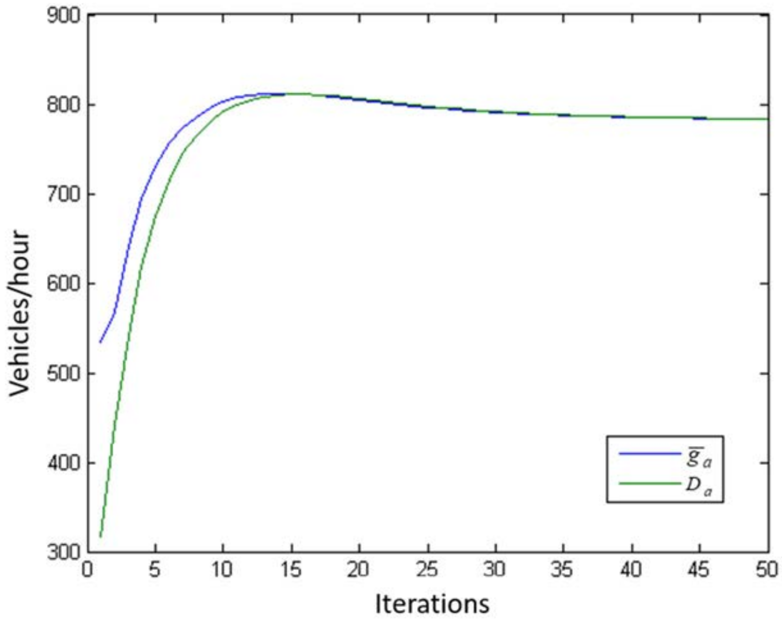

Fig. 10 – Convergence of the methodology in terms of traffic flow on the last link (*e*) of Path 1 using the 64 FE reduced model.

Finally, in Figure 11, a comparison of the convergence behaviour shown by Physarum, 16 FE and 64 FE reduced models, is shown in terms of the travel time from node 1 of Path 3 until the destination. As can be seen, the three approaches show a similar convergence behaviour.

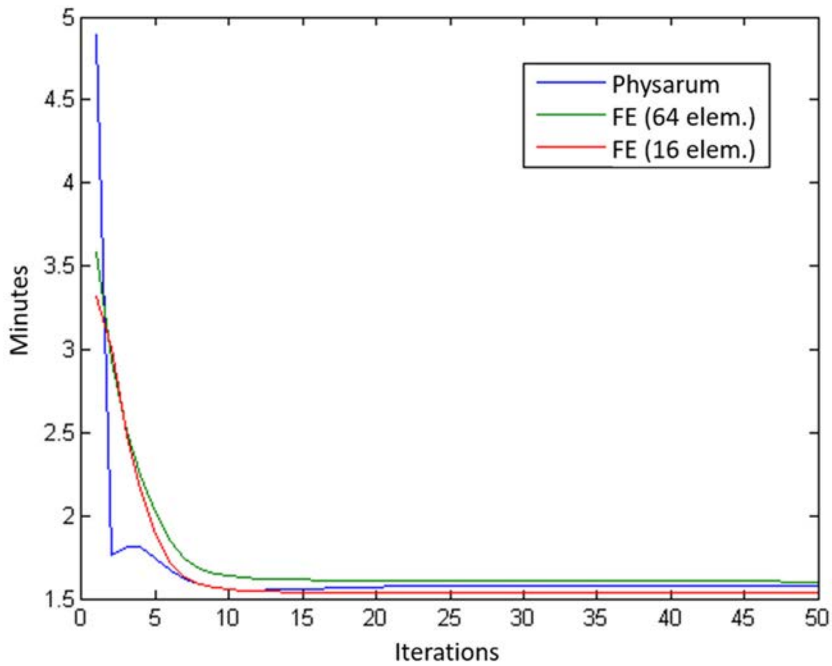

Fig. 11 – Convergence behaviour of travel time at node 1 of Path 3 for Physarum, 16 FE and 64 FE reduced models.

7. CONCLUSIONS

A finite element approach for reducing TAP unknowns is presented. This methodology employs an efficient iterative technique (Physarum analogy) to solve the governing non-linear equation system taking travel times as basic unknowns. This procedure works appropriately, even in presence of links with very low flow (avoiding indeterminacy of the system). The present approach allows a notable reduction of unknowns (more than 100 times in the analysed example), maintaining an accuracy similar to the full model, with an important reduction of the computing time. The methodology can be easily programmed in a context of parallel computing.

ACKNOWLEDGEMENTS

The present study is part of the projects "Mathematical models in environmental engineering: optimal design and control" (Secyt, Universidad Tecnológica Nacional) and "Optimization problems in civil engineering. Part III" (Departamento de Ingeniería, Universidad Nacional del Sur).

RESUMEN

A la hora de planificar nuevas vías, es importante utilizar todas las herramientas que estén a nuestro alcance para optimizar su diseño, de modo que no caigamos en infra o sobredimensionamientos, que pueden provocar un funcionamiento peor al esperado o un coste mucho mayor al necesario, respectivamente. Por ello, las herramientas de macrosimulación de tráfico pueden ser un interesante apoyo para este fin.

En el presente artículo, se va a exponer un caso práctico en el que el empleo de dichas herramientas informáticas ha permitido realizar un dimensionamiento más idóneo en cuanto al número de carriles de una nueva vía. En concreto, se trata del Estudio Informativo de la Autovía Orbital B-40, en el que se han utilizado técnicas de macrosimulación de tráfico para estimar las captaciones de demanda de las diferentes alternativas consideradas, y para finalmente calcular el Nivel de Servicio previsto en cada una de ellas en los diferentes horizontes temporales establecidos.

Los resultados obtenidos han permitido afinar el diseño de dicha Autovía, y la metodología empleada puede ser un ejemplo válido para otros casos de estudio similares.

1. INTRODUCCIÓN

Dentro de los trabajos del Estudio Informativo de la Autovía Orbital de Barcelona B-40 -tramo Terrassa-Granollers (enlace AP-7/C60)-, la empresa GPYO INNOVA, S.L. precisó la realización de un estudio de tráfico analizar las diferentes alternativas a plantear en dicho

Estudio Informativo. Conocida la experiencia del Grupo de Investigación LogIT (Logística e Ingeniería del Transporte) de la Universidad de Burgos en materias de tráfico, se les solicita colaboración para la elaboración del citado Estudio de Tráfico.

Para su realización, el trabajo se ha divido en dos fases, con diferentes alcances

- Fase A:
    - Estudio de antecedentes
    - Recopilación de datos básicos de tráfico, movilidad y socioeconómicos
    - Análisis de planes y programas de transporte
- Fase B
    - Delimitación del ámbito de estudio y planificación de encuestas
    - Realización y codificación de las encuestas, si se considerada necesario
    - Modelización de la situación actual: calibración matriz Origen/Destino, macrosimulación de la red y cálculo de capacidades y Niveles de Servicio por tramos
    - Prognosis de tráfico en distintos horizontes temporales y modelización de las situaciones futuras a considerar: actualización del modelo de macrosimulación para conocer tráfico futuro en cada tramo y cálculo de capacidades y Niveles de Servicio por tramos, en diferentes horizontes temporales, y para cada alternativa
    - Conclusiones

El presente artículo muestra los resultados obtenidos en el citado Estudio de Tráfico, y se estructura en 5 partes fundamentales. Tras una breve introducción y exposición de antecedentes, se incluye un resumen de los antecedentes y la información más relevante recogida en la Fase A. A continuación, se muestran las bases metodológicas seguidas. Por último, se muestran los resultados del modelo de asignación y de los cálculos de Niveles de Servicio. Finalmente, se muestra un resumen de las principales conclusiones extraídas del estudio completo.

2. DATOS BÁSICOS

La denominada autovía Orbital de Barcelona, que discurrirá entre las localidades de Terrassa y Granollers, atravesando diversos municipios del entorno en función de la alternativa finalmente seleccionada, tiene una funcionalidad múltiple, sirviendo para facilitar diversas tipologías de desplazamientos:

- Tráficos entre el centro de España y el Levante con Gerona y Europa.
- Movimientos longitudinales entre localidades del corredor.

- Ofreciendo una nueva vía de circunvalación para el municipio de Barcelona, alejada de la congestión provocada por la ciudad y sus vías de acceso y comunicando los grandes municipios del área (Terrassa, Sabadell y Granollers). El cierre de dicha Ronda es una de las actuaciones previstas en el Plan de Infraestructuras, Trasporte y Vivienda 2012-2024 PITVI (Ministerio de Fomento, 2015), dentro de las obras de circunvalación, así como en el Plan de Infraestructuras del Transporte de Cataluña (Generalitat de Cataluña, 2006).

2.1 Datos socioeconómicos

La población del área de análisis superaba los 670.000 habitantes en 2016, representando prácticamente el 12% de la población de la provincia de Barcelona. Los principales núcleos urbanos de la misma son Terrassa y Sabadell (origen del tramo objeto de estudio) con más de 200.000 habitantes, seguido con Granollers (fin del tramo objeto de estudio) con más de 60.000 habitantes. Estos tres municipios aglutinan el 72% de la población de la zona.

Todos los municipios del entorno han aumentado notablemente su población desde 2016, con tasas de crecimiento superiores al 10-20% en algunos casos. En su conjunto, estos municipios han incrementado su población con una tasa de crecimiento anual acumulada claramente superior a la tasa de la provincia de Barcelona, aunque se aprecia una ralentización en dicho crecimiento a partir del año 2010-2012.

Por otra parte, la tasa de motorización de la zona afectada por el cierre de la Orbital, muestra unas elevadas tasas en todos los municipios directamente afectados por la traza.

Los valores en casi todos los municipios son superiores en el año 2015 a la media de la provincia de Barcelona.

2.2 Datos de movilidad

En cuanto a las pautas de movilidad, el 78,8% de los desplazamientos de Cataluña se producen en día laborable, con una media de 24,4 desplazamientos/día y 3,57 desplazamientos/persona. El tiempo medio de desplazamiento ronda los 15 minutos para los viajes intramunicipales y los 31,50 minutos para los intermunicipales.

Si analizamos el reparto modal, observamos que la proporción en día laborable es de un 40,6% vehículo privado, 14,3% transporte público y 45,1% en modos no motorizados. Pero en día festivo, la proporción de viajes en vehículo privado alcanza un 49,1%, y el transporte público desciende hasta un 6,4%. Las ocupaciones medias de los vehículos (turismos) son de 1,22 personas/vehículo en día laborable, y de 1,40 en sábado y festivo.

Analizando la distribución horaria de los desplazamientos, vemos, en los días laborables, dos grandes puntas: una por la mañana, correspondiendo a las horas de entrada a los lugares de trabajo/estudio, y una por la tarde, en la salida.

En sábados y festivos ese patrón horario se altera bruscamente, siendo la punta de la mañana más suave y además en horas más tardías, distribuyéndose más el tráfico entre las 24 horas del día.

2.3 Planeamiento urbanístico

Finalmente, se ha analizado los diferentes desarrollos urbanísticos de la zona que pueden afectar al tráfico en la Ronda Orbital, no hallándose ninguna incompatibilidad entre los posibles corredores analizados y la planificación urbanística del área de estudio. Tampoco se observan grandes bolsas de suelo urbanizable (residencial o para actividades económicas) que puedan ser especialmente relevantes para el tráfico de la zona (más allá del crecimiento habitual ya observado).

2.4 Datos de tráfico

Para el análisis de tráfico en el entorno, se ha atendido a todas aquellas vías paralelas a la nueva actuación y perpendiculares a la misma, con independencia de su titularidad. Así se ha recopilado datos de 6 estaciones pertenecientes al Ministerio de Fomento (una de ellas secundaria y el resto de cobertura), y de 44 estaciones de la Generalitat de Cataluña (entre las que sí hay estaciones permanentes). Los datos han sido obtenidos del Mapa de Tráfico del 2015 (Ministerio de Fomento, 2016a) y del Plan de Aforos 2015 (Generalitat de Cataluña, 2016).

Las vías de la zona bajo titularidad estatal soportan unos índices de intensidad diaria muy elevados, con elevados porcentajes de pesados, que en algunos casos superan el 20% de la IMD. El tráfico existente en el corredor de la A-7 oscila entre los 83.000 y 138.000 vehículos diarios, siendo superior en el acceso al entorno de Barcelona desde el levante español que desde la frontera francesa. Además, el tramo de mayor intensidad corresponde al que conjuntamente suman la A-7 (ahora AP-7N) en el tronco y la B-30 en las vías de servicio, entre las carreteras de acceso a Barcelona C-16 y C-58, si bien dicho tráfico ha sufrido un importante descenso desde el 2014.

Como complemento, se han analizado de forma exhaustiva los datos concretos de 3 estaciones consideradas de especial relevancia: 2 permanentes (la 10181608, ubicada en la C-58, y la 17-308, en la C-17) y una secundaria (la B-220-2 en la B-30). En ellas se observan las siguientes pautas:

- La intensidad existente en esta estación del corredor cuenta con un tráfico constante a lo largo del año excepto en el mes de agosto que se produce un constante a lo largo del año excepto en el mes de agosto que se produce un descenso debido al periodo vacacional. Además, se producen en diciembre-enero y abril-mayo otros valles aunque menos marcados.
- La distribución del tráfico en la semana es relativamente uniforme en los días laborables, con una punta durante el viernes, y un importante descenso los fines de

semana, especialmente el domingo. Este comportamiento es similar para los vehículos ligeros y pesados, aunque la diferencia en porcentaje sobre la IMD entre laborables y fines de semana es mucho más marcada en el caso de los vehículos pesados.

- Finalmente, de los diagramas de frecuencias acumuladas de intensidades horarias, se observa que el tráfico para la hora 30 (IH-30) ronda el 8% de la IMD.

3. METODOLOGÍA

3.1 Delimitación y zonificación del área de estudio

Los términos municipales directamente afectados por el trazado de los distintos corredores considerados son los siguientes: L'Ametlla del Vallès, Caldes de Montbui, Canovelles, Cardedeu, Castellar del Vallès, Les Franqueses del Vallès, La Garriga, Granollers, Lliçà d'Amunt, Matadepera, Palau de Plegamans, Polinyà, La Roca del Vallès, Sabadell, Santa Eulàlia de Ronçana, Sentmenat y Terrassa. Sin embargo, obviamente el estudio no puede limitarse a considerar dichos municipios, sino que se ha extendido a un ámbito territorial, mucho mayor, que incluye toda la provincia de Barcelona, así como las provincias limítrofes, e incluso el resto de España.

El modelo finalmente elaborado se compone de 38 zonas, con desagregación en términos municipales en la zona de influencia más directa del nuevo tramo de Cierre de la Autovía Orbital de Barcelona, y en menor grado de detalle al alejarse de la zona de la actuación.

Todas las zonas están compuestas por municipios de forma individual o agregaciones de los mismos. La Figura 1 muestra la zonificación empleada.

Fig. 1 – Distribución geográfica de zonas

3.2 Obtención de la matriz origen/destino base

La principal fuente de datos utilizada en el proyecto han sido datos anonimizados de telefonía móvil procedentes de un operador de red. Adicionalmente, se han utilizado datos de usos del suelo y datos de población residente en España. Para ello, se ha contado con el apoyo de Kineo Mobility Analytics, una empresa tecnológica experta en el análisis de datos geolocalizados procedentes de dispositivos móviles y su fusión con otras fuentes de datos para proporcionar información sobre movilidad y demanda de transporte.

Como fuente de datos principal para el análisis de la movilidad general de la población se utilizaron datos anonimizados de telefonía móvil proporcionados por el grupo Orange España (Orange, Jazztel, Amena y Simyo), que cuenta con una cuota de mercado entorno al 27 % (CNMC, marzo de 2018). Estos datos contienen las posiciones geolocalizadas de los dispositivos móviles tanto para eventos activos (llamadas, mensajes SMS, conexiones a Internet) como para determinados eventos pasivos (cambios de áreas de cobertura, actualización de las conexiones a Internet, etc.), proporcionando una granularidad temporal muy elevada, que permite determinar con alto nivel de detalle la localización del dispositivo a lo largo del día.

En cuanto a la resolución espacial, se dispone de información de localización del dispositivo móvil a nivel de antena, lo que supone una precisión espacial de decenas/cientos de metros en ciudad y hasta varios kilómetros en zonas rurales.

Los datos proporcionados por el operador también incluyen información socio-demográfica ligada a los usuarios, como la edad y el género. Los datos utilizados en este estudio se corresponden con la actividad registrada durante el mes de marzo de 2018.

En cuanto a la población, para los procesos de elevación de la muestra se han utilizado los datos procedentes del padrón de habitantes. Se ha considerado a la población residente en España con edad superior a 16 años.

Agregando los diferentes motivos de viaje considerados, se obtuvo una matriz Origen/Destino global para un día laborable medio. Finalmente, atendiendo a los resultados obtenidos en la Fase A, a partir de la encuesta Movilia, observamos que la proporción de viajes en vehículo privado en día laborable es de un 40,6% vehículo privado, y que la ocupación media de los vehículos (turismos) son de 1,22 personas/vehículo en día laborable.

Además, es necesario tener en cuenta el factor K, correspondiente a las intensidades horarias correspondientes a la Hora 30, 50 o 100, que resulta de alrededor de un 8,3% para la zona de estudio (tomando un valor conservador). Teniendo en cuenta todos estos elementos correctores, se obtuvieron las matrices base finales de vehículos ligeros y pesados, que arrojaron valores similares a los obtenidos en la encuesta Movilia para el total de la provincia de Barcelona, lo que aporta confianza en la fiabilidad del proceso empleado para su obtención.

Sin embargo, al aplicar dichas matrices al modelo de red, no se reproducen con exactitud los valores de tráfico registrado en las estaciones reales de aforo. Por tanto, será necesario hacer un último ajuste, que se describirá en capítulos posteriores, una vez esté elaborado el modelo de oferta o modelo de red.

3.3 Modelo de oferta

El horizonte inicial de modelización fue el año 2016, último año con datos completos de tráfico disponibles en la zona. Se incluyó en la modelización la totalidad de las principales infraestructuras viarias comprendidas en el área comprendida por los tramos existentes de la B-40, ronda litoral de Barcelona y el Eje Transversal C-25, que comunica la A-7 al sur de Girona, con la A-2 a la altura de Cervera, en la provincia de Lleida. El escenario se completó con la inclusión de otras vías de la red de carreteras de la provincia de Barcelona, que podrían suponer cierta competencia con la nueva infraestructura, o que pueden influir en los resultados del modelo.

En la Figura 2 se muestra el grafo explicativo de la red actual modelizada en el escenario base, junto con las conexiones de los centroides dicha red.

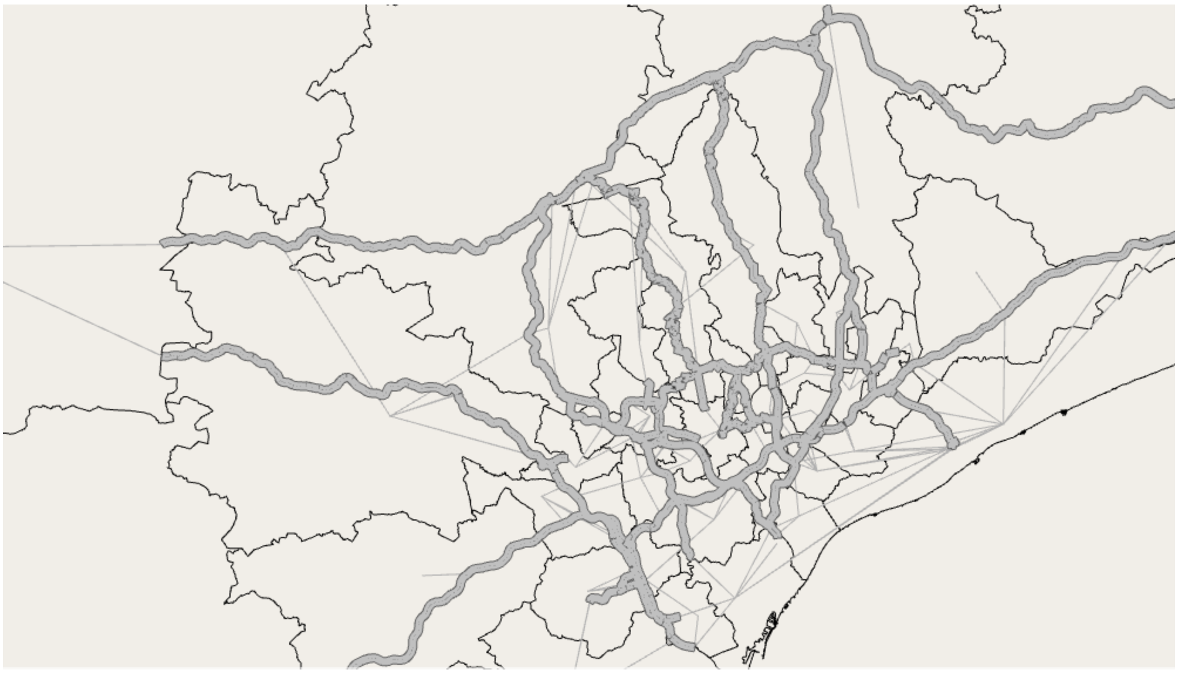

Fig. 2 – Red actual base

En total, la red actual modelizada se compone de 1232 secciones, 519 intersecciones, y de una longitud total de 1593 km (3251 km si desglosamos por carril), lo que muestra el alto grado de detalle conseguido en la misma, máxime si tenemos en cuenta la longitud total de la red de carreteras de la provincia de Barcelona, que era de 3929 km en 2016.

La red prevista para la modelización viaria futura, incluye la red actual, a la que se suma el cierre de la Orbital, desde Abrera hasta Terrassa, y desde Terrassa hacia Granollers (que consistirá en el tramo de actuación que se está evaluando). Además, se han analizado diferentes actuaciones previstas en la red, como el desdoblamiento de la C-59 entre Mollet y Caldes de Montbui, que en los escenarios futuros se ha considerado como una autovía con velocidad de proyecto 120 km/h.

El Estudio Informativo contempla seis posibles alternativas, que se estructuran en torno a dos corredores principales –Norte y Sur–. La Figura 3 muestra las diferentes alternativas consideradas.

Fig. 3 – Alternativas de trazado

3.4 Modelo de asignación

El modelo de asignación se ha llevado a cabo sobre el software AIMSUN, mediante herramientas de macrosimulación, más adaptadas para el tipo de estudio que se describe. Cada tramo de la red se ha ido delineando en dicho software a partir de la información base contenida en la plataforma OpenStreetMap, actualizando en caso necesario las infraestructuras nuevas o modificadas con respecto a la misma, obviamente.

Se ha calculado, para cada tramo, el Coste Generalizado de Viaje, con una expresión similar a la que sigue:

$$CG = \frac{t_{recorrido} \cdot VST}{60} + peaje_{por\ km} \cdot Longitud \quad (1)$$

La variable VST, valor subjetivo del tiempo, se ha extraído de la Nota de Servicio 3/2014, sobre "Prescripciones y recomendaciones técnicas relativas a los contenidos mínimos a incluir en los estudios de rentabilidad de los estudios informativos de la Subdirección General de Estudios y Proyectos", del Ministerio de Fomento.

Se ha considerado un factor de equivalencia para los vehículos pesados inicialmente igual a 3, correspondiente a terreno ondulado. Así, realizaremos la asignación bajo el método de equilibrio simple de distribución estadística con restricciones de capacidad y caminos múltiples, aplicando una función de congestión, que hace que el tiempo de recorrido de cada tramo aumente en función del tráfico que está soportando. Esta función difiere según el tipo de carreteras, y su formulación, tanto para vehículos pesados como para vehículos ligeros, es del tipo:

$$t_{recorrido} = t_0 \cdot máx\left[1 + \alpha \cdot \left(\frac{Vol}{c}\right)^{\beta}; 1 + \alpha \cdot 0{,}985^{\beta} + 15 \cdot \alpha \cdot \beta \cdot 0{,}985^{\gamma} \cdot \left(\frac{Vol}{c} - 0{,}985\right)\right] \quad (2)$$

El tráfico que soporta cada tramo de red influye en la velocidad del mismo, y ésta a su vez vuelve a influir en la idoneidad de dicho tramo, es decir, en el tráfico que capta. Así se genera una situación en la que ambas cuestiones –tráfico soportado y velocidad resultante– deben converger, según lo establecido en los modelos de equilibrio de usuario (Wardrop, 1952).

Dado que en nuestro caso las funciones de coste de cada arco dependen únicamente del flujo en dicho arco, es problema es separable y se puede resolver de una forma relativamente rápida mediante algoritmos como el de Frank & Wolfe (1956). Los criterios de convergencia establecidos fueron un límite máximo de 100 iteraciones o una diferencia de un 0,1% entre una iteración y la siguiente.

3.5 Ajuste de matrices origen/destino a partir de datos de aforo

Una vez que tenemos las matrices base de origen/destino (O/D) y el modelo de red, podemos introducir las primeras en el segundo y determinar el tráfico sobre cada tramo de vía. Sin embargo, es habitual (y nuestro caso no es una excepción) que el volumen de tráfico resultante no coincida con el realmente registrado en las estaciones de aforo dispuestas en la red. Por ello, es conveniente ajustar dichas matrices base, modificándolas ligeramente para que, al asignar el tráfico en la situación inicial, sea similar al realmente detectado en cada vía.

Desde cierto punto de vista, el problema de recalcular las matrices origen/destino a partir de datos de aforo se puede considerar como la inversa a un problema de asignación. En un problema de asignación, se conocen los flujos entre cada par de centroides, así como las características de la red y el modelo de comportamiento de los vehículos, y se busca encontrar el tráfico soportado por cada tramo de red. En el caso contrario, se trata de obtener una matriz O/D modificada, partiendo del tráfico realmente registrado, y teniendo en cuenta las características de la red y los modelos de comportamiento del usuario (Cascetta, 2001).

En nuestro estudio, se ha implementado una metodología de equilibrio de usuario, empleando el algoritmo de Frank & Wolfe (1956) en cada iteración, y estableciendo en este caso un número máximo de 50 iteraciones completas (cada una de ellas conteniendo un ajuste Fran & Wolfe de 100 sub-iteraciones internas). Finalmente, se han obtenido sendas matrices OD ajustadas para vehículos ligeros y pesados para el escenario base del año 2016.

Para validar la fiabilidad de dichas matrices, se han comparado los datos resultantes de la asignación de las mismas con los tráficos registrados en la red, tanto para tráfico ligero como pesado. Así, tal y como establece la Nota de Servicio 5/2014 del Ministerio de Fomento, sobre “Prescripciones y recomendaciones técnicas para la realización de estudios de tráfico de los Estudios Informativos, Anteproyectos y Proyectos de carreteras”, se ha verificado la validación del modelo a través de las dos metodologías que siguen:

- Análisis de regresión. Se elaboró una gráfica de dispersión, con las parejas de valores de volúmenes de tráfico obtenidos en cada tramo mediante la asignación (eje vertical) y mediante la observación real mediante aforos (eje horizontal). Sobre él, se ha ajustado una recta de regresión, de la que se comprueba que el valor de la pendiente es cercano a 1, el valor del intercepto en el eje de ordenadas es cercano a 0 (teniendo en cuenta el volumen de tráfico del que hablamos) y el coeficiente de determinación R^2 es claramente mayor que 0,7.
- Indicador %RMSE (raíz cuadrada del error cuadrático potencial).
  Tal y como se indica en la NS 5/2014 del Ministerio de Fomento, al tratarse de una red compleja y con muchos tramos, se ha dividido el total de observaciones en dos grupos: una muestra de contraste de al menos el 10% (en nuestro caso, del 28%, seleccionados aleatoriamente) y el resto de valores. Para cada grupo, se comprobó cómo ambos valores de %RMSE son inferiores al 30%.

3.6 Prognosis de tráfico y horizontes temporales considerados

Una vez calibrado y ajustado correctamente tanto el modelo como las matrices base Origen/Destino e de vehículos ligeros y pesados, el último paso, antes de proceder a estimar el tráfico a soportar por la nueva vía, es determinar los horizontes temporales a considerar, así como el crecimiento del tráfico previsto.

En cuanto a los horizontes temporales considerados, se parte del año 2025, en que se prevé que pueda estar puesta en servicio la infraestructura analizada, y se proseguirá durante 20 años más, en intervalos de 5 años. Así, los horizontes a calcular son los siguientes: 2025, 2030, 2035, 2040 y 2045.

No es necesario añadir situaciones intermedias a éstas, ya que el resto de actuaciones en el área de estudio se pueden asimilar perfectamente a los períodos anteriores.

Por otra parte, para el crecimiento estimado del tráfico, la Nota de Servicio 5/2014 del Ministerio de Fomento recomienda tener en cuenta los valores incluidos en la Orden FOM/3317/2010, “Instrucción para la mejora de la eficiencia en la ejecución de las obras públicas de infraestructuras ferroviarias, carreteras y aeropuertos” del Ministerio de Fomento. En ésta, se establece que el incremento anual acumulativo debe ser del 1,08% en el período de 2013 a 2016 y del 1,44% desde el año 2017 en adelante. Sin embargo, para analizar si estas tasas de crecimiento son suficientes para el área de estudio, se ha procedido a calcular tasas específicas de crecimiento para cada zona, tanto para vehículos ligeros como pesados, a fin de corregir estos valores en caso necesario.

Así, para analizar el crecimiento del tráfico ligero, se ha optado por extraer las series de población correspondientes a cada zona considerada, y se ha calculado una tasa anual para cada zona, introduciendo un peso mayor para los últimos años, como suele ser habitual. A partir de dicho valor, se han estimado las prognosis de población para los horizontes temporales considerados, y finalmente la tasa de crecimiento con respecto a nuestro escenario base, situado en el año 2016. Aunque las tasas de crecimiento resultantes son inferiores a las propuestas en la NS 5/2014, se considera más recomendable utilizar éstas, ya que se ajustan mejor a la realidad de la zona de estudio, y permiten establecer diferentes tasas de crecimiento para cada zona.

En cuanto al tráfico pesado, se ha procedido de forma similar, aunque en este caso, en lugar de la variable de población, se ha optado por otra mucho más orientada al tráfico de mercancías, como es el Índice de Producción Industrial (IPI), que tiene en cuenta la producción de bienes de consumo (distinguiendo entre consumo perecedero y no perecedero), bienes de equipo, bienes intermedios y energía. Con una formulación similar a la empleada para el tráfico ligero, se ha obtenido una media ponderada. De nuevo, esta tasa de crecimiento anual es inferior a la propuesta en la NS 5/2014, aunque se sigue considerando más conveniente emplear ésta, ya que es un valor más adaptado a la zona de estudio, en lugar de un valor agregado para todo el territorio nacional.

Por último, dado que no se dispone de datos de encuestas, no se ha podido elaborar modelos de generación de viaje sensibles a las variables de accesibilidad. Por ello, se ha optado por emplear la elasticidad media de la demanda respecto al tiempo de viaje en vías de tipo similar para determinar el nuevo tráfico inducido por la apertura de la nueva vía.

Considerando unas elasticidades de la demanda respecto al tiempo de -0,45 y -1,0 a corto y largo plazo, respectivamente, (Guirao, 2000), resultaría que el tráfico inducido es de un 1,69% a corto plazo y un 3,77% a largo plazo, respecto del total de viajes.

Se puede apreciar que el tráfico inducido por la nueva vía resulta un valor relativamente bajo con respecto al total de viajes, lo que resulta comprensible al no existir cambios en los usos del suelo condicionados a la realización de la actuación objeto del Estudio, sino que básicamente se trata de una redistribución de viajes como consecuencia de cambios en destinos.

4. RESULTADOS

Como resultado del proceso anteriormente indicado, se han realizado asignaciones para las seis alternativas seleccionadas en los años 2025, 2030, 2035, 2040 y 2045. Finalmente, en función de las condiciones de circulación, se calculan los Niveles de Servicio, a partir del procedimiento indicado en el Manual de Capacidad (TRB, 2016).

En primer lugar, se calcularon los resultados correspondientes a la hipótesis inicial de disponer suponiendo 2 carriles por sentido a lo largo de todo el recorrido. Sin embargo, se apreció que el Nivel de Servicio en la hora punta del año horizonte (2045) era inadmisible en los tramos iniciales, por lo que la configuración final seleccionada fue la disposición de 3 carriles por sentido desde la conexión con la actual B-40 hasta el enlace de Sabadell Oeste.

Como se puede observar en las Tablas 1 y 2 y en las Figuras 4 a 9, aunque los resultados son similares para todas las alternativas (dado el escaso margen de trazado para las mismas), la IMD global en el año estimado de puesta en servicio (2025) varía entre los 44.300 y los 46.500 vehículos/día, siendo las alternativas de mayor captación la 1 y la 4, es decir, las que discurren más al Sur del corredor. En el escenario del año 2045, los valores de IMD rondan entre los 52.500 y los 55.400 vehículos/día. El volumen de pesados se sitúa, en todos los casos, alrededor del 10-12%, en promedio.

Estos volúmenes implican que la Autovía Orbital de Barcelona sería capaz de captar alrededor de un 30% del tráfico de largo recorrido que actualmente transita por la B-30 y la AP-7 (unos 70.000 vehículos/día), lo que respalda su funcionalidad esperada como catalizadora del tráfico de largo recorrido ajeno a la metrópoli barcelonesa. Además, aporta un importante servicio a las localidades cercanas, al permitir que gran parte del tráfico que discurre entre ellas utilice la nueva vía.

En cuanto a Niveles de Servicio, en el año de puesta en servicio se alcanzaría un Nivel D únicamente en las Alternativas 1 y 4 (aquéllas que más tráfico captan), mientras que, en el año horizonte, 2045, dicha situación es generalizada.

Las únicas excepciones a la Norma 3.1-IC de Trazado son las alternativas 1 y 4, en las que el Nivel de Servicio D en sus tramos inciales no cumple estrictamente lo establecido en la Instrucción de Trazado, aunque no se considera recomendable ampliar la sección en ellos a 4 carriles por sentido.

5. CONCLUSIONES

El estudio informativo en análisis, en su fase A, planteó diversos corredores que discurren por varios municipios entre Terrassa, al inicio del estudio, y La Roca del Vallès, cerca de Granollers, en su final. Existe la previsión de dos grandes corredores, denominados: Corredor 1, que discurre por el Norte, y Corredor 2, por el Sur, que finalmente se han plasmado en 6 alternativas.

En la fase B, se incorporaron técnicas de macrosimulación de tráfico, mediante apoyo de software específico para tal fin, y se modelizaron las diferentes alternativas en varios horizontes temporales, comprendidos entre el año estimado de puesta en servicio, 2025, y el año horizonte, 2045. Con dichas herramientas, se ha podido realizar un mejor dimensionamiento de la red, evitando posibles Niveles de Servicio inadmisibles, y también costes más altos de lo necesario. Es por ello que este tipo de herramientas de simulación pueden aportar valor técnico y económico a la planificación de infraestructuras.

Queda pendiente verificar que los datos estimados se correspondan a las previsiones estimadas mediante la simulación, lo que sin duda aportará un componente de validación -o no- a dichas técnicas. En cualquier caso, resulta evidente que una herramienta de mejora del diseño como las empleadas en el presente estudio siempre va a mejorar la calidad de este tipo de estudios de planificación de nuevas infraestructuras.

AGRADECIMIENTOS

Este artículo está basado en el Proyecto de Investigación denominado “Simulación y Análisis de Tráfico dentro del Estudio Informativo de la Autovía Orbital B-40”, contratado por la empresa GPYO INNOVA, S.L. la elaboración del citado Estudio de Tráfico, y realizado por Universidad de Burgos.

MODELO DE MOVILIDAD DE EMT: PLANIFICACIÓN A PARTIR DE FUENTES BIG DATA

Cristina Valdés Serrano
Responsable del Modelo de Movilidad. Área de Diseño e Ingeniería de Transporte, Dirección de Servicios de Transporte. EMT Madrid
Ana Pérez del Olmo
Jefa de Área de Diseño e Ingeniería de Transporte, Dirección de Servicios de Transporte, EMT Madrid

RESUMEN

El Modelo de Movilidad desarrollado por EMT es un modelo multimodal que incluye vehículo privado y transporte público. Si bien su ámbito de actuación es la ciudad de Madrid, el Modelo abarca también el entorno metropolitano.

La red es una malla completa, basada en la cartografía de HERE. La oferta de transporte público incluye todos los sistemas de transporte colectivo – METRO, Cercanías, autobuses interurbanos y autobuses de EMT- , sumando un total de 405 líneas.

El aspecto más innovador de esta herramienta es la metodología seguida para la obtención de las matrices origen-destino. Éstas se han obtenido a partir de la combinación de datos de telefonía (CDR's) y validaciones de la tarjeta de transporte público. Esta combinación de datos ha permitido obtener un amplio abanico de matrices modales para diferentes periodos del año, distintos tipos de día y diferentes intervalos horarios.

La zonificación utilizada – 1259 zonas - es la definida por el Consorcio Regional de Transportes de Madrid para la Encuesta Domiciliaria de Movilidad realizada en 2018 (EDM 18) – 605 zonas para la ciudad de Madrid y 654 para el área metropolitana.

La obtención de unas matrices origen-destino tan detalladas, combinado con el diferente grado de precisión geográfica de origen y destino del viaje de las dos fuentes de datos utilizadas (CDR's y validaciones de la tarjeta de transporte público), ha supuesto un reto importante.

1. OBJETIVOS Y ESTRUCTURA

1.1. Objetivos y aspectos principales

El Modelo de Movilidad de Madrid es una herramienta de planificación para EMT que include tanto transporte público como vehículo privado. El Proyecto de construcción de este Modelo se inició en abril de 2017, terminándose en octubre de 2019.

El Objetivo Principal de este Modelo de Movilidad es dotar a EMT, el operador de movilidad pública de la ciudad de Madrid (100% propiedad del Ayuntamiento), de una herramienta de planificación que le permita una mejor planificación, así como propuestas relacionadas con los servicios de transporte que gestiona.

El principal aspecto innovador de este Proyecto es la obtención de matrices origen-destino a partir de fuentes de datos como los CDR's obtenidos de la telefonía móvil y las tarjetas inteligentes de transporte.

1.2. Etapas del Proyecto

El Proyecto se puede estructurar en 3 fases:

- Desarrollo del Modelo de Oferta: el Modelo, si bien se centra en la ciudad de Madrid, abarca el conjunto de la región, incluyendo tanto la red viaria como la oferta de servicios de transporte público (EMT, METRO, autobuses interubanos y Cercanías). La descripción de esta red está en el capítulo 2.

- Desarrollo del Modelo de Demanda: en este caso se ha planteado un amplio abanico de matrices origen-destino tanto para vehículo privado como para transporte público, así como para diferentes periodos del año (invierno, verano y entretiempo), días de la semana (l-j, viernes, sábados y domingos&festivos) e intervalos horarios (punta AM, punta PM, punta MEDIODÍA y horas VALLE).

Para el cálculo es estas matrices, se puso en marcha una plataforma BIG DATA, basada en una Distribución HORTON HDP 2.6, Actualmente esta Plataforma se está utilizando para otros proyectos en curso en EMT, como la estimación de aforo en los autobuses.

- Validación y Calibrado de resultados.

Los resultados obtenidos al asignar dichas matrices se han contrastado con los datos de aforos de tráfico, así como subidos y bajados en transporte público. Primeramente han servicio para afinar algunos parámetros del Modelo, y posteriormente para calibrar dichas matrices.

2. LA RED DE TRANSPORTE: DESCRIPCIÓN

La red viaria se ha construido a partir de la cartografía HERE para el conjunto de la región – 2.000 km. de vías de alta capacidad, 5.500 km. de carreteras y más de 22.000 km. de red urbana.

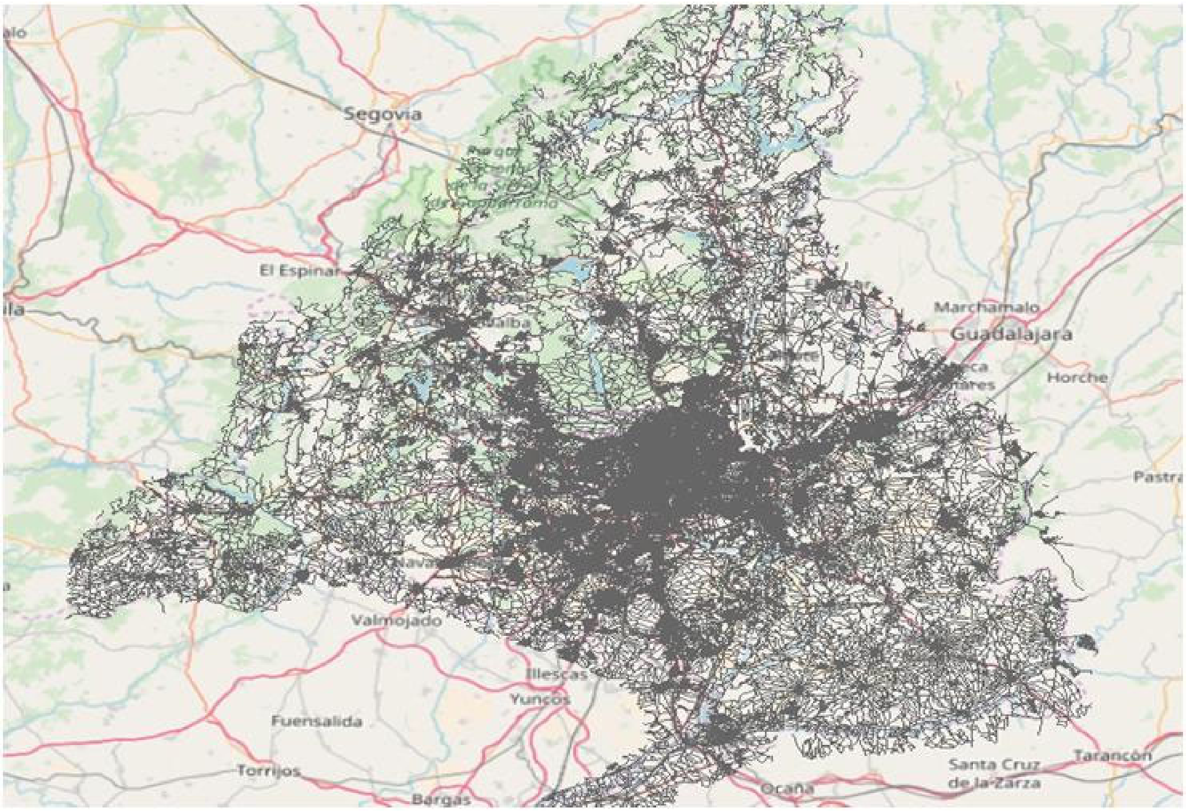

Fig. 1. Red viaria

También se han incluido las diferentes redes de (EMT, Metro, Cercanías, Metro ligero y autobuses interurbanos), junto con sus correspondientes horarios y/o frecuencias.

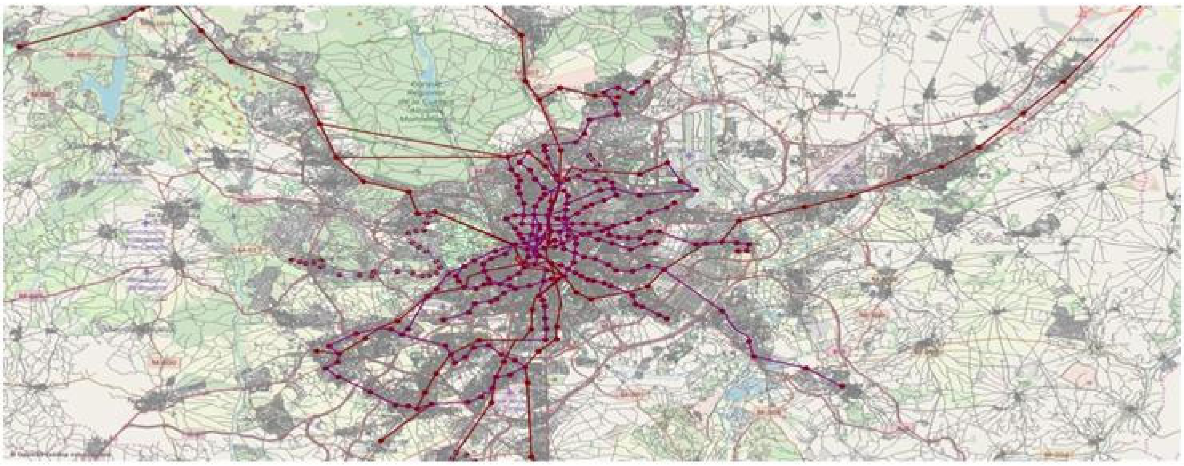

Fig. 2. Red de transporte público: CERCANÍAS Y METRO

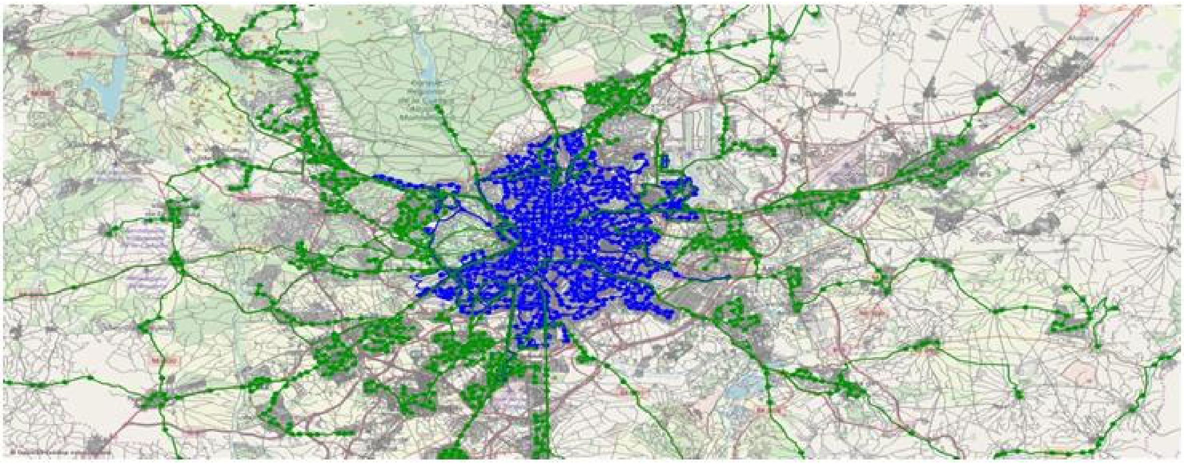

Fig. 3. Red de transporte público: Autobús urbano e interurbano

Esta oferta supone, en total, 393 líneas, más de 9.000 paradas y 62.000 servicios diarios.

La zonificación considerada es la definida por el Consorcio de Transportes de Madrid para la encuesta de movilidad llevada a cabo en 2016, 1259 zonas, de las cuales 605 zonas corresponden a la ciudad de Madrid mientras las otras 654 pertenecen a los otros 199 municipios que integran el conjunto de la región.

3. EL MODELO DE DEMANDA

3.1. Metodología para la obtención de matrices origen – destino (OD)

Los enfoques tradicionales de obtención de matrices O/D se basan en encuestas de hogares y / o recuentos de tráfico. Las encuestas origen / destino y las encuestas de hogares para obtención de orígenes y destinos implican una recopilación de datos costosa y, consecuentemente, tienen tamaños de muestra limitados y frecuencias de actualización más bajas de lo deseado, entre 5 y 10 años incluso en las ciudades más desarrolladas (Toole et al, 2015). De hecho, según Iqbal et al (2016), son propensas a sesgos de muestreo y errores de notificación.

Al mismo tiempo, solo proporcionan una instantánea del rendimiento del tráfico, ya que se realizan en un momento puntual y no de manera continua en el tiempo (White et al, 2002).

Frente a estos métodos clásicos de recopilación de matrices O-D, este trabajo se centra en la obtención de estas matrices de movilidad utilizando fuentes BIG DATA como los datos de telefonía o las tarjetas de transporte. La obtención de las matrices origen-destino mediante combinación de estas fuentes ha conllevado diferentes etapas, que se detallan a continuación.

El primer paso ha sido la obtención de matrices de movilidad general O-D para la Comunidad de Madrid a partir de telefonía móvil. Estos datos de telefonía proporcionan una información completa sobre viajes y distribución espacial con las siguientes ventajas en relación a los métodos convencionales: alto volumen de muestra, buena distribución, volumen de datos a lo largo de todo el año, lo que nos ha permitido considerar diferentes períodos del año, semana o día sin incrementar demasiado el coste. Además, permite capturar información sobre la movilidad de los no residentes en la ciudad de forma menos sesgada.

El segundo paso ha consistido en la obtención de las matrices O/D de transporte público de la ciudad de Madrid a partir de los datos recogidos en las tarjetas inteligentes de transporte público. Para ello, hemos realizado un cruce de información de los datos almacenados (con anonimización previa) con el resto de datos almacenados en la plataforma Big Data.

La información almacenada en estas tarjetas permite la estimación de los viajes realizados en diferentes modos de transporte público, teniendo en cuenta diferentes matices que se explicarán más adelante con más detalle.

Por último, una vez obtenidas ambas matrices OD (movilidad general y transporte público) el siguiente paso ha sido diseñar un procedimiento para obtener matrices de vehículos privados a partir de las anteriores, restando según diferentes zonas la matriz OD pública a la matriz de movilidad general. Este último paso, muy sencillo en apariencia, ha conllevado importantes dificultades derivadas de la diferente aproximación espacial de unos y otros datos.

3.2. Obtención de matrices O/D de movilidad general a partir de datos de telefonía

Las matrices de O / D de movilidad general para la Comunidad de Madrid se han obtenido a partir de datos de telefonía móvil, mediante registros de actividad de teléfonos móviles o CDR (Call Detail Records).

Los datos utilizados para la obtención de estas matrices han sido datos de telefonía celular (datos geolocalizados desde dispositivos móviles, Grupo Orange España), datos de población residente y datos de movimientos fronterizos (FRONTUR, INE), datos de movimientos fronterizos y datos de uso del suelo (Sistema de Información de Ocupación del Suelo).

Al mismo tiempo, se ha tenido en cuenta:

- Población de estudio: residentes en España mayores de 10 años y personas residentes en el extranjero que visiten España.
- Zonificación: las matrices origen-destino estarán referidas a la zonificación establecida por el Consorcio de Transportes de Madrid para la Encuesta de Hogares de 2018, ZT1259.
- Viajes objeto de estudio: viajes con origen y destino en la Comunidad de Madrid con una distancia superior a los 1.000 metros. Este criterio de distancia permite filtrar la mayor parte de los viajes no mecanizados, que no están cubiertos por este estudio.

- Períodos de estudio: se define como período de estudio la combinación de mes o tipo de mes (invierno, verano y temporada media), día o tipo de día (día laborable, viernes, sábado y domingos y festivos) y franja horaria (pico de la mañana, pico de mediodía, pico de tarde y horas valle). Esta combinación resultó en 32 períodos de estudio. En cada uno de ellos, el nivel de desagregación de viajes es el siguiente:
    - Segmentación por género y edad (menores de 20 años, 20-44 años, 45-64 años, 65-79 años y mayores de 70 años)
    - Segmentación por lugar de residencia (municipio de Madrid, resto de la Comunidad de Madrid, resto de España y fuera de España)

La metodología ha seguido los siguientes pasos:

- Preprocesamiento y depuración de telefonía móvil (los datos base se han extraído de los meses de junio, julio, septiembre, octubre y noviembre de 2017)
- Construcción de la muestra potencial de usuarios de telefonía móvil
- Identificación del lugar de residencia de los usuarios residentes en España y características de los no residentes
- Abstracción de la actividad y diarios de viaje
- Aumento de la muestra a la población general
- Generación de las matrices origen-destino

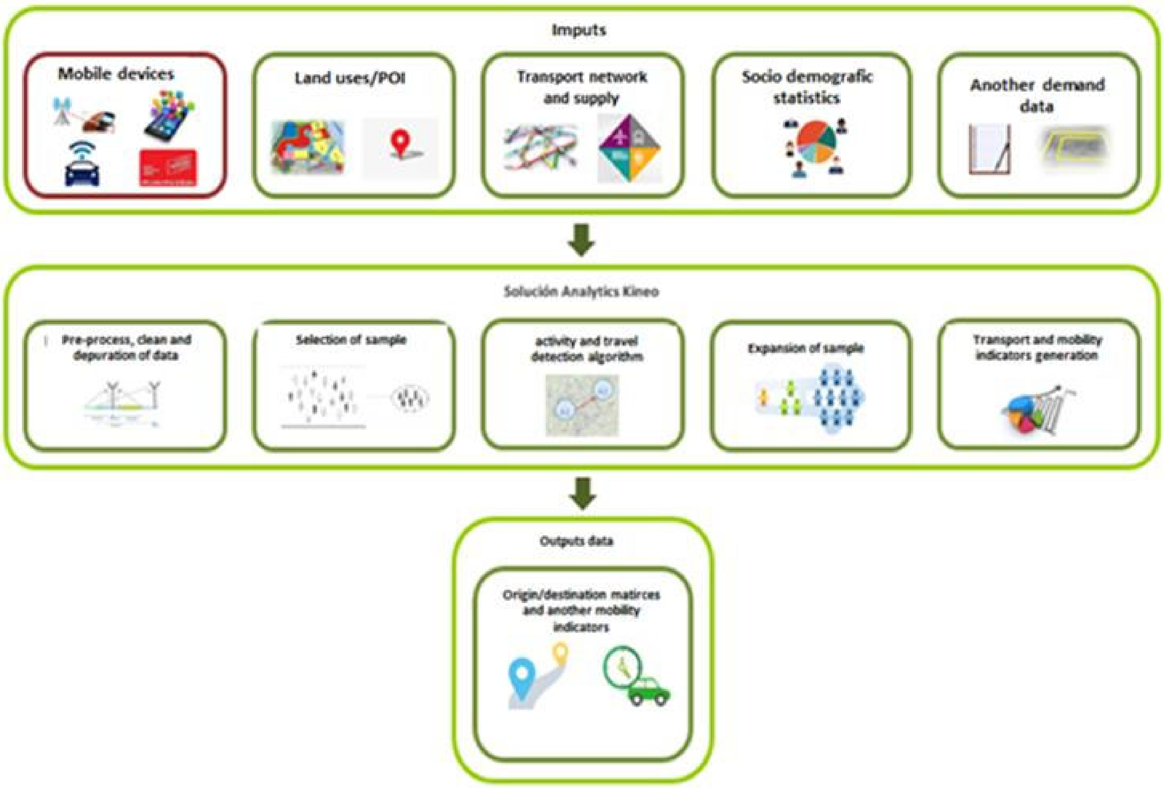

Fig. 4. Proceso de obtención de las matrices O/D generales

3.3. Obtención de matrices O/D de transporte público mediante los registros de las tarjetas inteligentes de transporte

Los datos de la red de telefonía nos dan la posibilidad de comprender mucho mejor los patrones de viaje dinámicos, lo cual tiene una gran cantidad de aplicaciones diferentes dentro de la gestión, el análisis y el apoyo a la toma de decisiones del tráfico y el transporte. Sin embargo, estas fuentes de datos tienen varias características clave que son diferentes de las fuentes de datos tradicionales y que deben manejarse con cuidado mientras se procesan los datos con fines de estimación y predicción. A diferencia de los sistemas de infraestructura fija para la recopilación de datos, los datos de señalización de teléfonos móviles no están limitados por ningún modo de transporte ni por ninguna región espacial específica. Esto no permite analizar la demanda de viajes y los tiempos de viaje según el modo de viaje (David Gundlegard et al., 2016). Esta es la razón por la que hemos utilizado la información de las tarjetas de transporte inteligent

Hoy en día, la mayoría de los sistemas AFC (recolección automática de tarifas) en todo el mundo solo registran la información de embarque de los pasajeros y se pierden los datos de bajada, como la ruta del autobús, la parada de embarque y la hora de embarque. (Daming Li, Xinliang Zhao et al. 2011). La estimación de orígenes y destinos (O/D) de trayectos en transporte público es un producto importante del procesamiento de datos de tarjetas inteligentes.

En los últimos años, varios métodos de estimación O/D que utilizan el enfoque de encadenamiento de viajes han atraído mucha atención tanto de investigadores como de profesionales.

En este caso, para estimar la cadena modal (monoetapa o multietapa) para cada usuario, hemos considerado a los usuarios de la tarjeta de transporte público de Madrid con billetes mensuales, anuales y de 10 viajes, ya que para el billete simple no es posible inferir la salida del viajero debido al uso ocasional de los servicios de transporte público.

En cuanto a la metodología para la recolección de viajes a partir de las validaciones, el proceso seguido se basó en el enfoque de encadenamiento de etapas.

Para unir las validaciones de viaje utilizamos el programa que predice la parada de salida (si no la tenemos) en función de la distancia mínima de transferencia y el tiempo de viaje por modo, que se fijará en función del tipo de día y franja horaria (estos límites se determinarán en función de los datos de otras fuentes externas, como Simplycity, CDRs, etc. .).

Paralelamente, se desarrolló un algoritmo que sirve para encontrar la parada más cercana a la siguiente validación en los casos en que no existan distancias calculadas previamente para poder saber qué parada se utilizó para el traslado, teniendo en cuenta que el operador y la línea de salida deben ser los mismos que la línea de entrada.

Los escenarios adoptados han sido los siguientes:

- Cuando la diferencia horaria entre validaciones en una misma tarjeta es inferior a 45 minutos, las hemos considerado como etapas de un mismo viaje y las hemos encadenado en un mismo viaje.
- Las tarjetas de transporte se almacenan en el punto de validación (parte superior de acceso a la red de transporte público). Para ir más allá de este punto de acceso a la red hasta la zona de disparo de origen, hemos redistribuido los viajes entre las áreas vecinas a cada parada de la red. Las zonas de influencia se generan con dos criterios diferentes en cuanto al radio de acción:
    - En las áreas de metro y ferrocarriles (es decir, en estos operadores) se necesitan 600 metros.
    - Se toman 500 metros al resto de operadores.
    - Para la redistribución se utiliza el producto cartesiano individual para cada zona de origen y destino.
    - La redistribución se realiza a nivel de viajes.

Para cada uno de los periodos de estudio, se ha tenido en cuenta la distribución espacial de viajes entre áreas de la matriz integral provenientes de la matriz de telefonía móvil.

Dado que no ha sido posible disponer de información suficiente de los viajes en transporte público con origen o destino fuera de la ciudad de Madrid, hemos optado por considerar solo aquellos viajes con origen / destino dentro de la ciudad de Madrid, excluyendo el análisis de los viajes al resto de áreas en la Comunidad. Para éstos, se ha estimado la misma distribución de viajes que había en la última Encuesta Domiciliaria.

3.4. Obtención de las matrices O/D de vehículo privado

El último paso ha consistido en la recogida de matrices de transporte privado. En este punto ya conocíamos las matrices integrales y las matrices de transporte público, por lo que procedimos de la siguiente manera:

- De las matrices de transporte público O D se han eliminado aquellos viajes cuya distancia sea inferior a 1.000 metros, ya que estos viajes no estaban incluidos en la matriz integral O/D obtenida de la telefonía móvil.
- A cada matriz de O/D integral obtenida de la telefonía móvil (considerando solo los viajes entre áreas de la ciudad de Madrid), se ha eliminado su contraparte de la matriz de transporte público, dando como resultado la matriz de viajes en vehículo privado.
- Cuando lo hacemos, en algunas combinaciones, se obtiene un resultado negativo restando información entre CDR y O/D público.

Para minimizar la densidad de valores negativos que no cubre la versión original del algoritmo, es necesario modificar el algoritmo entre la creación del “buffer” y la asociación de zonas candidatas (que se realizará a nivel desagregado).

Por último, se han calibrado estas matrices usando los datos de tráfico y de viajeros subidos por línea. Las figuras 5 y 6 muestran los resultados para el periodo punta de la mañana de un día laborable de invierno.

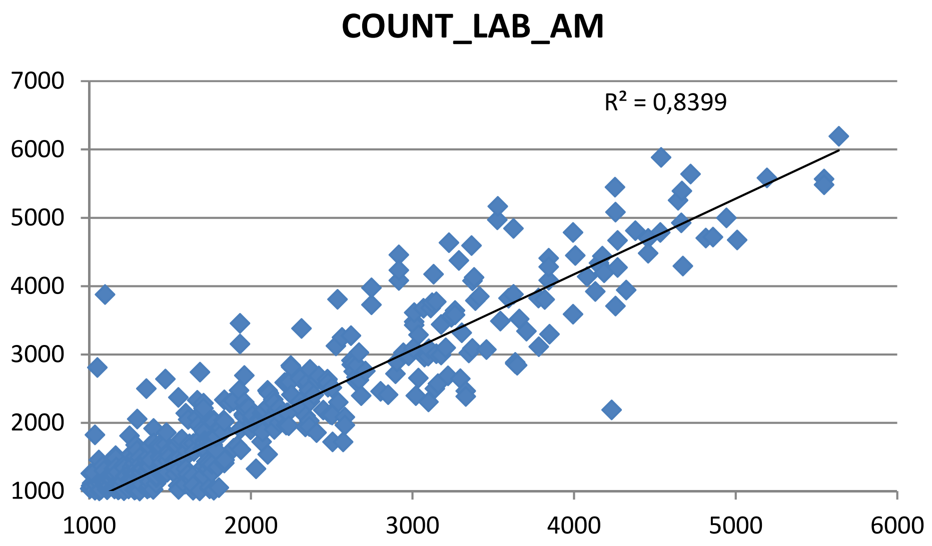

Fig. 5. Resultados calibrado matriz vehículo privado: periodo AM día laborable de invierno

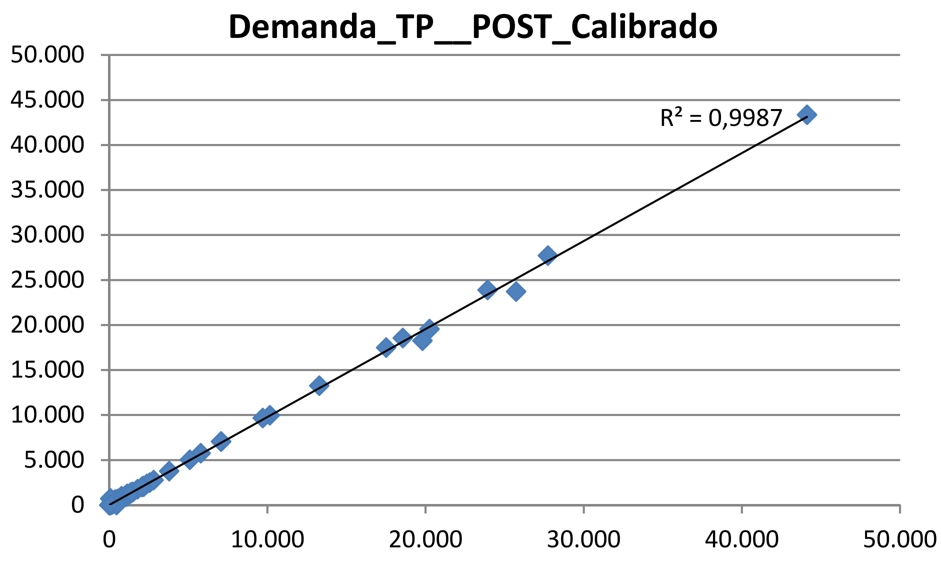

Fig. 6. Resultados calibrado matriz transporte público: periodo AM día laborable de invierno

4. UTILIDADES Y CASOS DE ESTUDIO

El Modelo de Movilidad se ha utilizado y se está utilizando actualmente para diferentes escenarios de análisis, tanto desde la necesidad operativa (1 y 2) como para la investigación (3), tales como:

1) Cierre del túnel de Recoletos de la red de Cercanías: variación de la movilidad y necesidades de refuerzo mediante servicio alternativo de EMT.

Fig. 7. Variación del tráfico con el cierre del túnel de Recoletos de Cercanías

2) Definición y selección de itinerario de las nuevas líneas de autobús 00 (cero coste, cero emisiones): 001 Atocha Renfe – Moncloa y 002 Argüelles – Puerta de Toledo

3) Proyecto europeo MOMENTUM: este Proyecto, perteneciente al Programa H2020, tiene entre sus objetivos caracterizar los cambios en las pautas de movilidad derivados de las nuevas opciones emergentes de movilidad, así como incorporar en el Modelo de Movilidad opciones para incorporar el impacto de estas nuevas opciones.

AGRADECIMIENTOS

Queremos expresar nuestro agradecimiento a las empresas VIRTUALDESK, TARYET y NOMMON por el gran trabajo realizado tanto en el desarrollo y puesta en marcha de la plataforma como en el trabajo de integración y analítica para la obtención de las matrices origen-destino.

RESUMEN

En las grandes ciudades el principal motivo de la pérdida de la calidad del aire es la emisión de los productos de combustión procedentes del tráfico de vehículos. El objetivo de este trabajo es mostrar los resultados de las predicciones realizadas para emisiones de partículas y de óxidos de nitrógeno por autobuses urbanos de ciudad de Madrid, utilizando modelos de minería de datos que consideran la influencia de variables cinemáticas, ambientales, altitud y pendiente. Para la realización de las predicciones se usó la herramienta estadística *Random Forests* de R.

Se obtuvo los perfiles de altitud y pendiente de manera teórica (usando la aplicación *GPS Visualizer)* y experimental (determinación del perfil de altitud sobre el nivel del mar). Se detectó un desfase entre las curvas de caudal de contaminantes respecto a las curvas de las variables cinemáticas, por ello se hizo corresponder el valor de la variable respuesta en el instante t con las cinemáticas en el instante t + r. Se determinó las mejores combinaciones del desfase a partir de la elaboración de modelos sencillos.

A continuación, a los mejores modelos sencillos se añadió las componentes ambientales como variables explicativas creando modelos globales, y finalmente se creó un modelo incorporando al mejor modelo global la altitud y pendiente como nuevas variables explicativas.

Se verificó que los modelos que consideran el retardo entre la variable respuesta y las cinemáticas y la incorporación de la altitud y pendiente como variables explicativas mejoran los modelos en términos de predicciones y errores. Los perfiles de altitud y pendiente determinados por el método teórico presentan mejores resultados, en ambos métodos la pendiente es la tercera variable más influyente en la emisión de los contaminantes, mientras que las variables cinemáticas son las que más contribuyen a reducir la impureza nodal y el error *MSE-OOB*.

1. INTRODUCCIÓN

La contaminación atmosférica, producida por los gases, provoca efectos negativos sobre el medioambiente y la salud de las personas. Las emisiones de partículas (PM) y los óxidos de nitrógeno (NOx) tienen en el tráfico rodado la principal fuente de emisión en grandes ciudades (Ministerio de Agricultura, 2013).

Pese a que el sector automovilístico ha incorporado importantes mejoras y novedades tecnológicas que han permitido reducir de manera notable el consumo de combustible y las emisiones de los vehículos, la calidad del aire no ha mejorado lo que se deseaba.

En el año 2018, la ciudad de Madrid, sufrió varios episodios de superación de los niveles recomendables de dióxido de nitrógeno y/o ozono troposférico que motivaron la adopción de medidas basadas en los Protocolos de Actuación para Episodios de Contaminación (Ayuntamiento de Madrid, 2018) La Dirección General de Tráfico (DGT), organismo dependiente del Ministerio del Interior, clasificó el parque automovilístico español en base a lo que cada vehículo contamina, con el objetivo de discriminar positivamente a los vehículos más respetuosos con el entorno y ser un instrumento eficaz en políticas municipales (DGT, 2016).

Jiménez et al. (2009) compararon dos alternativas de dispositivos de control de emisiones de autobuses urbanos circulando por zonas urbanas e interurbanas, haciendo uso de ensayos con equipos de medida embarcados.

Fonseca González (2012) estudió los problemas asociados a la medición de las emisiones gaseosas y los distintos factores que influyen en las emisiones y en el consumo de combustible de turismos en tráfico real y diseñó y construyó un equipo experimental, denominado MIVECO-PEMS, que permite medir las emisiones másicas instantáneas y los factores de emisión.

Carrese et al. (2013) evaluaron y cuantificaron el impacto de los patrones de conducción, la pendiente de la vía y la carga del vehículo (pasajeros) sobre el consumo de combustible y las emisiones de contaminantes atmosféricos en autobuses de Roma.

Román de Andrés (2014) propuso una metodología para la redistribución optimizada de una flota de vehículos en una red de rutas fijas urbanas con el propósito de reducir la emisión de sustancias contaminantes.

Ruiz Porro (2017) desarrolló una metodología para obtener ciclos de conducción optimizados de autobuses con los que identificar los patrones de conducción con mejor comportamiento en cuanto a emisiones contaminantes.

Cueto-Felgueroso (2018) estudió la influencia que las variables cinemáticas, ambientales, altitud y pendientes ejercen en la emisión de contaminantes y consumo de combustible en los autobuses urbanos de la ciudad de Madrid.

En el Proyecto ECOTRAM (2007) se desarrolló una metodología para calcular las emisiones de diversos contaminantes de la flota de autobuses de la Empresa Municipal de Transportes de Madrid (EMT) (López et al. 2017).

Este trabajo, enmarcado en el Proyecto CÍCLOPE (*Sistema de optimización de ciclos urbanos de conducción*) desarrollado por el INSIA, presenta los resultados de las predicciones de emisiones de PM y NOx de autobuses urbanos en la ciudad de Madrid, mediante modelos de minería de datos. Los datos de emisiones instantáneas se obtuvieron mediante equipos a bordo en una muestra de autobuses. Los modelos muestran la influencia de las variables cinemáticas, ambientales y del perfil altimétrico de los recorridos sobre los contaminantes PM y NOx.

2. BASE DE DATOS

La base de datos utilizada contiene información sobre las variables cinemáticas, posicionales, ambientales y de emisiones de un autobús MAN, de motor de encendido por compresión (MEC), con normativa europea EURO IV (Directiva 2005/55/CE) circulando en 4 líneas de la EMT (C1, 27, 63 y 145) durante distintos trayectos habituales de ida y vuelta, obtenidos de un conjunto de ensayos realizados durante los años 2007 y 2008 en el proyecto ECOTRAM (2007).

Carga	Línea / Itinerario								Total por carga
	C1		27		63		145		
	Ida	Vuelta	Ida	Vuelta	Ida	Vuelta	Ida	Vuelta	
Plena	1	2	2	2	2	2	-	-	11
Media	4	3	2	2	-	-	2	2	15
Vacío	2	2	2	2	-	-	2	2	12
Total									38

Tabla 1 – Número de ensayos realizados por nivel de carga con B100.

Se obtuvieron más de 152.000 observaciones o medidas por segundo mediante la instalación del equipo PEMS Horiba OBS-2200, en distintas condiciones de ensayo: distintas horas y días, en los itinerarios de ida y vuelta en las distintas líneas, con tres estados de carga (vacío, a media carga y a plena carga) y dos tipos de combustible, gasóleo y biodiesel 100% (B100).

A comienzos del año 2009 se sustituyó el gasóleo por un biocombustible (B100) en toda la flota de autobuses de la EMT (EMT, 2010), y en este trabajo se muestran los resultados considerando los 38 ensayos, con Biodiesel 100% (B100) de la Tabla 1.

3. METODOLOGÍA

La base de datos proporciona como variable cinemática la velocidad del autobús. Las variables aceleración y sobreaceleración, que tienen una importante influencia en la dimensión de las emisiones, se definen como un incremento entre dos valores en instantes consecutivos y fueron calculadas a partir de las velocidades instantáneas del autobús.

3.1 Determinación de los perfiles de altitud y pendiente

Los valores de altitud recogidos en la base de datos no presentan una fiabilidad suficientemente alta porque el aparato medidor no fue capaz de captar los datos adecuadamente debido a los obstáculos e interferencias, como túneles o edificios.

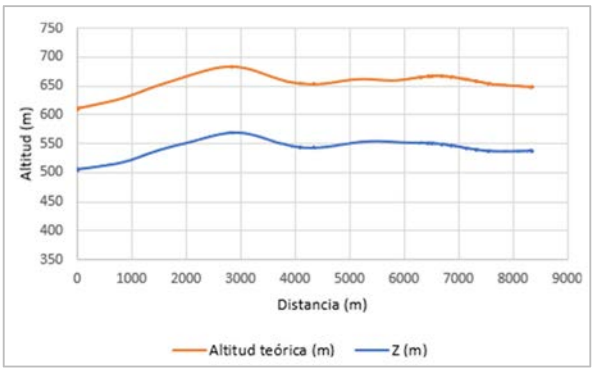

Fig. 1 – Evolución de las altitudes calculadas con *GPS Visualizer* y según el método de las presiones (Z) en un ensayo de media carga de B100 (Cueto-Felgueroso, 2018)

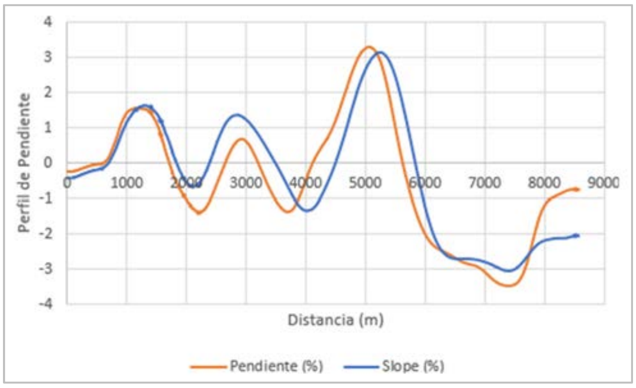

Fig. 2 – Comparación de los perfiles de pendiente obtenidos con el método teórico (Pendiente) y experimental (Slope) (Cueto-Felgueroso, 2018)

Se determinaron los valores de la altitud por dos métodos: teórico y experimental (Figura 1) (Cueto-Felgueroso, 2018). En el primero se utilizó la aplicación *GPS Visualizer* (GPS Visualizer, 2003) que utiliza valores de longitud y latitud recogidas en la base de datos. En el segundo se determina el perfil de altitud sobre el nivel del mar en base a la presión atmosférica, medida por el equipo embarcado en el autobús (Fonseca Gonzáles, 2012).

Se calcularon las pendientes como el cociente entre las variaciones de altitud y de distancia. En la Figura 2 se observa que no hay diferencias significativas entre los perfiles de pendientes calculados con los dos métodos de determinación de altitudes.

3.2 Modelado

Para elaborar los modelos de predicción se estudiaron las curvas de caudal de contaminantes respecto a las curvas de las variables cinemáticas (velocidad, aceleración y sobreaceleración) y debido al desfase entre ellas, se introdujeron retardos para la variable respuesta en el instante t con las cinemáticas en el instante t + r.

Se realizaron tres grupos de modelos de árboles aleatorios *(Random Forests):* el primer grupo, denominado *modelo sencillo* (solo con variables cinemáticas como variables de entrada), con el objeto de determinar las variables cinemáticas que presentan mejores resultados (menor MSE-OOB y mejor variabilidad explicada); el segundo grupo, *modelo global*, con la incorporación a los mejores modelos del primer grupo de las variables ambientales como variables explicativas; y finalmente el tercer grupo, *modelo global con altitud y pendiente*, con la adición al mejor modelo del segundo grupo (caracterizado por menores valores de MAPE, MSE-OOB y MSE y mejor variabilidad explicada) de la altitud y la pendiente como nuevas variables explicativas. Se compararon los resultados del modelo global sin y con incorporación de las variables altitud y pendiente, con el fin de analizar cómo se comporta el modelo ante esta nueva situación (Cueto-Felgueroso, 2018).

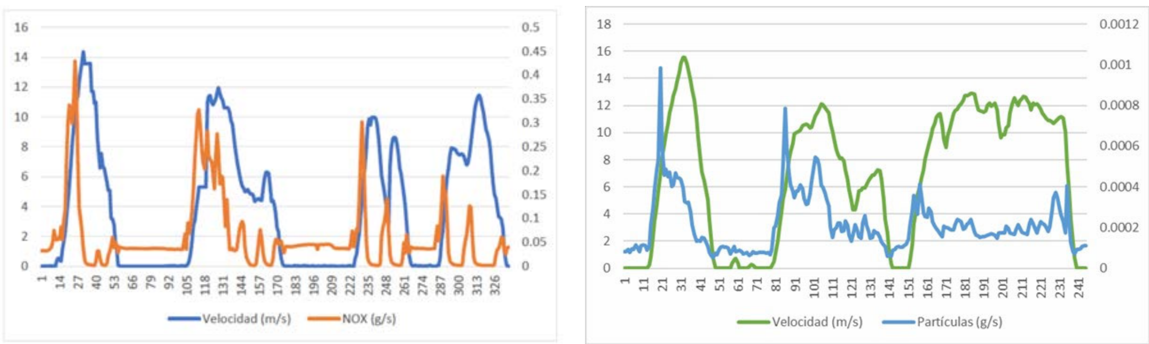
Para el modelado con *Random Forest* se definieron los parámetros *mtry*= 2 (Breiman et al. 1984), y *ntree*= 500. Al mismo tiempo, se compararon los resultados obtenidos con los dos métodos diferentes de obtención de los perfiles de altitud y pendiente.

Para la identificación de los modelos se empleó la nomenclatura: contaminanteABC, donde A es el desfase de la velocidad, B el de la aceleración y C el de la sobreaceleración, con respecto a la emisión del contaminante analizado.

4. RESULTADOS Y DISCUSIÓN

4.1 Caracterización del desfase

La Figura 3 muestra el desfase entre las curvas de velocidad y del caudal de contaminante, a) NOx y b) PM. Se estimó el tiempo de retardo para NOx entre 2 y 4 segundos, mientras que para PM se observó que el desfase es muy pequeño. Se verificó un comportamiento similar con la aceleración y el caudal másico de contaminante.



a) NOx b) PM

Fig. 3 – Curvas de velocidad y caudal másico de contaminante de un fragmento de un ensayo de B100 - vacío. a) NOx y b) PM (Cueto-Felgueroso, 2018)

4.2 Modelos

Se elaboraron los modelos sencillos para determinar la mejor combinación del desfase entre el caudal de contaminante y las variables cinemáticas (velocidad, aceleración y sobreaceleración). Para el caso de NOx, se observó que el retardo óptimo está entre 3 y 4 segundos, mientras que para PM está entre 0 y 1 segundo.

Tras determinar las mejores combinaciones de los modelos sencillos se elaboraron los modelos globales. El mejor modelo global para cada contaminante se muestra en la Tabla 2.

Modelo	Variabilidad Explicada	MSE-OOB	MAPE	MSE
NOx34	77,35	0,001162	1,66	0,001158
PM11	82,71	2,76E-09	0,206	3,00E-09

Tabla 2 – Resultados de los mejores modelos globales (Cueto-Felgueroso, 2018)

A continuación, al mejor modelo global se incorporó la altitud y la pendiente, obtenidas con los dos métodos, como variables explicativas, cuyos rangos de valores se muestra en la Tabla 3. En la nomenclatura de los modelos se incorpora una V en el caso de utilizar los perfiles de altitud y pendiente con la aplicación *GPS Visualizer*, y una E para el Método Experimental.

Variable	Unidades	Rango de valores
Altitud	m	500,13 – 729,39
Pendiente	%	-3,46 – 5,01

Tabla 3 – Unidades e intervalo de valores de las variables altitud y pendiente (Cueto-Felgueroso, 2018)

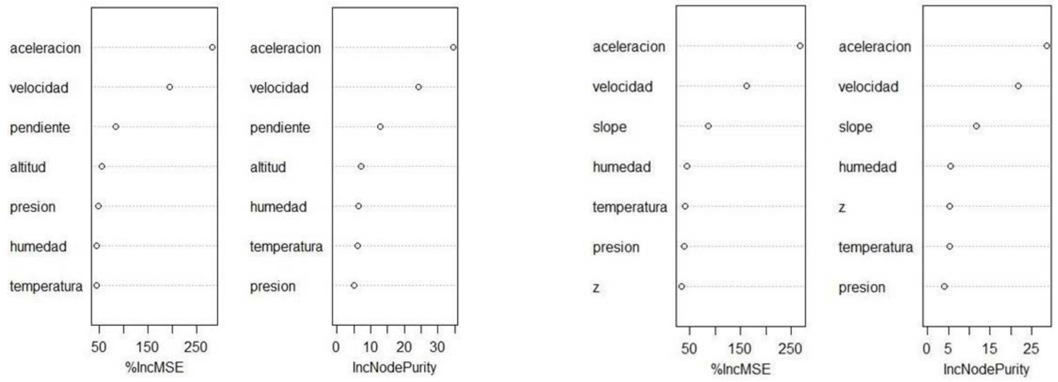
La Tabla 4 presenta los resultados de los *modelos globales con altitud y pendiente* de los dos contaminantes.

Modelo	Obtención de la altitud	Variabilidad Explicada	MSE-OOB	MAPE	MSE
		a) NOx			
NOx34V	**GPS Visualizer**	**83,14**	**0,000813**	**1,15**	**0,000816**
NOx34E	Método experimental	81,29	0,000836	1,22	0,000904
		b) PM			
PM11V	**GPS Visualizer**	**85,87**	**2,39E-09**	**0,18**	**2,62E-09**
PM11E	Método experimental	82,61	2,86E-09	0,20	4,19E-09

Tabla 4 – Resultados de los modelos globales con altitudes y pendientes. a) NOx y b) PM (Cueto-Felgueroso, 2018)

Tanto para NOx como para PM los mejores resultados se alcanzaron con los perfiles de altitud y pendiente obtenidos con la aplicación *GPS Visualizer* (modelos NOx34V y PM11V, respectivamente). No obstante, el método experimental proporciona unos valores similares, y la incorporación de estas variables explicativas mejoraron los modelos, aumentando la variabilidad explicada, un 7,48% en el caso del contaminante NOx y un 3,82% para PM.

Las Figuras 4 y 5 recogen la importancia de las variables explicativas para los dos métodos de obtención del perfil de altitud por los criterios MSE y Gini, para los contaminantes NOx y PM, respectivamente.

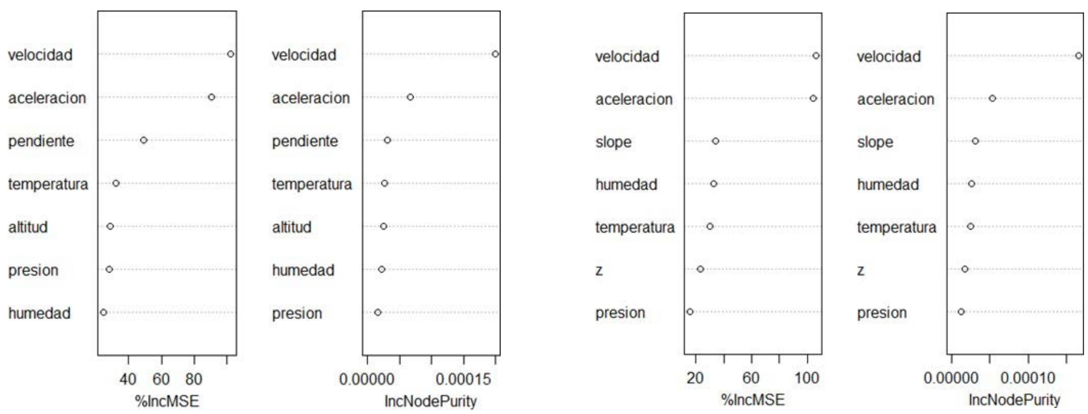


a) Método *GPS Visualizer* (NOx34V) b) Método Experimental (NOx34E)

Fig. 4 – Importancia de las variables en el modelo global de NOx con altitud y pendiente. a) Método *GPS Visualizer* y b) Método Experimental (Cueto-Felgueroso, 2018)

En la Figura 4 se observa que para el contaminante NOx en ambos métodos la variable más importante es la aceleración, seguida de la velocidad. La pendiente (*slope*) es más influyente que la altitud (*z*). Para el modelo NOx34V la altitud es la cuarta variable más influyente por los dos criterios. Mientras que para el modelo NOx34E la altitud está en la última posición por el criterio MSE y en la quinta por el criterio Gini, esto se debe a que los valores de las alturas se han obtenido a partir de la presión barométrica en cada cota, por lo que los perfiles obtenidos dependen en gran medida de las componentes ambientales.

La Figura 5 muestra que para el contaminante PM en ambos métodos la variable más importante es la velocidad, seguida de la aceleración. La diferencia entre ambas variables es muy notable según el criterio de Gini, y no ocurre lo mismo para el criterio MSE. En los dos métodos la pendiente ocupa la tercera posición siendo más influyente que la altitud.



a) Método *GPS Visualizer* (PM11V) b) Método Experimental (PM11E)

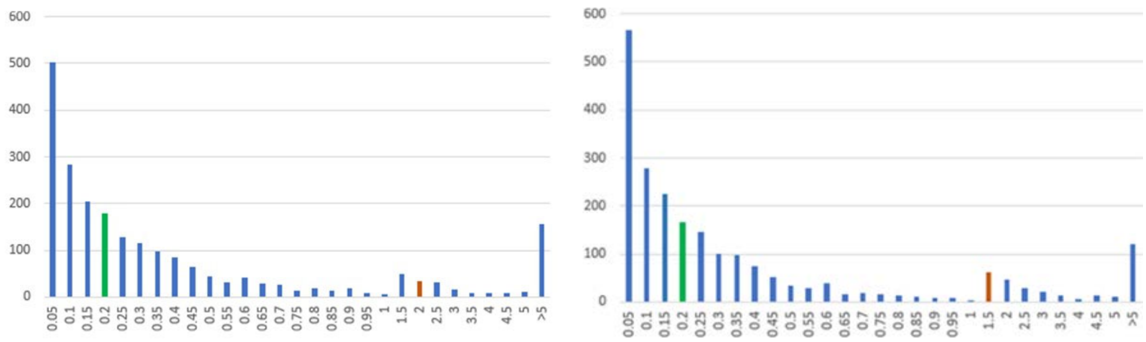
Fig. 5 – Importancia de las variables explicativas en el modelo global de PM con altitud y pendiente. a) Método *GPS Visualizer* y b) Método Experimental (Cueto-Felgueroso, 2018)

Las Figuras 6 y 7 presentan las distribuciones del error relativo de las predicciones realizadas con el conjunto de datos *test set* en el mejor modelo global para NOx y PM, respectivamente. Antes de incorporar la altitud y pendiente en (a) y después de la incorporación en (b). Se representa la mediana del error en verde y la media en marrón.

La Figura 6a presenta el histograma del error relativo del modelo NOx34**.** La mediana se sitúa en 0,18, la mitad de los datos presentan un error menor o igual al 20%. El valor medio es de 1,66. La diferencia entre la mediana y la media es muy elevada debido al número de observaciones concentradas en el final de la cola del histograma.

Aunque dicha cantidad suponga un 15% del total de datos del conjunto *test set*, al presentar valores que superan el 100% del error, contribuye a elevar significativamente la media, hasta alcanzar un valor casi diez veces más elevado que la mediana.

La Figura 6b presenta el histograma del error relativo del modelo NOx34V. El valor de la mediana es 0,16, por lo que la mitad de los datos presenta un error menor o igual a 20%, como ocurría antes de incorporar la altitud y pendiente. Sin embargo, se ha conseguido reducir su valor en un 11,11%. El valor medio es 1,15, un 30,7% menos que el *MAPE* antes de incorporar la altitud como variable explicativa. La diferencia entre la mediana y la media se ha reducido un 22,12%. Sin embargo, sigue demasiado elevada debido al número de observaciones del conjunto *test set* que se acumulan en el final de la cola del histograma, correspondiente a los valores más altos del error. Destacan la reducción en un 21,8% de la cantidad de datos que presentan un error superior a cinco y el incremento de un 11,3% de los datos que presentan el valor más bajo del error.

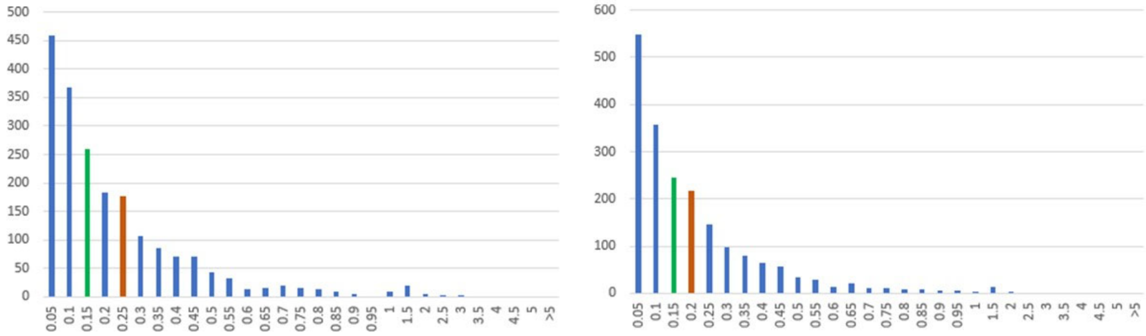


a) Sin altitud y pendiente (NOx34) b) Con altitud y pendiente (NOx34V)

Fig. 6 – Dispersión del error relativo para el conjunto de datos *test set* en el mejor modelo global para NOx. a) sin altitud y pendiente y b) con altitud y pendiente (Cueto-Felgueroso, 2018)

Se concluye que considerar la pendiente y la altitud en el estudio de las emisiones del contaminante NOx mejora el ajuste de los modelos. Se redujo de forma notable la cantidad de observaciones que se acumulan en cada uno de los intervalos del error relativo.

Sin embargo, existe un número de observaciones que, aunque no llegan a representar un cuarto del total de los datos, presentan unos valores tan elevados que incrementan de manera considerable el error relativo medio. Para esos datos, el modelo no se ajusta correctamente, a diferencia de lo que ocurre con la mayoría de las observaciones.



a) Sin altitud y pendiente (PM11) b) Con altitud y pendiente (PM11V)

Fig. 7 – Dispersión del error relativo para el conjunto de datos *test set* en el modelo global para PM. a) sin altitud y pendiente y b) con altitud y pendiente (Cueto-Felgueroso, 2018)

La Figura 7a presenta el histograma del modelo PM11. El valor de la mediana es de 0,13, indicando que la mitad de los datos presentan un error menor o igual a 15%. El valor medio es de 0,206, o sea 1,58 veces el valor de la mediana. Aunque la diferencia no es despreciable, es significativamente menor que la mostrada en el estudio del contaminante NOx. En la cola del histograma no hay observaciones con error mayor o igual a 3,5. Pese a que la cantidad de observaciones del conjunto *test set* con un error mayor o igual a 1 representa un 1,96% del total de observaciones, al presentar un error superior al 100% contribuyen a aumentar el valor medio del error relativo. La mayoría de los datos se agrupan en valores bajos del error, que son menores que los obtenidos en el análisis del contaminante NOx, demostrando que el modelado de PM se ve menos afectado por factores externos.

La Figura 7b representa el histograma del error relativo del modelo PM11V. La mediana es 0,12, por lo que la mitad de los datos presenta un error menor o igual a 15%, como ocurría antes de incorporar la altitud y la pendiente. No obstante, se redujo su valor un 8,46%. El valor medio del error es de 0,18, lo que supone una disminución de un 12,62%. Al introducir las dos nuevas variables explicativas se consiguió acortar aún más la cola del histograma, ya que ninguna observación del conjunto *test set* presenta un error superior a 2,5.

Disminuyó el número de datos con un error superior a 1 hasta un 1,26% del total. Sin embargo, la cantidad de datos con un error del 95% experimentó un ligero aumento, pasando de ser nulo a 7. Pese a ello, para el resto de los intervalos con errores elevados (0,5 a 0,75), el número de datos se ha mantenido o ha disminuido.

Se concluye que incorporar la altitud y la pendiente como variables explicativas contribuyó a mejorar el modelo de predicción de PM. La gran mayoría de las observaciones se agrupa en valores bajos del error.

Los errores son mucho menores que los obtenidos con el contaminante NOx, demostrando que cada uno de ellos se ve afectado por diferentes factores.

5. CONCLUSIONES

Los modelos que consideran el desfase entre las curvas de variables cinemáticas y de caudal de contaminante conducen a mejores predicciones. Sin embargo, los modelos obtenidos presentan unos errores significativamente elevados a raíz de las fuentes de variabilidad asociadas a las variables estudiadas, por lo que no han sido capaces de adaptarse de manera precisa a los datos.

La incorporación de la altitud y pendiente como variables explicativas contribuyó a una notable mejora de los modelos. Pese a que las predicciones son más precisas y se redujeron significativamente los errores, éstos siguen siendo no despreciables, por lo que es posible que no se esté considerando algún efecto que sea muy relevante en el modelado de las emisiones.

La utilización de los perfiles de altitud y pendiente elaborados a partir de la aplicación *GPS Vizualizer* conduce a mejores resultados en comparación con los perfiles determinados a partir de la altura sobre el nivel del mar.

Ambos métodos, teórico y experimental, coinciden a la hora de determinar que la pendiente es la variable que más influye después de las cinemáticas (velocidad y aceleración).

AGRADECIMIENTOS

Este trabajo se realizó en el proyecto de investigación CÍCLOPE (Sistema de optimización de ciclos urbanos de conducción. Aplicación a la generación de patrones adaptados a exigencias medioambientales y situaciones de explotación de flotas de vehículos) financiado por el Plan Nacional 2016-2018 del Ministerio de Economía y Competitividad- Programa Estatal de Investigación, Desarrollo e Innovación Orientada a los Retos de la Sociedad. TRA2015-68803-R. Los autores también agradecen a la Comunidad de Madrid, que contribuyó a la difusión de este trabajo a través del Programa SEGVAUTO 4.0-CM (S2018-EMT-4362).

NEW UNCONVENTIONAL SOURCES OF INFORMATION FOR TRANSPORT ANALYSIS. THE CASE OF A MODEL FOR PUBLIC TRANSPORT SERVICES IN MAJORCA

Oscar Martínez-Alvaro
Transport Professor (UPM). Transport Researcher (Transyt); Managing Partner (Tool Alfa)
Iván Hernández Santana
Junior Consultant (Tool Alfa)

ABSTRACT

Most transport modeling requires the use of data available in official sources plus complementary information that helps to fill gaps. This later information is mostly obtained with the help of private data and field data collection. But sometimes this field data collection is not possible for several reasons. On the other hand, there are more and more sources of information readily available, which may provide indirect clues about users' behavior.

Within the framework of a bidding process, a modelling of Majorca's public transport was carried out in order to ascertain elasticities of demand to several parameters of supply that were expected to change. For that purpose, there appeared a need of getting detailed information on tourist activities, which are a huge share of total mobility in summertime. Official information on population is rather detailed, but tourism data are available only on an aggregated basis.

Some indirect sources of information were analyzed. The easiest and most useful ones were *TripAdvisor* and *Booking*. The former is sort of a macro-survey of popularity and it seems logical that those nuclei with more opinions are those most visited, thus acting as an indicator of attraction. The latter provides information on location of accommodation offered, thus providing a tool for the geographical distribution of trip generation on a very detailed basis. In total, 933,934 opinions for 198 nuclei from *TripAdvisor,* and 2,114 accommodation assets for 51 Municipalities from *Booking* were used. With this information it was possible to calibrate different models for the whole Island, this opening the door to further analyses in the field of transportation and mobility.

The Transport Consortium of Majorca (CTM), entity in charge of planning and management of scheduled public transport services on that island, published in March 2019 the call for tenders for all intercity public passenger transport services by bus. It opened a scenario of important changes (CTM 2017a and 2017b) that sought to increase the total demand of the intercity bus network by 25% between 2015 and 2028, by means of a substantial variation in the supply side (travel times, timetables, connectivity between lines, etc.). For example, an increase in supply between 35.8% and 73.1% of vehicle-km was planned, with different figures for each of the three packs into which the tender was divided. In addition, a new fare system was introduced, with a very complex structure that imposed a heavy surcharge when purchasing the ticket on the bus. However, no technical study with more information on the expected demand figures was released.

Under these circumstances, any projection of the historical data was irrelevant and one of the bidding companies, which also operated a good part of the existing services, felt the need of calculating the expected demand with scientific tools.

The analysis of the problem in question faced, fundamentally, an important lack of detail of the available information:

- As for transport supply or demand, the official information was limited to total figures by line (CTM, 2017 and "Open Data" site).
- In terms of demand factors, the greatest disaggregation available in official sources (ibestat) was at municipal level.

The following sections focus on the cross-section analysis of the general services, without dealing with other issues analyzed at the time, such as the new lines to the airport and the time-series modeling.

1. THE CONTEXT

Majorca has about 3,600 km² and 868,700 inhabitants (2017). It has 53 municipalities, overshadowed by the capital, Palma, with 406,500 inhabitants (47% of the total). It is a top-level tourist destination: in 2017 Majorca received 11.6 million tourists.

The most important tourist areas are Calvià and Palma, as well as the east coast, while the municipalities in the center of the island have a much lower tourist activity. Tourism presents strong seasonality, with the maximum in the summer months and small volumes in winter.

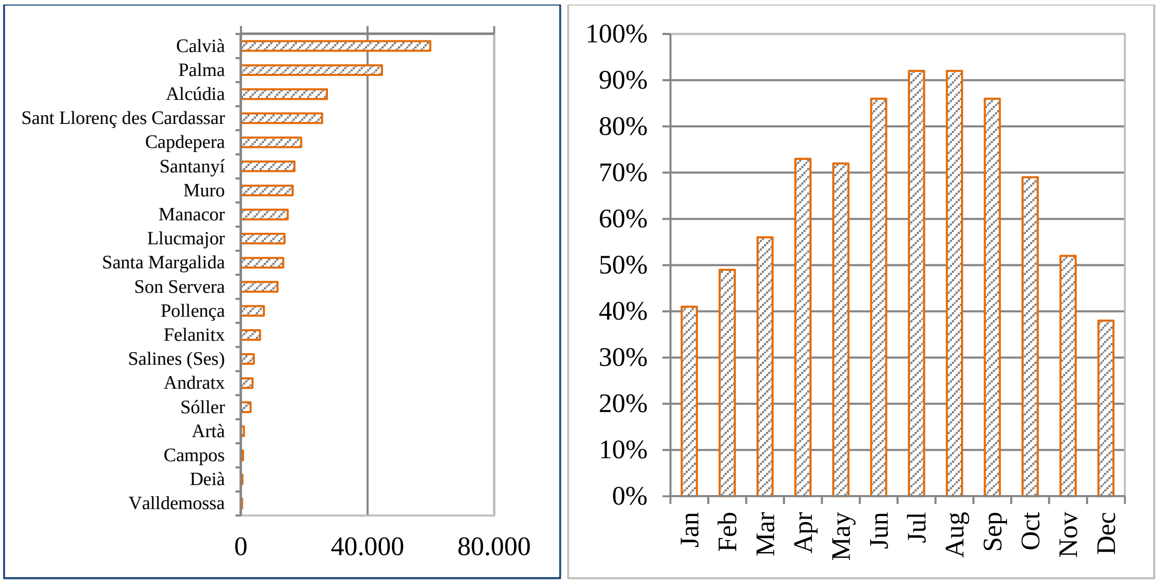

Fig. 1 - Bed capacity of the 20 municipalities with the highest volume (left) and hotel occupancy of the whole island per month (right). (2017). Source: Own elaboration with IBESTAD data

The number of vehicles is very high, due to the presence of an important rent-a-car activity. Vehicles are distributed territorially by fiscal considerations: the most extreme case is this of Escorca, where the car ownership rate is 22,000 vehicles per 1,000 inhabitants.

The island has two railway lines and one subway line, but its territorial coverage is feeble, particularly in tourist areas, with the exception of the Sóller railway, a tourist attraction in itself. The structure of the intercity bus network is essentially this of spokes directed towards Palma, with great concentration on the east coast.

The demand for the rail is not subject to the same seasonality of the intercity bus, whose demand is closely linked to tourism. The correlation between the airport demand and the bus demand is remarkable, while the huge share of the single ticket for bus users is another proof of the sporadic nature of its patronage.

2 THE INPUTS

2.1Conventional sources

The information available for calibration was initially of two types:

- The one from official sources, with disaggregation, at best, at municipal levela or at line level.
- The one available by the operator itself, of a strictly internal nature, on a line basis lines (lines 100, 102, 104, 105, 106, 107, 111, 500, 501, 502, 503, 505, 507, 515, 520, 525, 530 y 811). It included demand data for 271 Origin-Destination pairs in nine tariff groups and other data (pax-Km, total revenues per line, etc.).

Given the complexity of the variation of the new tariff structure (based on number of areas crossed and accumulation of travel points), a face-to-face survey of revealed preferences was carried out among almost one thousand users, which shed enough light on that particular problem.

2.2 Possible alternatives

As the problem of lack of enough granularity to characterize the demand factors persisted, a research of alternative means was carried out. Many references to the potential of big data were found (Anda, 2017) and a large sample of analyses based on mobile phone data were of public domain (Alexander, 2015; Bonnel, 2015), besides many other related to different innovative sources of information, such as smart cards. But no solution that could identify trips on a detailed basis was available. In particular, mobile phone data could not provide transport mode information with the required reliability.

Some warnings were also found on the topic of potential problems of trying to use data not oriented to mobility analyses, mainly in terms of data volume availability and owners' willingness to allow it to be used by third parties (Milne y Watling, 2019). But something had to be done and two highly atypical sources of information showed some interest:

- *TripAdvisor* as an indicator of attraction.
- *Booking* as an indicator of tourist residence location.

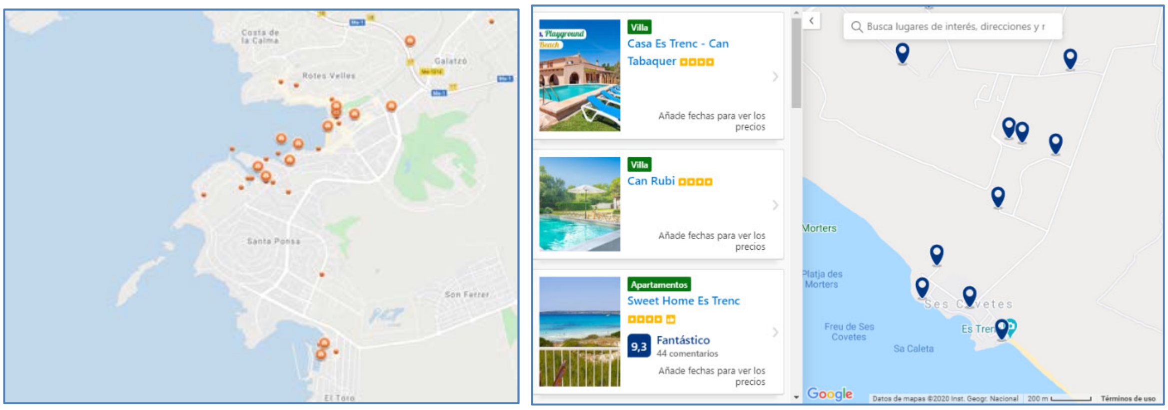

Fig. 5 - Screenshots of TripAdvisor (left) and Booking (right) websites.
Source: TripAdvisor.es and Booking.com.

2.3 TripAdvisor

TripAdvisor.com is a website owned by Tripadvisor, Inc. that provides reservations for travel-related activities, with the particularity of collecting user reviews. In that sense, *TripAdvisor* acts as a popularity survey. The basis of using this source is the hypothesis that the number of visits to a certain site of tourist interest is strongly correlated with the number of opinions recorded on *TripAdvisor*, irrespective of their attitude (positive, neutral or negative).

In total, 198 locations were analyzed manually on which 933,934 opinions were found.

The information obtained was as follows:

- Location of the tourist site.
- Type of tourist interest (general, leisure, accommodation, catering).
- Number of opinions collected.

2.4 Booking

In Majorca there is official information on the number of accommodation places per municipality, but without further disaggregation. As there is a notable dispersion and there is a great diversity of establishments of very different sizes, it was hypothesized that the territorial distribution of beds within each municipality could be significantly proportional to the location of establishments.

The source of information in this case was Booking, a virtual agency specialized in hotel reservations, owned by Booking Holdings Inc., a holding company listed on the American Nasdaq that includes other tourism-related companies such as Kayak or Momondo.

Booking offers reservations for establishments whose location can be viewed in an on line map. As in TripAdvisor, Booking has an option for user valuation, but this feature was not considered relevant and the analysis consisted of merely identifying the different locations according to a predefined zoning, related to the bus stops, simply using the “map view” available in the search engine. A total of 2,114 establishments were identified in a total of 203 different zones.

3. THE FORMULATION

In this case, the objective was to calculate the bus demand, so the analysis was focused only in this transport mode, leaving aside the railway (both because the corridors mostly do not coincide, and because of its very different seasonality) and the car (with a much larger market share).

A generalization of the classic gravity model was used, as follows:

$$T_{ij} = \alpha\ \pi(G_{rij}^{g})\ \pi(A_{sij}^{a})\ c_{ij}^{k} \qquad (1)$$

Where the notation is as follows:

- T_{ij} = volume of demand between zones “i” and “j”.
- α = parameter.
- π = multiplication operator.
- r = ordinal index of the different possible indicators of trip generation.
- s = ordinal index of the different possible indicators of trip attraction.
- G_{ij}= Generating potential of zone “i” and zone “j”.
- g = parameter of the generation factors, equal to the corresponding elasticity of demand.
- A_{ij}= Attractor potential of zone “i” and zone “j”.
- a = parameter of the attraction factors, equal to the corresponding elasticity of demand.
- c_{ij}= friction factor between both zones.
- k = parameter of the friction factor, equal to the elasticity of demand to the friction factor.

The selection of the different model formulations and the selection of the corresponding variables followed a trial and error process, through regression analysis between the 2017 demand data for the 271 origin-destination pairs and various independent variables (all of them oriented to the forecast in the following phase). The best explanatory capacity was found with the following variables:

- Sum of population of origin and destination.
- Sum of indicators of tourist attraction (*TripAdvisor*) of origin and destination.
- Sum of tourist places by zone (*Booking*) of origin and destination.
- Fare distance (km). It is the nominal distance between origin and destination used for pricing. It is almost identical to actual road distance, with minor differences.
- Fare rate (€/pax-km). It is the price per pax-km that multiplied by the fare distance gives the tariff.

The number of services per line was discarded out, although it is an excellent indicator of quality from the point of view of users. The reason was the high correlation between number of services and demand, as expected in any sensible operation: the lesser the demand volume, the less services the operator provides.

3.1 The results

The results can be synthesized as follows, expressed through the coefficients of the corresponding variables (which are the corresponding elasticity) and the regression statistics.

<table>
<tr><th colspan="2">Variable/Indicator</th><th>Tourist generation only</th><th>Tourist attraction only</th><th>Generation and tourist attraction</th></tr>
<tr><td rowspan="5">Elas-ticity</td><td>Population</td><td>0,72</td><td>0,64</td><td>0,56</td></tr>
<tr><td>Tourist attraction</td><td>-</td><td>0,70</td><td>0,51</td></tr>
<tr><td>Tourist generation</td><td>0,65</td><td>-</td><td>0,37</td></tr>
<tr><td>Fare distance</td><td>-2,27</td><td>-2,37</td><td>-2,41</td></tr>
<tr><td>Fare rate</td><td>-2,51</td><td>-2,53</td><td>-2,62</td></tr>
<tr><td rowspan="2">Statistic s</td><td>Multiple correlation coefficient</td><td>0,66</td><td>0,67</td><td>0,68</td></tr>
<tr><td>R2 adjusted</td><td>0,42</td><td>0,44</td><td>0,45</td></tr>
</table>

Table 1 - Elasticities and indicators obtained. Source: Own elaboration.

Although the quality of the adjustment is not high, the values of the exponents are very reasonable. From the point of view of forecasting, the similarity of exponents of the fare distance and the fare rate were interesting, corroborating the fact that the trip friction is given, simply, by the trip price.

4. CONCLUSIONS AND FINAL REFLECTIONS

An adequate understanding of mobility in a specific area requires data of according quality, which usually official sources do not provide, for lack of detail. Sometimes these data can be obtained through surveys or other measurements, but often there are important restrictions due, for example, to seasonality.

Many studies have a strict completion period, especially if they are related to tendering processes, and then it is not reasonable to waste any effort that is expected to be fruitless.

In today's world there are numerous sources of information that can act as explanatory variables of demand or as *proxies.* In the study described above, even with a very simple approach, it was possible to find some clues about the trip attraction and generation, in particular thanks to two portals with a purely commercial objective: *TripAdvisor* and *Booking*.

The results obtained, have not only been useful for the study, but also point in the direction of the potential value of the huge amounts of information currently available, which are usually a mere by-product of commercial businesses.

The data obtained in the study were manually obtained, but this did not entail excessive consumption of resources.

Although it is conceivable to obtain that information massively, thanks to some automation, the data is not designed for that purpose and the automation would foreseeably face strong protections.

But it is not unlikely that the companies that own this type of data can sell them to third parties, as some mobile phone operators are already doing, provided privacy and other legal issues are respected. For such companies, this is not their core business and it will never be a source of large-scale revenue.

But it seems that there is a certain market and the companies in question have experience in diversifying very intelligently. Everybody would benefit from it, not least transport planners and transport economists.

RESUMEN

El objetivo del presente artículo es exponer la metodología seguida para obtener matrices Origen/Destino a partir de datos masivos geolocalizados (trazas GPS). Se trata de una metodología que actúa de manera complementaria con los procedimientos tradicionales de aforo. Las principales ventajas derivadas de esta metodología radican en una reducción de tiempos y de costes en los proyectos, además de aportar mayor fiabilidad en los resultados de los modelos al tratarse de matrices muestra obtenidas a partir de valores reales.

Existen distintas variaciones de la metodología, pudiendo ésta adaptarse a proyectos tanto de micromodelación como de macromodelación, convirtiéndola en una metodología muy flexible.

Esta metodología ya ha sido probada en distintos proyectos, obteniendo resultados satisfactorios, aunque también es cierto, que se encontraron ciertas debilidades en los procesos. Estas debilidades se han subsanado mediante la aplicación de algoritmos de Inteligencia Artificial (IA).

El presente artículo detalla los diferentes procedimientos de obtención de matrices, así como un análisis de sus debilidades y mejoras desarrolladas. Finalmente, una comparativa con los modelos tradicionales de obtención de matrices y los resultados obtenidos en los proyectos en los que se implantó esta metodología.

1. PROCEDIMIENTOS

Como se ha mencionado previamente, existen ciertas diferencias a la hora de aplicar la metodología a un proyecto de macrosimulación o a uno de microsimulación. A continuación, se exponen mabas metodologías, así como sus diferencias y las debilidades.

1.1 Macromodelización

El proceso de macromodelización responde al siguiente esquema:

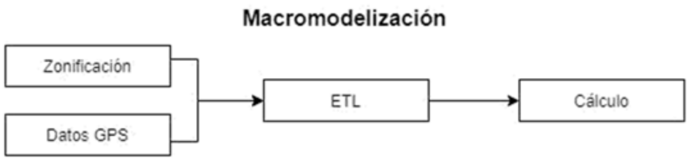

Figura 1. Esquema del proceso aplicado a macromodelización. Fuente: Elaboración propia

A continuación, se detalla cada uno de los componentes del proceso:

- Zonificación
  Se definen cada una de las áreas que servirán para establecer los posibles orígenes y destinos de los viajes. Aquellos viajes que comiencen o acaben fuera de las áreas establecidas, son agrupados en un área ficticia, denominada “Zona exterior”
- Datos GPS
  Cada registro representa la posición de un vehículo en un instante determinado.
- ETL (Extraxt Transform Load)
  En este proceso se transforman los datos existentes, se generan nuevas variables y se eliminan aquellos registros que no son necesarios para el proceso “Cálculo”. Con este proceso se reduce el tiempo de cálculo.
- Cálculo
  Una vez que se han realizado los pasos anteriores, se extraen los orígenes y destinos de cada uno de los trayectos. El resultado final es un archivo formato csv con la matriz OD deseada.

1.2 Micromodelización

El proceso de microsilulación responde al siguiente esquema:

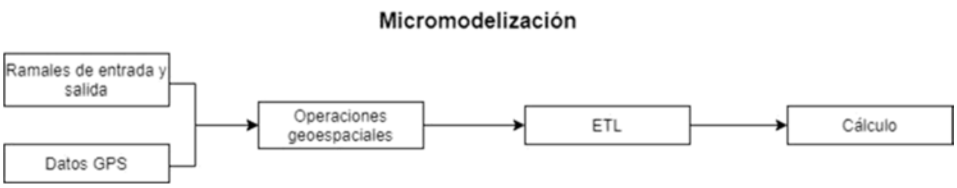

Figura 2. Esquema del proceso aplicado a microsimulación. Fuente: Elaboración propia.

Se observa cómo, las principales diferencias entre metodologías radican en los datos de entrada y en las operaciones geoespaciales.

A continuación, se detalla cada uno de los componentes del proceso:

- Ramales de entrada y salida
  Se definen cada uno de los ramales que intersectan con el contorno del área de estudio.
- Datos GPS
  Cada registro representa la posición de un vehículo en un instante determinado.
- Operaciones geoespaciales
  El objetivo de este paso es doble: disminuir la cantidad de registros que no se encuentran en nuestra área de estudio y eliminar posibles *outliers* o registros fuera de rango.
- ETL
  En este proceso se transforman los datos existentes y se generan nuevas variables necesarias para procesos posteriores. Este proceso es fundamental para reducir tiempo de cálculo.
- Cálculo
  Una vez que se han realizado los pasos anteriores, queda un conjunto de datos tratados de los cuales se extrae el ramal de entrada y salida de la zona de estudio de cada uno de los viajes. El resultado final es un archivo csv con la matriz deseada.

1.3 Debilidades encontradas

Como cualquier metodología, presenta una serie de ventajas, pero al mismo tiempo una serie de debilidades. Es importante realizar un análisis de estas a fin de conocer las flaquezas del proceso y poder implementar poco a poco medidas que permitan corregirlas.

A continuación, se enumeran las debilidades encontradas principalmente en la metodología de micromodelización. Cuando se aplica la metodología en los casos de micromodelización, existen una serie de inconvenientes que no ocurren en los casos de macromodelización. Esto se debe a que el detalle que se busca en este tipo de proyectos es mucho mayor.

Los dos principales inconvenientes son:

- Tiempo elevado a la hora de preparar los datos de entrada.
  La preparación de los datos de entrada es una tarea de carácter manual. Además, al tratarse de una tarea de esta naturaleza, hay que tener en cuenta la posibilidad de introducir errores de carácter humano.
- Tiempo elevado en el proceso “Cálculo”
  Se trata del proceso que más tiempo y recursos de la máquina consume.

1.4 Mejoras implementadas

A continuación, se describe una herramienta desarrollada que emplea una metodología mejorada que subsana los principales inconvenientes mencionados anteriormente.

Esta nueva metodología emplea algoritmos que provienen de distintos campos de la Inteligencia Artificial (IA), como son algoritmos de *machine learning* y algoritmos de búsqueda.

El esquema de esta nueva metodología es el siguiente:

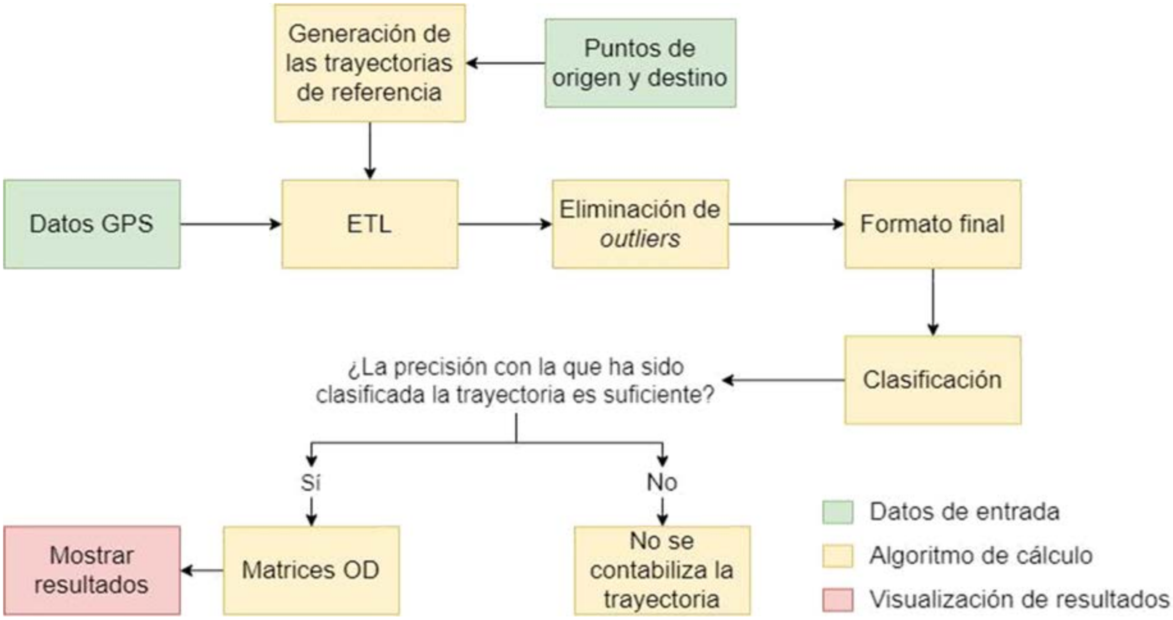

Figura 3. Metodología de mejoras implementadas. Fuente: Elaboración propia.

Los procesos de la metodología actualizada son los siguientes:

- Datos de entrada.
  - Datos GPS.
    Igual que en los casos anteriores, cada registro representa la posición de un vehículo en un instante determinado.
  - Puntos de origen y destino.
    Puntos en las calles que representan los orígenes y destinos de la matriz OD.
- Generación de las trayectorias de referencia.
  A partir de los puntos de origen y destino se generan todas las posibles rutas entre el cada origen y destino, que servirán para clasificar los viajes.
- ETL.
  Se transforman al formato deseado las variables existentes y se generan nuevas variables para hacer posible la clasificación de las trayectorias.

- Eliminación de *outliers*.
  Se eliminan las trayectorias que no cumplan con una serie de condiciones mínimas que, en el caso de tenerlas en cuenta, generarían ruido en la clasificación e, incluso, llegar a generar una clasificación errónea.
- Formato final.
  Una vez realizado los pasos anteriores, se preparan los datos para que puedan ser ingeridos por parte de los algoritmos de *machine learning.*
- Clasificación.
  Mediante algoritmos de *machine learning* se identifican las carreteras por las que entra y sale cada vehículo de la zona de estudio.
- Matrices OD.
  Se genera la matriz OD deseada.

Gracias a esta nueva metodología, no solo las debilidades de la metodología anterior son subsanadas, sino que además se obtienen nuevas mejoras:

- Los tiempos de preparación de los datos de entrada y de cálculo se han reducido.
  La preparación de los datos es sumamente menor empleando la nueva herramienta, siendo 15 veces menor en las pruebas realizadas. A su vez, el tiempo de cálculo se han reducido de manera destacable, siendo ahora aproximadamente 60 veces más rápido que la metodología anterior.
- Se convierte en un proceso automático.
  Se han automatizado todos los pasos que antes eran manuales (la única tarea manual es generar los puntos de origen y destino).
- Se ha creado una interfaz de usuario.

Ahora existe una interfaz gráfica que le permite al usuario no solo explotar los datos de manera sencilla, sino que además puede realizar un análisis exploratorio de los resultados obtenidos.

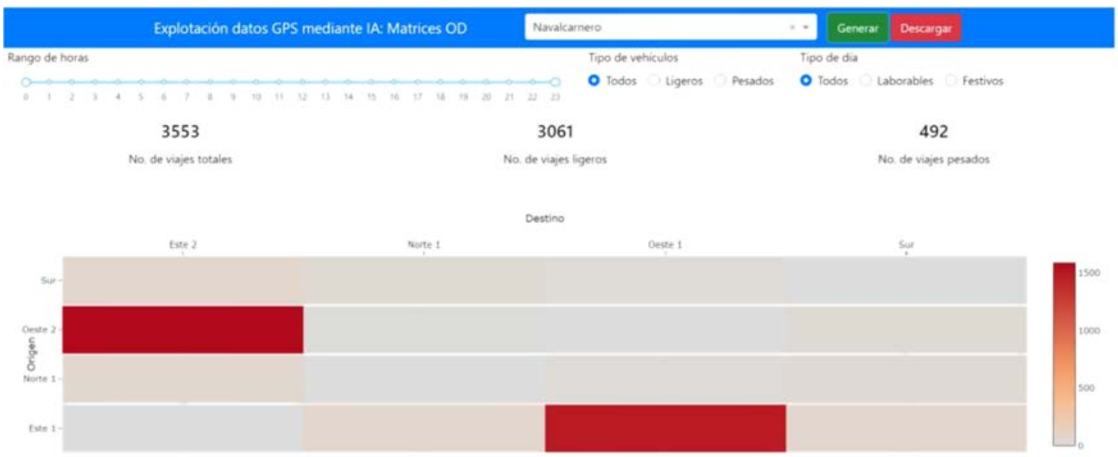

Figura 4. Interfaz de usuario desarrollada. Fuente: Elaboración propia.

Finalmente, la distribución de los vehículos obtenida mediante la nueva herramienta, como ocurría con la herramienta anterior, es similar a la distribución obtenida mediante aforamientos físicos (porcentaje de vehículos totales capturados por movimiento).

2. VENTAJAS Y DESVENTAJAS DE LA METODOLOGÍA CON RESPECTO A LAS METODOLOGÍAS TRADICIONALES

Actualmente se dispone de una amplia gama de metodologías para la detección de tráfico, desde la más tradicional, como es el caso del aforo manual, hasta las más actuales, como es el de lectores de matrículas o sistemas de detección por bluetooth.

La nueva metodología puede considerarse que comparte el mismo principio que los sistemas de detección por bluetooth, dando por hecho que hoy en día todo el mundo viaja con un móvil encima y que de la información que este generase puede obtener un beneficio, concretamente la información es el posicionamiento del aparato.

La diferencia es que los sistemas de bluetooth usan la detección de móviles que pasan por una sección en la que se colocan los detectores y esta nueva metodología es mucho más flexible y fiable.

Esta nueva metodología permite solventar los principales problemas de los métodos tradicionales disponibles, al ser una metodología basada puramente en la compra de datos de posicionamiento y su procesamiento. A continuación, se detallan las ventajas de la metodología:

- No son necesarios trabajos de instalación ni mantenimiento in situ en la zona de estudio, eliminando todos los problemas relacionados con: corte de vías por obras para su instalación o reparación, dependencia de las inclemencias meteorológicas o la no detección de vehículos a baja velocidad.
- Los resultados no se ven afectados por condiciones meteorológicas adversas.
- Proceso muy económico, puesto que no existen instalaciones al uso para la obtención de los datos, sino que el coste dependerá del volumen de datos que se quieran comprar y del ingeniero de datos que los procese bajo esta metodología.
- Reducción de tiempos, esta metodología permite obtener información de una zonificación mucho más amplia de la que permitirían el procesamiento por separado de cada una de las zonas como se realizaría de forma tradicional.
- Flexibilidad, al disponer de los datos en bruto el procesamiento de los datos se pueden orientar de diferentes enfoques de un mismo proyecto, permitiendo obtener matrices distintas si se desean cambiar la zonificación cambiando el proceso de tratamiento de los datos. Con las metodologías tradicionales requeriría la realización de nuevos aforos con el incremento del coste con cargo a proyecto que supondría.

- Mayor alcance temporal, permite tratar datos en bruto de varios días por lo que permite realizar por lo que permite un análisis del comportamiento del tráfico en la zona de estudio que no se encuentre limitada a horas como ocurre con las metodologías tradicionales.

Por contraposición se pueden mencionar las siguientes desventajas detectadas:

- Limitación de precisión en el posicionamiento, para casos microscópicos algunos datos pueden presentar desviaciones de posicionamiento. Esta desviación no depende tanto del dato sino del móvil que se encuentra emitiendo la señal.
- Como consecuencia del punto anterior, no es posible llevar a cabo una segregación de tráfico por carriles.
- Ratios de ocupación de vehículos, el proceso tiene en cuenta el posicionamiento de los móviles y GPS, pero no es capaz de detectar si esos móviles o GPS van en el mismo vehículo y por lo tanto el viaje sería solo uno.
- Representatividad de la muestra, al estar tratando con los datos de posicionamiento la representatividad dependerá en mayor o menor medida de las compañías que hayan cedido esos datos. En un supuesto idílico, si solo existiera una compañía la muestra obtenida con esta metodología sería prácticamente toda la población. Este es el principal motivo por el que estas matrices se usan como apoyo en los estudios de tráfico, pero no son, ni se pretende que sean, la matriz de origen y destino definitiva. Siendo necesario complementar esta metodología con otras tradicionales.
- Preprocesamiento, es necesaria una tarea de limpieza de los datos en bruto para incrementar la fiabilidad que se realiza de forma manual, por lo tanto, se encuentra sujeta a un porcentaje de error en el tratamiento de los datos.

3. APLICACIONES

3.1 Calibración de matrices

El principal objetivo de eso de la metodología es una mejora de la calidad de resultados en los trabajos de calibración de los modelos de tráfico. Llegado este punto es necesaria la diferenciación de la metodología a nivel macroscópico y microscópico.

- Nivel Macroscópico

Tradicionalmente la obtención se matrices obtenían a partir de métodos tradicionales de recogida de datos como las encuestas domiciliarias o de intercepción, y en función de la población se podía obtener una primera matriz para iniciar el proceso de calibrado manual.

- Nivel Microscópico

  Tradicionalmente la obtención de matrices se realiza a través de un ajuste (dinámico o estático) entre una matriz de ceros y unos y un plan de aforos de la red del modelo. La matriz resultante del ajuste es el punto de partida para el inicio de la calibración manual.

En ambos casos el proceso de calibración manual es muy sensible a los datos de entrada, resultados de encuestas para macro y de los aforos para micro. La calidad de estos condiciona en gran medida el tiempo que posteriormente se invierte en la calibración manual del modelo para el cumplimiento de los estándares de calidad del modelo.

El uso de las matrices estimadas a partir del posicionamiento GPS añade un grado de robustez a todos estos procesos.

A nivel macroscópico permite corregir los sesgos que derivan de las encuestas. Puesto que el posicionamiento es un dato real que queda registrado, y no depende del sesgo generado por el comportamiento real del usuario versus comportamiento que el usuario afirma tener.

A nivel microscópico permite obtener una matriz resultante del ajuste más cercana al comportamiento real en la red, eliminando los errores derivados de un uso de matriz ficticia de ceros y unos que requiere un amplio conocimiento de la red y puede generar grandes inconsistencias que dan lugar a procesos de calibración manual muy tediosos.

En cualquier caso, es importante remarcar que no se trata de emplear directamente la matriz de posicionamiento GPS como la matriz a partir de la cual iniciar el proceso de calibrado manual. Si no como un elemento complementario a las metodologías tradicionales repercutiendo en un incremento de la fiabilidad de los resultados y una reducción de tiempos de calibrado manual.

3.2 Comprobación del tamaño de la muestra

Una vez estimada, calibrada y validada la matriz a partir de la matriz de datos de posicionamiento GPS y las metodologías tradicionales, se realiza una última comprobación que consiste en estimar si la muestra es estadísticamente válida sobre el universo.

Esta comprobación se realiza debido a que la matriz que se usa como complemento a los procedimientos tradicionales en el proceso de calibración es una matriz que representa una muestra de la población, dado que los datos derivan de las compañías y usuarios que hayan compartido esa información.

Para ello, se utiliza lo indicado en la Nota de Servicio 5/2014, obre la obtención del tamaño de la muestra, por medio de la siguiente expresión:

$$T_{ij} = \alpha \, \pi(G_{rij}^{g}) \, \pi(A_{sij}^{a}) \, c_{ij}^{k} \qquad (1)$$

$$m = \frac{k^2\, N\, p\, (1-p)}{e^2\, (N-1) + k^2\, p\, (1-p)} \qquad (1)$$

Donde:

m: Tamaño estimado para la muestra lauestra.
n: N: Tamaño del universo
e: Error muestral deseado, en tanto por uno. El error muestral es la diferencia que puede haber entre el resultado que obtenemos preguntando a una muestra de la población y el que obtendríamos si preguntáramos al total de la población.
p: Proporción de individuos que poseen en la población la característica de estudio. Este dato es generalmente desconocido y se suele suponer que p=0,5 que es la opción más segura.
k: Constante que depende del nivel de confianza que asignemos.

Valor de k	1.15	1.28	1.44	1.65	1.96	2.24	2.58
Nivel de confianza (%)	75	80	85	90	95	97.5	99

Tabla 1. Valor de k en función del nivel de confianza. Fuente: Nota de Servicio 5/2014.

El procedimiento se basa en obtener el error muestral y el nivel de confianza, en función del universo y la muestra de partida, para cada tipología de vehículo (ligeros y pesados). Siendo la muestra representativa si la suma de los vehículos es superior a la obtenida teóricamente a partir de esta fórmula.

3.3. Costes

3.3.1. Tiempos

Los tiempos de espera en un proyecto para poder llevar a cabo los aforos y el pretratamiento y limpieza de los datos depende de muchos factores: del periodo de contratación de los trabajos, del número de puntos a aforar, la complejidad de los enlaces a aforar, el número de días aforados, etc. Y en ocasiones, tras la realización de los trabajos, en el caso de que se detecten errores de medida por fallos en los equipos de medida o que el día seleccionado a priori no sea representativo y por condicionantes del proyecto finalmente se decida que debe realizarse otro día, requiere iniciar todos los trabajos desde cero.

Toda esta problemática queda reducida a los tiempos de contratación de los datos en bruto y su tratamiento a partir de esta nueva metodología.

Si bien es cierto, dependiendo de la zonificación del modelo los tiempos pueden variar en la fase de tratamiento de los datos, una vez tratados los tiempos de cálculo son prácticamente independientes de la zonificación seleccionada.

Añadiendo la ventaja de que esta metodología permite tener a disposición del modelizador valores de comportamiento del tráfico para días medio de un mes en cualquier punto de la zonificación del proyecto. Esto resultaría imposible de llevar a cabo con las metodologías tradicionales, por ejemplo, tener controlados cada uno de los accesos y salidas d la vía de análisis de un proyecto concreto durante 24 horas, durante 1 mes o más tiempo.

Incluso proporcionando la flexibilidad de poder seleccionar otros días para el análisis del tráfico, en el caso de que se detecte cualquier anomalía en los datos del día seleccionado a priori. Esto supone que no sería necesario tener que repetir los trabajos, solo se repetiría el proceso de cálculo modificando las condiciones de salida de los datos.

3.3.2 Económicos

El coste derivado de un plan de aforos va a depender en gran medida del número de aforos, la complejidad de estos, la tecnología de los medios materiales y el número de horas/días que se decidan aforar.

Mientras que, para esta nueva metodología el coste deriva principalmente de la zonificación y de la cantidad de días.

Es importante tener en cuenta, como ya se ha mencionado, que la metodología no es sustitutiva de los aforos. Por lo que, el ahorro económico deriva de la posibilidad de reducir el número de aforos realizados a través de metodologías tradicionales, realizando solo en aquellos puntos que sean de mayor interés.

4. CASOS DE USO

4.1. Anteproyecto de Adecuación, Reforma y Conservación del Corredor Oeste de la autovía A-5

El presente apartado desarrolla los trabajos realizados en el Anteproyecto de adecuación, reforma y conservación del corredor oeste de la autovía A-5 comenzando en el p.k. 10 y finalizando en el p.k. 74, correspondiendo con el ámbito territorial de las provincias de Madrid y Toledo.

En el ámbito de este proyecto se llevaron a cabo de forma complementaria tres modelos de microsimulación para analizar el comportamiento del viario de estudio mediante la representación explícita e individual de los vehículos en la simulación, contemplándose todos los efectos dinámicos derivados de los mismos (aceleraciones, pendientes, velocidades, etc.).
El software de microsimulación permite el análisis detallado de todos los vehículos del modelo y sus interacciones en cualquier elemento existente en la zona de estudio, así como su influjo en los elementos existentes en el entorno, tales como rotondas, intersecciones, ramales, etc. correspondientes a los siguientes tramos:

- Tramo 1: Discurre desde la M-40 hasta la M-143, pk 0+000 – 25+500. En dicho modelo se incluye enlaces como: el acceso al centro comercial Tres Aguas y Alcorcón, el enlace que da acceso a Móstoles por el sur, zona de Parque Coimbra y los accesos al centro comercial Xanadú.
- Tramo 2: Zona de Navalcarnero, discurre desde el pk 27+000 hasta el pk 35+000. En el se incluyen los distintos accesos a Navalcarnero.
- Tramo 3: Discurre integramente por la provincia de Toledo, empezando en el pk 35+000 y finalizando en el 75+900. En él se incluyen los enlaces restantes hasta Toledo.

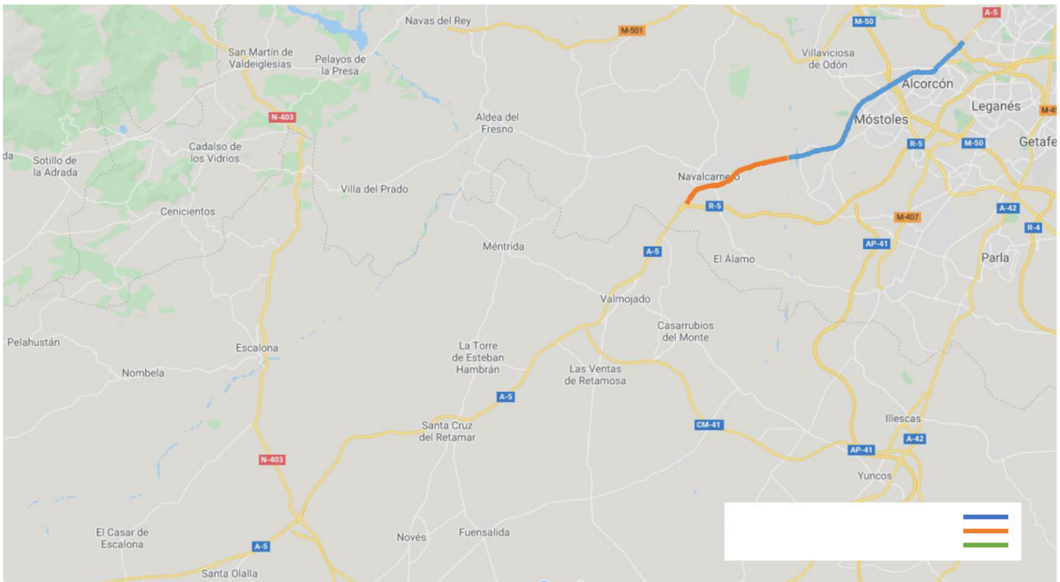

Figura 5. Ámbito de aplicación del estudio. Fuente: Elaboración propia.

A fin de comprobar la idoneidad del tamaño de la muestra de los datos de la matriz obtenida de posicionamientos GPS, se calculó el tamaño de la muestra con la fórmula que se indica en la Nota de Servicio 5/2014.

Para su aplicación se tomó como tamaño del universo el número total vehículos ligeros y pesados de la matriz final calibrada del modelo, de esta forma se puede obtener un valor del tamaño de muestra hipotético para un nivel de confianza del 99% y una porción de individuos que poseen en el universo la característica de estudio del 0.5.

Las ecuaciones de estimación de tamaño muestral tienen unos valores mínimos recomendado por la Nota de Servicio 5/2014, el error muestral debe de estar por debajo del 10%. Las pruebas realizadas con este valor proporcionan tamaños muestrales muy inferiores al tamaño de las matrices de los datos GPS.

Por lo tanto, el análisis se centra en la estimación del error muestral que se comete al usar esas matrices GPS. Para ello se llevó a cabo un proceso iterativo del error muestral que finaliza una vez que el tamaño estimado de la muestra es mayor que el tamaño de la muestra de partida (las matrices de los datos GPS).

A continuación, se muestran los resultados del análisis llevado a cabo para cada tramo y la estimación del error de muestreo que se alcanzado por el uso de esta metodología.

TRAMO 1

		LIG	PES
m	tamaño estimado de la muestra	22.623	210
N	tamaño del universo	47.387	2.359
e	error muestral deseado	< 0,01	0,09
p	proporción de individuos que poseen en el universo la característica de estudio	0,50	0,50

k	constante que depende del nivel de confianza que asignemos (99%)	2,58	2,58
m	tamaño de la muestra de partida	3.367	148

Tabla 2. Análisis del error muestral alcanzado con la implantación de las metodologías de matrices a partir de datos GPS. Fuente: Elaboración propia.

Se observa cómo, en cualquiera de los tres tramos analizados el error muestral se encuentra por debajo del 10% tanto para ligeros como para pesados, siendo esta diferencia mucho mayor para el caso de los vehículos ligeros con errores inferiores al 2%. Para los vehículos pesados se observa como el ajuste del error es menor, pero en todo caso permite el cumplimiento de las especificaciones de la Nota de Servicio 5/2014.

4.2 Proyecto de Trazado en la Autovía A-68

El presente apartado desarrolla los trabajos realizados en el Proyecto de Trazado. Autovía A-68. Tramo: Enlace Autovía A-68 / Autopista AP-15 - Calahorra. El estudio comprende el tramo de la N-232 localizado en la parte más oriental de La Rioja, desde pasado el enlace con la AP-15 (límite con la Comunidad Foral de Navarra), hasta la entrada del núcleo de Calahorra. Concretamente, entre el p.K 331,7 y el p.K 356.

Para este proyecto se realizó una microsimulación de todo el tramo, un total de 25 kilómetros de autovía con 24 centroides tal y como muestra la siguiente imagen.

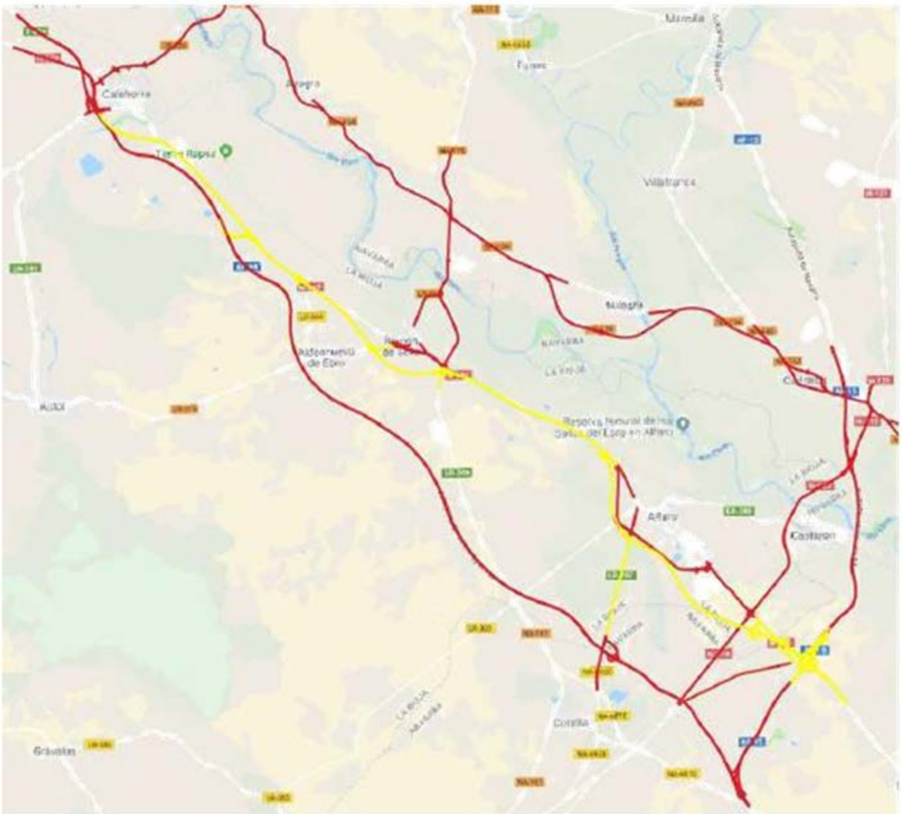

Figura 6. Ámbito de aplicación del estudio. Fuente: Elaboración propia

Para la calibración del modelo se emplearon datos del Mapa de Tráfico de 5 estaciones de aforo y los datos obtenidos de la aplicación de la metodología de posicionamiento GPS.

A fin de comprobar la idoneidad del tamaño de la muestra de los datos de la matriz obtenida de posicionamiento GPS, se calculó el tamaño de la muestra con la fórmula que se indica en la Nota de Servicio 5/2014.

Para su aplicación se tomó como tamaño del universo el número total vehículos ligeros y pesados de la matriz final calibrada del modelo, de esta forma se puede obtener un valor del tamaño de muestra hipotético para un nivel de confianza del 99% y una porción de individuos que poseen en el universo la característica de estudio del 0.5.

Las ecuaciones de estimación de tamaño muestral tienen unos valores mínimos recomendados por la Nota de Servicio 5/2014, el error muestral debe de estar por debajo del 10%. Las pruebas realizadas con este valor proporcionan tamaños muestrales muy inferiores al tamaño de las matrices de los datos GPS.

Por lo tanto, el análisis se centra en la estimación del error muestral que se comete al usar esas matrices GPS.

Para ello se llevó a cabo un proceso iterativo del error muestral que finaliza una vez que el tamaño estimado de la muestra es mayor que el tamaño de la muestra de partida (las matrices de los datos GPS).

A continuación, se muestran los resultados del análisis llevado a cabo para cada tramo y la estimación del error de muestreo que se alcanzado por el uso de esta metodología.

		LIG	PES
m	tamaño estimado de la muestra	2.911	538
N	tamaño del universo	4.132	1.114
e	error muestral deseado	0,013	0,04
p	proporción de individuos que poseen en el universo la característica de estudio	0,50	0,50
k	constante que depende del nivel de confianza que asignemos (99%)	2,58	2,58
m	tamaño de la muestra de partida	2.871	463

Tabla 3. Análisis del error muestral alcanzado con la implantación de las metodologías de matrices a partir de datos GPS

Se observa cómo, tanto para vehículos ligeros como para pesados el error muestral queda por debajo del 10% y siendo mucho menor el error en el caso de los vehículos ligeros con un 1,3% y un 4% para el caso de vehículos pesados.

5. CONCLUSIONES

Esta metodología permite alcanzar unos niveles de calidad en los proyectos de modelización superiores a los obtenidos en proyectos en los que solo se usan las metodologías tradicionales de aforo.

Además de alcanzar unos niveles de error muestral inferiores a los recomendados por la Nota de Servicio 5/2014 empleando el máximo nivel de confianza muestral (99%). Siendo este error menor en el caso de los vehículos ligeros con valores del 1% - 2%

Para vehículos pesados se alcanzan valores superiores, pero siempre inferiores a la recomendación de la Nota de Servicio 5/2014.

La mayor calidad de los datos de partida se traduce en unos mejores resultados del modelo y por lo tanto una mayor fiabilidad de estos, así como una reducción del tiempo necesario para una calibración adecuada del modelo.

En cuanto a los costes del proyecto, esta metodología permite una reducción directa de los mismos. Por un lado, con la reducción del tiempo de calibración del modelo como se ha mencionado anteriormente, y por otro, permite disminuir la contratación de campañas de campo.

En base a los dos proyectos expuestos queda demostrado que la muestra de los datos obtenidos a partir de la matriz de posicionamientos GPS es lo suficientemente representativa para usarla como elemento de apoyo y complementario a las metodologías tradicionales. Aumentando la fiabilidad del modelo, reduciendo los tiempo y costes en campañas de campo y calibrado del modelo.

ABSTRACT

Barcelona SUMP (Sustainable Urban Mobility Plan) for the 2013-2018 period included a set of measures to stimulate the change to more sustainable transportation modes, among which traffic signal configuration based on bus frequencies can be found. This document describes the pilot case implemented in the 22@ area of the city.

The approach consists of the development of a mobility simulation model including different transportation modes, relying on the commercial software Aimsun and integrating *ad-hoc* components, having a tool supporting decision-making as a result.

During the first stage of the project, a microscopic simulation model was built, including all details of the infrastructure concerning the road network (lane configuration, traffic signaling, driving constraints…), traffic light configuration and interface with input data from the City Council, public transport surface network and private vehicle demand.

Together with the model, an optimizer component implementing specific constraints to ensure a safety, efficient, sustainable mobility was developed. In this way, the resulting tool generates an optimal configuration for traffic lights that can be used for traffic management purposes, giving priority to the bus network with no relevant penalties for the private vehicle and, of course, guaranteeing safety for pedestrians.

A relevant improvement of the bus service has been obtained for the three considered scenarios, achieving an increase of the speed between 13% and 25% (average for all lines).

As expected, both travel time and the number of stops have been reduced, which results on a better level of service as the users directly perceive these two factors.

1. BACKGROUND

The Barcelona City Council continuously performs adjustments in the traffic lights configuration at local level, either because modifications of the civil infrastructure or for adapting them to new traffic conditions.

However, measures that may have an impact beyond a specific location or on more than one transportation mode require certain mechanisms for a previous assessment from the mobility point of view.

Barcelona SUMP (Sustainable Urban Mobility Plan) for the 2013-2018 period fosters the use of advanced tools in order to improve the implementation of proposed measures, from the inception and design to the deployment and maintenance, if necessary.

In that context, local authorities identified the necessity of having a flexible enough software allowing both assessment about the real impact in the whole city but also having means to test innovative mobility measures such as the ones this paper focuses on, increase of the bus network performance while preserving safety for the people in the pedestrian’s crosses.

Optimizing traffic lights settings is a well-known problem in traffic engineering and minimizing the sum of delays the most common objective. For example, for the particular case of a two-stage traffic signal, the first analytical solution can be found in Webster (1958) but many other approaches appeared from these years on, addressing both fixed-time and adaptive control.

Adaptive models are based on dynamic phase changing defined by traffic flow fluctuations detected by means of real-time sensors, forecasted from historical data or combining both as shown in Mirchandani (2001).

These models can also add stochastic parameters in terms of uncertainty for inflow or outflow at intersections as described in Tong (2015).

On the other hand, fixed-time systems are based on deterministic values for the cycle and green times that have been previously calculated for specific time intervals and day types, which is the operating mode in the case of the city of Barcelona since regular patterns exist.

In these situations, dealing with signal coordination (offsets) is a key factor to provide required performance for a certain transportation mode, such as buses.

How the concept of the offset can provide support to coordinate and synchronize a network can be found in Gartner (1975) and later evolved by Möhring (2006) where non-uniform cycle lengths are also introduced.

Next sections describe the mathematical approach to tackle the problem of prioritizing public transport against private vehicle in the study area, where the bus network is composed of horizontal and vertical lines creating a grid with shared intersections which add a degree of complexity.

2. MATHEMATICAL APPROACH

2.1 Delay at signalized intersections

Over the last decades, several models have been developed to estimate vehicle delay at signalized intersections. One of the first expressions was made by Wardrop (1952) assuming that the arrival flow rate was uniform, leading to a very simple formula (1):

$$d = \frac{\left(r-\frac{1}{2s}\right)^2}{2c(1-f)} \tag{1}$$

Where,

d = average delay per vehicle
r = effective red time
s = saturation flow
c = cycle length
f = traffic flow

Afterwards, a few models appeared by Newell (1956), Webster (1958) or Miller (1968), who developed new expressions where the uniform arrival hypothesis were no longer used.

The model proposed by Webster assumes that arrivals are random but with a uniform departure flow. It offers a better approach on the delay calculation for low traffic intersections (intersections with high intensity usually tend to an exponential behavior when it comes to arrivals). Webster expression (2) is as follows:

$$d = \frac{c(1-\lambda)^2}{2(1-\lambda X)} + \frac{X^2}{2f(1-X)} - 0.65\left(\frac{c}{f^2}\right)^{1/3} X^{2+5X} \tag{2}$$

Where,

d = average delay per vehicle
λ = green ratio

X = degree of saturation
c = cycle length
f = traffic flow

The first term corresponds to the delay due to uniform arrival flow, which is equivalent to Wardrop expression (1). The second term is the delay caused by the random arrival assumption. Finally, Webster added a third empirical term as a tuning to the formulation.

Miller solved the delay calculation with a different approach; in this case, he focused on the overflow delay. In most cases, the excessive delay at intersections are due to a peak in the arrival flow. Miller took into account the average number of vehicles missing a traffic light cycle. The first term of the expression (3) is the delay due to a uniform flow rate. The second term express the average delay when there are vehicles left in the queue when red phase starts.

$$d = \frac{c(1-\lambda)}{2(1-\lambda X)}\left(c(1-\lambda) + \frac{(2X-1)I}{q(1-X)} + \frac{I+\lambda-1}{s}\right) \quad (3)$$

Where,

d = average delay per vehicle
λ = green ratio
X = degree of saturation
c = cycle length
f = traffic flow
I = variance to mean ratio of flow per cycle

Newell, on the other hand, focused on the distribution arrival at the intersection. He studied general arrival and departure distributions for delay models at signalized intersections. He expressed (4) that the average delay experienced by a vehicles is as follows:

$$d = \frac{c(1-\lambda)^2}{2(1-y)} + \frac{IH(y)X}{2f(1-x)} \quad (4a)$$

$$y = \frac{sg-qc^{0.5}}{Isg} \quad (4b)$$

Where,

d = average delay per vehicle
λ = green ratio
X = degree of saturation
c = cycle length

f = traffic flow
I = variance to mean ratio of flow per cycle
y = flow ratio

Due to the difficulty obtaining some of the variables that define the arrival flow variance, various institutions started to develop simpler expressions based on empirical experimentation. One of the best known is the High Capacity Manual, which proposed a first equation in 1985 that was improved later by Reilly (1994) with this expression (5):

$$d = 0.38 \frac{C(1-\lambda)^2}{1-\lambda[Min(X,1)]} + 173x^2 \left[(X-1) + \sqrt{(X-1) + \frac{mX}{C}}\right] \quad (5)$$

Where,

d = average delay per vehicle
λ = green ratio
X = degree of saturation
c = cycle length
C = capacity
m = calibration term representing the effect of arrivals type

The utilization of a minimum term is due the fact that it is considered that oversaturated intersections have infinite delay (no estimation when X > 1).

2.2 Offset coordination

The formulation proposed regarding offsets is based on the paper written by Estrada (2009). There, authors proposed a reduction of travel time for several bus lines by means of offset modifications. To do so, they stablishes an expression (6) in function of the offset to be minimized, including the sum of the following three terms concerning buses:

- *Travel time in links*: average time to travel from one signalized intersection to another without taking into account the time a bus spends at stops.
- *Time lost at stops*: time spent at stops due to the passengers entering or leaving. It also includes the time lost due to acceleration and deceleration during maneuver.
- *Time lost at intersections*: time spent during red phase. Same as before, the acceleration and deceleration times are included.

Since travel time and time lost at intersections will be obtained by means of a simulation model, they will not be further developed from the theoretical point of view. On the other hand, the formulation developed by Estrada will be used further as a starting point to estimate the delay in links.

The evaluation of the total amount of time that a bus is stopped at intersections is a function (6) of the cycle time, green time and signal offset. To evaluate the intersection time, it requires determining the number of signal cycles that had passed since a bus arrives, by referencing the arrival to the signal cycle.

$$n_s = [\frac{t_{av} - theta}{T_c}] \quad (6a)$$

$$s = t_{av} - n_s T_c - theta \quad (6b)$$

Where,

s = arrival time referred to signal cycle
t_{av} = arrival time
$theta$ = offset referred to previous intersection
T_c = cycle length
n_s = number of cycles

Once the arrival times is referenced, it can be then determined if the bus will pass (green phase) or stop (red phase). Therefore, the expected delay in the link will be as detailed in expression (7):

$$t_{in} = \begin{cases} T_c - s & if \quad s > g \\ -s & if \quad s < 0 \\ 0 & if \quad 0 \leq s \leq g \end{cases} \quad (7)$$

Where,

t_{in} = time stop at the intersection
s = arrival time refereed to signal cycle
g = start of the green signal

3. METHODOLOGY

Proposed methodology envisages an underlying traffic simulation model since even unable to generate a solution by themselves, simulation models are useful as a tool for the analysis of a system and its behavior under certain conditions. Aimsun is used as the simulation environment.

For each simulation, inputs can be changed manually after analyzing the outputs of the previous one. Nevertheless, as the number of parameters or size of the model grow, this process becomes as inefficient as it is inappropriate. Then, the need for a custom component giving support to the optimization process raises.

This component must implement an import and export interface with the model together with analysis capabilities through an *ad-hoc* algorithm that runs in the context of a loop process until a suitable solution is found.

As shown in Figure 1, the initial step of the iterative process is the model simulation and the corresponding export of information about the behavior of private vehicles and tracking of buses to a custom database.

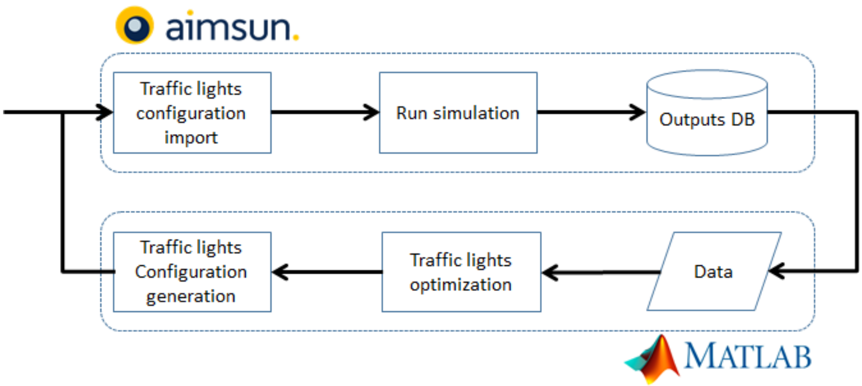

Fig. 1 – Optimization loop process

Then, simulation outputs are read by a component developed in Matlab, where optimization takes place in two sequential stages, deeply explained in next section:

- *Phases*: calculation of the available green time for each of the different existing phases in such a way that vehicles have the least delay possible while satisfying safety constraints for both vehicles and pedestrians as requested by the City Council.
- *Offsets:* calculation of optimal offsets between consecutive traffic lights to improve the performance of the bus network by means of generation of green waves considering stop and travel times.

4. OPTIMIZATION

4.1 Phases

This stage has two objectives: the extension of green windows for buses and the reduction of delay time for private vehicles at the rest of intersections. The following steps are taken to achieve the objectives this stage aims at:

1. A mathematical formulation gets the optimal starting time and duration of green phases for each signal group at every intersection in such a way that safety structure of the junction is preserved.

2. Definition of the optimization variable (e.g. delay time) respect to decision variables, in this case the phases. That way, it is possible to find a combination of phases that minimizes the optimized variables for each intersection.
3. Definition of the boundary conditions of the problem which are obtained from the constraints: crossing time for pedestrians, minimum duration of phases and intersection saturation.

4.1.1 Structure of traffic lights

In traffic lights, start and end of the green time for each signal is defined by its structure in addition to the existing phases and the definition of programs and control plans.

- *Phases*: As they are the time intervals that compose a cycle, the sum of their durations must be equal to the cycle to preserve the structure. Each phase is composed of sub phases that may have variable length (susceptible to be optimized) or fixed (for example, there are phases that, for safety reasons, are red for all signal groups, lasting 3 s or 6 s.).

Fig. 2 – Example of phases for each signal group of an intersection

Figure 2 shows an example in terms of a bar chart. The intersection has 3 signals (G1V, G2V and G3V) and 3 phases (A, D and H). Each phase is also divided in sub phases; for example, phase D also includes sub phases e, f and g.

- *Programs*: they define combinations of duration for each phase and the corresponding offset, which is used for synchronization with other intersection. Table 1 defines 4 programs, from P1 to P4 (values in bold face are used in Expression (8)).

Programs			A	b	c	D	e	f	g	H	i	j
			#	**3.0**	**3.0**	#	**3.0**	**3.0**	**3.0**	#	**3.0**	**3.0**
Plan	Cycle	Offset										
P1	96	94	**40.0**			**30.0**				**26.0**		
P2	96	53	41.0			27.0				28.0		
P3	96	56	47.0			27.0				22.0		
P4	72	12	32.0			27.0				18.0		

Table 1 – Example of signal programs of an intersection

- *Control plan*: hourly and daily distribution of the programs, which is used to synchronize groups of intersections into specific areas. Table 2 shows an example where P1 is the active program during the morning, P4 is reserved for some nights and both P2 and P3 are used during the rest of the time.

Time	Mon.	Tues.	Wed.	Thurs.	Fri.	Sat.	Sun.
2:30						P4	P4
6:30	P1	P1	P1	P1	P1		
10:30	P2	P2	P2	P2	P2		
17:00	P3	P3	P3	P3	P3	P3	
21:30	P2	P2	P2	P2	P2	P2	
23:00				P4	P4		P4

Table 2 – Example of a control plan (some time intervals are omitted)

Since the optimization works by changing the duration of the phases from the green perspective, it is necessary to define the existing relationship.

In expression 8, matrix A contains information about states (green or red) for each phase (columns) and, for each turn (rows). The vector $\vec{p}$ contains the total phase duration and the vector $\vec{f}$ contains the fixed part of the phase. The difference between vectors is the variable duration of the phase, which multiplied with the matrix A gives the variable green duration as a result, for each turn $\vec{g}_{var}$.

$$A \cdot (\vec{p} - \vec{f}) = \vec{g}_{var} \qquad \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 1 & 1 \end{bmatrix} \cdot \left(\begin{bmatrix} 40 \\ 30 \\ 26 \end{bmatrix} - \begin{bmatrix} 6 \\ 9 \\ 6 \end{bmatrix} \right) = \begin{bmatrix} 34 \\ 21 \\ 41 \end{bmatrix} \qquad (8)$$

The next step is to process the fixed sub phases, which are sub divided into small intervals supporting transition and coordination between phases. To get the green time it is necessary to add the existing green length in these intervals, $\vec{g}_{ctt}$, to the variable green duration as shown in Expression (9):

$$\vec{g} = \vec{g}_{var} + \vec{g}_{ctt} \quad \begin{bmatrix} 34 \\ 21 \\ 41 \end{bmatrix} + \begin{bmatrix} 0 \\ 6 \\ 9 \end{bmatrix} = \begin{bmatrix} 34 \\ 27 \\ 50 \end{bmatrix} \tag{9}$$

4.1.2 Formulation

There are three different formulations depending on the degree of saturation of the intersection. For example, since it is assumed that the delay is infinite when the intersection is saturated, the formulation aims at reducing queues in those cases.

Figure 3 shows depicts diagram showing the decisions taken during the optimization process in terms of which is the specific objective in function of the degree of saturation.

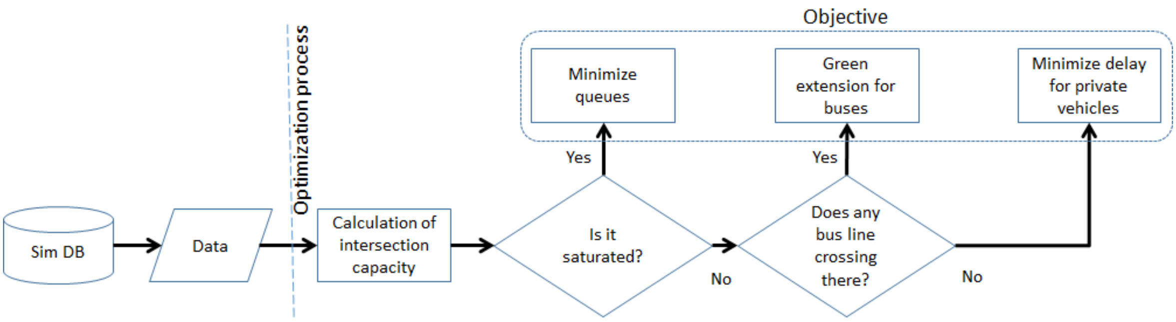

Fig. 3 – Decision diagram during the optimization process

- *Degree of saturation:* indicates the state of an intersection based on the capacity of the turns and the incoming flow. Given a turn, if traffic flow exceeds its specific threshold, then the intersection is not able to process all vehicles, resulting on the generation of queues. In those cases, there are two consequences: vehicles miss, at least, a cycle and queues being generated can eventually stuck adjacent intersections.

  The degree of saturation, as expressed in (10), is the ratio between number of vehicles arriving to the interaction and maximum number of vehicles that can be processed during one cycle. If the value is greater than one the intersection is oversaturated.

$$X = \frac{f \cdot c}{s \cdot g} \tag{10}$$

Where,

X = degree of saturation
f = traffic flow
c = cycle length
s = saturation flow
g = effective green time

- *Delay time of non-saturated intersections:* In these cases, the High Capacity Manual formulation, as expressed in (11), is used:

$$d = \frac{f \cdot 0.5 \cdot c^2 \cdot \left(1 - \frac{g}{c}\right)^2}{1 - \left(X \cdot \frac{g}{c}\right)} \tag{11}$$

Where,

d = delay time
X = degree of saturation
f = traffic flow
c = cycle length
g = effective green time

- *Over-saturated intersections:* The objective here is not to minimize the delay time but to optimize the queue distribution to reduce the impact on adjacent intersections. First, queue growth rate per cycle is obtained by calculating vehicles that miss a cycle divided by the cycle duration, as detailed in (12).

$$Q = \frac{q \cdot c - s \cdot g}{c} \tag{12}$$

Where,

Q = queue growth rate
q = traffic flow
c = cycle length
s = saturation flow
g = effective green time

Since an intersection can have multiple turns, the growth rate is calculated in a per turn basis. The first turn that collapses determines the so-called obstruction time. The algorithm optimizes the obstruction time using the expression (13).

$$U_i = \frac{C_i}{Q_i} \rightarrow U_{min}(\vec{g}) = \min(U_1, \dots, U_i) \tag{13}$$

Where,

U = lane obstruction time
Q = queue growth rate
C = capacity

- *Green extension:* For cases where a bus line circulates, an adjustment of the green phase is used to prioritize public transport. To be more specific, the duration is increased just for signals the buses cross along (degree of saturation calculated for each signal group) using expression (14). A safety factor is added to take into account potential fluctuations in the arrival flow. Finally, the green extension is configured considering the minimum green times already calculated.

$$G = \lambda \cdot \frac{f \cdot c}{s} \tag{14}$$

Where,

G = minimum green duration
λ = safety factor
q = traffic flow
c = cycle length
s = saturation flow

4.2 Offsets
The main objective when optimizing offsets is the improvement of the bus network service. This network layout was designed as a grid where users can easily transfer from vertical to horizontal lines as needed. This ease of use, however, becomes a drawback from a whole perspective because the vertical lines limit improvements in horizontal lines (and vice versa) since there are shared intersections.

In this case, the objective function does not come out of a formulation, but from the simulation model results. Input variables are the offsets of the intersections and the commercial speed is the decision variable. Therefore, the process consists of varying these variables to maximize the commercial speed.

4.2.1 The problem
First, what must be taken into account is the size of the problem to solve. In the study area, there are more than 150 intersections (with their dependencies), which is a relevant number of variables. At the same time, travel times depend on the offsets, establishing an additional dependency.

Given these characteristics, the application of conventional optimization methods such as Newton's method is not feasible. Computationally speaking, the calculation time for a matrix of 150 variables is not a handicap. However, as it has so many variables, it is very likely that Newton's method ends up after finding a local optimum of the problem, which may be very far from the global optimum.

4.2.2 Heuristic method

As a consequence of the abovementioned, a heuristic method (a genetic algorithm, to be more specific) is used, which does not ensure finding an optimal solution but very close to and being a global optimum, which better fits with such a complex problem. An additional advantage is that heuristic methods require lower computational time, which is a very interesting feature for iterative algorithms.

4.2.3 Hybrid modelling

Since a large number of generations are needed for a genetic algorithm to work properly, and for each generation, to simulate many times (one per individual) a drawback arises because each simulation lasts about 40 minutes.

To tackle with that, the methodology includes a simplified mathematical model where the genetic algorithm is applied, which results on a slight loss of accuracy but also on a significant reduction of computing time.

Thus, a hybrid approach is finally used. Every time a solution is found in the mathematical model, it is simulated to get certain parameters (time at stops and speed), which will feedback again the mathematical model. This iterative process stops when a kind of convergence is reached.

4.2.4 Mathematical model

It models the trajectory of a bus taking into account the travel time between nodes and the time a bus is stopped (stops or traffic lights). The latter will depend on the offsets while the other parameters are static during the optimization process and only change after each iteration.

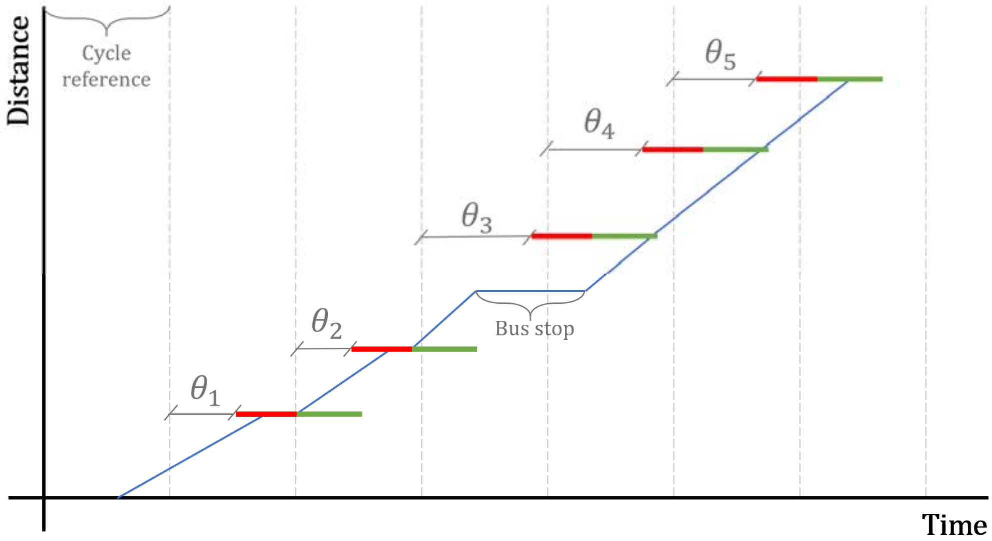

Fig. 4 – Graphical representation of the mathematical model bus trajectory

The model calculates the time that the bus stops (see Figure 4) for all traffic lights based on the offset configured and parameters coming from the simulation. The mathematical model could be understood again as a function to be optimized, where the input variables are the offsets and the output is the travel time as shown in expression (15):

$$t_1 = f_1(\theta_1, \dots, \theta_n) \tag{15}$$

As previously mentioned, the bus network is composed of m corridors that must optimized as a whole. As a consequence, the function to be optimized will not only minimize the travel time of a corridor but the sum of all of them as detailed in (16) where some variables are shared between components of the sum, representing the dependencies.

$$T = t_1 + \dots + t_m = f_1(\theta_1, \theta_2, \dots, \theta_n) + f_2(\theta_2, \theta_3, \dots, \theta_n) + \dots + f_m(\theta_3, \theta_4 \dots, \theta_n) \tag{16}$$

5. CASE STUDY

Figure 5 highlights the area of the city of Barcelona where the study is located. There are many reasons why this area was selected, remarking the following as the most relevant:

- It represents a logical extension of an existing model to which is geographically adjacent and therefore, focusing to a future model of the whole city.
- Includes a comprehensive representation of surface transportation network, where traffic lights have an impact.
- Testing new methodologies and algorithms in a reduced scope before their application to a wide are is always a best practice.

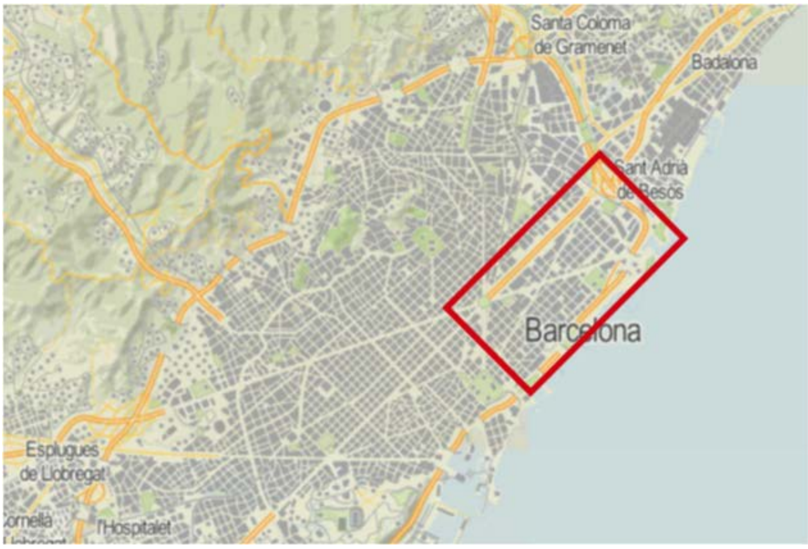

Fig. 5 – Selected area for the case study

5.1 GTFS import

Bus service is configured in the simulation model by means of real schedules included in the official GTFS-compliant files coming from the operators. *General Transit Feed Specification* defines a common format for public transportation schedules and their associated geographic information.

Aimsun has a built-in feature to import GTFS files, which unfortunately, is not totally free from some errors.

To speed up this process and to ease the detection of bugs, some mechanisms developed in python language for both pre-processing (selection of relevant services) and post-processing (completion of missing data).

5.1 Origin-Destination matrix calibration

Private traffic demand is configured by means of an OD matrix provided by the City Council.

To be more specific, the matrix was processed to get hourly matrices for the case study area since it was a daily matrix for all the Metropolitan Area.

Afterwards, a calibration step is needed to enhance quality by adjusting resulting trips:

- *Calibration tool:* Used together with traffic loop sensors, the software performs traffic assignments based on the OD matrix trying to match simulated flow with detected flow for each detector location (macro level).
- *Route definition:* Since traffic loops do not cover the entire study area, it is necessary to check whether the routes generated by the simulator are coherent or not in order to avoid traffic jams where they really do not exist.
- *Model parameters:* Some additional parameters need to be calibrated to ensure a valid behavior from the microscopic level perspective: aggressiveness, lane changes, the reaction time, etc.

5.2 Time intervals

As in most of big cities, traffic behavior in Barcelona depends on the time of day. Therefore, it is important to set the configuration for traffic lights according to the situations identified after analyzing traffic loops in the area. These time intervals define the simulation scenarios: morning and afternoon peaks, off-peak between the two previous and nightly which was finally discarded because of the low traffic and since the bus network changes a lot respect the others.

5.3 Other constraints and limitations

The study area and the City Council guidelines impose additional constraints that must be taken into account:

- *Pedestrians*: For each signal group, a minimum green time based on the crossing's length and the average speed of elderly population must be ensured.
- *High traffic and TRAM roads*: Roads with higher flows and included in the path of TRAM lines are already optimized and therefore, they are not included in the optimization process. However, their offsets are taken into account.

6. RESULTS

This section shows the main results obtained for three scenarios based on the time intervals for a typical working day. All charts have the same style: two series with values for a total of 30 iterations with bus speed (red color, left axis) and delay for private vehicles (blue color, right axis).

A relevant improvement of the bus service has been obtained for the three scenarios, achieving an increase of the speed between 13% and 25% (average for all lines). As expected, travel time is reduced as well as the number of stops, which means that green light is often found when arriving to traffic lights since commercial stops don not change between iterations.

It is important to remark that the objective was to improve the bus network as a whole not just individually lines. For that reason, although there is a global improvement, several lines can have worst indicators. There is not a fixed pattern for this behavior since it depends on some time dependent parameters resulting on having lines that improve given a scenario while they get worst in other.

6.1 Morning peak

In this time interval, modifications in the parameters lead to a significant change in the behavior of private vehicle as shown in Figure 6. Potential traffic jams do not have an impact on the bus because of most of the optimized lines are circulating through reserved lanes.

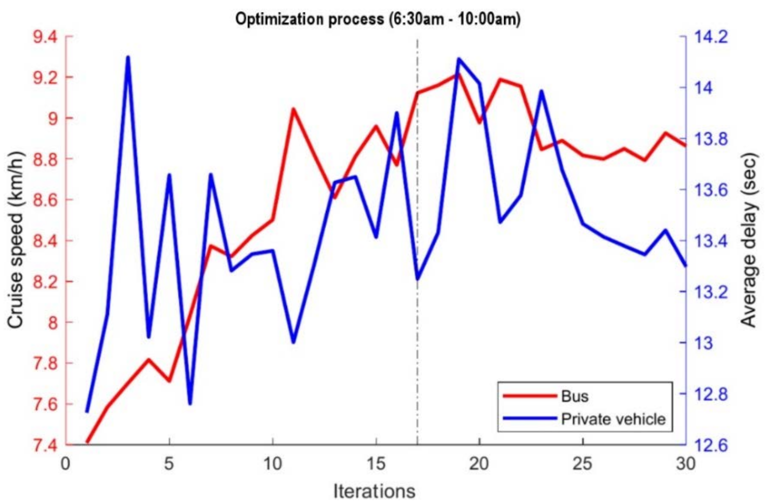

Fig. 6 – Results obtained: morning peak

Even private vehicle does not reach to a convergence, bus lines do until iteration 20 approximately. From this point on, bus speed is not improved anymore, thus going further in the optimization process has no sense.

Vertical dotted line remarks the iteration providing the best global performance.

Table 3 shows more details about the results of the simulation for bus lines. The average cruise speed has been increased by a 25,5 %, reducing both travel time and number of stops by 12,9 % and 6,4 % respectively.

Line	First iteration			Best iteration			Improvement		
	Cruise speed (km/h)	Travel time (min)	Num. Stops (#)	Cruise speed (km/h)	Travel time (min)	Num. Stops (#)	Cruise speed (%)	Travel time (%)	Num. Stops (%)
H14-0	7,4	17,7	18,4	8,3	15,8	15,9	12,2	-10,4	-13,5
H14-1	6,8	19,5	19,2	11,1	13,4	17,2	62,2	-31,1	-10,3

Table 3 – Results obtained: morning peak

6.2 Off peak

Despite its name, traffic flows are relevant for this time interval and are just slightly lower than the peaks before and after. For this scenario, both series reach a stable state simultaneously being iteration number 11 the one that offers the best configuration.

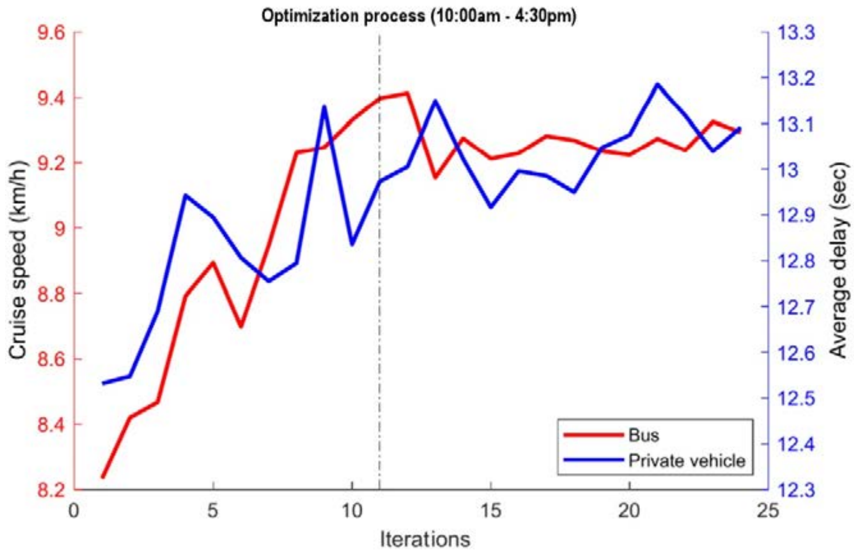

Fig. 7 – Results obtained: off-peak peak

Table 4 shows more details about the results of the simulation for bus lines. The average cruise speed has been increased by a 21,2 %, reducing both travel time and number of stops by 14,2 % and 10,8 % respectively.

Line	First iteration			Best iteration			Improvement		
	Cruise speed (km/h)	Travel time (min)	Num. Stops (#)	Cruise speed (km/h)	Travel time (min)	Num. Stops (#)	Cruise speed (%)	Travel time (%)	Num. Stops (%)

Table 4 – Results obtained: off-peak

6.3 Afternoon peak

Behavior is similar to the peak in the morning but variation of delay for private vehicle along the iterations is not as severe. While buses reach an asymptote, private vehicle has a decreasing trend. The best configuration for traffic lights is found in iteration number 27.

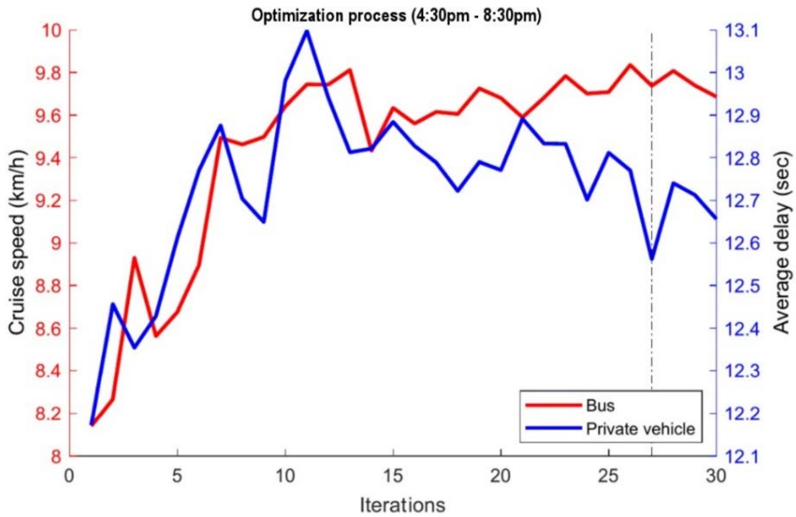

Fig. 8 – Results obtained: afternoon peak

Table 5 shows more details about the results of the simulation for bus lines. The average cruise speed has been increased by a 12,9 %, reducing both travel time and number of stops by 9,3 % and 11,3 % respectively.

Line	First iteration			Best iteration			Improvement		
	Cruise speed (km/h)	Travel time (min)	Num. Stops (#)	Cruise speed (km/h)	Travel time (min)	Num. Stops (#)	Cruise speed (%)	Travel time (%)	Num. Stops (%)

RESUMEN

En la última década se ha producido un incremento significativo de las personas que practican el "running" como deporte principal para mejorar su calidad de vida. Este hecho ha producido un aumento de la celebración de carreras populares, entre las que cabe destacar la maratón por el volumen de personas que concentra. Para evitar aglomeraciones y que la carrera se celebre bajo condiciones de flujo libre, las organizaciones separan a los corredores en olas y cajones de manera que los corredores son lanzados con un desfase de tiempo determinado. Sin embargo, el número de estudios sobre el comportamiento de los corredores a lo largo de la carrera es escaso.

Así, el objetivo principal de esta investigación fue caracterizar la movilidad de los corredores desde el punto de vista de su operación, analizando el ritmo de cada uno de ellos de manera individual y grupal. Para ello, se realizó un análisis macroscópico y microscópico de los corredores que participaron en las maratones de Valencia entre 2016 y 2019.

Todo ello permitió caracterizar el comportamiento de los corredores que pertenecían a la misma ola. Como resultado, la variación del ritmo a lo largo de la carrera es mayor a medida que el ritmo promedio de la carrera aumenta. Además, mientras que la descarga de corredores en la primera ola presentaba intensidades muy elevadas durante los primeros minutos, en el resto de las olas se observó una descarga más homogénea y tendida.

Finalmente, se identificó que tanto la intensidad, expresada en número de corredores por unidad de tiempo, como la densidad, expresada en número de corredores por unidad de longitud, alcanzaban sus valores máximos en la primera parte de la carrera, indicando que la zona con mayor interacción entre corredores se produce en los primeros 5-10 kilómetros de la carrera.

Estos resultados pueden sentar la base para la definición de modelos de simulación para una organización más eficiente y segura de este tipo de eventos, principalmente cuando existan medidas excepcionales como las establecidas por la pandemia de la COVID-19.

1. INTRODUCCIÓN

A pesar de que a partir del año 2016 se observa un decaimento de la participación global en carreras, los maratones siguen aglutinando un mayor número de corredores con el paso de los años registrando una tasa de crecimiento anual ligeramente menor al 2% (RunRepeat y IAU, 2019). Los motivos para participar en este tipo de carreras están cambiando y son muy diversos. A principios de siglo, la mayoría de los corredores buscaban batir sus propios registros, mientras que hoy en día predominan los motivos relacionados con la fisiología, la salud y la sociedad. Este hecho ha producido una mayor movilidad por parte de las personas que se desplazan para correr, un incremento de los tiempos de finalización de la carrera y una menor proporción de participantes con edades comprendidas entre los 30 y los 50 años (RunRepeat y IAU, 2019).

El aumento de la participación en este tipo de carreteras ha generado que la salida se estructure en lo que comúnmente se conoce como *olas* y, a su vez, estas en *cajones* (Treiber, 2014). Cada *ola* y *cajón* tiene asociado un tiempo objetivo, es decir, el tiempo en que un corredor considera que finalizará la carrera. Con el fin de minimizar las interacciones entre corredores y garantizar que la carrera se produzca en flujo libre – ningún corredor ve afectado su ritmo por la afección de otro –, algunos organizadores solicitan a los participantes, en el momento de inscribirse en la carrera, prueba de que puede lograr ese tiempo objetivo – habitualmente a partir de resultados de carreras anteriores –. Sin embargo, la influencia de la estructura de la salida no ha sido todavía estudiada, principalmente porque cada organizador lo hace de manera particular para el evento que organiza y la comparación de los resultados obtenidos es compleja al depender de otros factores clave como, por ejemplo, el ancho de la sección. En este sentido, cuanto mayor es el ancho, mayor puede ser la intensidad de descarga de corredores por unidad de tiempo.

En los últimos años se han desarrollado varias investigaciones con el fin de modelizar la evolución del ritmo de los corredores a lo largo de la carrera (Rodriguez et al., 2014; Kwong y Nadarajah, 2019; Lin y Meng, 2018). Estas se desarrollaron en base a los resultados de los maratones de Nueva York, Chicago, Berlín, Londres y Boston, en distintas ediciones. Las distribuciones globales de velocidad – considerando todos los corredores en cada carrera – siguen, en general, una distribución log-normal (Lin y Meng, 2018). En este sentido, se identificó que las distribuciones de velocidad de los grupos de edad más rápido tenían la misma forma – distribución log-normal – que el resto de los finalistas. Mientras que Kwong y Nadarajah (2019) observaron mayores variaciones del ritmo cuanto más lento era un corredor y con el avance de la carrera, Lin y Meng (2018) identificaron mayores variaciones de ritmo individual en los primeros 5 kilómetros de la carrera y a partir del kilómetro 30. En el resto de longitud – desde 5k hasta 30k – el ritmo se mantenía relativamente constante (Lin y Meng, 2018).

Por su parte, Rodriguez et al. (2014) modelizó la dinámica del pelotón del maratón a través de una ecuación diferencial parcial de convección-difusión con velocidad media dependiente de la posición y coeficiente de difusión. De esta forma, se concluyó que la velocidad media del pelotón disminuye mientras que el coeficiente de difusión aumenta con la distancia. Esto significa que la intensidad y densidad de corredores se diluye a lo largo del recorrido.

Adicionalmente, Treiber (2014) analizó las distribuciones de tiempos finales por categorías – edad y sexo – en medias maratones. En este caso, se observó que, en ausencia de perturbaciones importantes, la distribución de la velocidad dentro de cada grupo es casi gaussiana. Particularmente, solo se observaron desviaciones significativas en: (i) grupos de élite pequeños por efecto pelotón; y (ii) colas de baja velocidad, que producían distribuciones más amplias.

Como conclusión, el estado actual del conocimiento en cuanto a los patrones de comportamiento de los distintos grupos o categorías que conforman un maratón es escaso, pues las investigaciones presentadas anteriormente se centran principalmente en el análisis del ritmo global de la carrera o para categorías muy específicas. Además, todavía cobra mayor importancia la caracterización de los factores más importantes en el desarrollo de maratones a partir de las medidas de seguridad establecidas por la pandemia de la COVID-19, puesto que la distancia social supone una restricción a tener en cuenta a la hora de diseñar el trazado de la carrera.

2. OBJETIVOS E HIPÓTESIS

El objetivo principal de esta investigación es el análisis descriptivo y cuantitativo de aquellos factores que permiten caracterizar el comportamiento de maratones.

Concretamente, las principales variables exploradas en este estudio están estrechamente ligadas al ritmo de los corredores, el cual ha sido analizado tanto de manera agregada como desagregada, la intensidad de corredores, entendida como la cantidad de corredores que atraviesan una sección por unidad de tiempo, y la densidad de corredores, expresada en términos de número de corredores por unidad de longitud. Todas estas variables se examinan teniendo en cuenta la configuración inicial o de salida de este tipo de pruebas, habitualmente estructurada en olas.

Las hipótesis más importantes del estudio son: (i) la distribución general de ritmos presenta una asimetría positiva debido a la baja proporción de corredores con condiciones de mantener ritmos de carrera muy bajos y una cola situada en la zona de ritmos altos debido a la dispersión existente de las condiciones físicas de corredores amateur; (ii) la intensidad de descarga de corredores en la salida disminuye a lo largo del tiempo y, además, también lo hace de una a otra ola; (iii) la variación del ritmo a lo largo de la carrera incrementa conforme lo hace el ritmo medio de la carrera, es decir, los corredores más rápidos tienen mayor facilidad para mantener un ritmo constante a lo largo de la carrera; y (iv) las intensidades y densidades más elevadas se producen en la parte inicial de la carrera debido a la mayor interacción entre corredores.

3. MÉTODO Y MATERIALES

Para llevar a cabo el presente trabajo se procedió según el diagrama de flujo de la Figura 1.

En primer lugar, se realizó una descarga masiva de los resultados de los maratones celebrados en la ciudad de Valencia desde 2016 hasta 2019, ambos inclusive. Los resultados de estas carreras están disponibles de manera gratuita a través de la página web del maratón (https://www.valenciaciudaddelrunning.com/maraton/maraton/). No obstante, no existe la posibilidad de descargar los datos de manera directa – p.ej., en formato csv – a través de dicho repositorio web. Por ello, se programó un script de *web scraping* mediante lenguaje de programación Python. Este proceso trata usar *bots* para extraer contenido y datos de un sitio web mediante el acceso a su código *HTML* y, a partir de este, obtener los datos almacenados en la base de datos.

Adicionalmente, también se descargaron los datos de los resultados de la página web que aloja los vídeos de la carrera (https://corriendovoy.com) con el fin de obtener información extra de los corredores como, por ejemplo, el tiempo de desfase en la salida con respecto al origen de tiempos general. Este tiempo, como se verá posteriormente en el análisis, es clave para determinar en que *Ola* salió cada uno de los participantes.

Fig. 1 – Diagrama de flujo de la investigación

La Tabla 1 indica los datos obtenidos de cada uno de los participantes de los maratones de Valencia celebrados de 2016 a 2019. Estos han sida agrupados en tres categorías de datos: (i) general; (ii) salida; (iii) puntos de paso. Los datos que se integran en la categoría "general" han sido empleados principalmente para caracterizar de manera global las carreras celebradas.

En este sentido, posteriormente se analiza la distribución de corredores según el ritmo promedio de estos y se evalúa la evolución de la participación de hombres y mujeres de manera desagregada – por categoría – y agregada – total por sexos –.

Los datos de la categoría "Salida" hacen referencia al *desfase*, que se define como la diferencia entre el tiempo oficial de la prueba – comenzando a contar desde que se da la salida de la primera ola – y el tiempo real del corredor – desde que cruza la salida hasta que llega a meta –. Principalmente, este tiempo permitió identificar a qué *ola* pertenece cada corredor y analizar la descarga de corredores en la salida.

Finalmente, los datos correspondientes a la categoría "puntos de paso" proporcionaron información sobre el tiempo de paso real de cada corredor en los puntos de control de la carrera. Estos datos fueron empleados para analizar la evolución del ritmo de cada corredor y cuantificar la intensidad de corredores en cada uno de estos pasos y la densidad de corredores entre los mismos.

Categoría de datos	Variable
General	Posición
	Dorsal
	Categoría
	Nombre y apellidos
	Tiempo oficial
	Tiempo real
Salida	Desfase
Puntos de paso	Tiempo en: • 5k • 10k • 15k • 21,097 (media maratón) • 25k • 30k • 35k • 40k • 42,195 (meta)

Tabla 1 – Resumen de datos obtenidos por corredor

Cabe destacar que una vez descargados los datos se realizó una reducción de los mismos con el fin de eliminar cualquier dato anómalo o incompleto. Para ello, al disponer de diferentes fuentes de datos – clasificación general y datos individuales –, se cruzaron los tiempos reales de cada corredor haciendo una búsqueda por su nombre. Se decidió utilizar el nombre del corredor para este proceso debido a las inconsistencias detectadas en las variables *dorsal* y *posición*.

4. ANÁLISIS Y RESULTADOS

El análisis que se presenta a continuación se ha dividido en cuatro bloques principales, yendo desde aspectos más generales a más particulares: (i) caracterización general; (ii) análisis de la salida; (iii) análisis de ritmo; y (iv) análisis espacio-temporal. Mientras que el primero de los bloques presenta datos de todos los maratones disponibles (2016-2019), los bloques siguientes se centran exclusivamente en los datos del maratón del año 2019. En este sentido, las tendencias que muestran los años anteriores (2016-2018) son similares al año que se presenta.

4.1 Caracterización general

Esta sección se centra en el análisis de los participantes por categoría, la evolución de la participación de hombres y mujeres a lo largo de los años y la distribución de corredores según su ritmo medio.

La Figura 2 muestra el tanto por ciento de hombres y mujeres que participaron en las ediciones del maratón de Valencia entre 2016 y 2019. A pesar de la baja participación de las mujeres en este tipo de pruebas (< 20%), se puede apreciar que año tras año su presencia es mayor.

Este mismo fenómeno se puede observar si analizamos los tantos por ciento de cada una de las categorías en las que se divide el maratón (Figura 3). Concretamente, la mayor reducción de corredores masculinos (categorías *M*) se produce en tres categorías de las que mayor presencia tienen en el maratón – *Senior Masc*, *M35* y *M40* –. Sin embargo, la proporción de hombres para el resto de categoría – hombres menores que 23 años y mayores de 40 años – se ha mantenido e incluso ha crecido a lo largo de los años. Por su parte, la participación de mujeres ha aumentado en prácticamente todas las categorías.

A grandes rasgos, el grueso de la carrera se concentra en la franja de edad comprendida entre los 23 años – incluso superior, aunque no se puede verificar con los datos disponibles – y los 45 años.

La presencia de cada una de las categorías restantes se va diluyendo con la edad. También es llamativa la poca participación de jóvenes menores de 23 años, confirmándose que la práctica del *running* se desarrolla en edades más avanzadas, muchas veces cuando las personas dejan de realizar otro deporte considerado como principal (p.ej., fútbol o baloncesto).

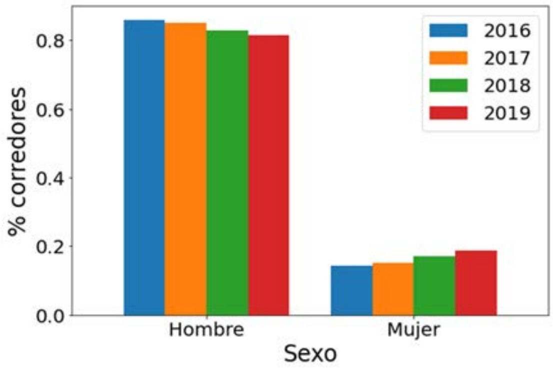

Fig. 2 – Proporción de hombres y mujeres entre 2016 y 2019

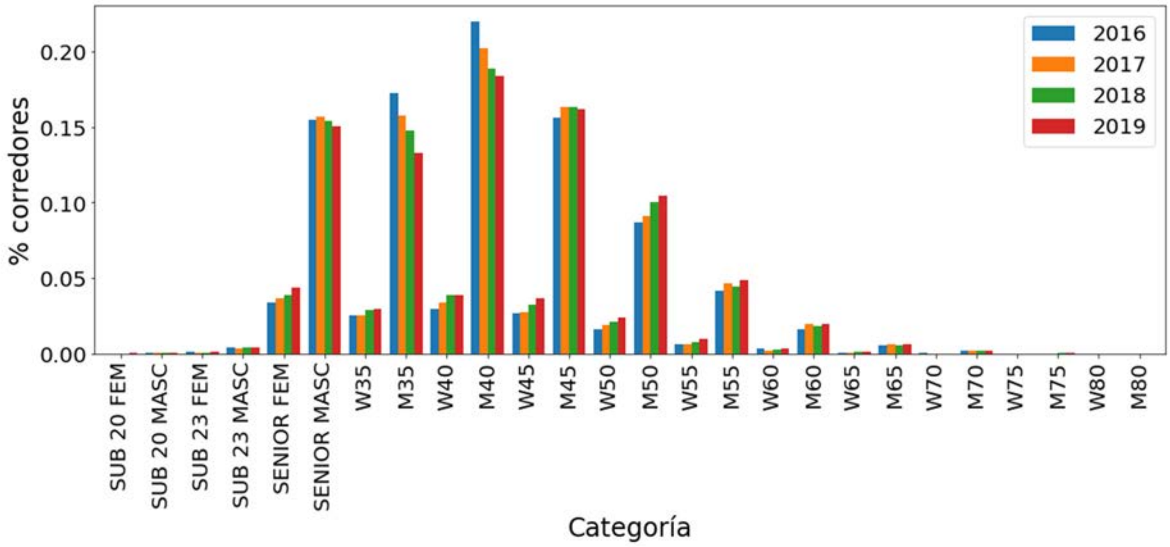

Fig. 3 – Proporción de hombres y mujeres por categorías entre 2016 y 2019

La Figura 4 presenta la distribución de corredores según el ritmo promedio para los distintos maratones evaluados. Como se puede apreciar, la distribución de ritmos es prácticamente similar. Este hecho confirma que existe un patrón o comportamiento común en este tipo de pruebas y, por tanto, los resultados de los análisis que se presentan más adelante para el maratón de 2019 pueden ser extrapolables a las carreras desarrolladas con anterioridad a pesar de que el número de corredores ha crecido desde 2016 a una tasa anual aproximadamente del 10% (Tabla 2).

Particularmente, la distribución presenta una asimetría ligeramente positiva, con un ritmo promedio de alrededor de 5:25 min/km (Tabla 2). El crecimiento repentino de la distribución desde ritmos bajos indica que existen pocos corredores rápidos o de élite, mientras que la cola que se observa para los ritmos más altos es sinónimo de una mayor proporción de corredores lentos (Figura 4). Asimismo, el 50% de los corredores presentan ritmos medios entre 4:50 min/km y 6 min/km (Tabla 2).

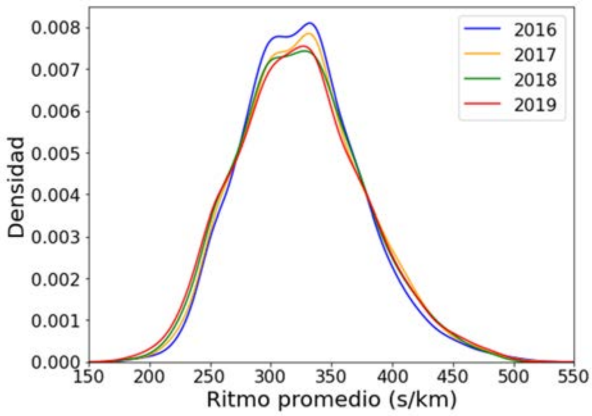

Fig. 4 – Distribución de corredores por ritmo medio entre 2016 y 2019

	2016	2017	2018	2019
Número de participantes	15858	16187	19243	21196
Ritmo promedio (s/km)	326.00	326.98	325.14	324.68
Desviación estándar del ritmo (s/km)	49.23	51.36	51.64	53.33
Ritmo mínimo (s/km)	181.44	178.1	177.01	176.09
Percentil 25 (s/km)	291.84	291.27	288.85	287.62
Percentil 50 (s/km)	323.51	324.73	322.67	322.36
Percentil 75 (s/km)	356.32	358.88	359.41	358.29
Ritmo máximo (s/km)	526.51	522.95	494.94	520.49

Tabla 2 – Resumen estadístico del ritmo

4.2 Análisis de la salida

El análisis de la salida se ha realizado exclusivamente para el maratón del año 2019. En este caso, la salida se organizó en 4 olas (Tabla 3). Adicionalmente, la *Ola 1* se distribuyó en 5 cajones, la *Ola 2* y *3* en 2 cajones y la *Ola 4* en un único cajón. Aunque sí se ha podido identificar la ola a la que pertenece cada corredor gracias a los datos relativos al desfase de la salida para cada corredor, la asignación en cajones no se pudo llevar a cabo.

Ola	Desfase (min)	Tiempo objetivo (hh:mm:ss)
Ola 1	0	< 03:31:00
Ola 2	10	< 03:46:00
Ola 3	20	< 04:01:00
Ola 4	30	≥ 04:01:00

Tabla 2 – Distribución de olas en el maratón de 2019

La Figura 4 muestra la intensidad de descarga de corredores por segundo junto al número de corredores acumulado a lo largo del tiempo. Como se puede apreciar, entre cada una de las olas existe un cierto intervalo de tiempo que se emplea para el posicionamiento en la salida de los corredores de la siguiente ola.

Focalizando la atención en la descarga de corredores de las olas, se puede intuir una reducción de las intensidades de descarga de cada una de ellas con el paso del tiempo.

Además, comparando las intensidades de unas olas con otras, se observan mayores valores de la intensidad en la *Ola 1* que en la *Ola 2* y, a su vez, mayores en la *Ola 2* que en la *Ola 3* y *4*. Este fenómeno también se puede apreciar por la pendiente de la recta tangente a la curva que muestra el número de corredores acumulado por segundo (línea negra a puntos en Figura 5). En este sentido, la pendiente ligada a la *Ola 1* es mayor que la de la *Ola 2*, siendo la pendiente de esta última ola mayor que las observadas en la *Ola 3* y *4*.

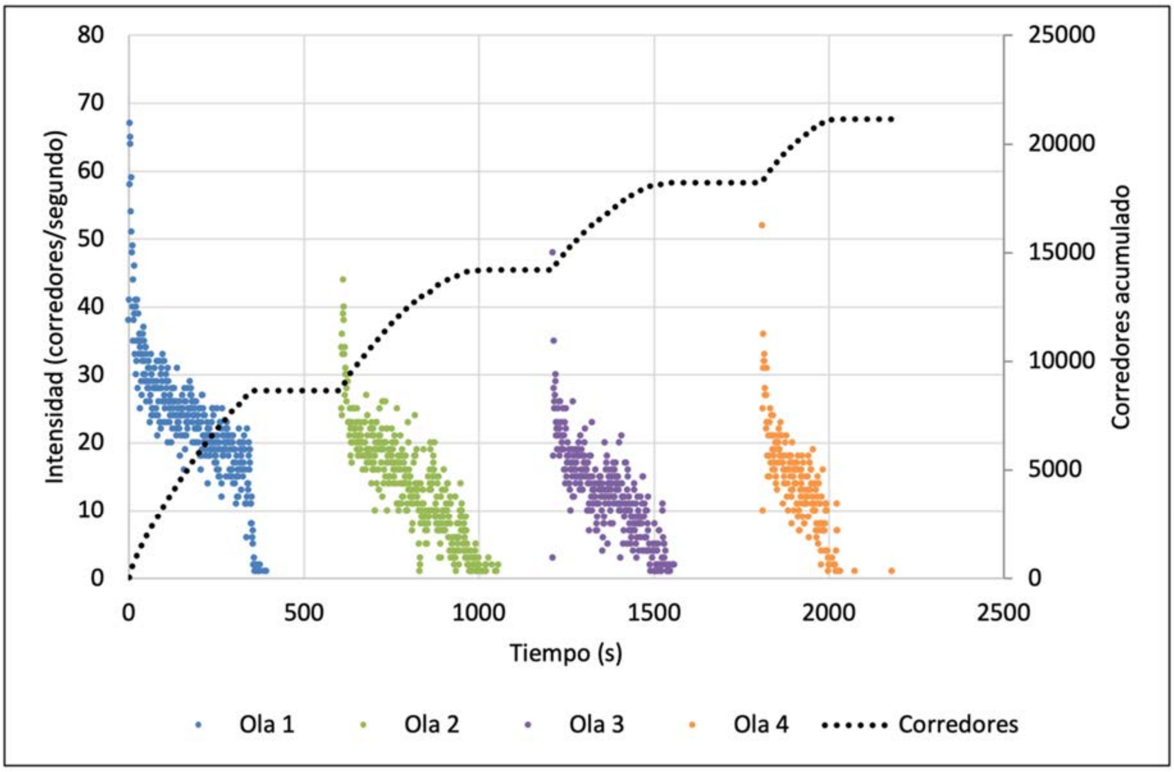

Fig. 5 – Descarga de corredores

Para analizar con mayor detalle la descarga de corredores en cada una de las olas, se ha establecido un origen de tiempos similar para todas ellas (Figura 6) y se ha calibrado un modelo para cada una de ellas según la forma funcional de la Ecuación (1), que responde al comportamiento asintótico, tanto horizontal como vertical, que presenta la intensidad a lo largo del tiempo.

$$y(t) = \frac{\beta_1}{t^{\beta_2}} + \beta_3 \qquad (1)$$

donde *y(t)* es la intensidad de descarga de corredores medida en corredores por segundo; *t* es el tiempo transcurrido en segundos; y β_i son los coeficientes del modelo.

La Tabla 3 presenta un resumen de la calibración de los modelos, mientras que la Figura 6 muestra cada modelo junto a los datos observados de la intensidad de descarga de corredores.

En primer lugar, cabe destacar que los modelos calibrados presentan una precisión adecuada – coeficiente de correlación entre 0.60 y 0.71 – para el fenómeno estudiado. Además, ponen de manifiesto todas las observaciones indicadas anteriormente para la Figura 5. A este respecto, los modelos estiman mayores intensidades de descarga para la *Ola 1*, intensidades bastante menores para la *Ola 2* y, a su vez, intensidades bajas tanto para la *Ola 3* y *4*, que prácticamente presentan resultados similares.

	Ola 1	**Ola 2**	**Ola 3**	**Ola 4**
$\boldsymbol{\beta_1}$	1621.48	1585.48	1660.00	1741.83
$\boldsymbol{\beta_2}$	0.00479	0.00396	0.00315	0.00315
$\boldsymbol{\beta_3}$	-1560.48	-1540.67	-1622.90	-1704.06
$\mathbf{R^2}$	0.71	0.66	0.60	0.66

Tabla 3 – Modelos de descarga de corredores en salida

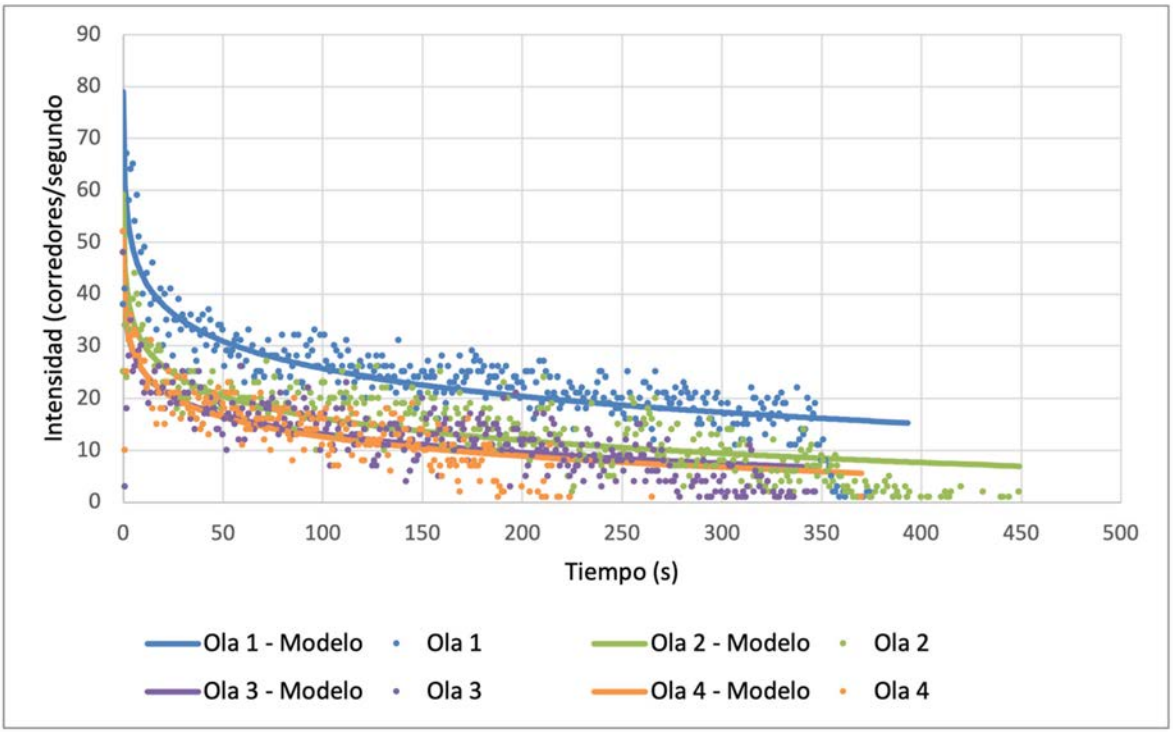

Fig. 6 – Modelos de intensidad de descarga de corredores en la salida según ola

Los resultados obtenidos en cuanto a la intensidad de descarga están estrechamente asociado a los ritmos de los corredores de cada una de las olas. En principio, los ritmos son más rápidos en las primeras olas, lo que se traduce en mayores intensidades de descarga. Por el contrario, los ritmos lentos asociados a la *Ola* 3 y *4* producen intensidades de descarga mucho más reducidas.

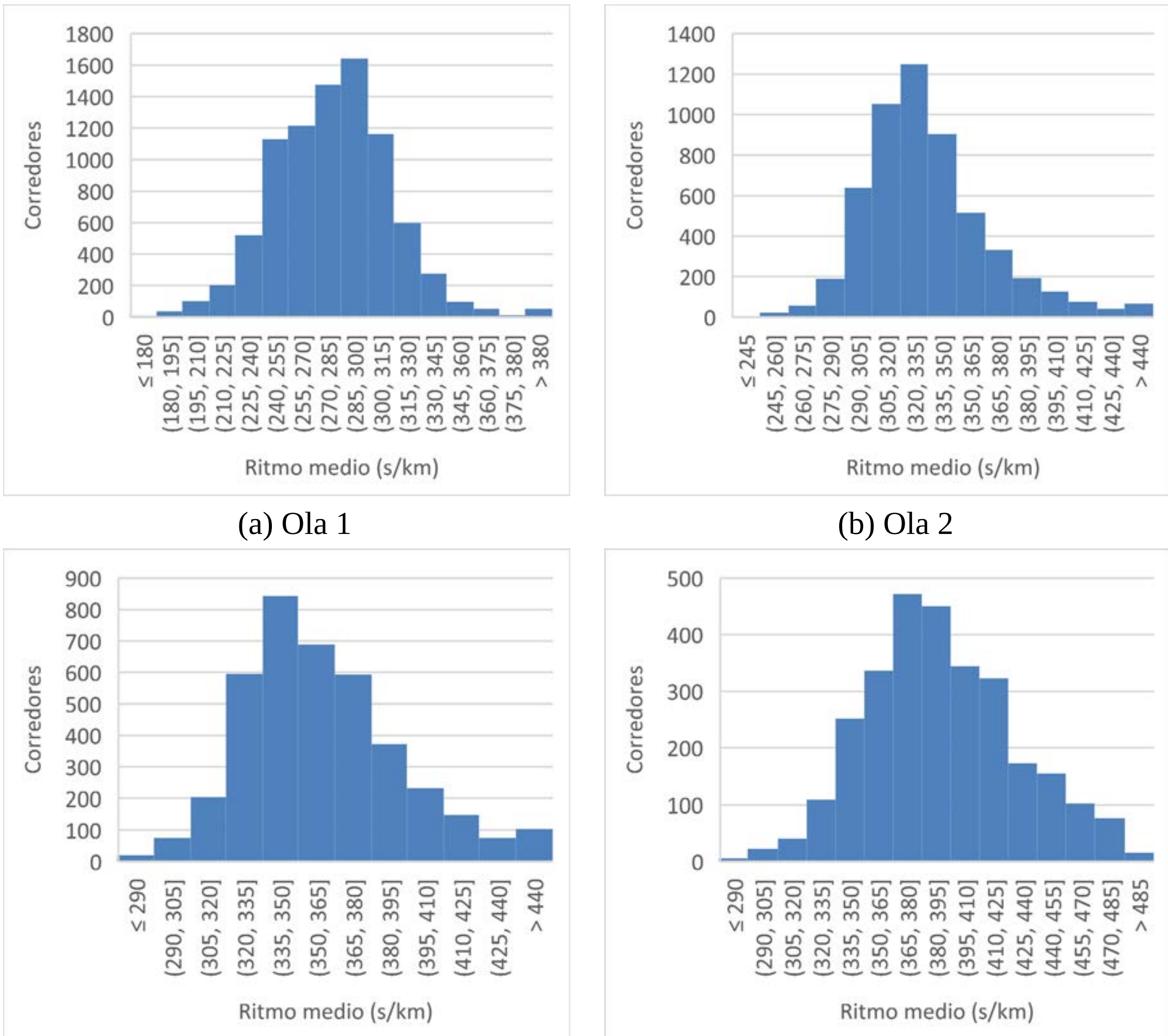
4.3 Análisis de ritmo

En las secciones anteriores se ha analizado el ritmo promedio de la carrera y la distribución de corredores en función de su ritmo medio.

Ahora se estudio con mayor nivel de detalle la evolución del ritmo de cada corredor a lo largo de la carrera, es decir, si aumenta de manera progresiva su ritmo o si el propio desgaste de la carrera le lleva a reducir el ritmo en los kilómetros finales.

Para ello, se cuenta con los tiempos de paso por el kilómetro 5k, 10k, 15k, 21.097k – media maratón –, 25k, 30k, 35k, 40k, 42,195k – meta –. A partir de estos tiempos se ha estimado, para cada corredor, el ritmo promedio de cada uno de los intervalos de distancia producidos por los puntos de paso.

En primer lugar, la Figura 7 muestra la distribución de ritmos de los corredores de cada una de las olas. Por tanto, la forma de la distribución general (Figura 4) es el resultado de la suma de otras distribuciones. Mientras que las distribuciones asociadas a la *Ola 2* y *3* presentan claramente una asimetría positiva, en aquellas ligadas a la *Ola 1* y *4* la asimetría no es tan evidente. El ritmo medio de cada una de la *Ola 1*, *2*, *3* y *4* es 4:40, 5:34, 6:00 y 6:30 min/km, respectivamente.



(a) Ola 1 (b) Ola 2

(c) Ola 3 (d) Ola 4

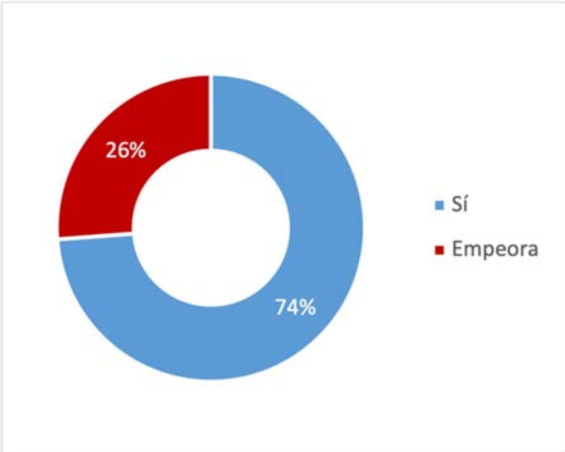
Fig. 7 – Distribución de ritmos por ola

A la hora de participar en el maratón, cada participante debe proporcionar un tiempo estimado de finalización de la carrera que la organización utiliza para la distribución de corredores en olas y cajones. En algunos maratones se suele pedir alguna prueba de ello – basado en carreras previas –, pero en otros no.

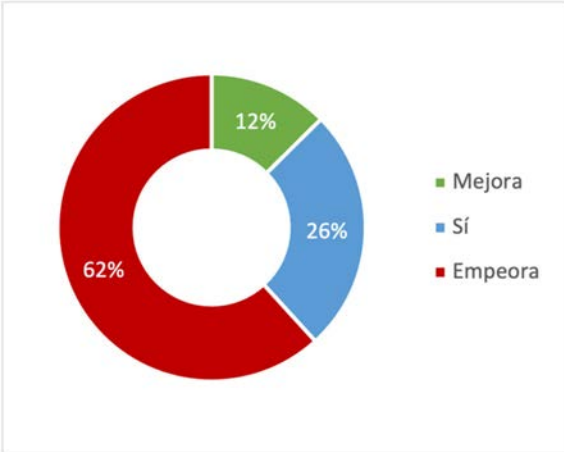
Para determinar el grado en que los corredores cumplieron su objetivo en el maratón de 2019, se ha comparado el tiempo asociado a cada ola (Tabla 2) con el tiempo real de la prueba (Figura 8).

De este modo, se ha identificado que el tanto por ciento de corredores que empeoran el tiempo previsto aumenta conforme mayor es el tiempo previsto para finalizar la carrera, desde el 26% de corredores de la *Ola 1* al 65% de la *Ola 3*. Por otro lado, se observa una pequeña parte de corredores – alrededor del 10% en cada ola – que mejoran su tiempo previsto.

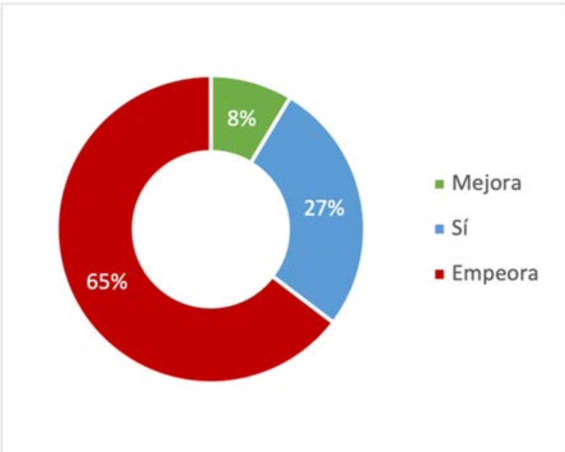
Además, destacar que en las olas centrales – *Ola 2* y *3* – únicamente un cuarto de los corredores cumple – *"Sí"* – con el tiempo esperado (Figura 8). Finalmente, es necesario resaltar que sería necesario estudiar, dentro de la *Ola 1*, el cumplimiento de los tiempos previstos asociados a cada uno de los cajones que la integran.



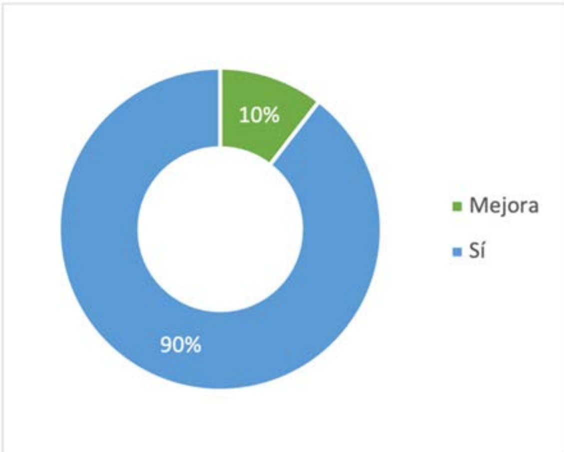
(a) Ola 1



(b) Ola 2



(c) Ola 3



(d) Ola 4

Fig. 8 – Cumplimiento de tiempo estimado de finalización

Una vez estudiadas las distribuciones de ritmos de cada ola e identificada la poca proporción de corredores que cumplen con los tiempos previstos, a continuación se compara el ritmo medio de cada corredor con la variación del ritmo a lo largo de la carrera (Figura 9. Para ello, la variación del ritmo ha sido estimada como la desviación típica de los ritmos promedios estimados en cada punto de control.

Estos ritmos promedios son estimados como el ritmo medio entre dos puntos de control consecutivos. De esta manera, para cada corredor se dispone de un total de ocho ritmos promedios, asignados a cada punto de control (ver Tabla 1). Por ejemplo, el ritmo promedio en el punto de control 5k será el ritmo medio, en s/km, desde la salida hasta el kilómetro 5.

Por su parte, el ritmo promedio en el punto de control 30k será el ritmo medio entre el kilómetro 25 y 30.

En primer lugar, se ha observado un aumento de la variación del ritmo conforme el ritmo promedio de los corredores incrementa. Este fenómeno se debe al hecho de que cuanto más rápido es un corredor, teóricamente, en mejor forma física se encuentra para desarrollar la carrera, lo que conduce a experimentar menores cambios de ritmo a lo largo de la carrera.

Además, para un mismo ritmo medio de carrera, aquellos corredores que mejoran el tiempo previsto presentan variaciones del ritmo significativamente menores a aquellos que empeoran su tiempo esperado de carrera.

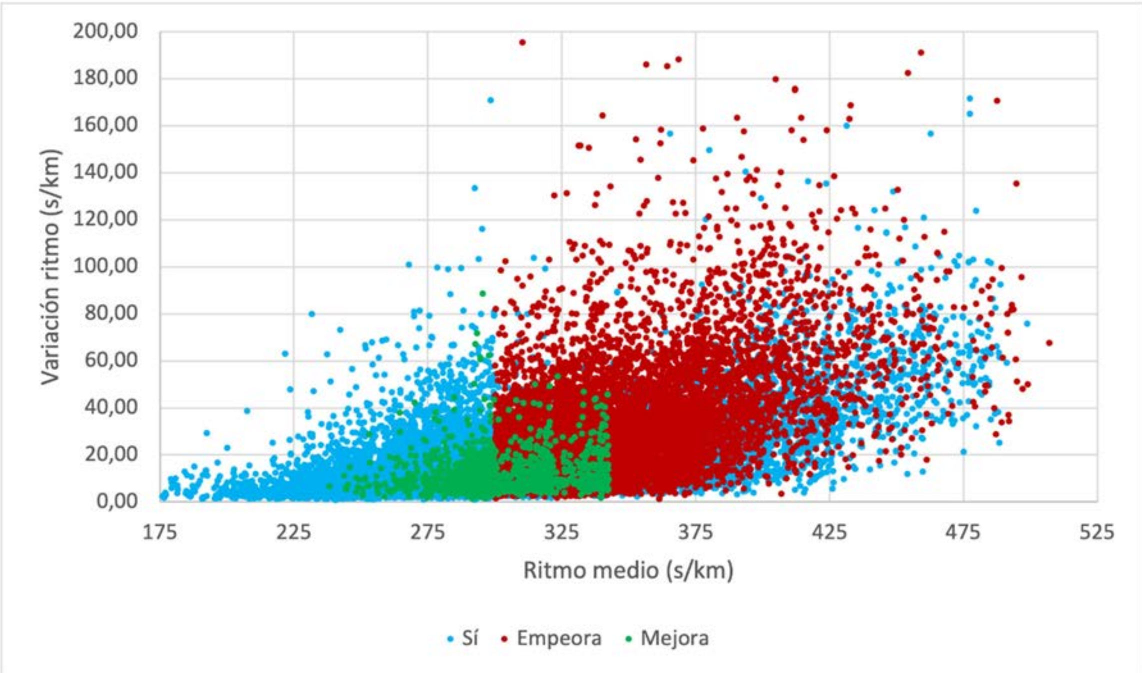


Fig. 9 – Cumplimiento de tiempo estimado de finalización

Una vez identificadas las diferencias generales entre los grupos analizados – corredores que cumplen tiempo previsto, lo mejoran o lo empeoran –, ahora se compara el ritmo medio de la carrera con el ritmo promedio estimado en cada punto de control. En la Figura 10 se representa el ritmo medio de la carrera frente a la ratio entre dicho ritmo y el ritmo en un determinado punto de control.

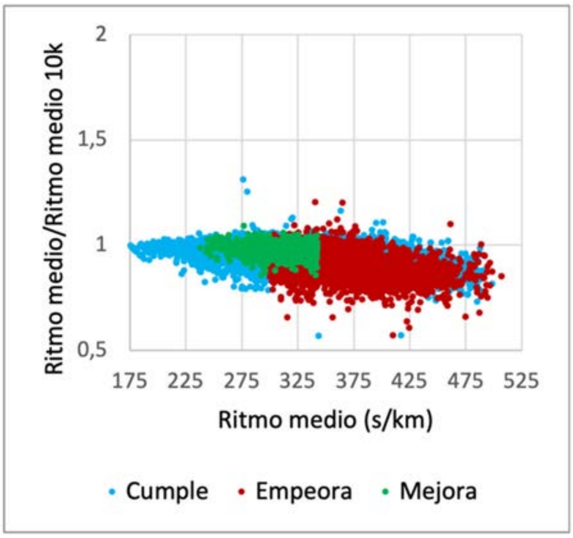
De esta forma, una ratio mayor que 1 significa que el ritmo del corredor asociado a ese punto de control es superior al medio de la carrera, es decir, va más lento. Por el contrario, un valor menor que 1 indica que el corredor ha recorrido a un ritmo más rápido que el ritmo promedio de la carrera la longitud que separa ese punto de control y el anterior.

De manera general, cuanto mayor es el ritmo medio de la carrera, más se aleja la tasa evaluada del valor 1.

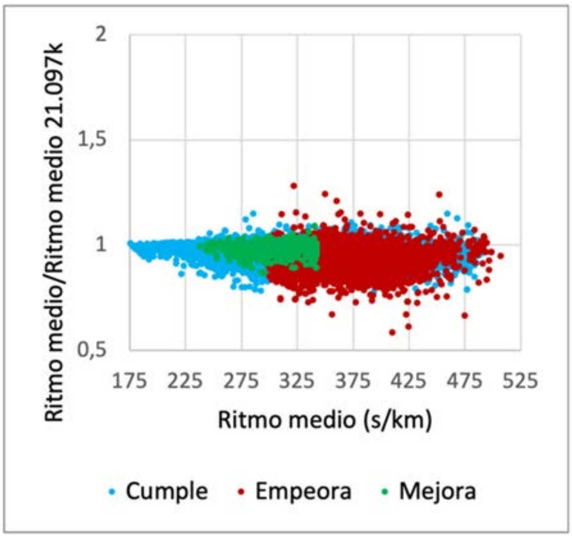
Aquellos corredores que cumplen o empeoran el tiempo previsto experimentan una reducción del ritmo conforme avanza la carrera.

En este sentido, se observan ritmos más rápidos – ratio menor que 1 – en la primera mitad de la carrera (Figura 10a y 10b) y ritmos lentos – ratio mayor que 1 – en la segunda parte de la misma (Figura 10c y 10b).

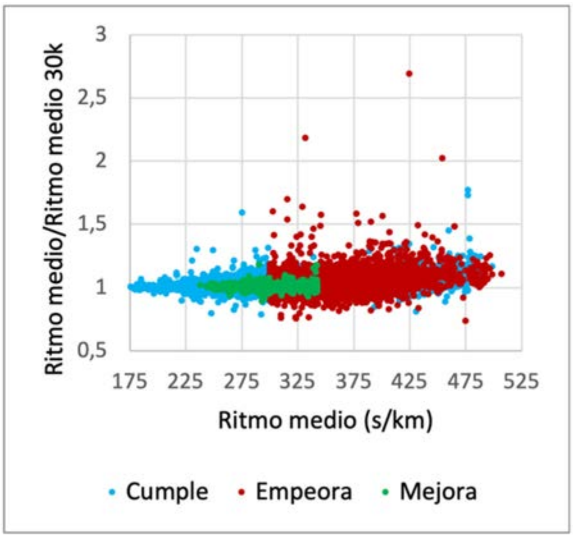
Por otra parte, los corredores que mejoran su tiempo esperado parecen ser más conservadores al inicio de la carrera – ratios ligeramente menores a 1 –, lo que les permite mantener un ritmo muy similar al promedio de la misma – ratio igual a 1 – en la parte final (Figura 10c y 10d).



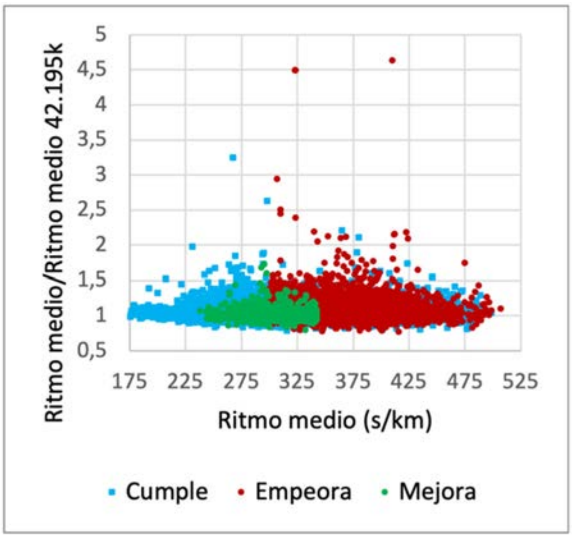
(a) 10k



(b) 21.097k



(c) 30k



(d) 42.195k

Fig. 10 – Evolución del ritmo a lo largo de la carrera

Concluyendo, la variación del ritmo de los corredores aumenta a medida que lo hace el ritmo medio de la carrera. Mientras que los corredores élite – asociados a ritmos muy bajos – y los corredores que mejoran su tiempo previsto son capaces de mantener un ritmo aproximadamente constante a lo largo de la carrera, el resto de los corredores tienden a ir más rápido en la primera parte de la carrera, lo que les conduce – principalmente por fatiga muscular – a ritmos significativamente mayores al ritmo promedio de la carrera en la parte final de la misma.

4.4 Análisis espacio-temporal

Esta última sección del análisis se centra en el estudio de la intensidad y la densidad de corredores a lo largo de la carrera, considerando un intervalo espacial de un kilómetro. Para ello, se ha asumido que cada participante corre cada kilómetro de carrera al ritmo promedio asociado al siguiente punto de control – ritmo calculado a partir de los tiempos de paso entre ese punto de control y el anterior –. Por ejemplo, en el kilómetro 26 se asume que el corredor lleva el ritmo asociado al punto de control 30k, ya que dicho ritmo se ha estimado a partir de la diferencia de tiempos entre los puntos de control 25k y 30k, dividido entre cinco kilómetros (30-25).

La Figura 11 presenta la intensidad de corredores por minuto, en cada punto de control de la carrera (representados por colores), a lo largo del tiempo. La intensidad de corredores en la salida presenta ciertos saltos bruscos que están asociados, como ya se ha comentado anteriormente, a la salida de cada una de las olas. Estos saltos se van laminando conforme la carrera avanza, es decir, en los puntos de control sucesivos, de manera que las intensidades más altas se observan en los primeros puntos de control. En este sentido, la Figura 12 muestra las intensidades máximas en cada kilómetro de la carrera.

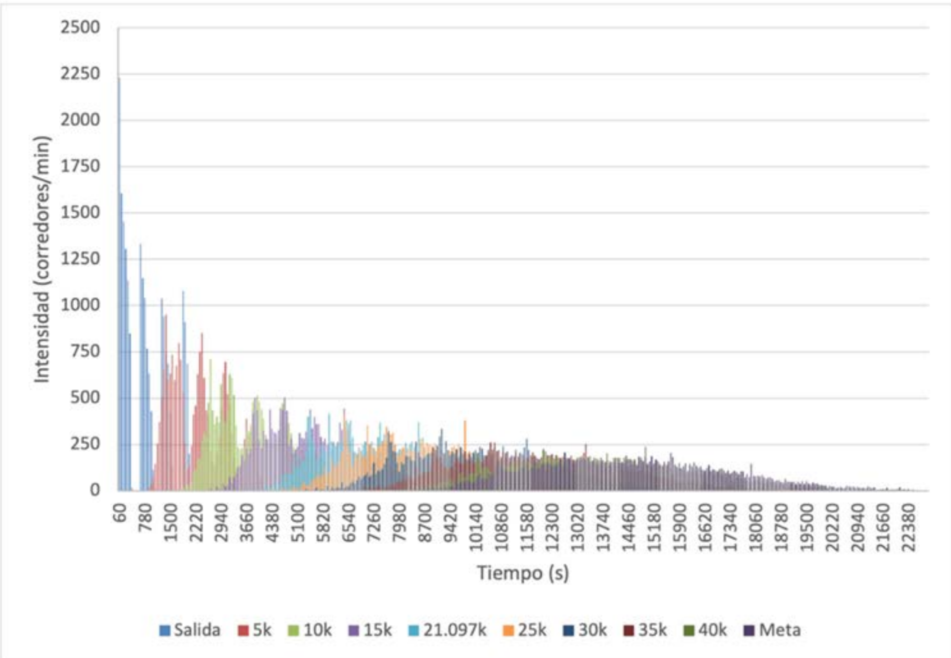


Fig. 11 – Intensidad de corredores por minuto en puntos de control

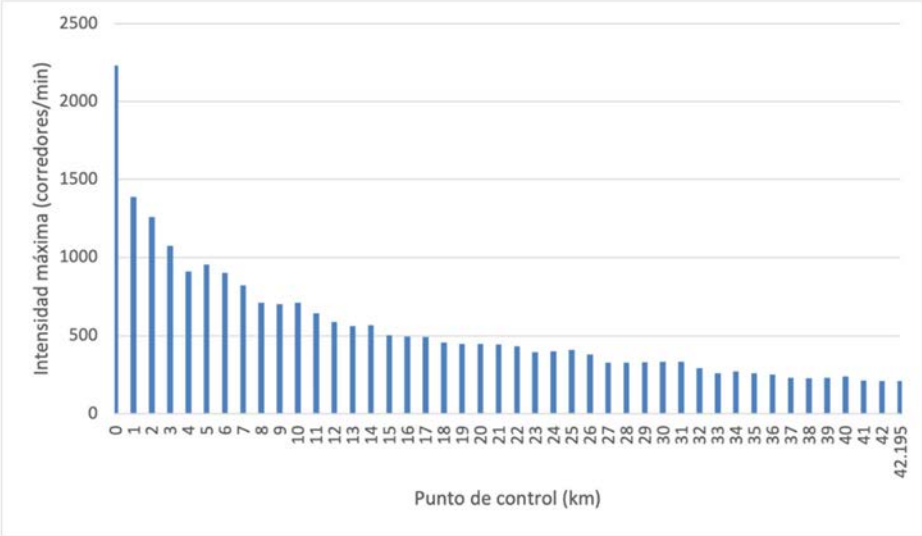

Fig. 12 – Intensidad máxima de corredores en puntos de control

Paralelamente, también se ha estudiado la evolución de la densidad de corredores, estimada como la cantidad de corredores por kilómetro (Figura 13). Para ello, se ha identificado el número de corredores que se encuentran entre dos puntos de control a lo largo del tiempo.

Al igual que ocurre para la intensidad, las mayores densidades de corredores se producen en los primeros kilómetros de la carrera. A medida que la carrera avanza las densidades van disminuyendo, lo que conduce a que la llegada de corredores a meta se realice paulatinamente.

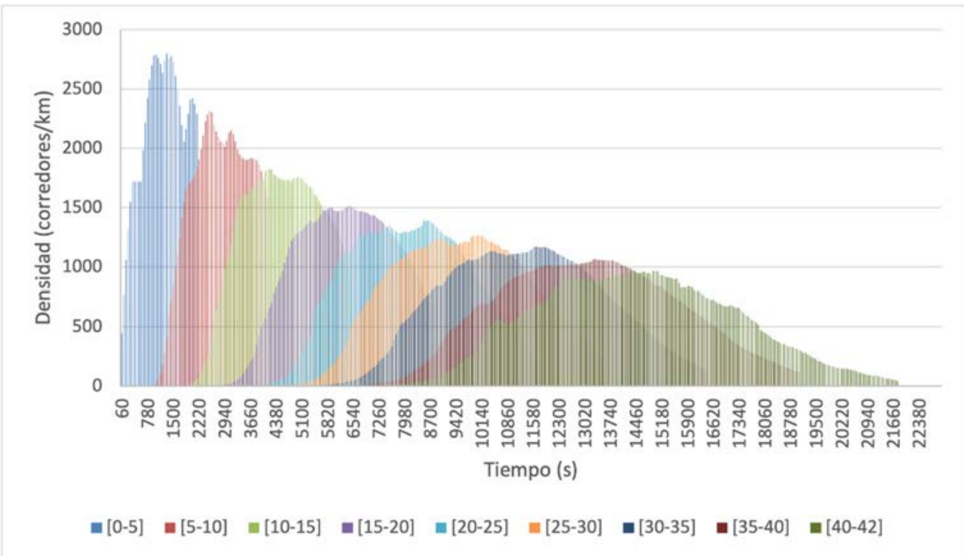

Fig. 13 – Densidad de corredores por kilómetro en intervalos de longitud entre puntos de control

Finalmente, la Figura 14 presenta la densidad de corredores máxima en cada kilómetro de la carrera.

En este sentido, la densidad máxima en cada valor del eje de abscisas está asociada a la cantidad de corredores entre ese valor y el siguiente. Por ejemplo, la densidad máxima para el valor 5 expresa la densidad entre los kilómetros 5 y 6. De acuerdo con lo observado anteriormente, la máxima concentración de corredores se produce en los primeros kilómetros de carrera mientras que a partir del kilómetro 10 la densidad experimenta una reducción muy pausada.

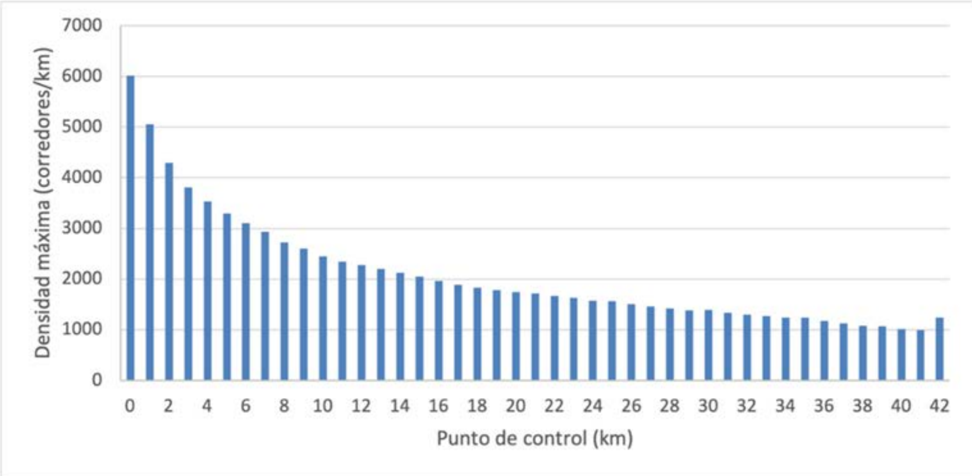

Fig. 14 – Densidad máxima de corredores por kilómetro

Resumiendo, las secciones más críticas durante la carrera se encuentran al inicio de la misma, cuando la intensidad de corredores, expresada en número de corredores por minuto, y la densidad de corredores, expresado en número de corredores por kilómetro, alcanzan sus valores más elevados. Conforme avanza la carrera, ambas variables se reducen considerablemente fomentando una llegada a meta con un flujo de corredores constante y pausado.

5. DISCUSIÓN

Conocer la distribución de corredores a lo largo del tiempo en carreras populares con gran participación puede permitir una gestión más eficiente de la carrera, desde aspectos relacionados con la configuración de la salida en olas y cajones, hasta la disposición de avituallamientos y los anchos mínimos requeridos por unidad de longitud.

Particularmente este último aspecto – ancho mínimo por sección – cobra especial importancia debido a la pandemia de la COVID-19. Conociendo la intensidad de corredores en cada sección, la densidad de corredores por kilómetro y el ritmo medio de los corredores en cada instante y sección se puede estimar el ancho mínimo para garantizar una distancia de seguridad entre participantes.

Para ello, se puede partir del modelo teórico ideal representando en la Figura 15 en el que todos los corredores están equiespaciados a una distancia de seguridad *d*. Bajo esta premisa, en un área específica de la carrera – ancho (a) de sección por longitud (L) de sección – se pueden concentrar un total de N corredores resultado del producto del número de corredores n situados a lo largo de a y el número de corredores m dispuesto a lo largo de L. Las variables de este modelo se relacionan a través de la Ecuación (3), (4) y (5).

$$a = d \cdot (n - 1) \quad (2)$$

$$L = d \cdot (m - 1) \quad (3)$$

$$N = n \cdot m \quad (4)$$

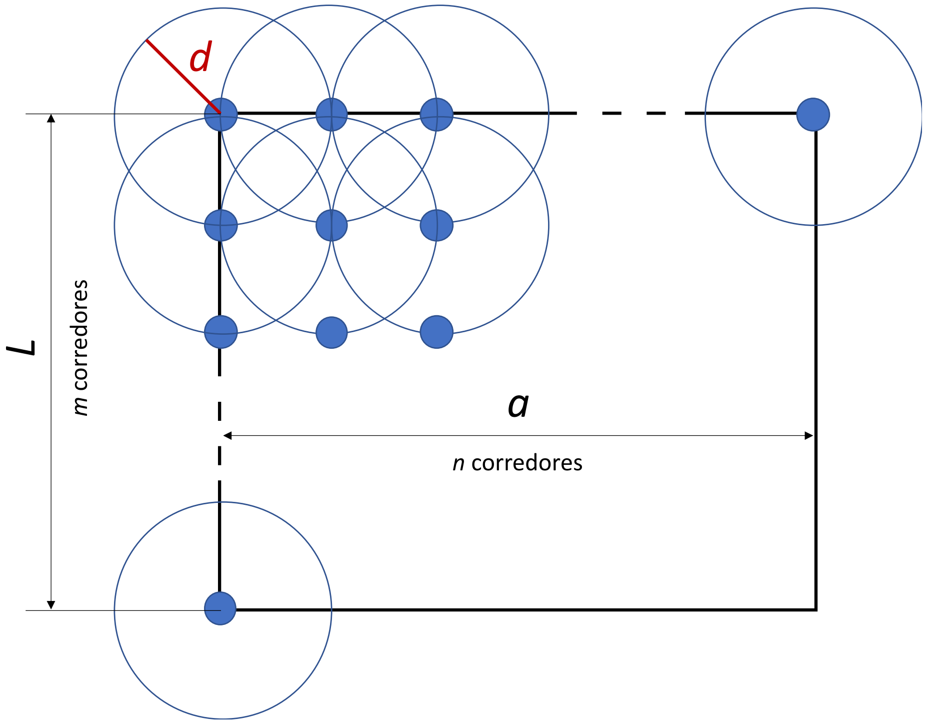

Fig. 15 – Modelo teórico ideal de distribución de corredores

Partiendo de la relación fundamental del tráfico (Ecuación 5) aplicado a este fenómeno concreto, la relación entre la velocidad (V) y el ritmo (R) (Ecuación 6) y la relación que existente entre la densidad de corredores longitudinal (D_l) y transversal (D_t) (Ecuación 7), se obtiene la expresión de la Ecuación 8, que relaciona la densidad transversal (D_t) con la intensidad (I), el ritmo (R) y el ancho de la sección (a).

$$I = D_l \cdot V \quad (5)$$

$$V = 1/R \quad (6)$$

$$D_t = \frac{D_l}{a};\ D_l = D_t \cdot a \quad (7)$$

$$D_t \cdot a = \frac{I}{V} = I \cdot R;\ D_t = \frac{I \cdot R}{a} \tag{8}$$

Por otro lado, la densidad transversal también se puede estimar como el cociente entre el número de corredores *n* que puede atravesar una sección – limitado por la distancia de seguridad (Ecuación 2) – y su anchura (Ecuación 9).

$$D_t = \frac{n}{a} = \frac{\frac{a}{d}+1}{a} \tag{9}$$

Combinando la Ecuación 8 y 9 se obtiene la expresión que permite estimar el ancho requerido en una sección dada una intensidad de corredores, con un ritmo específico y asumiendo una determinada distancia de seguridad (Ecuación 10).

$$\frac{I \cdot R}{a} = \frac{\frac{a}{d}+1}{a} \tag{10}$$

$$a = (I \cdot R - 1) \cdot d \tag{10a}$$

donde a es el ancho requerido (m); I la intensidad máxima de la sección (corredores/s); R el ritmo promedio de los corredores asociado a la intensidad máxima (s/m); y d la distancia de seguridad (m).

La Figura 16 muestra el ancho mínimo requerido al paso por cada kilómetro de la carrera asumiendo diferentes distancias de seguridad. Como se esperaba, los anchos más restrictivos se encuentran en las secciones iniciales de la carrera, cuando la intensidad de corredores es más elevada. Concretamente, la sección que requiere de un mayor ancho se encuentra en el kilómetro 2, con un valor de casi 16 m para una distancia de seguridad de 2 m.

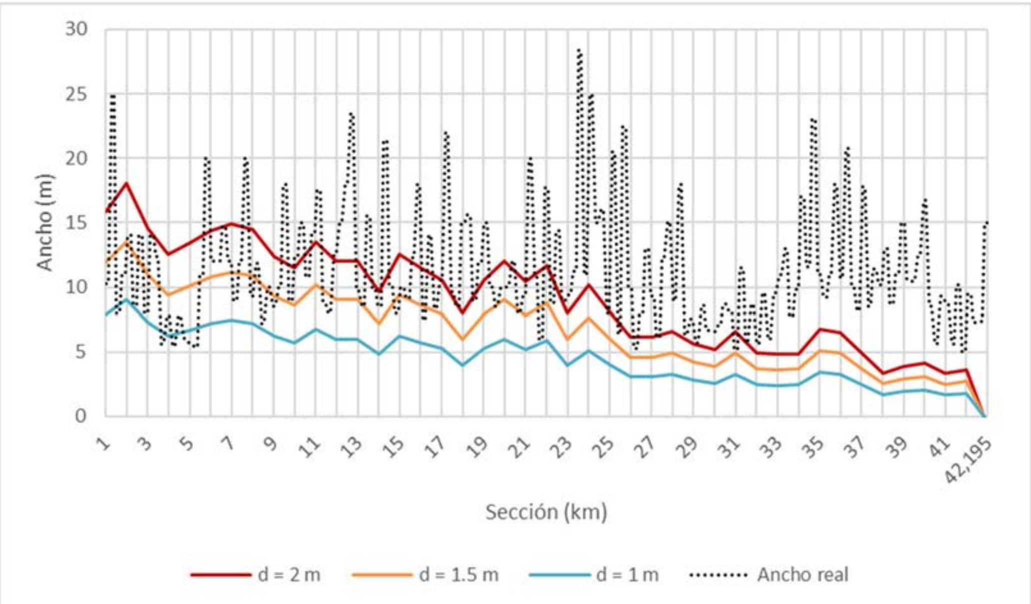

Fig. 16 – Ancho mínimo por sección según intensidad máxima

Comparando los anchos reales de la carrera con los obtenidos se puede afirmar que la carrera no puede desarrollarse en condiciones de seguridad en escenarios de pandemia que requieran asegurar un distanciamiento social como es el caso de la pandemia provocada por la COVID-19 durante el último año, puesto que el ancho real es inferior a los anchos mínimos requeridos para una distancia de seguridad de 2 m en los primeros 6 kilómetros de carrera.

Asimismo, a lo largo de la primera mitad de la carrera se suceden, para la distancia citada, multitud de secciones críticas. No obstante, considerando distancias menores – 1.5 y 1 m – el número de secciones con anchos menores a los requeridos disminuye considerablemente.

Particularmente, para una distancia de seguridad de 1.5 m se observan secciones críticas hasta el kilómetro 10, mientras que considerando 1 m solo se identifican problemas de ancho de sección en los primeros 5 kilómetros.

En caso de mantener el trazado actual, para garantizar que se cumple la distancia de seguridad establecida, se podría reconfigurar la salida, es decir, modificar el número de olas y cajones y el desfase entre olas. Con ello se podría suavizar las altas intensidades y densidades de corredores en los primeros kilómetros.

6. CONCLUSIONES

Las maratones se han convertido en los últimos años en las carreras más populares aglutinando a miles de corredores. Concretamente, la maratón de la ciudad de Valencia ha experimentado un crecimiento anual de un 10% entre sus ediciones de 2016 y 2019, lo que supone que en este último año se sobrepase la cifra de 21,000 participantes. A medida que estas carreras crecen en magnitud su gestión es más complicada y conocer el comportamiento de las variables que definen el flujo de corredores es clave para garantizar que la carrera se desarrolle en condiciones de seguridad. Entre otras cuestiones, la caracterización del comportamiento del flujo de corredores permitirá una mejora de la gestión relativa a la configuración de la salida – definición de olas y cajones –, la disposición de avituallamientos y el establecimiento del recorrido a partir de los anchos mínimos requeridos en cada sección. Este último aspecto todavía cobra mayor importancia en situaciones de pandemia como la actual en la que se debe respetar una distancia social.

Para caracterizar el comportamiento de los corredores esta investigación se ha centrado en el análisis de los maratones celebrados en la ciudad de Valencia (España) desde 2016 a 2019. Los datos generales e individuales de estas carreras están disponibles de manera gratuita en la web de la organización del evento y fueron obtenidos mediante un script de *web scraping* programada exclusivamente para tal fin. A partir de los datos filtrados se estimaron, entre otras variables, los ritmos individuales de cada corredor a su paso por cada punto de control, el desfase de tiempo en la salida, la intensidad de corredores en las secciones correspondientes a cada kilómetro de la carrera y la densidad de corredores por kilómetro.

Como resultado, se identificó un aumento de la participación de las mujeres a lo largo de los años, situándose en 2019 en alrededor de un 20%. En general, el grueso de la carrera se concentra en la franja de edad comprendida entre los 23 años y los 45 años. La presencia de cada una de las categorías restantes se va diluyendo con la edad.

En cuanto a la evolución de corredores en la salida, se verifica que cuanto menor es el tiempo objetivo ligado a la ola, mayor es la intensidad de descarga de corredores. Asimismo, en todas las olas se observa una reducción de la intensidad de descarga con el paso del tiempo.

En este sentido, los modelos calibrados podrían ser empleados para estimar el número de corredores máximo por ola y/o el desfase entre olas.

A la hora de participar en el maratón, cada participante proporciona un tiempo objetivo que la organización utiliza para la distribución de corredores en olas y cajones. Aunque en este caso solo se ha podido analizar el cumplimiento de este tiempo por olas, resulta bastante claro que el tanto por ciento de corredores que empeoran el resultado previsto aumenta conforme mayor es el tiempo objetivo, desde el 26% de corredores de la *Ola 1* al 65% de la *Ola 3*. Asociado a este incumplimiento, se ha verificado que cuanto mayor es el ritmo medio de la carrera, mayor es la variación del ritmo a lo largo de esta.

Concretamente, aquellos corredores que cumplen o empeoran el tiempo objetivo experimentan ritmos más rápidos en la primera mitad de la carrera y ritmos lentos o muy lentos en la segunda parte de la misma. Por el contrario, los corredores más rápidos – ritmos medios menores a 225 s/km – y los que mejoran su tiempo objetivo parecen ser más conservadores al inicio de la carrera y mantienen su ritmo constante a lo largo de esta.

Finalmente, el análisis de la intensidad y la densidad refleja que las secciones más críticas durante la carrera se encuentran al inicio de la misma, cuando ambas variables alcanzan sus valores más elevados. Conforme avanza la carrera, tanto la intensidad como la densidad se reducen considerablemente fomentando una llegada a meta con un flujo de corredores constante y pausado.

Conocer de manera previa estas dos variables es fundamental para la definición del recorrido de la prueba – condicionada por el ancho de las secciones – con el fin de garantizar que todos los corredores se encuentren en flujo libre – no condicionados por otros corredores – a lo largo de toda la carrera.

Todavía es más interesante si cabe la determinación del ancho mínimo requerido en cada sección de la prueba con el fin de garantizar una distancia social entre corredores – sobre todo en la situación actual de pandemia provocada por la COVID-19 –.

Este ancho mínimo puede ser estimado a partir de la intensidad máxima y el ritmo promedio que se producirá en cada sección del recorrido asumiendo el modelo teórico presentado en este trabajo.

Los resultados de esta investigación están limitados a los resultados obtenidos en los maratones de la ciudad de Valencia. Con el fin de generalizar las conclusiones obtenidas es necesario el análisis preferiblemente de otros maratones que también ofrezcan sus datos de manera abierta como, por ejemplo, la maratón celebrada en Berlín, Londres o Nueva York.

Asimismo, sería conveniente ampliar el análisis centrándose en cada cajón, para lo que sería necesario en algunos casos, como el del maratón de Valencia, la colaboración de la organización del evento, pues este tipo de datos habitualmente no es proporcionado ni se puede inferir de manera precisa, aunque sí podría ser estimado de manera aproximada por el desfase en la salida. Por último, sería interesante estudiar cómo la configuración de la salida influye en la intensidad y densidad de corredores en la parte inicial de la carrera con el fin de garantizar el cumplimiento, si es necesario, de la correspondiente distancia de seguridad por motivos sanitarios.

RESUMEN

A nivel mundial existen experiencias prácticas de políticas de gestión del aparcamiento en la calle basadas en tarifas dinámicas (San Francisco, Los Ángeles y otras ciudades) que han permitido administrar de forma más eficiente los espacios de parking y reducir el número de vehículos en busca de un espacio libre. Para ello, el presente trabajo analiza el impacto que podrían tener, en el comportamiento de los usuarios, diferentes políticas de gestión del aparcamiento en la vía pública.

Para simular los efectos de las distintas políticas, se ha creado un modelo de aparcamiento basado en un submodelo de elección de lugar de aparcamiento y en un submodelo de búsqueda de plaza de aparcamiento. Los parámetros de los submodelos han sido estimados con datos recolectados en un área del centro de la ciudad de Santander (España) y mediante una encuesta de preferencias declaradas respondida por usuarios de aparcamiento.

El modelo ha sido implementado en el software de simulación Aimsun, construyendo una API personalizada programada en Python 3.7. Este modelo ha permitido simular varias políticas centradas en la tarificación de los espacios de aparcamiento en la calle de forma dinámica con actualizaciones de la tarifa en intervalos cortos de tiempo de entre 5 y 15 minutos.

1. INTRODUCCIÓN

Debido al amplio uso de los vehículos privados, la oferta de aparcamiento es un componente clave en la generación de la congestión del tráfico y los altos niveles de contaminación atmosférica en las zonas urbanas.

En el pasado, la planificación y el desarrollo de políticas de aparcamiento tenían como objetivo ofrecer el mayor número de plazas de aparcamiento posible para facilitar el uso de los vehículos privados. Sin embargo, la búsqueda de plazas de aparcamiento se ha convertido en una dificultad para la mayoría de los usuarios de vehículos privados y en un problema importante que afecta a los sistemas de transporte en las ciudades. La planificación y gestión del transporte se ha enfrentado a varios retos en las últimas décadas.

La mayoría de las ciudades pretenden desincentivar el uso del vehículo privado y promover los modos de transporte no motorizados para la movilidad dentro de las zonas urbanas. Las administraciones públicas tratan de crear zonas peatonales y verdes que puedan dar lugar a ciudades más sostenibles, vivas y seguras. El número de plazas de aparcamiento disponibles en las ciudades se está reduciendo, y el suelo destinado a las actuales plazas de aparcamiento se está utilizando para otros fines con el fin de promover modos de movilidad alternativos y espacios públicos habitables. Por ello, la gestión de las plazas de aparcamiento se ha convertido en un factor esencial para conseguir sistemas de transporte eficientes.

La oferta de aparcamiento en la calle en las zonas urbanas conlleva varias consecuencias negativas. Según un estudio realizado por Shoup (2006), el proceso de búsqueda de aparcamiento representa aproximadamente el 30% del tráfico total en las zonas urbanas. Esta investigación concluyó que la búsqueda de aparcamiento dura entre 3,3 y 14 minutos en las ciudades estadounidenses. Por lo tanto, la búsqueda de aparcamiento conlleva un aumento considerable del tiempo total de viaje de todos los usuarios, no sólo de los que buscan aparcamiento, y un aumento del tráfico y la congestión.

Además, según la RAC Foundation (2012), los vehículos privados están aparcados el 80% del tiempo. Esto significa que hay una ocupación muy ineficiente e infrautilizada del suelo, especialmente en los centros de las ciudades, que de otro modo podría utilizarse para fines más eficientes, como carriles adicionales para el transporte público.

La búsqueda de aparcamiento contribuye a generar tráfico y congestión en las zonas urbanas. Esto conlleva un aumento considerable del tiempo total de viaje de todos los usuarios del transporte y la generación de emisiones de gases de efecto invernadero. La aplicación de políticas de aparcamiento puede ayudar a gestionar la demanda y reducir los problemas derivados del estacionamiento.

Este estudio pretende explorar y comparar diversas políticas de estacionamiento, especialmente en lo que respecta a la tarificación dinámica del estacionamiento y la limitación de la duración de la estancia en el mismo, para concluir qué medidas de restricción del estacionamiento son más favorables para reducir el impacto sobre el tráfico y el medio ambiente. En primer lugar, se va ha hacer un repaso al estado actual de la práctica en cuanto a modelos de aparcamiento y sistemas de tarificación dinámica.

A continuación, se describirá la metodología del modelo de aparcamiento diseñado y, posteriormente se realizará una aplicación práctica describiendo los principales resultados obtenidos para finalmente establecer las conclusiones del estudio.

2. ESTADO DEL ARTE

La mayoría de las políticas de aparcamiento se basan en estrategias que pretenden desincentivar el uso del vehículo privado (Buehler et al., 2017; Nurdden et al., 2007). Como se ha mencionado anteriormente, las administraciones públicas utilizan estrategias y políticas de aparcamiento para regular y gestionar la demanda y la oferta de aparcamiento.

En primer lugar, una de las estrategias más comunes para reducir la demanda de aparcamiento en las grandes ciudades es el peaje por conducir dentro de la ciudad. Aunque no es una política directa de aparcamiento, tiene un gran impacto en la demanda de estacionamiento. Los precios de los peajes pueden ser más bien fijos; basados en el horario, por lo que varían en función de la hora del día, siendo considerablemente más altos durante los periodos punta; o dinámicos. Por ejemplo, en 2003, la ciudad de Londres introdujo una tasa de congestión de 5 libras diarias por circular por la Inner Ring Road (Blow et al., 2003). Esta estrategia pretendía reducir el tráfico en la zona en un 15%.

En segundo lugar, otra estrategia de aparcamiento habitual es la denominada Park and Ride, que pretende descongestionar los centros urbanos mediante la implantación de aparcamientos en las afueras de las ciudades. Estos aparcamientos están conectados con el transporte público, que transporta a los usuarios al centro de la ciudad. Por ejemplo, la ciudad de Barcelona implementó una estrategia de Park and Ride para descongestionar y reducir las emisiones en la ciudad (Vila Serrano, 2019). En la actualidad hay aproximadamente 1500 plazas de aparcamiento en tres áreas de Park and Ride en las afueras de la ciudad, en los barrios de Besòs, Sarrià y La Ciudad de la Justicia, que se encuentran cerca de las estaciones de tren.

En tercer lugar, la limitación del tiempo de estacionamiento es otra estrategia que restringe el tiempo de estacionamiento para desalentar el estacionamiento de larga duración y promover la rotación del estacionamiento. Los periodos más cortos restringen las actividades de los usuarios, mientras que los periodos más largos fomentan la accesibilidad al aparcamiento para los habitantes de la zona de influencia. Las investigaciones recomiendan que las zonas comerciales establezcan un estacionamiento limitado a corto plazo en el 10-30% de las plazas de aparcamiento para aumentar la actividad de los negocios (Litman, 2020). Al mejorar la rotación de los aparcamientos, los administradores pueden favorecer a los negocios de la zona al aumentar el tránsito y la accesibilidad de los clientes. Aunque la limitación de tiempo es una estrategia eficaz, es difícil de aplicar debido a que los usuarios tienden a trasladar sus vehículos a otras plazas de aparcamiento una vez alcanzada la limitación de tiempo (Simićević et al., 2013).

En cuarto lugar, otras estrategias comunes de regulación del estacionamiento son (Litman, 2016): (i) limitación del acceso al estacionamiento en determinadas zonas solo para residentes u otros usuarios permitidos (vehículos de servicios públicos, usuarios de corta duración, etc.), (ii) restricción del estacionamiento en vías arteriales durante periodos de alta demanda para facilitar el tráfico, (iii) limitación del periodo de tiempo a determinadas horas del día en función del uso deseado del estacionamiento durante cada periodo de tiempo, etc.

Por último, el pago por estacionamiento es otra estrategia común de estacionamiento, en la que un usuario paga por ocupar una plaza de aparcamiento. Esta estrategia puede definirse como tarificación del aparcamiento (Shoup, 2017). El peaje del aparcamiento puede producir múltiples cambios en el sistema de transporte, como la reducción de la propiedad del coche privado, el cambio a modos de transporte activos, la modificación de la ubicación del aparcamiento, los cambios en el horario de transporte, la modificación de la duración de la estancia en el aparcamiento, la reducción del tiempo de viaje de los usuarios (Litman, 2010).

También se suele aplicar para lograr uno o varios de los siguientes objetivos: reducir la congestión del tráfico, disminuir los tiempos de búsqueda de aparcamiento, lograr la tasa de disponibilidad de aparcamiento deseada, aumentar los ingresos derivados de los impuestos de aparcamiento, etc.

En cuanto a políticas de precios, se pueden establecer 2 tipos de medias de gestión. Las tasas estáticas que son una de las tarifas más comunes de aparcamiento. Estás suelen aplicarse durante un periodo de tiempo establecido durante el día cuando se prevé que la demanda del aparcamiento sea mayor. El problema suele ser la infravaloración del precio del aparcamiento dando lugar a pérdidas de bienestar (Arnott & Inci, 2006).

Por otro lado, las tarifas dinámicas permiten adaptar el precio del aparcamiento para lograr una tasa de ocupación óptima. Estas políticas permiten una gestión de precios dinámica en base a la ocupación, sin alterar prácticamente la infraestructura existente, lo que las hace muy atractivas de implantar por los múltiples beneficios que ofrecen. Mediante la gestión de precios se alcanzan unas ratios bastante exitosas también en la reducción de tráfico de cruce y plazas libres ofertadas (Millard-Ball et al., 2014).

Finalmente, en lo que a modelos de aparcamiento se refiere, se ha realizado una comparativa de los principales modelos desarrollados en los últimos años Tabla 1.

Modelo	Tipo	Propósito	Método	Tratamiento del espacio	Modo de búsqueda	Software	Referencia
PARK-SIM	Micro	Simulación de elección de aparcamiento dentro de un lote	Eventos discretos	SI	Gestión de colas	CAD	Young and Thompson (1987); Young and Weng (2005)

Tabla 1 Análisis de diferentes modelos de aparcamiento

3. METODOLOGÍA

A partir del análisis del estado del arte, se ha constatado la escasez de estudios en la literatura internacional sobre el análisis del impacto de la aplicación de diferentes políticas de aparcamiento en la vía pública. Por ello, se ha diseñado un modelo de aparcamiento que permita paliar las carencias de aquellos modelos desarrollados en el estado del arte.

3.1 Modelo de utilidad de plaza

El modelo, basado en agentes desarrollado se codificó en Python 3.7 y 2.7, requerido por la API de Aimsun, y se integró en Aimsun a través de la API proporcionada por este software. Aimsun permite modelar el comportamiento individual de los usuarios dentro de una red de tráfico basándose en diferentes teorías microscópicas de comportamiento, como (i) el seguimiento de coches, (ii) el cambio de carril y (iii) la aceptación de huecos.

El modelo permite simular el comportamiento de los usuarios a la hora de buscar una plaza de aparcamiento vacía en diferentes situaciones, políticas de precios de aparcamiento, porcentaje de usuarios informados, tasas de ocupación, etc. El modelo ayuda a establecer y analizar el efecto de diferentes políticas de tarificación, principalmente estáticas y dinámicas.

Para la definición de los parámetros de entrada se realizó un modelo logit multinomial que define las utilidades de cada una de las alternativas de acuerdo con las siguientes ecuaciones.

$$V(Libre) = \beta_0 + \beta_{TD}TD_{Libre} + \beta_{TB}TB_{Libre} + \beta_{OCU}OCU_{Libre} \quad (1)$$

$$V(Calle) = \beta_0 + \beta_{TD}TD_{Calle} + \beta_{TB}TB_{Calle} + \beta_{OCU}OCU_{Calle} + \beta_{TAR}TAR_{Calle} + \beta_{TMAX}TMAX_{Calle} \quad (2)$$

$$V(Sub) = \beta_0 + \beta_{TD}TD_{Sub} + \beta_{TB}TB_{Sub} + \beta_{OCU}OCU_{Sub} + \beta_{TAR}TAR_{Sub} \quad (3)$$

Según esta especificación, la elección de aparcar pagando en la calle depende de la tarifa del aparcamiento (*TAR*), del tiempo a destino (*TD*), del tiempo de búsqueda (*TB*), de la ocupación de las plazas (*OCU*) y del tiempo máximo posible de estancia (*TMAX*). La alternativa aparcamiento libre depende del tiempo de búsqueda (*TB*), del tiempo al destino (*TD*) y de la ocupación de las plazas libres (*OCU*). En el caso de la elección de aparcamiento privado fuera de la calle (parking subterráneo), la elección dependería de la tarifa (*TAR*), el tiempo al destino (*TD*), el tiempo de búsqueda (*TB*) y la ocupación de las plazas (*OCU*).

En el segundo nivel de elección de sección de aparcamiento, la elección depende de la utilidad que se derive por aparcar en una sección según la siguiente expresión:

$$V(seccion) = \beta_{TD}TD_{seccion} + \beta_{TB}TB_{seccion} + \beta_{OCU}OCU_{seccion} + \beta_{TAR}TAR_{seccion} + \beta_{TMAX}TMAX_{seccion} \quad (4)$$

Con parámetros y variables similares a las presentadas en la elección de tipo de aparcamiento.

$$V(seccion) = \beta_{TD}TD_{seccion} + \beta_{TB}(\gamma_{usuario}\, TB_{seccion} + TB_{acumulado}) + \beta_{OCU}OCU_{seccion} + \beta_{TAR}TAR_{seccion} + \beta_{TMAX}TMAX_{seccion} \quad (5)$$

La introducción del parámetro dummy $\gamma_{usuario}$ permite considerar un tiempo de búsqueda esperado igual a 0 en el caso de que el usuario esté informado y sepa que en esa sección encontrará sitio. Por otro lado, las variables ($OCU_{seccion}$) y ($TAR_{seccion}$) mediante su modificación, adoptando valores en tiempo real o estándar de la red basados en históricos, permiten introducir las variaciones que afectan a los diferentes usuarios informados o no informados teniendo en cuenta su comportamiento en el modelo.

Por lo tanto, la elección de sección para aparcar depende de la tarifa (*TAR*), el tiempo a destino (*TD*), el tiempo de búsqueda de aparcamiento (*TB*), la ocupación de la sección (*OCU*) y el tiempo máximo de estancia permitido (*TMAX*) así como del ya mencionado tipo de usuario ($\gamma_{usuario}$).

Finalmente, la elección conjunta de tipo y sección de aparcamiento consiste en la especificación de un modelo Logit Jerárquico (*HL*) en la que la utilidad de la alternativa aparcar en la calle depende de la utilidad máxima esperada de las alternativas que están relacionadas con ella, es decir, de las distintas posibilidades de aparcamiento en las secciones. Estas dos elecciones encadenadas se pueden esquematizar tal y como se muestra en la Figura 1. En este caso, la utilidad de aparcar en la calle vendría dada por la utilidad máxima esperada (*EMU*), es decir:

$$V(Calle) = \frac{1}{\lambda} EMU = \frac{1}{\lambda} ln\{\textstyle\sum_i e\,[\lambda V(seccion_i)]\} \quad (6)$$

En la que λ es el parámetro de escala de la distribución de los términos de error dentro del nido e *i* son el conjunto de secciones agrupadas dentro de la alternativa aparcar en la calle (o cierto subconjunto de ellas), las cuales pueden presentar un cierto nivel de correlación.

Este segundo tipo de modelización mediante LH permite que las distintas secciones de aparcamiento, en las que se puede aparcar en la calle, pueden presentar cierto nivel de correlación al tener características comunes tanto en su utilidad sistemática como en sus errores aleatorios.

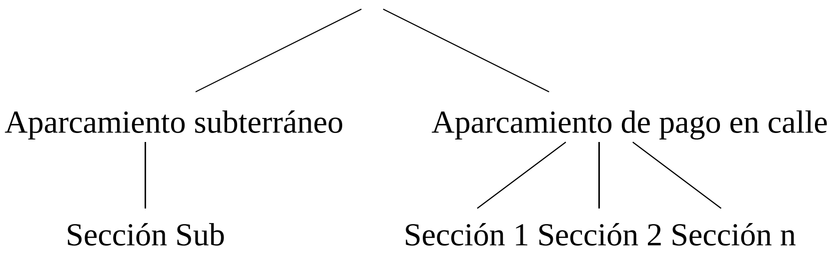

Figura 1 Modelo de elección de tipología y sección de aparcamiento

3.2 Modelo de búsqueda de aparcamiento

El modelo de búsqueda de aparcamiento, como se ha dicho, es un modelo basado en agentes, que, a diferencia de otros, tiene en cuenta diversos factores para asignar distintas utilidades a cada una de las secciones. Para la ejecución del modelo con cada uno de los vehículos se sigue la siguiente secuencia Figura 2

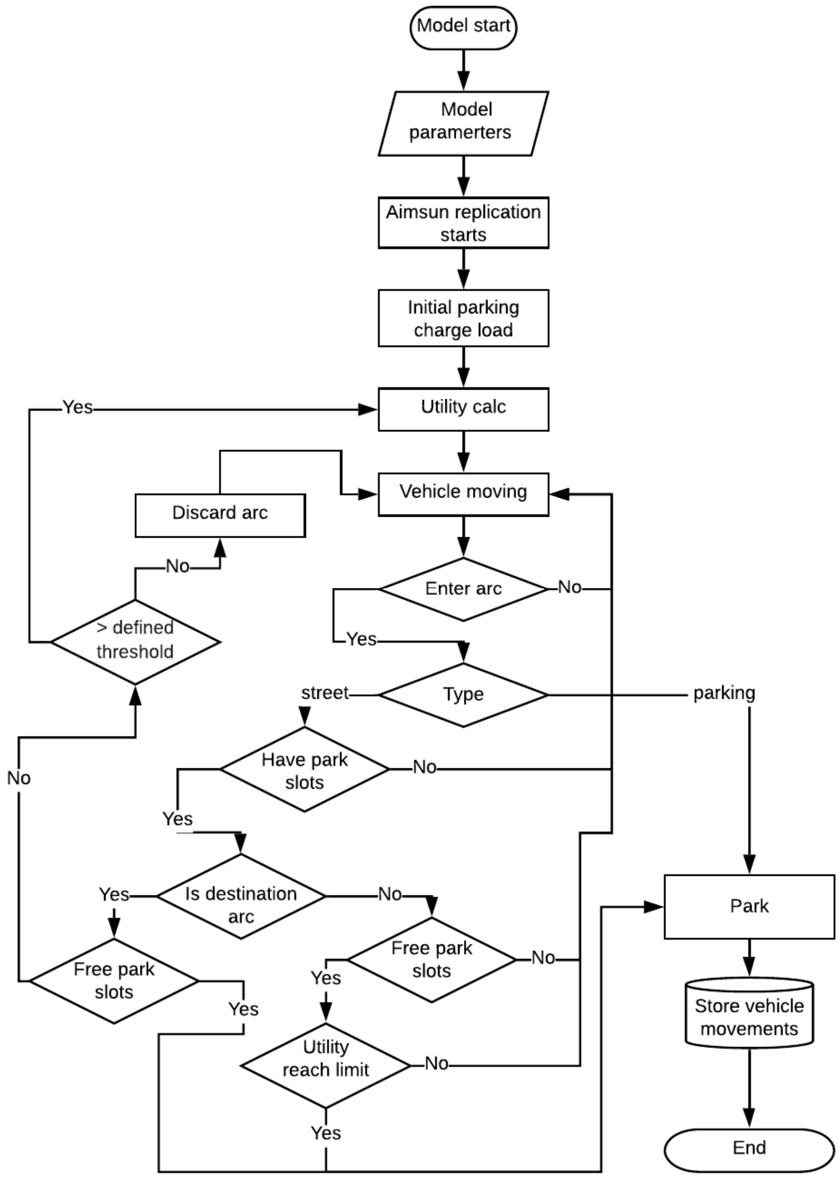

Figura 2 Funcionamiento del modelo de búsqueda

Además de los datos de demanda y oferta de aparcamiento, el modelo requiere la introducción de diversos parámetros del modelo y variables de restricción relacionadas con las políticas de aparcamiento, que se pretenden analizar en el presente estudio. Estos parámetros de entrada del modelo se enumeran la Tabla 2

Variables de entrada del modelo
Tiempo de maniobra de aparcamiento (s)
Tiempo mínimo de estacionamiento (s)
Tiempo máximo de estacionamiento (s)
Ocupación inicial (%)
Rangos de tarifas (€)
Rangos de ocupación (%)
Tarifa estándar en la calle (€)
Tasa estándar fuera de la vía pública (€)
Búsqueda del tiempo de aparcamiento: media y desviación (s)
Máxima utilidad relativa
Tiempo de actualización de la tasa (s)
Porcentaje de usuarios informados (%)

Tabla 2 Variables de entrada requeridas por el modelo

4. APLICACIÓN PRÁCTICA

Para la aplicación del modelo DYNAPARK en un ámbito de estudio real se ha procedido a la modelización de un área de la ciudad de Santander, simulando los escenarios descritos en la Tabla 3.

	Esc. 1	**Esc. 2**	**Esc. 3**
Aplica modelo aparcamiento		X	X
Aplica tarifa fija		X	
Aplica tarifa dinámica			X
Aplica tarifa actual		X	X

Tabla 3 Escenarios ejecutados

Para la aplicación de los cinco escenarios descritos se ha seleccionado un área céntrica de la ciudad de Santander que está ubicada en la zona oriental del centro urbano (Figura 3). El motivo de elección del área viene motivado por la existencia dentro de la misma de:

- Aparcamientos regulados de pago en la calle.
- Aparcamientos privados.
- Aparcamientos privados, de pago, de uso público fuera de la calle.

Figura 3 Área de estudio

Con el objetivo de extraer los parámetros del modelo se realizó una encuesta de preferencias declaradas a usuarios habituales y no habituales de esta zona de aparcamiento. Obteniendose los parámetros presentes en la Tabla 4

Variable	Parámetro	Z
Tarifa (€/h)	-0.95057	-4.88
Tiempo de Búsqueda (min)	-0.07261	-0.68
Tiempo a destino (min)	-0.07761	-1.15
Ocupación (%)	0.00707	0.71
Tiempo máximo de estancia (h)	0.52876	2.90
Constante Subterráneo	2.59822	4.58
Nido Calle	0.68133	2.79
Log-Likelihood	-69.515	
Log-Likelihood (Null)	-138.629	
Log-Likelihood (Constantes)	-136.591	
McFadden Pseudo R-squared	0.4985	

Tabla 4 Parámetros estimados para el modelo de elección de tipología de aparcamiento y utilidad

El valor elegido para los parámetros de entrada del modelo se ha establecido en base a varios criterios, se muestra en la Tabla 5. Algunos datos de entrada, como el tiempo máximo de estacionamiento y la tarifa general, se han extraído de las ordenanzas municipales que regulan el estacionamiento (Santander, 2014). Otros parámetros, como el precio por hora de los aparcamientos subterráneos, vienen dados por los gestores de éstos y son de conocimiento público. Por otro lado, las crecientes fuentes de información disponibles hoy en día de manera online han permitido la extracción de otros datos, como el tiempo medio de estacionamiento de los vehículos que ha sido obtenido a través de un análisis de los datos del portal de Open data de Santander (Santander, 2021).

Variable	**Unidades**	**Escenario 1**	**Escenario 2**	**Escenario 3**
Tiempo parada de estacionamiento	seg.	No se aplica el modelo, cada usuario acude a su centroide final y encuentra aparcamiento	22.3	22.3
Tiempo mínimo estacionamiento	seg.		300	300
Tiempo máximo estacionamiento	seg.		7200	7200
Ocupación inicial	%		95	95
Rangos tarifa aparcamiento on-street	€/h		En el caso de aplicación de la tarifa actual no es necesario aplicar tarifas dinámicas	[0.5,1,1.75]
Rangos ocupación on-street	%			[60,80,100]
Tarifa genérica on-street	€/h		0.75	0.75
Tarifa aparcamiento off-street	€/h		1.60	1.60
Tiempo de búsqueda medio	seg.		240	240
Tiempo de búsqueda desviación	seg.		120	120
Utilidad mínima relativa	%		90	90
Tiempo actualización tarifas	min.		15	15
Usuarios informados	%		No aplica	50

Tabla 5 Parámetros de entrada al modelo de búsqueda de aparcamiento

5. RESULTADOS

Se han realizado 15 simulaciones para cada uno de los escenarios propuestos lo cual permite eliminar la aleatoriedad de los resultados de realizar un número reducido de ejecuciones del modelo. Para poder comparar los resultados obtenidos de forma numérica, se han analizado varios parámetros de salida de la microsimulación como son: consumo de combustible, cola media generada, densidad de vehículos, distancia total viajada por los vehículos, flujo, tiempo de viaje, vehículos dentro de la red, velocidad y emisiones generadas, parámetros todos ellos que nos permiten tener una visión concreta para comparar los escenarios.

Para poder valorar las emisiones de contaminantes se ha usado el modelo descrito por el estudio de Lizasoain-Arteaga et al. (2020). Los resultados obtenidos para cada uno de los indicadores se muestran en la tabla 6. En dicha tabla se muestran algunos resultados desagregados para los coches en tránsito y los coches que aparcan identificados como "park".

Indicador	Unidades	Esc. 1	Esc. 2	Esc. 3
Cola Media - Coche	veh	7.02	22.49	16.59
Cola Media - Coche- park	veh	1.25	24.9	14.1
Consumo de Combustible - Coche	l	167.87	201.71	193.14
Consumo de Combustible - Coche- park	l	29.16	107.51	79.1
Densidad - Todos	veh/km	4.23	27.1	26.29
Densidad - Coche	veh/km	3.65	6.06	5.21
Densidad - Coche- park	veh/km	0.58	21.05	21.09
Distancia Total de Viaje - Todos	km	1056.95	1228.45	1199.76
Distancia Total de Viaje - Coche	km	925.28	920.71	936.17
Distancia Total de Viaje - Coche- park	km	131.67	307.74	263.59
Emisión - Coche - CO2	g	323719.01	384119.86	371121.39
Emisión - Coche - PM	g	99.05	113.53	111.22
Emisión - Coche- park - CO2	g	79239.64	242598.53	184244.02
Emisión - Coche- park - PM	g	29.21	71.95	59.03
Tiempo de Demora - Coche	seg/km	46.8	114.66	88.42
Tiempo de Demora - Coche-park	seg/km	57.25	242.24	212.69
Tiempo de Viaje - Coche	seg/km	116	183.84	157.62
Tiempo de Viaje - Coche-park	seg/km	128.62	312.56	282.49

Tabla 6 Resultados para los 3 escenarios simulados

Como era de esperar se producen 2 efectos. Por un lado, el escenario 1 muestra unos resultados teóricamente más beneficiosos en todos los factores que se han extraído. Sin embargo, en este escenario se ha excluido el tráfico de búsqueda de aparcamiento, por lo que sus resultados no son realistas. Por tanto, queda demostrada la influencia del tráfico generado por la búsqueda de aparcamiento (Shoup, 2005) tal y como se refleja en el incremento de los indicadores en los escenarios 2, y 3 respecto al escenario 1.

Comparando los resultados de los diversos escenarios con el escenario 1, se ve como algunos factores, como el tiempo que los coches permanecen en la red, aumentan significativamente hasta un 26%.

Evidentemente un aumento en el número de vehículos conllevará el consiguiente aumento del consumo de combustible, que se ha estimado en el entorno del 63%, provocando asimismo un aumento promedio del 60% en las emisiones reales que se producen durante el periodo estudiado en la zona. Estos resultados demuestran, por tanto, la relevancia de añadir una capa extra a la microsimulación de vehículos en las ciudades para tener en cuenta todas las maniobras que se llevan a cabo debido al aparcamiento y búsqueda de este. Un aspecto que respalda los estudios realizados sobre la gran influencia del tráfico de búsqueda de aparcamiento en la movilidad de las ciudades.

Una vez demostrada la influencia de los itinerarios de búsqueda y las maniobras de aparcamiento en las simulaciones, es posible analizar los resultados de aplicar un sistema de tarificación dinámica respecto a un sistema de cobro por uso tradicional mediante la comparativa de los escenarios 2 (tarifa actual) y 3. La tabla 7 contiene las variables de salida de la simulación como resultado de aplicar tarifas de forma dinámica. En dicha tabla se comparan los resultados obtenidos en el escenario 3 respecto al 2, donde las diferencias son aún mayores en cuanto a diferenciación de políticas. Todos los indicadores estudiados presentan datos más beneficiosos en el caso de aplicación de tarifas dinámicas y más aún en el caso de tener tarifas máximas más elevadas.

Parámetro	**Var. 2/3 (%)**	**Parámetro**	**Var. 2/3 (%)**
Cola Media - Todos	-35.2	Emisión IEM - Todos - CO2	-11.4
Consumo de Combustible - Todos	-12	Emisión IEM - Todos - PM	-8.2
Consumo de Combustible - Coche- park	-26.4	Tiempo de Demora - Todos	-22.7
Distancia Total de Viaje - Coche- park	-14.3	Tiempo de Viaje - Todos	-14.2

Tabla 7 Comparativa de resultados entre los escenarios 2/3

Es muy llamativa la diferencia que se produce en la variación de las colas medias y en el claro descenso entre escenarios de los consumos de combustible, especialmente de los usuarios que deciden aparcar en la zona. La existencia de usuarios informados, dentro de los escenarios dinámicos, facilita una buena distribución de las plazas, favoreciendo las reducciones observadas.

Al introducir tarifas dinámicas se producen 2 fenómenos, por un lado, la reducción del consumo de combustible y por otro de las emisiones.

Cuantificado el ahorro para esta zona en el caso más significativo, supondría un consumo de 24,40 litros menos de combustible cada hora, un ahorro de unos 0.10€ para cada usuario y aparcamiento en el caso analizado. En niveles de contaminantes supondría una reducción importante de emisiones de CO_2 y otros contaminantes a la atmósfera debido a la disminución del tráfico de paso, tanto al introducir tarifas dinámicas como al subir las tarifas.

En contraprestación, el modelo arroja que los usuarios aparcarían más lejos del destino, incrementando sus tiempos de acceso a la actividad para la que se desplazaban debido a la variabilidad de tarifas. Entre el escenario 3 dinámico y el escenario 2 actual se produce una diferencia de distancias en acceso a destino de 25 metros, siendo 155.78m para el escenario dinámico y de 130.03 para la situación actual. Este aumento de distancia es debido al mayor peso que tiene entre los usuarios aparcar en plazas más baratas y libres, al estar presentes las tarifas dinámicas, penalizando en cierta medida la cercanía con el destino final, pero mostrando unos resultados globales muy positivos en relación al resto de variables.

Por otro lado, empleando los datos de las 15 iteraciones para cada uno de los escenarios, se han extraído, mediante el empleo de la API del software de microsimulación y el empleo del lenguaje de programación Python, resultados comparativos de los usuarios que aparcan de los escenarios 2 y 3 en función del tipo de usuario tal y como se refleja en la tabla 8. Cabe destacar que el escenario 2 no contempla la diferenciación entre usuarios informados o no, por lo que se ofrece el conjunto de los resultados.

Parámetro	Esc. 2	Esc. 3		
Tipo usuario	Conjunto	Informado	No Informado	Conjunto
Distancia recorrida media	1163.92	650.31 (-44.13)	1258.16 (8.1)	943.86 (-18.91)
Distancia a destino media (m)	130.03	183.66 (41.24)	125.93 (-3.15)	155.78 (19.8)
Promedio de Intentos aparcamiento	3.43	1.01 (-70.55)	3.78 (10.2)	2.35 (-31.49)
Tiempo de búsqueda medio (min)	9.00	3.66 (-59.33)	7.32 (-18.67)	5.43 (-39.67)
Usuarios de aparcamiento off-street (%)	21.91	34.63 (58.06)	15.72 (-28.25)	25.5 (16.39)
Usuarios que aparcan en una sección diferente a la de máxima utilidad (%)	33.61	14.4 (-57.16)	36.58 (8.84)	25.11 (-25.29)

Tabla 8 Resultados de distintos indicadores en los escenarios con usuarios que aparcan (Entre paréntesis el porcentaje de variación respecto al Escenario 2)

Los indicadores ponen en evidencia la diferencia existente dentro de los mismos escenarios entre los tipos de usuario. En primer lugar, la distancia media recorrida por cada usuario desciende entre los escenarios dinámicos y con tarificación estática, e incluso se reduce un 48% entre usuarios informados y no informados en el escenario 3.

Estrechamente relacionado con la distancia recorrida, se puede analizar el promedio de intentos de aparcamiento, es decir, el número de veces que cada usuario intenta aparcar en una plaza en la calle. Este indicador baja significativamente en el conjunto de los usuarios, siendo inferior a 1, o en torno a 1, en el caso de tarificación dinámica más barata para usuarios informados, quienes en la mayor parte de los casos acuden directamente a plazas vacías o a aparcamientos privados, cuyo uso también refleja una clara variación. Se observa además un rechazo muy grande al uso del aparcamiento de pago fuera de la calle por su elevada tarifa, en el caso de usuarios no informados mientras que los usuarios informados, hacen un mayor uso de este. Otro de los indicadores relacionados es el tiempo de búsqueda, que se sitúa en torno a los 10 minutos en el caso del sistema sin tarificación dinámica, tiempo similar al de la encuesta realizada por el estudio de Antolín (2019).

Cabe destacar el aumento de la distancia al destino final de los usuarios informados, en parte por el uso del aparcamiento privado fuera de la calle y por acudir a zonas de aparcamiento más alejadas por el menor precio de estas.

5. CONCLUSIONES

En esta investigación se ha propuesto un modelo escalable de elección y búsqueda de aparcamiento basado en agentes. Este modelo se ha implementado en un software de simulación, el cual ha permitido aprovechar todas las características de este tipo de herramientas para la evaluación de distintos escenarios de aparcamiento. Además, el modelo se ha aplicado en un área de estudio concreto con el objetivo de simular escenarios de aparcamiento en la calle sin y con tarificación dinámica basada en la ocupación en tiempo real de los espacios de aparcamiento.

Las simulaciones realizadas han permitido demostrar la influencia del tráfico de búsqueda de aparcamiento, que no tienen en cuenta los softwares de microsimulación del tráfico existentes, en distintos indicadores. Así se ha comprobado que la densidad de tráfico puede incrementarse en torno al 50%, tal y como reflejaba White (2007) en su estudio para la ciudad de New York, un dato que evidencia la necesidad de simular este tipo de tráfico si quieren obtenerse estimaciones realistas.

Los resultados obtenidos verifican las hipótesis de partida respecto a que la introducción de tarifas dinámicas permite obtener mejoras significativas en todos los indicadores analizados reduciéndose las emisiones (-11.4%), el consumo de combustible (-26.4%) y el número de vehículos en el interior de la zona (-30.3%). Se comprueba la influencia evidente de las subidas de precios en los escenarios analizados, pudiéndose constatar que las mayores tarifas producen unos mejores resultados globales en los principales indicadores analizados. La distribución de los usuarios entre diversos modos de aparcamiento con un aumento del uso de aparcamientos privados del 16.4%, favorece la utilización óptima del área urbana destinada al aparcamiento y permite reducir el tráfico de paso.

Además, se ha probado la influencia de la introducción de usuarios informados de las tarifas y las ocupaciones dentro de la red y se ha modelado su comportamiento a través de un parámetro en el modelo de elección de utilidad de plaza. Este análisis ha arrojado unos resultados positivos para el fomento de las políticas de implantación de información al usuario y se han verificado las predicciones realizadas por investigaciones anteriores (Panja et al., 2011). Los resultados obtenidos arrojan mejoras muy significativas para el tiempo de búsqueda, que se reduce en torno al 60% mediante la introducción de tarifas dinámicas. Estas tarifas también han servido para obtener menores tasas de ocupación, con tan solo una hora de simulación.

Con el desarrollo del modelo y la aplicación de tarifas dinámicas se abren un gran abanico de posibilidades de investigación en este campo de estudio para tratar de detectar tarifas óptimas y estudiar, en un futuro, la influencia de nuevas formas de movilidad como la que pueden generar la irrupción de vehículos autónomos y sus capacidades de estacionamiento también autónomo.

AGRADECIMIENTOS

Esta investigación ha sido financiada mediante el proyecto TRA2017-85853-C2-1-R del Ministerio español de Economía y Competitividad

ABSTRACT

For many decades, there have been plenty of analyses all over the world about the relationship between socio-economic attributes and transport flows. One of the most fruitful tools is the gravity model, in the beginning used for road transport, but recently widely used for air transport and international trade.

India is an outstanding example of complexity, with a mixture of megapolises and vast rural areas. Its road network shows plenty of six and four lane expressways spanning hundreds of kilometers, complemented by a dense web of State and local secondary and tertiary links.

In the last decades, National and State Governments have improved vast tracts of roads, but there is still a huge gap. Investment priorities are usually decided on the ground of existing congestion or strategic issues, but not much on demand analyses.

For ascertaining whether in India socio-economic structure and transport flows follow a common pattern, complete corridor OD matrices were calibrated from partial screen matrices for a sample of long-distance corridors (NH-1, NH-6, NH-8, NH-58, NH-73). These matrices were later analyzed by means of gravity models that included parameters such as population or GDP per district (as zone attributes) and road distance among district centroids (as friction factors). Several formulae were tested, and the best fit was selected.

Results for main corridors are rather homogeneous, and rather consistent with research carried out in other countries. Simple formulae have a high explanatory capacity, even if the huge mega-cities of Delhi and Mumbai are included in the analysis. But results for rural corridors are much less consistent, probably due to a less mature structure in terms of spatial distribution and transport relationships.

1. BACKGROUND AND OBJECTIVES

India is one of the largest countries in the world, with well above 1.2 billion inhabitants and a road network of around 3.3 million kilometers. This size in itself entails a high complexity, with huge long distance corridors spanning hundreds of kilometers linking very large cities, surrounded by a web of secondary links, many of which have local importance. Although the road network has greatly improved in the recent past, it still needs important investments for implementing further improvements in terms of quantity and quality. Owing to the importance of the investment needs, priorities should be clearly supported by analytical tools. But data are scarce and scattered and, accordingly, it is not easy to have a clear, simple vision of traffic flows beyond the usual, *ad hoc* vehicle traffic counts.

This paper's objective is to find out whether in India, as in other countries, there is a simple explanation for the traffic flow volume between different cities and, in particular:

- Taking into account the vast extension of the country and its huge diversity, do traffic flows in India follow a common, simple pattern on all long distance corridors? Are there groups of different corridors?
- Since the city size is highly diversified, does the size of cities on different corridors affect their traffic flow structure? Do huge metropolitan areas behave differently to the rest of cities?
- In spite of the general scarcity of data, are there any independent variables that can explain the aforementioned patterns?
- If any common flow pattern does exist, can it be used for supporting the investment decision-making process?

2. THE GRAVITY MODEL

Gravity models have been widely used in many fields of human activity, from phone calls to commuting trips, to describe behaviors that follow patterns that are somehow similar to the gravitational interaction as described by the famous Newton's law of gravity. There is some dispute as to who introduced this idea in the analysis of land use and transport. In the 1860s H. Carey first applied Newtonian Physics to the study of human behavior by means of the so-called "gravity equation" but it seems that it was H.N. Pallin, a Swedish researcher, who in 1930 (Schmidt & Campell, 1956), came up with the first gravity formula for metropolitan traffic.

For some time this gravity model got wide and deep attention, not just because of the mentioned similarity to Newton's law, but because it was found to have the potential of a higher level of generality (Wilson, 1970).

With this broader approach, the flows between any pair of zones (T_{ij}) are the “dependent” variables and have to be explained by some “independent” variables (x_i, x_j, f_{ij}).

$$T_{ij} = f(x_i , x_j, f_{ij}) \qquad (1)$$

where:

- x_i and x_j are attributes of the origin and destination, such as population, domestic product, etc.
- f_{ij} are “friction factors”, such a trip time or distance between zones.

Lately the gravity model has been used in many studies, to predict both freight and passenger flows, as well as international trade (Kepaptsoglou, Karlaftis & Tsamboulas, 2010). Its usefulness has been demonstrated for other transport modes, such as air transport. (Arvis & Shepherd, 2011).

In India, the gravity model has been used for freight flows at national level within a comprehensive several-steps model: it provided the distribution of generated and attracted flows (Dalvi & Das, 1983). It has also been widely used for India’s international trade analysis (Batra, 2004; Bhattacharyya & Banerjee, 2006) and, to a large extent, for urban transport. (Jaiswal & Sharma, 2012).

3. METHOD

The analysis of long-distance flows requires information on origin and destination of trips that is not easily available in India. Although there are some databases with some information on traffic, there is a general lack of structured information and most researches and consultancy studies on road traffic are carried out with information collected on an ad-hoc basis, by means of vehicle traffic counts and screen origin-destination surveys. In fact, there are several procedures clearly defined by the codes published by the Indian Road Congress (The Indian Road Congress, 1988 & 2001).

This usual method provides information that describes, with some detail, the attributes of users crossing the screen where the survey in question is being done. But, owing to the physical impossibility of obtaining statistically balanced and representative samples for all flows, some flows may be under-represented, while others may be over-represented.

Besides, some flows may cross several screens while others may cross only one. In order to solve this problem, the most used method (Ortuzar & Wilumsen, 1995) is a procedure of maximum likelihood calibration, by means of which a “seed matrix”, obtained as a combination of matrices obtained in the survey, is assigned to the network and the traffic volumes estimated by the model are compared to the vehicle traffic counts.

Any mismatches are adjusted on an iterative process to make sure the final traffic flows reproduce the traffic counts with enough accuracy.

The next step is to try to explain the matrices obtained. After an analysis of available socio-economic data, the ones that seemed best suited as independent variables were the following:

- "Attraction factors" (x_i): Population per district or, alternatively, domestic product per district. Also some other attempts were made with other variables that could be related to traffic: the most obvious candidate was the number of vehicles per district.
- "Friction factors" (f_{ij}): distance between districts' centers of gravity.

A further problem was this of the heterogeneous time reference, since for some variables there were reliable data for some years, but for others the time reference was different. Some simple algorithms to overcome this problem, such as making the assumption that GDP or population at District level has evolved at the same pace as the corresponding whole State, just introduces more hypothesis. Therefore, it was decided not to make any changes to the official data, except in the case when for the same variable there were different horizons (notably in the case of vehicle data). As a consequence, all values for each variable were referred to the same year, but different variables could be referred to different years, which changes formula as follows:

$$T_{ij\,y'} = k\,\frac{x_i^{\alpha\,y''}\,x_j^{\alpha\,y''}}{f_{ij}^{\beta\,y'''}} \tag{2}$$

Where y', y'' and y''' are the reference years for each variable.

Formula (2) can be calibrated easily thanks to the use of logarithms that transform the expression into a linear one, which allows for a very simple regression calibration. The software used was Microsoft's Excel.

4. CASES AND DATA AVAILABLE

In order to have a proper picture of the situation in India, a broad sample was needed: covering different parts of the country as well as different corridor types. According to the information available to the researchers, the following corridors were chosen:

- **NH-1**: Panipat - Jalandhar. 285 km. NH1 is, as expected from its code name, one of the main corridors in India. It connects the Indo-Pakistan border to Delhi. Major towns are Panipat, Jalandhar, Ambala, Ludhiana, Chandigarh and Delhi. Panipat oil refinery and industries at Ambala, Jalandhar and Ludhiana are major centers of activity.

Ludhiana is home to 90% of all woolen garments in India and Jalandhar is known for its sports good industry. There are many short distance and long distance routes competing with this corridor.

- **NH-6**: Gujarat/Maharashtra border - Amravati. 484 km. NH6 is the major national highway connecting East India to West India. Main cities around the corridor are Amravati, Akola, Jalgaon, Dhule, Nagpur, Surat and Mumbai. The project corridor mainly lies in the most backward economic regions of Maharashtra state with agriculture as the main occupation. The corridor is full of many small local bypasses and long alternate routes.
- **NH-8**: Kishangarh – Udaipur - Ahmedabad. 555km. This corridor runs through some feebly populated areas of Rajasthan, but it connects Delhi to Mumbai via many important economic hub cities like Jaipur, Kishangarh, Ahmedabad, Vadodara and Surat. NH3 could potentially compete with NH8, but its poor current condition prevents it from being a real alternative.
- **NH-58**: Meerut - Muzaffarnagar. 79 km. This corridor runs through the sugar belt of India wherein sugarcane production and processing is the main industry. Meerut, Ghaziabad and Muzaffarnagar are known for many industrial and agro-based activities. Sacred sites of Haridwar and Rishikesh attract thousands of pilgrims all year round. SH57 is a major competing route for NH58, though it is in a very poor condition at present.
- **NH-73**: Yamunanagar - Panchkula. 108 km. Chandigarh and Panchkula are major cities near or along the corridor. Yamunanagar, Ambala and Saharanpur are industrial towns around the corridor. Baddi, an industrial township near Panchkula, is being developed as pharmaceuticals industry capital of India. NH1 and a combination of some State highways pose choices to users of NH73 for both short and long distance routes.

For each of the aforementioned corridors, data on volume of traffic and on origin-destination flows on the very road and on competing ones were available on many screens, as shown in Table 1. On the other hand, independent variables were available from official sources at different years. The distance between District capitals was easily obtained by means of TransCAD on the corresponding network graphs.

Corridor	Section	Year	Number of traffic count screens	Number of OD screens	Number of OD surveys
NH-1	Panipat-Jalandhar	2010	34	14	15,675
NH-6	Gujarat/Maharashtra border-Amravati	2012	10	10	18,376
NH-8	Kishangarh-Udaipur-Ahmedabad	2011	17	14	(*)
NH-58	Meerut-Muzaffarnagar	2013	2	2	2,423
NH-73	Yamunanagar to Panchkula	2011	11	2	6,035

(*) The precise figure was not available, but the sample was between 15,000 and 20,000 vehicles.

Table 1 – Year of available traffic data and number of screens per analyzed corridor

5. INTERMEDIATE RESULTS: OD MATRICES

Not all previous studies available had the same vehicle type structure, because they had been merged according to particular needs.

Therefore, the first step was a calibration of OD matrices following the existing vehicle types.

The goodness of fit between OD matrix and traffic counts was high in all cases, as shown in Table 2.

Corridor	Car/Van/Jeep	LCV/Minibus	2AT/3AT/Bus	2AT/Bus	3AT	MAV
NH1	0.992	0.992	0.974	n.a.	n.a.	0.982
NH6	0.997	0.996	n.a.	0.943	0.870	0.932
NH8	0.992	0.992	n.a.	0.969	0.966	0.976
NH58	1.000	1.000	1.000	n.a.	n.a.	1.000
NH73	0.997	0.995	n.a.	0.965	0.763	0.998

LCV = Light Cargo Vehicle; 2AT = Two Axle Truck; 3AT = Three Axle Truck; MAV = Multiaxle vehicle (> 3 axles); n.a. = not available.

Table 2 – Coefficient of determination (R2) of regression analysis between assigned traffic values and traffic counts

This somehow heterogeneous classification of vehicles prevented from a detailed, homogeneous analysis of vehicle types, but this was not a big hurdle, as the lack of proper independent variables made it useless to try a very detailed analysis of dependent variables.

Besides, the classical differentiation between passenger vehicles and goods vehicles could not be done in detail due to the mixture of types within some matrices (e.g. LCV and minibuses, trucks and buses).

The decision made was to distinguish between light and heavy vehicles for two reasons:

- This aggregation is fully compatible with existing data.
- This definition is based on the nature of the presumed distance for which each vehicle is best suited, which is coherent with the distance as the friction factor.

Therefore, two matrices were obtained for each corridor:

- One matrix for light vehicles, which in practice was almost reduced to cars and small cargo vehicles.
- One matrix for heavy vehicles, that is, buses and trucks of any size, which is in practice mostly trucks of any size.

6. FINAL RESULTS: GRAVITATION MODEL CALIBRATION

In order to have a broader analysis, the parameter k in the aforementioned formula was considered under two hypothesis: fixed (k=1) and calibrated. Thanks to the data available, for all large corridors (NH1, NH6, NH8) it was possible to carry out the regression analysis taking into account population, GDP or number of vehicles. For second-rank corridors (NH58 and NH73) it was possible only with population and GDP. In all cases, the friction factor was the distance.

When it was assumed that $k = 1$, results showed a high coefficient of determination, with values of 0.9 or above for all calibrations.

Corridor	Attraction factor	Light vehicles				Heavy vehicles			
		R2		F significance		R2		F significance	
		(1)	(2)	(1)	(2)	(1)	(2)	(1)	(2)
NH1	Population	0.92	0.92	0.0%	0.0%	0.92	0.92	0.0%	0.0%
	GDP	0.92	0.92	0.0%	0.0%	0.92	0.92	0.0%	0.0%
	N of vehicles	0.92	0.92	0.0%	0.0%	0.89	0.90	0.0%	0.0%
NH6	Population	0.99	0.99	0.0%	0.0%	0.99	1.00	0.0%	0.0%
	GDP	0.99	0.99	0.0%	0.0%	0.99	1.00	0.0%	0.0%
	N of vehicles	0.99	0.99	0.0%	0.0%	0.99	1.00	0.0%	0.0%
NH8	Population	0.96	0.97	0.0%	0.0%	0.96	0.97	0.0%	0.0%
	GDP	0.96	0.97	0.0%	0.0%	0.96	0.97	0.0%	0.0%
	N of vehicles	0.95	0.97	0.0%	0.0%	0.94	0.98	0.0%	0.0%
NH58	Population	0.98	0.98	0.0%	0.0%	0.94	0.94	0.0%	0.1%
	GDP	0.98	0.98	0.0%	0.0%	0.94	0.94	0.0%	0.1%
	N of vehicles	n.a.	n.a.	n.a.	n.a.	n.a.	n.a.	n.a.	n.a.
NH73	Population	0.94	0.94	0.0%	0.0%	0.95	0.95	0.0%	0.0%
	GDP	0.94	0.94	0.0%	0.0%	0.95	0.95	0.0%	0.0%
	N of vehicles	n.a.	n.a.	n.a.	n.a.	n.a.	n.a.	n.a.	n.a.

(1) With Delhi and Mumbai; (2) Excluding Delhi and Mumbai; n.a. = data not available

Table 3 – Values of coefficient of determination by corridor, type of city and independent variable

Focusing on the first-rank corridors (NH1, NH6, NH8), the sample excluding Delhi and Mumbai showed a slightly better coefficient of determination, but again in negligible amounts. In all cases, population, GDP and number of vehicles were good independent variables, not much different to one another in statistical significance. The values obtained for the calibrated parameters are presented in Table 4.

Corridor	Attraction factor	Light vehicles				Heavy vehicles			
		α		β		α		β	
		(1)	(2)	(1)	(2)	(1)	(2)	(1)	(2)
NH1	Population	0.44	0.50	-1.58	-1.91	0.45	0.48	-1.75	-1.92
	GDP	0.47	0.52	-1.61	-1.90	0.48	0.51	-1.77	-1.92
	N of vehicles	0.49	0.55	-1.56	-1.92	0.51	0.55	-1.30	-1.46
NH6	Population	0.39	0.43	-1.36	-1.57	0.29	0.32	-0.80	-0.98
	GDP	0.47	0.49	-1.60	-1.70	0.37	0.38	-1.06	-1.11
	N of vehicles	0.52	0.58	-1.64	-1.93	0.45	0.46	-0.94	-0.98
NH8	Population	0.46	0.63	-1.60	-2.55	0.36	0.56	-1.10	-2.22
	GDP	0.59	0.78	-2.04	-2.97	0.48	0.71	-1.51	-2.67
	N of vehicles	0.51	0.87	-1.57	-3.29	0.36	1.05	-0.53	-3.13
NH58	Population	0.26	0.21	-0.45	-0.14	0.17	0.12	-0.19	0.13
	GDP	0.26	0.23	-0.34	-0.09	0.18	0.13	-0.14	0.15
	N of vehicles	n.a.	n.a.	n.a.	n.a.	n.a.	n.a.	n.a.	n.a.
NH73	Population	0.75	0.75	-3.51	-3.51	0.64	0.64	-2.92	-2.92
	GDP	0.72	0.72	-3.08	-3.08	0.62	0.62	-2.61	-2.61
	N of vehicles	n.a.	n.a.	n.a.	n.a.	n.a.	n.a.	n.a.	n.a.

α = power of attraction factors; β = power of friction factor (distance); (1) With Delhi and Mumbai; (2) Excluding Delhi and Mumbai; n.a. = data not available.

Table 4 – Values of parameters calibrated by corridor, type of city and independent variable

For all first-rank corridors (NH1, NH6, NH8), the sign of the powers of the attraction variables (population, GDP, number of vehicles) and friction (distance) were correct, while the two lesser corridors showed problems of sign consistency (NH58) or of statistical significance (NH73).

According to values in Table 4, the introduction or exclusion of the largest cities meant interesting variations in the values of the calibrated parameters: for corridors with only one of these large metropolitan areas in the surroundings (Delhi for NH1, Mumbai for NH6) the variation in the values was relatively low (from 3% to 23%, depending on the cases), but when both cities were relevant (NH8) the variation was much larger (above 32% and up to 491%).

A deeper analysis of values obtained for the power (β) of the distance is shown in Table 5, where minimum, maximum and non-weighted average values are presented by type of vehicle and independent variable.

Attraction factor	Light vehicles						Heavy vehicles					
	With Delhi & Mumbai			Excl. Delhi & Mumbai			With Delhi & Mumbai			Excl. Delhi & Mumbai		
	Min	Max	Av	Min	Max	Av	Min	Max	Av	Min	Max	Av
Population	-1,60	-1,36	-1,51	-2,55	-1,57	-2,01	-1,75	-0,80	-1,22	-2,22	-0,98	-1,71
GDP	-2,04	-1,60	-1,75	-2,97	-1,70	-2,19	-1,77	-1,06	-1,45	-2,67	-1,11	-1,90
N of vehicles	-1,64	-1,56	-1,59	-3,29	-1,92	-2,38	-1,30	-0,53	-0,92	-3,13	-0,98	-1,86

Min = minimum; Max = Maximum; Av = non-weighted average.

Table 5 – Values of power (β) of the distance as friction factor

According to Table 5, average values of this β parameter are quite homogeneous:

- In absolute terms, taking into account Delhi and Mumbai, they are around 0.9-1.5 for heavy vehicles and around 1.5-1.8 for light vehicles.
- Without these metropolitan cities, values are around 1.7-1.9 for heavy vehicles and around 2.0-2.4 for light vehicles.

It is noteworthy that for NH58 the values of this β parameter are much lower (in absolute terms, from 0.2 to 0.5), this showing again the difference between large corridors of National relevance and corridors of mere local importance.

The introduction of the parameter k reduced the accuracy of the calibration, which showed low values of the coefficient of determination.

7. CONCLUSIONS

The analysis summarized in this paper clearly shows the following:

- In India, as in all other developing countries, the lack of data introduces some degree of inaccuracy in traffic analyses. But results described in this paper are so consistent that can be considered, at least, good orders of magnitude.
- In large corridors, volumes of vehicles can be explained by the classical gravity model. Population, GDP and number of vehicles at District level have a noticeable explanatory capacity. Parameter values are remarkably homogeneous: as a rule, the friction due to distance has exponent values between 1.0 and 2.0 if all cities are included and between 1.5 and 3.0 if the largest cities are excluded. These values are not very much different from the ones obtained in more developed countries. Probably people tend to behave similarly in trips between large cities all over the world.

- In corridors in rural areas, the parameters are quite different from one area to another. There are no obvious patterns and each corridor has its own characteristics. It remains to be seen whether these rural corridors converge to the pattern found in the largest ones when GDP grows or whether their peculiarities are intrinsic.

RESUMEN

Un correcto seguimiento del funcionamiento del sistema de Metro de Madrid desde la perspectiva del usuario exige disponer de información del número de viajeros en todo momento y para cada elemento del sistema: estaciones, vestíbulos, andenes y vehículos. La contraposición de volúmenes y capacidades de cada uno de estos elementos permiten deducir densidades que se relacionan de forma directa con el concepto de calidad del servicio.

Frente a la opción de monitorización ubicua de los volúmenes de viajeros a lo ancho del sistema, Metro de Madrid ha optado por una inteligente combinación de datos de registros discretos (vinculados a los accesos al sistema), datos de patrones de movilidad espaciales y dinámicos (basados en encuestas y uso de títulos de transporte) y el uso de técnicas de modelización para completar una fotografía permanentemente actualizada del uso de cada elemento del sistema de Metro.

La comunicación que se presenta describirá la arquitectura y problemática enfrentada, así como el desempeño actual del sistema y planteamiento de futuro.

Finalmente, la comunicación incluirá una descripción de cómo tal sistema, diseñado y elaborado con anterioridad a la situación pandémica actual, ha resultado clave para la construcción de sistemas de control dinámico automatizado de las instalaciones de acceso a la red mediante la explotación de las estimaciones de flujo de viajeros proporcionadas por el modelo.

1. INTRODUCCIÓN: PLANTEAMIENTOS ESTRATÉGICOS PARA LA GESTIÓN AVANZADA DEL TRANSPORTE PÚBLICO

La correcta supervisión y gestión del funcionamiento de un sistema de transporte como el Metro de Madrid exige disponer de información de volúmenes de viajeros en todo momento y para cada elemento del sistema: acceso a estaciones, vestíbulos, andenes y vehículos.

La contraposición de volúmenes y capacidades de cada uno de estos elementos permiten deducir densidades que se relacionarán de forma directa con el concepto de calidad del servicio.

Todo operador de transporte que aspire a colocar al cliente y su experiencia de viaje en el centro debe de procurar tener bajo control este parámetro.

Al mismo tiempo, la optimización en la toma de decisiones operativas implica pasar de la mera observación del "fenómeno" a tratar de predecir su evolución. Así, el operador aspira a pasar del enfoque reactivo de resolución de incidencias al proactivo de evitación de éstas.

Este sería el contexto conceptual en el que tienen cabida los trabajos descritos en la presente comunicación. Trabajos que, es importante destacar, parten de la propia compañía de transportes contando con colaboraciones externas especializadas, procedentes del mundo académico y de la investigación.

En un plano más prosaico, se daba la circunstancia de que la *División de Operación* venía recibiendo de su homóloga de *Calidad*, entre otras, requerimientos de informes periódicos que incluyeran indicadores del tipo: densidad de personas en puntos de la red, zonas de mayor tránsito o volumen de viajeros afectados por determinados fallos en la operación.

Estos fallos podían hacer referencia a situaciones tales como retrasos en servicios o afecciones por escaleras mecánicas averiadas.

Para poder dar respuesta a estos requerimientos, el equipo de *Movilidad* del *servicio de Planificación y Estudios de Operación de Metro de Madrid* (en adelante, "Metro") venía explotando una herramienta de modelización cuya configuración había quedado obsoleta, como diagnosticó la auditoría técnica encargada a los servicios profesionales de *PTV Group*.

Es en ese momento cuando Metro decide reformular el sistema al completo (no solo el modelo) para dar respuesta adecuada al reto planteado y al mismo tiempo preparar las bases para nuevas formas de explotar la información disponible en beneficio de los procesos de programación de la oferta de servicio.

Idealmente, pudiera pensarse que una opción hubiera sido la de monitorizar de forma ubicua, mediante dispositivos, los volúmenes de viajeros a lo ancho del sistema. Sin embargo, tal opción, a pesar de proporcionar información situacional valiosa se demostraría insuficiente, además de costosa por la extensión y complejidad de la Red, si no se completara con algún tipo de artefacto predictivo. Dicho lo cual, no se descarta ampliar en el futuro las capacidades de monitoreo para aprovechar la evolución de la tecnología especializada para recuento y transmisión de datos.

De otra manera, podría confiarse en la realización de encuestas origen – destino de forma periódica, como ya se venía trabajando. Sin embargo, las encuestas OD solo se podían realizar cada 4 o 5 años por su elevado coste y las simulaciones que se basaban en sus resultados pronto perdían fiabilidad a pesar del esfuerzo en mantenerlas actualizadas mediante el uso de técnicas de corrección. Y es que la encuesta OD no deja de ser una foto fija del momento, lo que no permite afrontar el tratamiento, no ya de incidencias, sino tampoco de actualizaciones de la red, como se puso de manifiesto al introducir las últimas ampliaciones del Metro.

El análisis de las asignaciones de esas matrices permitía estimar únicamente los movimientos en el total del día y en hora punta de la mañana de un día genérico, sin poder acceder al detalle de lo que sucedía durante el resto del día, ni en los días especiales como festivos o fines de semana. Otra limitación de esta manera de proceder es que las simulaciones están basadas en las encuestas realizadas un determinado día.

Todo ello llevó a plantear qué cambios había que hacer para conocer mejor el comportamiento de los viajeros y así ayudar a planificar la oferta de trenes de manera óptima.

Así es cómo Metro decidió optar por buscar una combinación de datos de registros discretos (vinculados a los accesos al sistema), datos de patrones de movilidad espaciales y dinámicos (basados en encuestas y uso de títulos de transporte) y el uso de técnicas de modelización para completar una fotografía permanentemente actualizada del uso de cada elemento del sistema de Metro.

El resultado es una herramienta de simulación con actualización continua de la representación teórica de los viajes que se realizan cada día con origen y destino en estaciones de Metro y del volumen de pasajeros a bordo de los trenes de las distintas líneas a lo largo de la jornada.

Este modelo diario constituye el soporte esencial para diversos procesos de adecuación de la oferta a la demanda, optimización del servicio programado y cálculo de indicadores corporativos, así como para dar respuesta a múltiples consultas que plantean frecuentemente tanto los departamentos de Metro como algunos organismos externos.

La imprevista llegada de la Covid-19 planteó un reto no previsto inicialmente: cómo utilizar el sistema desarrollado para la producción de estudios de demanda de soporte a la adecuación a corto plazo de las condiciones de servicio de Metro a las restricciones impuestas por el Consorcio de Transportes de Madrid.

Entre las muchas actuaciones orientadas a asegurar el viaje en condiciones sanitarias adecuadas en lo referente a la ocupación de los trenes, la autoridad de transporte requirió a Metro garantizar que los trenes no superaran cierto umbral de número de viajeros por Metro cuadrado (densidad de viajeros) y que se limitara el número de asientos disponibles.

El cumplimiento de las restricciones de densidad ha supuesto, por una parte, ajustes en la oferta de servicios y, por otra, limitaciones al acceso de viajeros en estaciones. Este requisito plantea la cuestión de en qué estaciones aplicar la limitación, cuándo y en qué cantidad.

Dado que la saturación en un tren, entendida como superación del umbral de densidad, es originada por el acceso en estaciones “aguas arriba” del tramo saturado, se precisa de una aplicación que identifique con anticipación los tramos en los que, si no se actuara, registrarían saturación. A continuación, el procedimiento debe identificar las estaciones que más contribuyen a la carga de las secciones críticas y, como resultado final, ayude a calcular unas cuotas máximas de viajeros compatibles, para cada intervalo de tiempo, con el criterio límite de saturación.

Esta comunicación presenta el esquema general del sistema de modelización de Metro y expone en concreto la utilización de las prestaciones de *PTV Visum* que participan en el sistema de cálculo de cuotas para control dinámico de acceso.

2. PLANTEAMIENTO Y METODOLOGÍA

2.1. Enfoque global

En un primer momento se planteó la posibilidad de mejorar la precisión de las asignaciones de las matrices origen-destino proveniente de las encuestas mediante el uso de “series temporales”. Las “series temporales” en *Visum* distribuyen la demanda de la matriz en el tiempo, típicamente en intervalos horarios del día tipo.

Además, con objeto de precisar el ajuste al comportamiento real de la demanda, *Visum* permite aplicar series temporales diferentes a distintas categorías de pares origen-destino que presenten similitudes en su distribución temporal de la demanda.

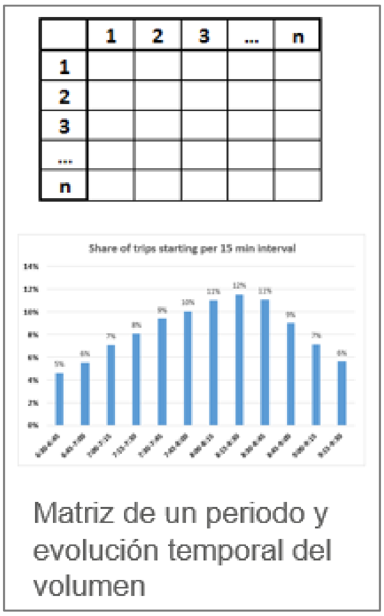

Fig. 1: Ilustración de la consideración de la dinámica de la demanda mediante aplicación de una serie de temporal de proporciones a una matriz OD

No obstante, este procedimiento pronto se reveló insuficiente porque no recogía adecuadamente la dinámica de la demanda a lo largo de la jornada, razón por la cual se optó por un procedimiento alternativo más detallado.

Bajo este nuevo enfoque, las estaciones pasan a modelizarse de forma independiente y los intervalos de tiempo a efectos de análisis de la demanda pasan a ser de 15 minutos aprovechando para ello la información de registros de entradas al sistema disponibles.

Fig. 2: Ilustración de consideración de la dinámica de la demanda mediante series de matrices OD por intervalos de tiempo

Desde una perspectiva metodológica, el proceso consta de tres etapas:

a. Explotación de los datos de las validaciones recurriendo a técnicas Big Data para:
   i. Inferir el destino del viaje
   ii. Estimar matrices de viajes origen-destino para intervalos de 15 minutos
   iii. Estimar unos intervalos de trenes teóricos según las frecuencias de paso previstas

En esta etapa se infieren las matrices diarias que alimentan la siguiente etapa del proceso. Para ello Metro de Madrid ha realizado un desarrollo software propio cuya descripción excede el alcance de esta comunicación.

b. Explotación de un modelo de transportes utilizando *Visum* para determinar los tramos de mayor intensidad

En esta etapa se aprovecha toda la potencia de la herramienta para simular el comportamiento de los usuarios tanto espacialmente, en sus decisiones de itinerarios a tomar, como temporalmente.

c. Establecimiento de un sistema de cuotas

Se trata de un proceso iterativo de optimización cuyo resultado son las cuotas de paso, entendidas como límites al acceso de viajeros, a aplicar en las estaciones de origen para reducir el riesgo de congestión en tramos críticos de la red.

Estas cuotas son grabadas en ficheros que son leídos por los sistemas de gestión de las instalaciones de peaje (pasos de entrada en estaciones).
Esta etapa ha precisado de desarrollos ad-hoc en comunicación con utilidades nativas del software de modelización.

Los bloques funcionales a) y b) corresponden al proceso básico que construye la actualización diaria del modelo, mientras que el bloque c) constituye el caso de uso específico de elaboración del listado de cuotas.

Es preciso mencionar que el sistema completo denominado *"Control temporal de accesos de Metro de Madrid"* se compone de varios subsistemas: el software de telemando de los elementos físicos que abren/cierran el paso según las órdenes recibidas, los recursos de comunicación y gestión de datos para analizar el comportamiento real, los procedimientos y el despliegue de personal que vigila in situ el correcto desarrollo de los dispositivos y cuida la atención a los viajeros, la información local en las estaciones mediante megafonía y teleindicadores y, finalmente, la presentación del estado de las barreras de peaje en la app oficial que los usuarios pueden consultar on line desde sus dispositivos móviles.

La descripción del sistema completo excede el ámbito de este artículo, por lo que, en este contexto, debe entenderse que por “control de acceso” se hace referencia exclusivamente al software de elaboración de los listados de cuotas, como pieza de cálculo que alimenta al resto de componentes.

2.2 Detalles de configuración

Respecto a la herramienta de modelización, se ha empleado el “gestor de escenarios” disponible en la versión más reciente de *Visum*. Esta funcionalidad permite estructurar los distintos escenarios de análisis sobre un mismo modelo base común sobre el que se aplican modificaciones relativas a la oferta de servicios o a la demanda que los solicita.

Con periodicidad anual se genera un nuevo proyecto del gestor de escenarios. En él se integran los distintos escenarios, cada uno de los cuales hace referencia a un periodo diario.

Estos escenarios pueden hacer referencia bien a días tipo (por ejemplo, un día tipo laborable del mes de octubre) o a días concretos del calendario (por ejemplo, el 28 de octubre).

Asimismo, los escenarios pueden ser *a posteriori*, esto es, con datos de demanda de días pasados y por tanto reales, o *a priori*, esto es, con datos de demanda previstos para días futuros.

Cada escenario consta de tres entradas básicas: la red de Metro, la oferta de servicios (oferta de trenes en terminología Metro), y las matrices Origen-Destino de los viajes.

La red de Metro es fija, y por tanto común a todos los escenarios, aunque sufre cambios circunstanciales en determinados periodos, como cortes de línea o estaciones cerradas al público que se manejan con estudios específicos para simulación de cambios en la infraestructura.

La oferta de trenes se introduce como una relación de expediciones teóricas, que es fija para cada periodo del año y para cada tipo de día, por ejemplo, las expediciones teóricas de un día laborable de invierno.

Las matrices Origen-Destino son únicas para cada día.

La Figura 3 representa el esquema conceptual de la metodología utilizada:

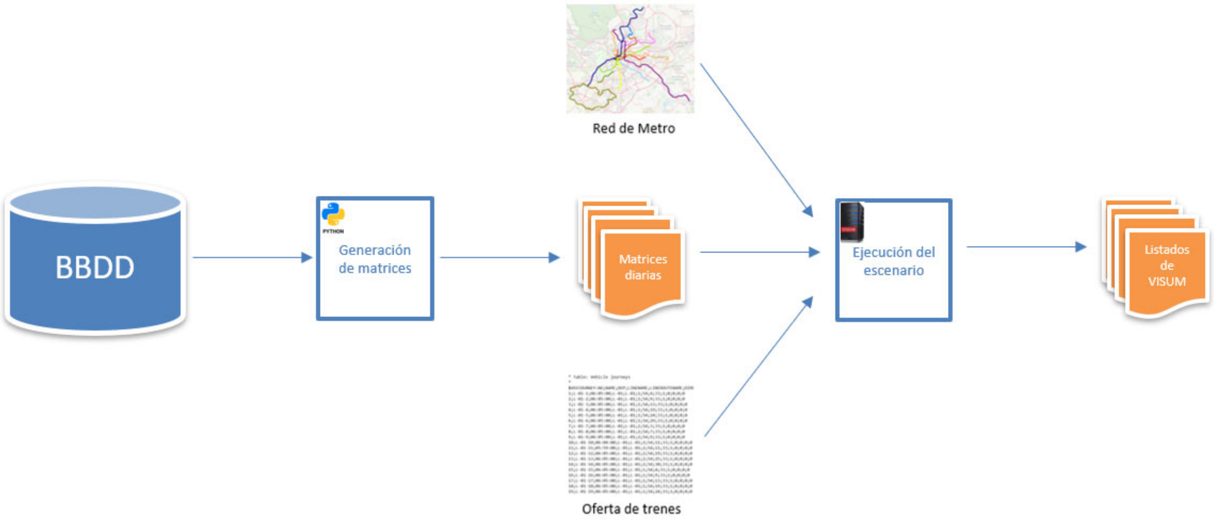

Fig. 3. Esquema conceptual del proceso metodológico

2.3 Evolución tecnológica y acceso a datos: el recurso a Big Data para la modelización y análisis de la demanda

Como ya se ha indicado, el punto de partida convencional para la modelización son los datos que proporcionan las encuestas y aforos, de gran valor estadístico, pero con los inconvenientes de estar referidos a un determinado momento y de no cambiar hasta que se realiza un nuevo trabajo de campo, con un importante coste asociado.

Desde 2019, Metro viene utilizando los registros de paso con tarjetas "inteligentes" de transporte, para construir matrices Origen-Destino diarias.

La base de datos de los pasos con tarjetas sin contacto informa de forma individualizada pero anónima en qué estación y a qué hora se producen las entradas por las barreras de peaje. Mediante inferencia de los destinos de los viajes por la actividad subsiguiente de las tarjetas, y técnicas de corrección de matrices, se obtiene un conjunto de matrices Origen-Destino para los intervalos de tiempo relevantes.

En este caso se han elegido periodos de 15 minutos, por lo que, para cada jornada completa, se construyen 96 matrices O-D.

Estos datos aportan la ventaja de estar siempre actualizados sin necesidad de realizar ninguna encuesta ni aforo. De esta forma, la utilidad de las encuestas y aforos pasa a ser la de su uso para comprobar si el modelo generado está bien calibrado o es necesario realizar algún ajuste.

El esquema lógico conceptual de esta fase del proceso desarrollado es el que ilustra la Figura 4.

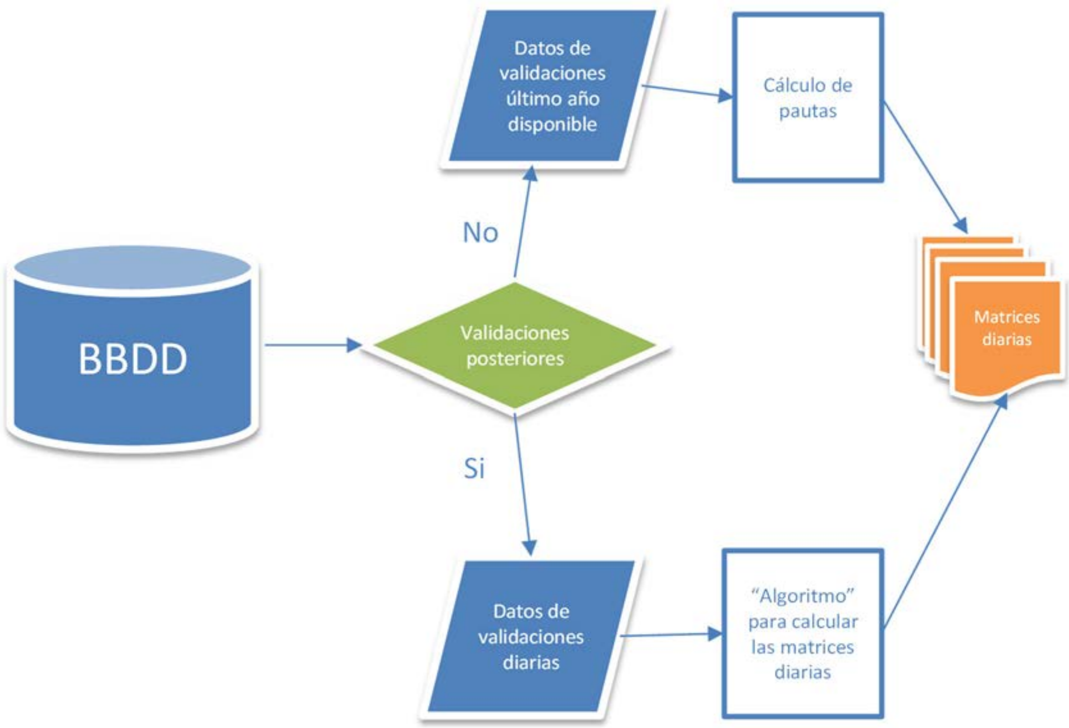

Fig. 4. Esquema lógico de la generación de matrices OD a partir de las validaciones

Dado que la mayor parte de la red de Metro tiene salida abierta, para completar la información de origen de los viajes con los destinos se emplean diversas técnicas de asignación en las que se combinan factores como el tiempo de viaje, tipo de estación, frecuencia de viaje, y pautas repetitivas, a partir de las cuales se aplican como reglas de decisión para la asignación de punto de salida más probable.

También hay que señalar que los tipos de títulos más usados, los abonos de transporte y los billetes de 10 viajes, tienen validez en otros operadores de la ciudad, lo que añade la necesidad de aplicar reglas especiales para reconstruir los trayectos multimodales y derivar la parte que corresponde exclusivamente a etapas en Metro.

El algoritmo desarrollado genera asignaciones de destino para los orígenes de viaje y califica la calidad de dicha asignación en función de las condiciones y certezas que se han podido aplicar en cada caso según los patrones reconocidos.

2.4 Validación de resultados y construcción del modelo diario de movilidad

A pesar de las limitaciones mencionadas, el contraste de resultados realizado mediante observación directa en campo ofrece un nivel de confianza muy elevado.

La calidad de las matrices Origen – Destino diarias así generadas se ha visto avalada también por la utilización en otros sistemas de información que se deriva de las mismas, como es por ejemplo, la estimación estadística de la carga de trenes a su paso por cada estación, por franjas temporales discretas.

Con el grado de ajuste actual, se estima que el 86% de las asignaciones de destino tienen una probabilidad de acierto “ALTA” y que de ellas, la probabilidad es “MUY ALTA” en el 62% de los casos. La asignación de destinos se ajusta mejor en días laborables que en fines de semana porque los viajes obligados, por trabajo o estudios, presentan pautas más repetitivas.

Estos resultados se consideran suficientemente fiables como para permitir el paso siguiente: realizar la modelización diaria de la movilidad por la red a lo largo de todo el horario de servicio y para todos los tipos de día.

Para ello, se cargan en *Visum*:

- Las 96 matrices del conjunto de matrices Origen-Destino por jornada que genera la aplicación, cada una de las cuales corresponde a los datos de entrada a la red cada 15 minutos.

- El fichero con información de la red. Este fichero incluye la descripción de los distintos tipos de día que se contemplan, algunas características de las líneas, los distintos perfiles de tiempo de recorrido, o las expediciones teóricas en función del periodo (invierno, verano, …), visualizado gráficamente en la Figura 5.

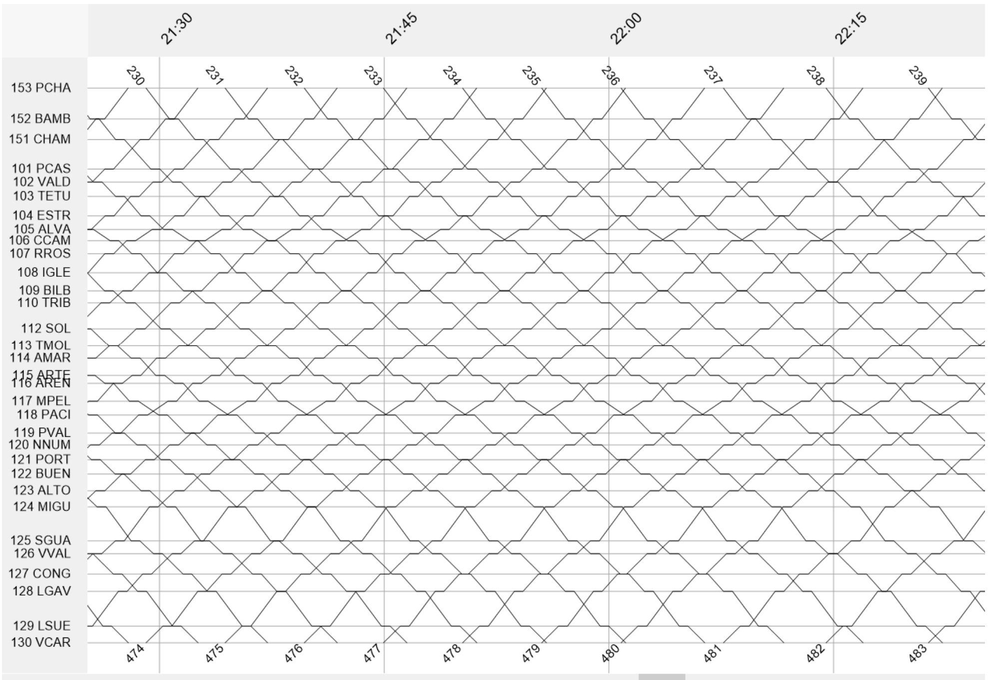

Fig. 5. Gráfica de trenes teóricos

La asignación del escenario en *Visum* proporciona la identificación de todos los viajes realizados, asequible en forma de listados (Figura 6), que muestran la secuencia de unidades de viaje elementales (*vehicle journey item* en vocabulario de *Visum*), y da información de la densidad (en pasajeros/m^2) que hay al paso de cada tren por cada estación:

Fig. 6. Información de densidades (en viajeros/m2) al paso de cada tren por cada estación

O en forma gráfica, en la Figura 7 se muestra, sobre la malla de expediciones, cuán cargadas han ido éstas para un determinado día.

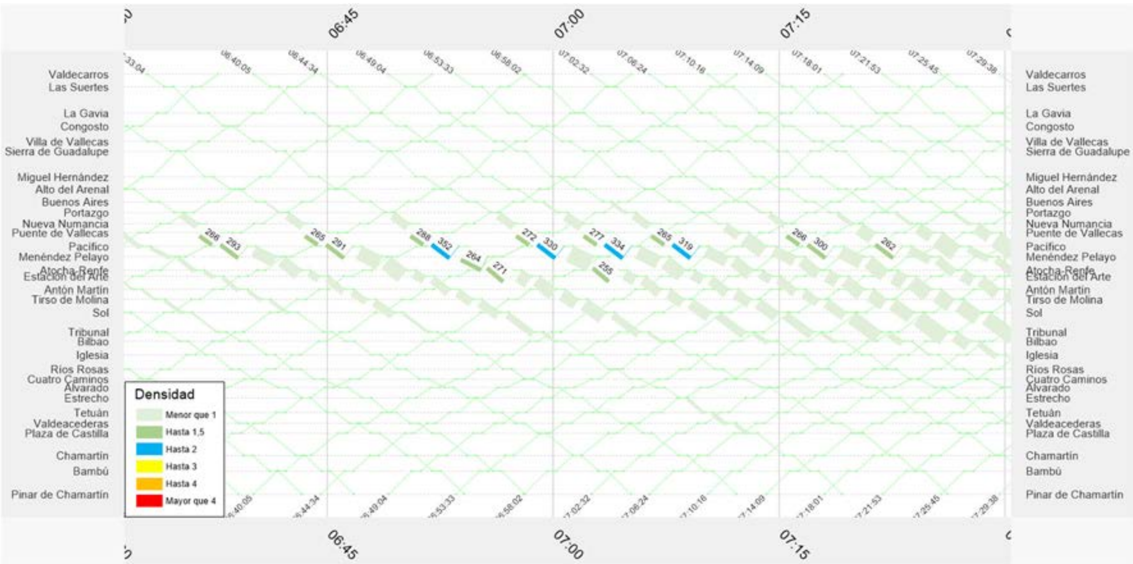

Fig. 7. Carga de trenes teóricos para una demanda dada en un periodo dado

La información detallada en cada punto de la red, en concreto, los datos de subidos y bajados en cada parada, así como el volumen de viajeros en cada inter-estación son datos clave.

Estos datos se calculan tanto para cada día concreto, como para cada patrón de día (laborables, viernes, sábados, y festivos) y periodo (un mes concreto o un periodo especial) que interese estudiar.

Los datos se obtienen desagregados a nivel de expedición y parada y, por tanto, se pueden tratar al nivel que interese: jornada completa, periodos significativos del día (hora punta de mañana, hora punta de mediodía, hora punta de tarde y periodos valle) o a nivel de hora o de media hora.

El contraste continuo con fuentes de información cualitativa permite mantener un adecuado nivel de confianza en la parametrización de los procesos automáticos. Como ejemplo de la necesaria calibración, se realizaron unos aforos en ciertas estaciones que llevaron a la conclusión de que había que realizar ciertos ajustes en los tiempos de trasbordo entre andenes en la estación de Nuevos Ministerios. O en las estaciones de Moncloa y Argüelles, que constituyen una singularidad por ser dos estaciones consecutivas en las que se puede realizar transbordo entre las líneas 3 y 6 de Metro. La medición real del tiempo que se tarda en transbordar en una y en otra, proporciona unos resultados que modificaron los datos asociados a ambas estaciones para que el porcentaje de transbordos en una y otra estación se ajustase a la realidad.

El modelo así construido está sirviendo actualmente de apoyo a múltiples decisiones operativas, permitiendo, por ejemplo:

- Anticipar el efecto de cortes planificados en líneas, tramos o estaciones. La redistribución de la demanda reflejada en el modelo en tales casos permite tomar las decisiones oportunas para canalizarla convenientemente en la realidad. Asimismo, la consideración temporal de la demanda permite apoyar decisiones relativas a la programación de estas afecciones al servicio.
- Analizar el efecto sistémico en la red de cambios en la demanda en determinadas estaciones debida a alteraciones puntuales tales como la celebración de eventos públicos en su proximidad o cambios en la oferta de transporte en superficie.

Con independencia de estas aplicaciones particulares del modelo, las asignaciones de demanda diaria, agregadas por periodos estacionales de demanda estable y días tipo, se han convertido en pieza fundamental de la planificación operativa de Metro en lo que se refiere a la adecuación de la oferta de servicios a la demanda en todo momento.

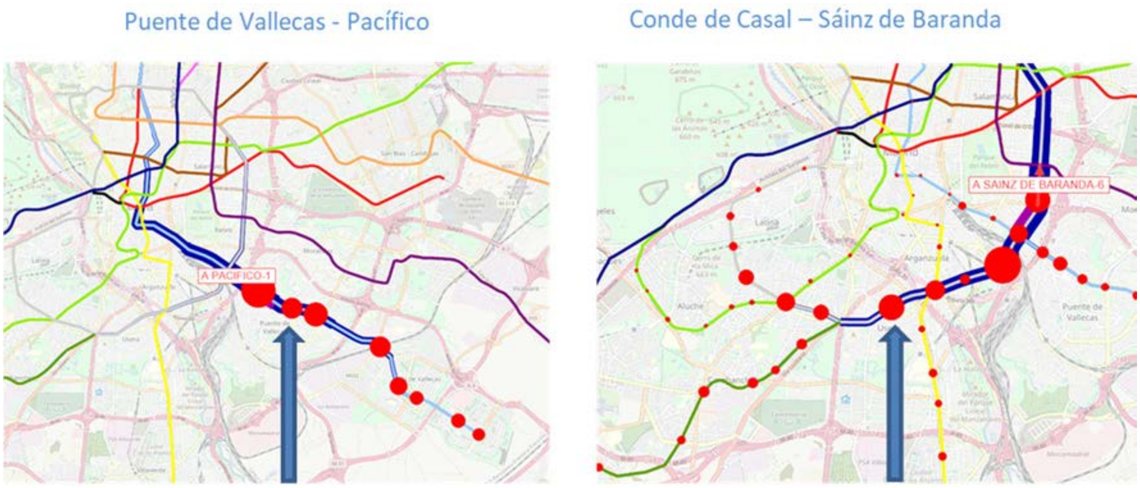
Desde que se dispone de matrices Origen-Destino basadas en los registros de acceso con tarjetas de transporte el modelo diario se está utilizando para todos los propósitos en los que hasta el momento se contaba con modelos estáticos ajustados periódicamente, y se han abierto nuevas posibilidades de explotación, inabordables antes de disponer de una estimación con gran nivel de detalle y de un soporte tecnológico adecuado.

3. UN CASO DE USO ASOCIADO A COVID-19: CÁLCULO DE CUOTAS DE ACCESO PARA PREVENIR LA SATURACIÓN DE LOS TRENES

Una situación de congestión, valorada como tal por superación de la densidad límite establecida, en un tren en una determinada inter-estación, viene provocada por la entrada de viajeros no sólo por la estación en que se inicia, sino por las entradas y trasbordos acumulados desde otras estaciones anteriores en la misma expedición. Por tanto, uno los objetivos de la aplicación desarrollada es determinar en qué estaciones hay que limitar el acceso de viajeros y en qué cantidad, para que no se congestione la red en ningún punto.

De esta manera, es necesario identificar en primer lugar en qué puntos de la red se presenta riesgo de exceso de carga a bordo y buscar a continuación por dónde han entrado los viajeros que lo provocan. Con esto, es posible calcular una cuota teórica de entrada en dichas estaciones para un cierto periodo de tiempo que reduciría el riesgo de que llegara a producirse.

En la implementación de este procedimiento, *Visum* juega un doble papel. Por un lado, ofrece un listado detallado de caminos denominado *PuT Path Legs* (en terminología *Visum)* que permite trazar el origen de cada viaje que pasa por un determinado punto de la red en un determinado momento, como el que ilustra la Figura 8 para dos casos distintos.



origzoneno	estacion	15min	Viajes
120	Nueva Numancia	6:00:00	57
120	Nueva Numancia	6:15:00	122
120	Nueva Numancia	6:30:00	196
120	Nueva Numancia	6:45:00	177
120	Nueva Numancia	7:00:00	65
120	Nueva Numancia	7:15:00	74

origzoneno	estacion	15min	Viajes
606	Usera	6:00:00	34
606	Usera	6:15:00	61
606	Usera	6:30:00	2
606	Usera	6:45:00	19

Fig. 8. Utilización de Visum para el análisis de los orígenes de secciones críticas de la red

Por otro lado, una vez se ha establecido la cuota de cada estación y se han generado matrices corregidas, es necesario comprobar que el nuevo conjunto de matrices no genera congestión en ningún otro punto de la red.

La Figura 9 ilustra la lógica de este procedimiento iterativo, para el que es preciso establecer condiciones de convergencia compatibles con la realidad del tránsito por las estaciones. Este procedimiento automatizado precisa de la actuación del personal de Metro que, basado en su experiencia, valida la idoneidad de la solución propuesta, haciendo balance del perjuicio ocasionado a viajeros a los que se deniega el acceso con el beneficio esperado en los sectores en riesgo de congestión.

Esta parte de la lógica está implementada mediante un software complementario a los procesos estándar de *Visum*.

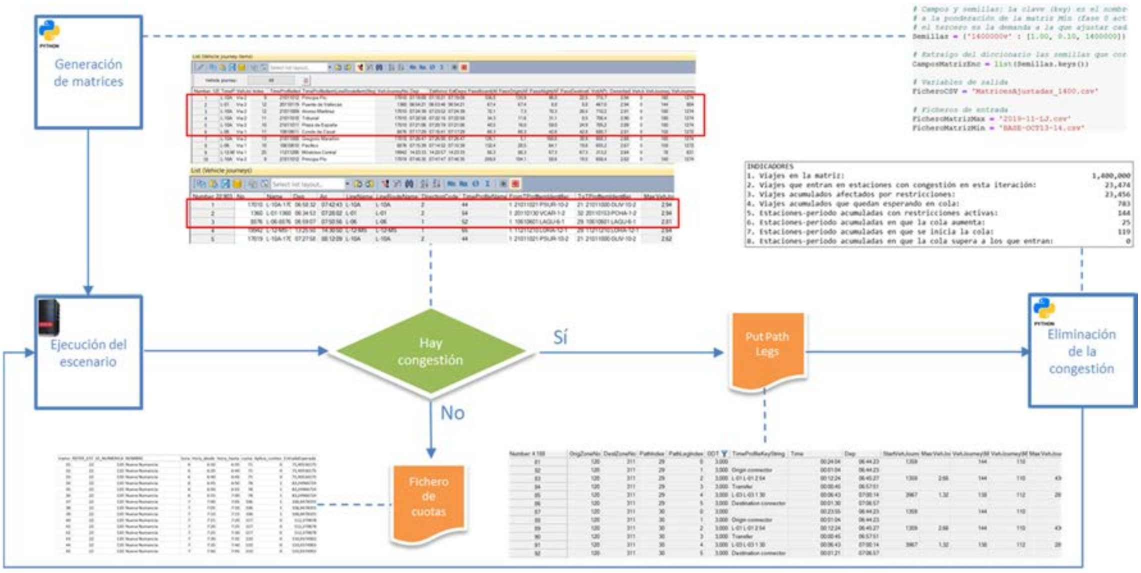


Fig. 9. Establecimiento de cuotas por estación y periodo de 5 minutos

Es preciso insistir en que los productos de este caso de uso tienen una repercusión directa e inmediata en la percepción de los viajeros, que pueden verse detenidos unos momentos en las barreras de paso sin conocer el motivo, situación cuando menos incómoda para ellos y difícil de manejar para el personal de las estaciones. Por este motivo, el procedimiento implantado trata con la misma importancia la exactitud de los cálculos teóricos como la oportunidad de aplicarlos en la práctica.

4. IMPLEMENTACIÓN Y RESULTADOS PRELIMINARES

El producto de la ejecución del proceso descrito en el apartado anterior es un listado con la cuota máxima de viajeros por estación y periodo de 5 minutos, como el que ilustra la Figura 10.

tramo	ID_NUMERICA	NOMBRE	hora	Hora_desde	Hora_hasta	cuota	Aplica_conteo	EntradaEsperada
31	120	Nueva Numancia	6	6:30	6:35	70	0	70
32	120	Nueva Numancia	6	6:35	6:40	70	0	70
33	120	Nueva Numancia	6	6:40	6:45	70	0	70
34	120	Nueva Numancia	6	6:45	6:50	78	1	83
35	120	Nueva Numancia	6	6:50	6:55	78	1	83
36	120	Nueva Numancia	6	6:55	7:00	78	1	83
37	120	Nueva Numancia	7	7:00	7:05	95	1	96
38	120	Nueva Numancia	7	7:05	7:10	95	1	96
39	120	Nueva Numancia	7	7:10	7:15	95	1	96
40	120	Nueva Numancia	7	7:15	7:20	118	0	113
41	120	Nueva Numancia	7	7:20	7:25	118	0	113
42	120	Nueva Numancia	7	7:25	7:30	118	0	113

Para la estación 120 (Nueva Numancia) y los periodos 34 (6:45 – 6:50), 35 (6:50 – 6:55) y 36 (6:55 – 7:00):

- **cuota = 78 -> La cuota máxima de viajeros es 78 (234 en los 15 minutos)**
- **Aplica_conteo = 1 -> Es necesario establecer dispositivo para limitar el acceso**
- **EntradaEsperada = 83 -> Se estima que 83 (249 en los 15 minutos) viajeros quieren acceder**
- **83 – 78 = 5 -> Se quedan 5 viajeros esperando en cada periodo (15 en los 15 minutos)**

Fig. 10. Ejemplo del establecimiento de cuotas.

Este listado con las cuotas se utiliza en los sistemas de control de los accesos que programan los torniquetes de entrada en las estaciones, de forma que para cada lapso se permita o no la entrada de viajeros en función de si el recuento de entradas en tiempo real cumple los cupos parametrizados mediante dicho listado.

Para asegurar el buen funcionamiento del sistema completo de "control de aforos", el personal de la estación y el del puesto de telemando se encarga de comprobar continuamente todos los componentes y proporciona el retorno tanto a los mantenedores de los equipos físicos de peaje y de información a viajeros, como a los responsables del establecimiento de cuotas.

5. CONCLUSIONES

El proceso de estimación de la ocupación de los trenes en Metro de Madrid ha presentado hasta el momento grandes dificultades por la ausencia de medios físicos de conteo a bordo.

Actualmente, la Compañía estudia diferentes prototipos de diversas tecnologías. No obstante, la red de Metro de Madrid es extensa, compleja en sus infraestructuras y equipamientos y con un gran parque móvil. Por tanto, el desarrollo e implantación de los citados prototipos se realizará cuando lo aconsejen las condiciones de retorno de la gran inversión que supone su instalación y, sobre todo, su despliegue completo.

Con los medios de simulación disponibles para los estudios de Movilidad y Planificación de Operación, se ha construido un sistema de estimación de densidades de viajeros basado en los registros de entradas al sistema con resultados muy satisfactorios.

El modelo de asignación de demanda elaborado sobre la plataforma *Visum* de PTV Group constituye una de las piezas clave del motor de cálculo del sistema. Sus potentes procedimientos de asignación y análisis proporcionan las herramientas básicas para resolver el problema de relacionar numéricamente el origen de los viajes con la carga a bordo de las expediciones teóricas de los trenes para cada unidad elemental de la red por localización y unidad de tiempo.

Son muchas las utilidades prácticas a las que Metro aplica el modelo diario de movilidad.

Es este artículo se ha presentado una de ellas, el cálculo de cuotas para control temporal de acceso que permite reducir el riesgo de congestión en las secciones críticas de la red. Esta práctica, siempre importante, pero particularmente sensible en las actuales condiciones sanitarias en las que la distancia interpersonal en el transporte público no es ya un asunto de confort sino una necesidad social.

La experiencia expuesta muestra como la comunicación entre desarrolladores de software especializado y operadores de transporte público constituye un campo de colaboración fructífero. Con la ayuda de empresas de desarrollo que aportan profesionales de alta categoría para materializar los objetivos, y con la acertada visión global desde la academia y organismos transversales, se pueden obtener productos de gran beneficio a coste asequible gracias a la inteligencia de la modelización teórica avanzada.

Esperamos seguir avanzando juntos por este camino.

AGRADECIMIENTOS

Los autores quieren reconocer la aportación al sistema de monitorización y gestión de la demanda de Metro descrito en este artículo a:

- Resto de áreas de la compañía de Metro de Madrid que intervienen en la operación del sistema: Área de Comunicación y Tecnologías de Información, Área de Ingeniería de Instalaciones y al Área de Medios.
- Grupo TEMA Consultor por su aportación en materia de modelización de transportes y programación.
- Servicios profesionales y de soporte técnico de PTV Group

RESUMEN

Disponer de datos correctos, adecuados y actualizados de las redes de transporte es una condición necesaria tanto para la correcta modelización del transporte, como también para la comercialización de diferentes productos que requieran el uso de dichas redes. Aunque actualmente existen multitud de servidores, tanto abiertos como de acceso con licencia, conseguir el dato que se necesita puede convertirse en una tarea de bastante dificultad.

Una alternativa, disponible a escala mundial y con gran detalle también en países en vías de desarrollo, es el mapa colaborativo online Open Street Maps (OSM). Pese a que OSM, por su naturaleza de proyecto colaborativo y abierto a todo aquel que quiera contribuir, suele presentar redes topológicamente incorrectas o falta de algunos atributos, en él se pueden encontrar soluciones de manera automática a gran parte de estos problemas con herramientas basadas en software libre.

Dentro del proyecto HIPROMO, actualmente en versión para uso interno, se ha desarrollado un conjunto de herramientas en Python para QGIS que permiten limpiar, filtrar, tratar, enriquecer con otras fuentes de datos y transformar a las especificaciones propuestas en la aplicación de la directiva INSPIRE las redes viarias de OSM. Las redes tratadas se transforman en grafos adaptados a cada tipo de transporte disponible para, posteriormente, poder obtener haces de rutas entre diferentes orígenes y destinos.

1. INTRODUCCIÓN

El proyecto HIPROMO surge de la necesidad de construir una herramienta inteligente de prognosis de movilidad. El objetivo principal del proyecto es predecir con exactitud las rutas que toman los usuarios en sus desplazamientos gracias a los datos que se recogen a través de las antenas de telefonía móvil.

En este documento se muestra la primera parte de HIPROMO basándose en la obtención de una red fiable con capacidad de obtener haces de rutas óptimas y veraces, mediante una adaptación del algoritmo “link penalty” propuesto por (Park D. y Rilett LR., 1997), con las que poder trabajar. Esta funcionalidad ofrece múltiples posibilidades de utilización; como el análisis de tráfico ante cortes de carreteras por mantenimiento, el impacto de la movilidad frente a la peatonalización de zonas urbanas, entre otras. En definitiva, la herramienta ofrece una solución rápida y eficaz para la obtención de datos correctos, adecuados y actualizados de las redes de transporte.

A lo largo del documento se describe cómo se obtienen los datos, cómo se tratan y transforman para la obtención de la red deseada y finalmente se muestran los resultados obtenidos.

2. METODOLOGÍA

2.1 Herramientas utilizadas

Para la construcción de la herramienta se ha utilizado el siguiente software libre:

- QGIS (3.12.3): lectura de datos, ejecución de los procesos y visualización de los resultados.
- Python (3.7): lenguaje de programación utilizado.
- PostgreSQL (11.5) y su extensión de PostGIS (3.0.3): almacenamiento de los datos

2.2 Elementos de la red

La red de HIPROMO está compuesta por arcos y nodos, cada uno de los arcos representa una carretera, calle, vía, etc. y los nodos representan el inicio y fin de cada arco. Se cumplen las siguientes propiedades:

- Todo arco tiene un nodo origen y un nodo destino
- Al menos uno de los dos nodos de cada arco será uno de los dos nodos de otro arco.

Este nodo compartido por dos o más arcos es en el que se podrá cambiar de arco.

- Los arcos se pueden cortar sin generar un nodo en el punto de cruce si no es posible cambiar de arco en ese punto, por ejemplo, arcos a distintos niveles (puentes y túneles). Cuando en alguno de los niveles existe una intersección real en la misma ubicación que en el caso general del punto, se establece un nodo ficticio entre arcos de diferente nivel.
- Los arcos tienen definidos sentidos de circulación y se permite realizar cualquier cambio de arcos en aquellos nodos en los que la combinación de sentidos de los arcos afectados lo permitan.

2.3 Procesos

Los procesos de HIPROMO se dividen en dos bloques, el primero construye la red y el segundo extrae los datos que se desean de la red y calcula las rutas entre cada par Origen-Destino (OD).

Dentro del primer bloque se encuentran los siguientes procesos:

- h11_OSM2postGIS: recoge los datos en bruto de OSM y los carga en la base de datos.
- h12_Network_ExternalInformation: alimenta a la herramienta con información externa que no viene incluida en los datos de OSM.
- h13_postGIS2Network: realiza una depuración y transformación de la red de OSM a un formato más amigable.
- h14_Network_Hierarchies: procesos para asegurar la conectividad de la red en todos los niveles de jerarquía de la red.
- h15_Turn_Restrictions: analiza e incluye las restricciones de giro a la red.
- h16_Network_ImpedanceModificators: (opcional) alimenta a la red con las zonas del suelo y establece unos factores de reducción a la velocidad según dichas zonas.

Los procesos que se ejecutan en el Segundo bloque son:

- h21_CreateGraphs: se realiza un filtrado de la red según las especificaciones del usuario y se genera una nueva red.
- h22_GetRoutes: calcula las rutas entre cada par OD dado.

Todo el control de la herramienta se realiza desde QGIS. Una vez se tiene definida la zona de estudio que se desea, se realiza la descarga de los datos de OSM para dicha zona y se puede comenzar la ejecución de la herramienta.

2.3.1 h11_OSM2postGIS

El primer proceso recoge los datos descargados y ejecuta el programa "Osm2pgsql" que carga los datos sin procesar de OSM a la base de datos de PostGIS.
Todo el funcionamiento de este programa viene explicado en la página web de (Hoffmann, 2020).

2.3.2 h12_Network_ExternalInformation

Una vez se tienen los datos en bruto cargados, se pasa al siguiente proceso, que es el encargado de alimentar la base de datos con toda la información externa que no viene incluida en los datos de OSM.

- Fichero de anexos con la parametrización de los procesos.
- Fichero de velocidades legales de la región. Este fichero es necesario ya que muchos de los arcos vienen sin velocidad asignada por OSM, por lo que es necesario asignarles una velocidad según el tipo de vía y tipo de vehículo.
- Factores de reducción (opcional): contiene las reducciones a la velocidad de las carreteras, según los usos del suelo, tipo de vía y la hora a la que se recorre esa vía.
- Coste de los peajes (opcional): Contiene el coste monetario necesario para el uso de las carreteras de peaje. Se utiliza para calcular las diferentes rutas alternativas teniendo en cuenta el coste económico que supondría el viaje.

2.3.3 h13_postGIS2Network

En este proceso se hace una depuración exhaustiva de los datos en bruto de OSM para tener una primera versión de la red. Se le pide una serie de datos al usuario: el nivel de red que desea (los arcos tienen una clasificación jerárquica de 7 niveles distintos de red) y el número de componentes conexas que debe tener la red. En un primer paso se recoge toda la información de los arcos para los niveles de vía seleccionados para obtener el conjunto de arcos que interesa. Una vez se tienen los arcos se realizan una serie de arreglos topológicos para mejorar la calidad de la red: (a) unir los arcos contiguos con mismos atributos y sin intersecciones; (b) solucionar errores de tolerancia; (c) analizar las intersecciones que existen entre los arcos viendo en cada caso si las intersecciones se realizan en el mismo nivel o por el contrario existe algún puente o túnel, en el caso de que se produzca al mismo nivel, el arco se segmenta y se divide en dos arcos generando un nuevo nodo en la intersección de ambos arcos; (d) asignar nuevos identificadores a cada arco y a cada nodo; (d) calcular la longitud de cada arco y el centroide.

Al final del proceso se mira el número de componentes conexas que tiene la red y dicho número debe coincidir con el número introducido por el usuario. Con este análisis eliminamos posibles errores que vienen de origen, por ejemplo, si estamos trabajando con una ciudad, solo debería haber una componente conexa, si existe algún grupo de arcos aislados se deberá a un error de origen por lo que sería eliminado o, por el contrario, si se está trabajando con un conjunto de islas habrá que introducir el número de componentes que serán igual al número de islas del estudio.

Toda la información es clasificada en 7 tablas (Fig. 1), donde la tabla de arcos es alimentada con la información del resto de las tablas.

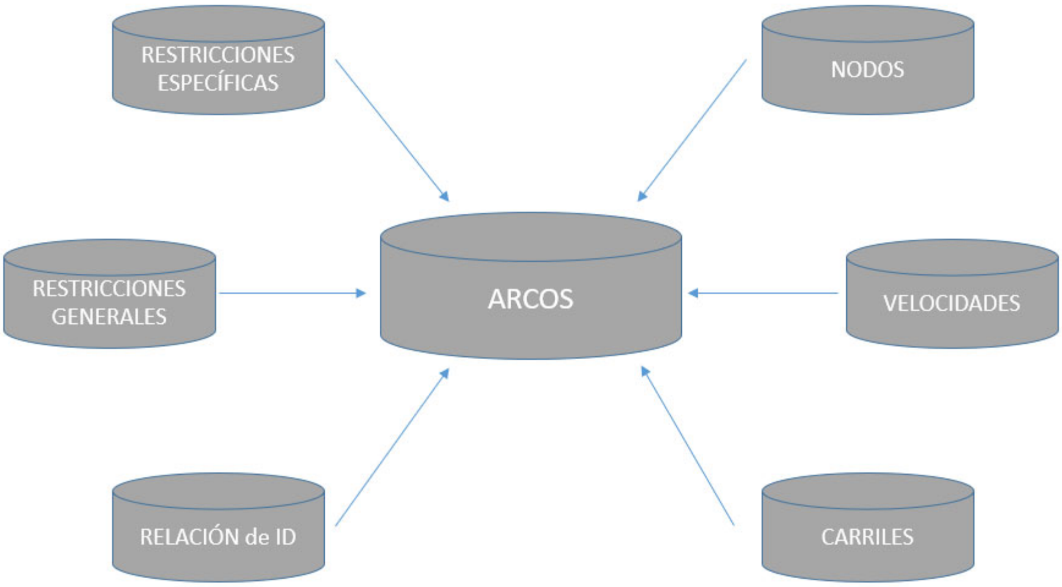

Fig 1- Relación de las tablas de HIPROMO. Fuente: los autores.

- Arcos: contiene la información de los arcos y sus características (tipo de vía, dirección del arco, nombre de la vía, etc.)
- Nodos: contiene la localización de los nodos, que indican el inicio y fin de cada uno de los arcos.
- Carriles: número de carriles que tiene cada arco.
- Velocidades: velocidad máxima y mínima en cada uno de los arcos por tipo de vehículo.
- Restricciones generales: indica que arcos tienen algún tipo de restricción general (peaje, carretera privada, carretera de uso estacional, etc.) y a qué vehículos afecta.
- Restricciones específicas: restricciones de peso, altura, longitud y ancho del vehículo que afectan a cada arco.
- Relación de id: guarda la trazabilidad entre los identificadores que han sido asignados en la herramienta de HIPROMO con los identificadores que vienen del dato origen en OSM.
-

Este conjunto de tablas es la red principal con la que se va a trabajar.

2.3.4 h14_Network_Hierarchies

Como se ha comentado anteriormente los arcos se clasifican en diferentes niveles de jerarquía según el tipo de vía:

Nivel de jerarquía	Tipo de vía
Red Principal	"motorway", "motorway_link", "trunk", "trunk_link"
1ª clase	"primary, "primary_link"
2ª clase	"secondary, "secondary_link"
3ª clase	"tertiary, "tertiary_link"
4ª clase	"residential, "road", "unclassified"
5ª clase	"living_street, "service"
6ª clase	"pedestrian, "track"

Tabla 1 -Niveles de jerarquía. Fuente: los autores.

En este proceso, se comprueba que la red es conexa en cada uno de los niveles de jerarquía, es decir, que si se selecciona como filtro de nivel de la red “Red principal” la red resultante será conexa. En caso de que algunos arcos queden sueltos y la red sea inconexa se utiliza los niveles inferiores, en este caso 1ª y 2ª clase, y se comprueba que arcos son necesarios para hacer conexa la red. Dichos arcos utilizados para hacer la red conexa se suben de categoría.

En el caso que se desee un nivel inferior de jerarquía el proceso comprobará que la red es conexa con los arcos del nivel seleccionado teniendo en cuenta los arcos de los niveles superiores.

2.3.5 h15_Turn_Restrictions

Anteriormente hemos visto que se tienen restricciones específicas y restricciones generales, pero ninguna de las dos contiene la información de las restricciones de giro.

Existen dos tipos de restricciones de giro:

- Restricciones de giro por circulación. Este tipo de restricciones se obtiene de los datos origen de OSM. Hace referencia a dos arcos que tienen un nodo en común, por lo que según la definición de la red se podría cambiar de arco, pero legalmente en ese arco está prohibido girar en esa dirección.
- A parte de las restricciones de giro que vienen de los datos origen, se ha incluido una restricción de giro dependiendo del ángulo de giro entre dos arcos, es decir, si dos arcos comparten un nodo y por definición se podría cambiar de arco, pero en cambio el ángulo que forman ambos arcos es menor a “x” grados donde ”x” lo define el usuario de la herramienta, se le aplica una restricción de giro.

Toda la información de restricciones de giro se almacena en una nueva tabla que alimenta a la tabla de arcos.

2.3.6 h16_Network_ImpedanceModificators

Este proceso es opcional. Se le asigna a cada arco unos factores para la reducción de velocidad utilizando el fichero cargado en el proceso donde se alimenta la herramienta de información externa.

Los factores de reducción se asignan según las características del arco. Se tiene en cuenta el tipo de vía, el uso del suelo en el que se encuentra el arco y la hora a la que se desea recorrer el arco, ya que recorrer un arco de una zona urbana en hora punta no se puede realizar a la velocidad máxima permitida de la vía. Para poder hacer una asignación de factores de reducción a los arcos es necesario disponer de una capa de usos del suelo de la zona de estudio con la que poder asignar a cada arco su uso del suelo para hacer una correcta asignación de las reducciones de velocidad a cada arco.

2.3.7 h21_CreateGraphs

Los procesos del primer bloque han definido una red principal, esta red principal alimenta todos los procesos del segundo bloque. Este primer proceso del segundo bloque genera redes más pequeñas según los filtros que elige el usuario (fig.2).

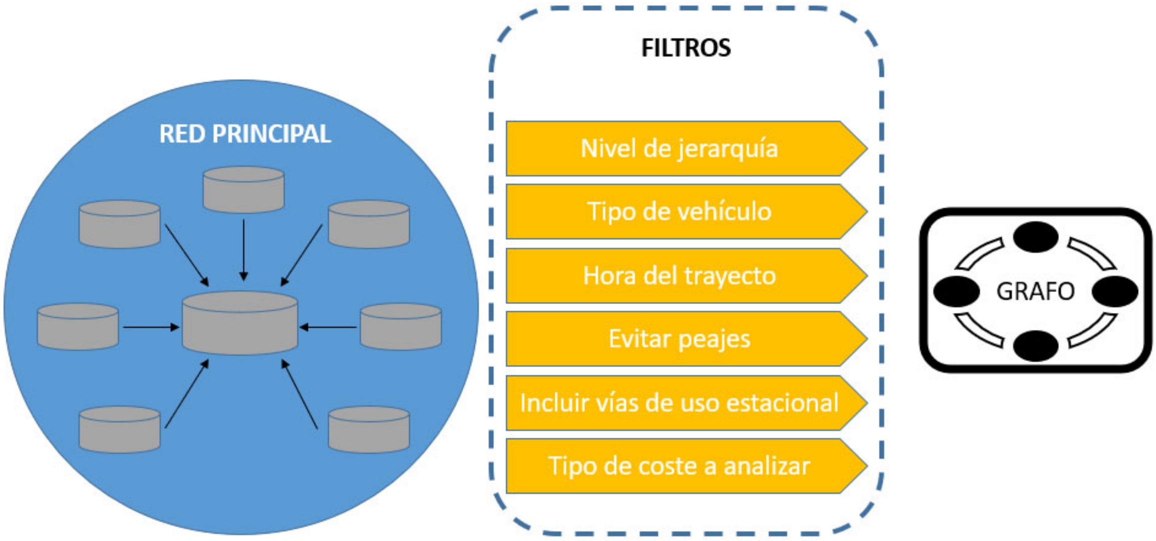

Fig 2- Filtros para la generación de grafos. Fuente: los autores.

Las opciones que tiene el usuario para definir los grafos son:

- Nivel de la red: Nivel de la jerarquía de la que se desea generar el grafo (escenario), se debe tener en cuenta que el nivel de la red del grafo que se desea generar no puede ser inferior al que se ha generado la red principal.

- Tipo de vehículo: existe una larga lista de vehículos (coche, bici, peatón, vehículo para transporte de mercancías, etc.), dependiendo del vehículo elegido los arcos que se podrían recorrer, así como el coste a la hora de recorrerlos varía.
- Incluir carreteras de peaje: Sí/No
- Incluir carreteras de uso estacional: Sí/No
- Coste que se desea analizar: el algoritmo utilizado para calcular las rutas para cada par OD minimiza el coste a la hora de recorrer los arcos entre dos puntos dados. Los costes que se pueden elegir son tres: (1) ruta más corta, teniendo en cuenta la distancia; (2) ruta más rápida, mirando el tiempo que se tarda; y, por último, (3) el coste generalizado que es el coste económico que supone ir del origen al destino.
  Este último tipo de coste, se ha calculado en función del estudio sobre el coste generalizado del transporte (Tool Alfa S.L., 2020) en el cuál para vehículos ligeros se tiene en cuenta el tiempo del trayecto con un coste generalizado de 20,97 €/h, y para vehículos pesados se tiene en cuenta la distancia con un coste generalizado de 0,289 €/km. Si alguna de las rutas utiliza carreteras de peaje, este coste económico también se incluye a la hora de calcular la ruta más económica. Los costes de distancia se miden en metros, el tiempo en minutos y el coste generalizado en euros.

El resultado que se obtiene al finalizar el proceso es un grafo en donde cada arco tiene asociado el coste que supone recorrer dicho arco. Este proceso se puede ejecutar tantas veces como se desee. Para cada ejecución se creará un grafo distinto y se almacenará en la base de datos.

2.3.8 h22_GetRoutes

El h22_GetRoutes es el proceso final de la herramienta. En este proceso se calculan las diferentes rutas entre cada par OD dado para el grafo seleccionado. Se utiliza el algoritmo "pgr_trsp" de pgrouting (pgRouting Contributors, 2021), el cuál devuelve la ruta más corta entre dos puntos dados teniendo en cuenta las restricciones de giro.

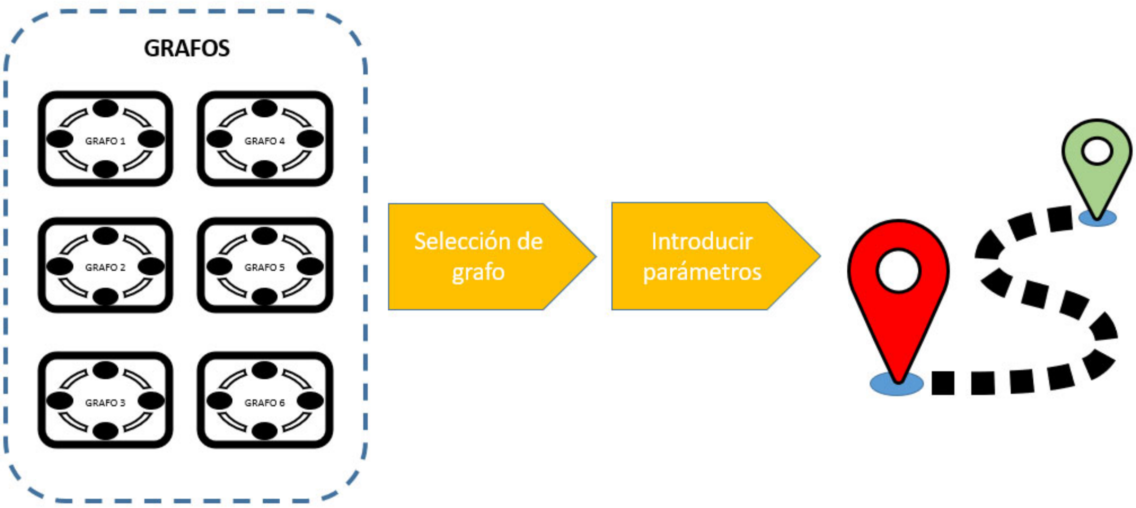

Fig 3- Filtros para la generación de grafos. Fuente: los autores.

En la ejecución del proceso influyen varios parámetros que afectan considerablemente el cálculo de las rutas óptimas.

Estos parámetros son introducidos por el usuario a la hora de ejecutarlo por lo que es necesario tener un conocimiento claro de cómo influye cada parámetro a la hora de generar las rutas. Los parámetros necesarios para el cálculo de las rutas son:

- Número de rutas máximo a calcular para cada par OD: número de rutas que vas a obtener como máximo en la salida del proceso. Primero se calcula la ruta óptima y luego se obtienen las rutas alternativas.
- Desviación máxima permitida: porcentaje, el cual, no pueden desviarse las rutas alternativas con respecto a la ruta óptima calculada.
- Máximo solape entre rutas: indica el porcentaje de arcos en común que puede tener las rutas calculadas.
- Incremento de impedancia en cada iteración: porcentaje que se incrementan los costes de los arcos que han sido utilizados, es decir, cuando se utiliza un arco, el coste de dicho arco aumenta, para que la siguiente ruta alternativa busque otras rutas diferentes.
- Zona cerna a origen y destino sin incremento de impedancia: tamaño del buffer en los puntos de origen y destino a los que no se va a aplicar el aumento de la impedancia.
-

Para saber si las rutas obtenidas son robustas se hace una prueba de sensibilidad, la cual consiste en modificar ligeramente los parámetros necesarios para el cálculo de las rutas, y ver si las rutas obtenidas son iguales. Si con parámetros ligeramente diferentes se obtienen las mismas rutas, dichas rutas serán robustas.

3. RESULTADOS

Se han realizado una gran variedad de pruebas de la herramienta, generando redes para diferentes niveles de jerarquía y para los diferentes tipos de vehículo. Se han calculado rutas dentro de una misma ciudad, rutas entre distintos municipios de una provincia y viajes entre provincias. Todas las rutas han sido comparadas con las obtenidas de Google Maps obteniendo resultados muy positivos.

A continuación, se ilustra el proceso con un ejemplo de la zona de Alicante; para ello se ha realizado una descarga de la zona desde la web de OSM y se han cargado los datos en bruto en la herramienta (fig.4).

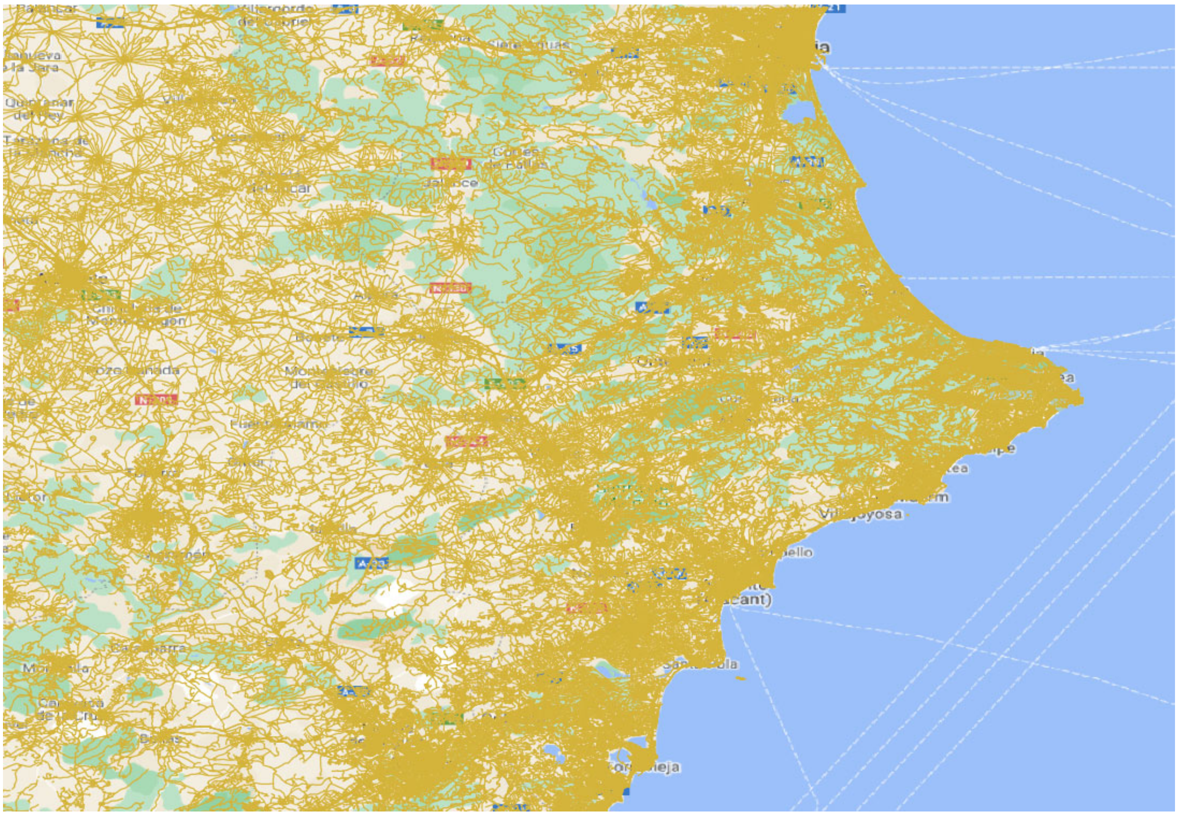

Fig 4- Red obtenida de Open Street Maps. Fuente: los autores.

Hay mucha información, pero no viene bien estructurada, y en muchos casos la información no viene completa. En la tabla 2 se pueden ver varios ejemplos de cómo viene la información de OSM, donde las características del arco vienen en un único campo, y muchos de ellos vienen sin información.

ID del arco	tags
543004957	"name"=>"Carrer del Escultor Leonardo Julio Capuz", "oneway"=>"yes", "highway"=>"residential"
543004957	"ref"=>"A-31", "name"=>"Autovía de Alicante", "lanes"=>"2", "oneway"=>"yes", "highway"=>"motorway", "maxspeed"=>"120"
299525589	"access"=>"private", "oneway"=>"yes", "highway"=>"residential"
41060120	"ref"=>"CV-905", "name"=>"Carretera Benijófar - Torrevieja", "lanes"=>"2", "oneway"=>"yes", "highway"=>"secondary", "surface"=>"asphalt"
331962212	"ref"=>"AP-7", "name"=>"Autopista del Mediterráneo", "toll"=>"yes", "lanes"=>"2", "oneway"=>"yes", "highway"=>"motorway"

Tabla 2 -Datos en bruto de Open Street Maps. Fuente: los autores.

Sobre esta red, HIPROMO realiza los arreglos topológicos para mejorar la calidad de la red, extrae la información de cada uno de los arcos y la almacena de manera bien estructurada.

En los casos en los que falte información, se intenta completar con las características disponibles del arco o por una fuente externa, como es en el caso de las velocidades, ya que la mayoría de los arcos vienen sin una velocidad límite incluida, por lo que se le asigna una velocidad según el reglamento general de circulación (Ministerio de la Presidencia, 2003) y con la modificación de dicho reglamento aprobada el 21 de Noviembre del 2020 (Ministerio de la Presidencia, 2020).

El resultado final es una red bien estructurada, completa y con la información bien detallada. Para el caso de la red de la zona de Alicante, se ha seleccionado un nivel de jerarquía de 4ª clase, filtrando toda la información de los niveles 5 y 6 que hacen referencia a vías peatonales o más residenciales, ya que no se van a necesitar. La red resultante después de aplicar el primer bloque de procesos de HIPROMO se puede observar en la figura 5.

Fig. 5- Red principal de HIPROMO. Fuente: los autores.

La información obtenida tras aplicar el primer bloque de procesos se encuentra estructurada en las siguientes tablas de base de datos. La información mostrada en las tablas no es completa, sino una pequeña muestra para ver el dato real.

TABLA DE ARCOS					
ID	**fromnode**	**tonode**	**Nivel de jerarquía**	**longitud**	**dirección**
371550	296546	296695	mainRoad	635,04059	inDirection
200597	299306	299310	firstClass	29,55969	bothDirections
232858	301527	301555	secondClass	13,91384	bothDirections
418277	184310	184357	thirdClass	76,03465	inDirection
239271	302446	302301	forthClass	98,2555	bothDirections

Tabla 3 -Tabla de arcos de HIPROMO. Fuente: los autores.

TABLA DE VELOCIDADES				
ID	**Tipo de vehículo**	**Tipo velocidad**	**velocidad**	**fuente**
371550	carWithTrailer	maxspeed	80	regulation
371550	carWithTrailer	minspeed	60	regulation
371550	passengerCar	maxspeed	120	regulation
371550	passengerCar	minspeed	60	regulation
371550	privateBus	maxspeed	100	regulation
371550	privateBus	minspeed	60	regulation
371550	pedestrian	maxspeed	0	regulation
371550	pedestrian	minspeed	0	regulation

Tabla 4 -Tabla de velocidades HIPROMO. Fuente: los autores.

La tabla de velocidades (tabla 4) almacena para cada arco, las velocidades por tipo de vehículo. Si un tipo de vehículo tiene velocidad máxima 0, es que tiene prohibida su circulación por dicha vía, como es el caso de los peatones en autopistas. También en esta tabla viene un campo de fuente, que indica de donde se ha obtenido el valor de la velocidad, si viene directamente de los datos de OSM vendrá con un “OSM”, en caso de venir del reglamento general de circulación tendrá el valor “regulation”.

TABLA DE CARRILES		
ID	**dirección**	**Número de carirles**
371550	inDirection	2
200597	bothDirections	2
232858	bothDirections	2
418277	inDirection	2
239271	bothDirections	2

Tabla 5 -Tabla de carriles HIPROMO. Fuente: los autores.

La tabla de carriles (tabla 5) contiene el número de carriles por cada arco, en el caso de que sea de doble sentido "bothDirections", el número de arcos será la mitad para cada sentido. Por último, tenemos las tablas de restricciones que son 3: (i) restricciones generales (tabla 6); (ii) restricciones específicas (tabla 7); y (iii) restricciones de giro (tablas 8).

TABLA DE RESTRICCIONES GENERALES		
ID	**Restricción**	**Tipo de vehículo**
371550	forbiddenLegally	bicycle
371550	forbiddenLegally	pedestrian
291000	seasonal	allVehicle
134701	toll	allVehicle
140293	private	allVehicle

Tabla 6 -Tabla de restricciones generales HIPROMO. Fuente: los autores.

Hay diferentes restricciones generales, "seasonal" o "toll", que a la hora de construir los grafos en el bloque dos, se pregunta si se desea incluirlas, y luego se tiene "forbiddenLegally" y "private" en las cuales no se permite circular dependiendo del tipo de vehículo.

TABLA DE RESTRICCIONES ESPECÍFICAS		
ID	**Restricción**	**Valor**
277325	maxheight	4,5
277325	maxweight	15
290068	maxlength	10
179654	maxlength	8
411667	maxwidth	2,5

Tabla 7 -Tabla de restricciones específicas HIPROMO. Fuente: los autores.

Las restricciones específicas (tabla 7) informan que arcos tienen algún límite de peso, altura, anchura y longitud.

TABLA DE RESTRICCIONES DE GIRO			
Arco Origen	**Arco Destino**	**Vía**	**Tipo de vehículo**
311869	155358	39891	passengerCar
136165	239679	49542	passengerCar
413346	192814	67329	allVehicle
282141	424689	166399	allVehicle
282142	88218	166405	allVehicle

Tabla 8 -Tabla de restricciones de giro HIPROMO. Fuente: los autores.

El formato de las restricciones de giro es diferente a las otras dos tablas de restricciones.

En este caso se tiene el arco por el que estás circulando “Arco Origen”, el “Arco Destino” es al cual está prohibido hacer el giro desde el arco origen, y hay un campo más, que es el “Vía” que indica la intersección entre ambos arcos. Este último puede ser tanto un arco como un nodo. Las tablas anteriores la información de la red principal o red maestra. A partir de esta información se pueden empezar a generar los grafos que uno necesita para realizar el análisis. Gracias a la estructura de tablas que tiene la herramienta la convierte en una herramienta muy flexible facilitando la entrada de información proveniente de otras fuentes.

A partir de la red principal, se han ido generando grafos, los cuáles se incluyen en la base de datos, con la finalidad de poder saber cuántos grafos han sido generados, con qué características y saber cuál utilizar para calcular las rutas (tabla 9). Por lo que la herramienta permite tener una gran variedad de grafos con diferentes características, lo que a la hora de trabajar facilita su identificación y utilización.

LISTA DE GRAFOS						
ID Grafo	**Tipo de vehículo**	**Coste**	**Nivel de jerarquía**	**Hora de viaje**	**Peaj e**	**Seasonal**
1	passenger Car	Tiempo	forthClass	Mañana	Si	Si
2	passenger Car	Tiempo	mainRoad	Mañana	No	No
3	transportT ruck	Coste generalizado	forthClass	Sin horario	No	No
4	passenger Car	Distancia	forthClass	Tarde	Si	Si

Tabla 9 -Tabla de lista de grafos. Fuente: los autores.

La tabla anterior sólo muestra el listado de grafos que existen en la base de datos, es una especia de índice, por lo que si se desea saber toda la información de los grafos se encuentra en la tabla de detalle (tabla 10), en la cual seleccionando el grafo que se quiere analizar, se obtiene los arcos que pertenecen a dicho grafo, el coste de recorrer el arco (según el coste seleccionado para el grafo), el coste de recorrerlo a la inversa (si el arco es de doble sentido), y la longitud de este.

DETALLE DE GRAFOS						
ID Grafo	**ID Arco**	**Fromnode**	**Tonode**	**Coste**	**R-coste**	**Longitud**
1	160264	150327	150535	0,1296	0,1296	60,0571
1	225581	195981	195914	0,7055	-1	95,2385
1	199822	240777	240706	0,0774	0,0774	59,7900
1	330234	241643	241675	0,0109	0,0109	15,2786
1	109728	241539	241423	0,0717	-1	66,4214
1	324117	210709	210696	0,0498	0,0498	38,5188

Tabla 10 -Tabla de detalle de grafos. Fuente: los autores.

Al final la tabla 10 no es más que la información de un grafo dirigido con pesos, donde la estructura de la tabla facilita la utilización del algoritmo del cálculo de rutas. La utilidad de esta información es muy amplia, ya que es aplicable a muchas áreas de estudio, no sólo para el cálculo de rutas.

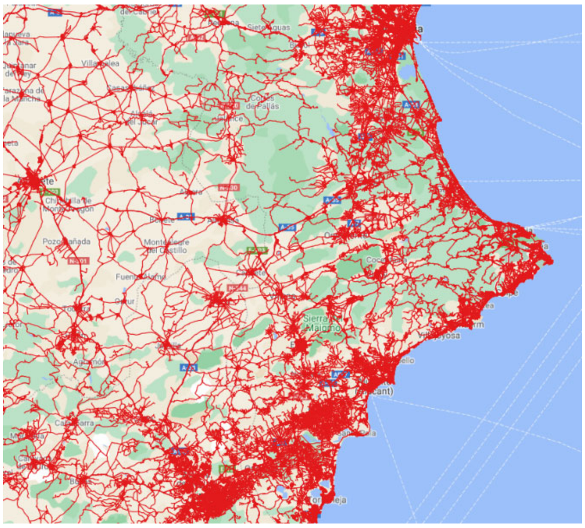

Fig 6- Grafo 1. Fuente: los autores.

Fig 7- Grafo 2. Fuente: los autores.

Se pueden generar tantos grafos como uno desee. Al final del proceso se tiene un conjunto de grafos con toda la información necesaria para poder calcular haces de rutas entre los diferentes orígenes y destinos.

Para el último proceso se ha seleccionado el grafo 1 (Fig. 6) para calcular las diferentes rutas tomando como origen la ciudad de Valencia, y como destino las ciudades de Murcia, Albacete y Almería. Los resultados obtenidos han sido comparados con los que ofrece Google Maps obteniendo unos resultados muy parecidos (figs. 8, 9 y 10).

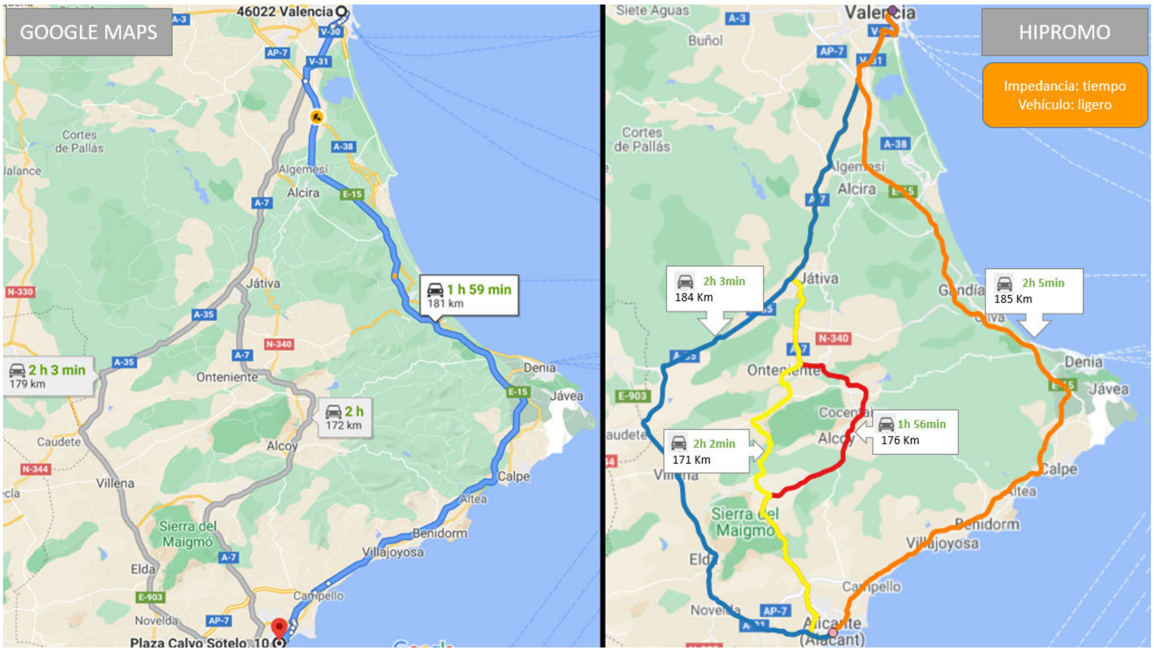

Fig. 8- Rutas Valencia - Alicante. Fuente: los autores.

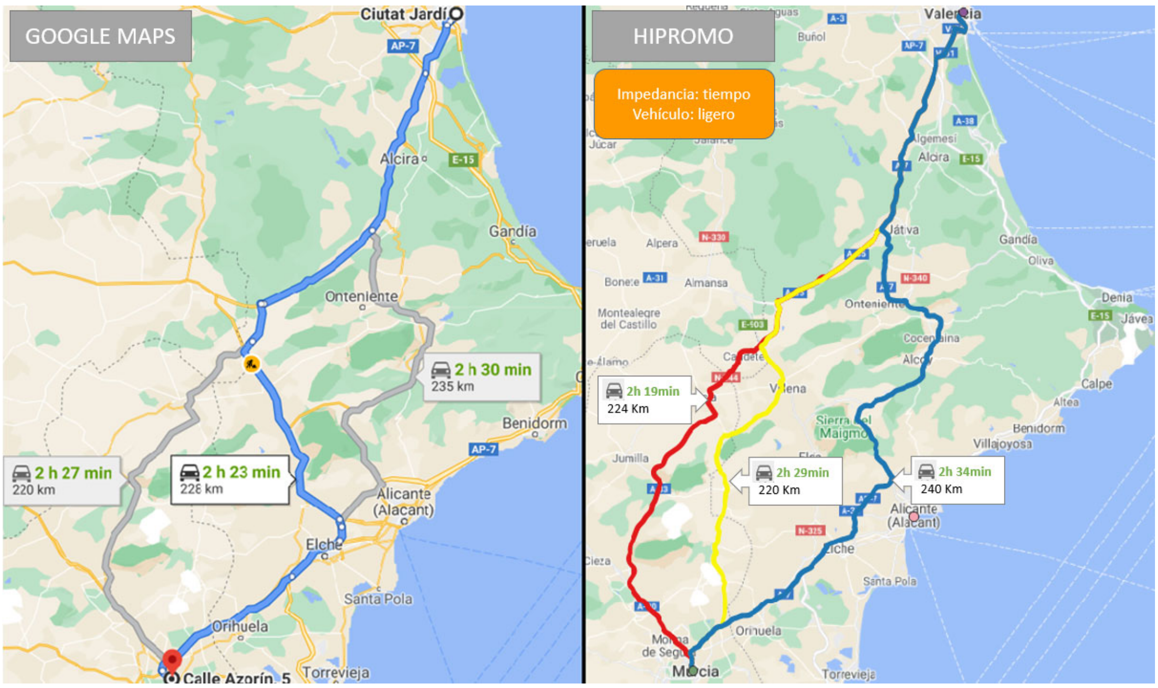

Fig. 9- Rutas Valencia - Murcia. Fuente: los autores.

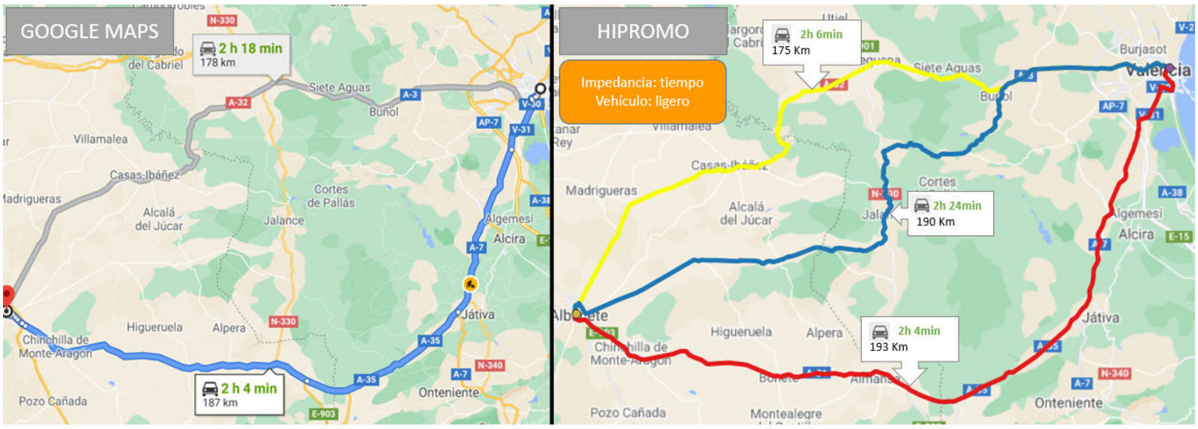

Fig. 10- Rutas Valencia - Albacete. Fuente: los autores.

Como se puede observar en los resultados anteriores, las rutas calculadas por HIPROMO son muy semejantes a las rutas calculadas por Google Maps, la principal diferencia es que las rutas de HIPROMO podemos acceder a todo el detalle de estas, así como acceder a la red principal e incluso a los datos origen de OSM gracias a la trazabilidad de la herramienta.

El detalle de las rutas se guarda en base de datos (tabla 11), donde se puede consultar la secuencia de la ruta, es decir, de que arco a que arco se va moviendo y el coste acumulado según va avanzando. La ruta óptima o de menor coste, siempre será la ruta “0”, las rutas alternativas serán las siguiente (1,2, 3, …) dependiendo del número de rutas alternativas que se desee obtener.

DETALLE DE RUTAS								
ID Grafo	**OD**	**Ruta**	**Sec. Ruta**	**ID Arco**	**Coste**	**Coste Agregado**	**Longitud**	**Longitud Agregada**
1	1-4	0	0	175023	0,1593	0	124,7134	0
1	1-4	0	1	123753	0,6335	0,1593	62,7148	124,7134
1	1-4	0	2	123750	0,5220	0,7928	10,3388	187,4282
1	1-4	0	3	351037	0,6706	1,3148	80,1169	197,767
1	1-4	0	4	351032	0,6972	1,9854	92,6219	277,8839

4. CONCLUSIONES

En el presente estudio se presenta la metodología de uso de la red de HIPROMO, la cual se ha elaborado a partir de Python para QGIS que permite limpiar, filtrar, tratar, enriquecer determinadas fuentes de datos. La idea principal es la obtención de unos datos flexibles y fiables con lo que poder trabajar en diversos estudios, ya que cuando se quiere estudiar una determinada zona requiere bastante tiempo y esfuerzo el conseguir unos datos óptimos con los que poder trabajar. Esta herramienta da respuesta a este problema, y permite la obtención de una red completa, con una información detallada de la zona de una manera rápida y sencilla, ahorrando mucho tiempo, dinero y esfuerzo en la obtención, limpieza y transformación de los datos. Otra ventaja, es que la red principal está preparada de manera que se puedan obtener redes (grafos) según los diferentes parámetros que uno desea para el estudio obteniendo un abanico muy amplio de posibilidades, ya que, se puede generar redes para cada tipo de vehículo (coche, bici, moto, etc.) y cada una de ellas da como resultado distintos grafos con distinta información.

Cabe destacar la importancia del software colaborativo, en cómo utilizando herramientas de software libre se puede crear una herramienta capaz calcular haces de rutas entre diferentes orígenes y destinos con unos resultados bastante buenos, y poder disponer de todo el detalle para poder trabajar con la información.

RESUMEN

Los sistemas de navegación implementados en los dispositivos móviles permiten a los usuarios buscar las rutas más cortas entre pares de puntos. Muchos de los productos comerciales existentes suponen de manera simplificada que el tiempo de viaje para atravesar cada arco de una red de carreteras es fijo, una vez establecida una hora de inicio. Sin embargo, el tiempo real de viaje a lo largo de un tramo de carretera dentro de las ciudades depende de muchos factores que están relacionados con la congestión del tráfico, las condiciones climáticas, posibles incidencias, etc. y, en consecuencia, depende del tiempo.

Como se puede mostrar fácilmente, la determinación de los itinerarios más cortos en un contexto dependiente del tiempo puede dar como resultado diferentes rutas óptimas desde el mismo origen según diferentes horarios de salida. Suponiendo la disponibilidad de los datos estimados del tiempo requerido para transitar a lo largo de cada tramo de la red de calles, una vez que se ha fijado previamente la hora de salida, proponemos en este trabajo un algoritmo eficiente de obtención de rutas más rápidas sobre arcos dependientes del tiempo, de tal modo que la suma de los tiempos de conducción se minimice, lo que en paralelo permite mejorar el consumo de combustible y reducir las emisiones contaminantes asociadas. Una evaluación experimental se lleva a cabo para mostrar la efectividad del algoritmo aportado.

1. INTRODUCCIÓN

La determinación de itinerarios óptimos en las redes de carreteras es un ingrediente básico en la planificación logística y la simulación del tráfico. En los problemas de planificación de rutas de acuerdo con un simple objetivo, se tiende a seleccionar un único mejor camino desde un origen a un destino.

Debido a su eficiencia y eficacia, el algoritmo de Dijkstra (Dijkstra, 1959) se suele utilizar preferentemente para obtener la solución al problema de la determinación del camino más corto entre dos nodos de un grafo conexo. Se puede afirmar por consiguiente que, desde un punto de vista teórico, el problema de encontrar un camino más corto desde un nodo a otro en un grafo con longitudes (o tiempos de viaje) fijas sobre sus arcos está satisfactoriamente resuelto. De hecho, la implementación de la estructura de datos conocida como montículo de Fibonacci en el algoritmo de Dijkstra requiere sólo un tiempo O (m + n log n), donde n es el número de nodos y m el número de arcos del grafo subyacente (Cormen et al., 1994).

Sin embargo, este algoritmo puede resultar impráctico en varios escenarios de aplicación real.

Uno de estas situaciones surge cuando las ponderaciones asociadas al tránsito entre dos nodos adyacentes son dependientes del tiempo. Esta circunstancia puede darse tanto en la determinación de rutas óptimas de transporte público (autobús, metro o redes densas de trenes de cercanía) como en las de transporte privado (vehículo motorizado propio, bicicleta o similar). Entre las variantes del problema de la determinación del camino más corto estudiadas en Dreyfus (1969) está aquella en la que los tiempos de viaje requeridos para las conexiones entre nodos son dependientes del tiempo de partida de los vehículos.

Esta específica perspectiva es la que se analiza en el presente trabajo, aunque no es la única que puede despertar interés en la literatura especializada en el transporte.

Por ejemplo, los usuarios del transporte público pueden mostrar diferentes preferencias desde una percepción personal (punto de vista del usuario), lo que implicaría una adaptación de los algoritmos iniciales para dar cabida a la existencia de otros tipos de preferencias. Entre estas adaptaciones está la consideración del uso de algoritmos que produzcan K-caminos más cortos (problema denominado KSP) para obtener un número razonable (K) de caminos factibles más cortos y jerarquizarlos a partir de la incorporación de las preferencias del usuario. Las preferencias de los usuarios del transporte público suelen ser varias. A modo de ejemplo:

1. Lograr un tiempo mínimo de recorrido, lo que significa llegar al destino en el menor tiempo posible a partir de la hora de salida establecida como inicio desde el punto origen.
2. Minimizar el número de transbordos: algunos viajeros prefieren viajar en un único vehículo (autobús o tren), antes que soportar los inconvenientes de los transbordos, a pesar de que la duración global del trayecto pudiera ser más larga.
3. Conseguir un recorrido de distancia mínima de desplazamiento: un viajero cargado con objetos pesados o incómodos podría preferir caminar hasta la parada de autobús más cercana, como primera etapa, en lugar de recorrer una distancia mayor hasta otra parada de autobús, aunque esta segunda opción le supusiera una ruta más rápida en tiempo.

La planificación de rutas para vehículos en general sobre mapas geográficos a escala ciudad, región o país, es un problema importante y bien conocido, debido a su amplia gama de aplicaciones para cualquier medio de transporte (Preuss y Syrbe, 1997). El cálculo rápido de las rutas más rápidas de punto a punto en redes de carreteras muy extensas y cuyos arcos dependan del tiempo debe llevarse a cabo mediante la participación de servicios centralizados de información basados en una web accesible, donde se gestionen tanto los patrones de congestión como datos actualizados de tráfico en tiempo real. Para un servidor central que tuviera que responder a un número potencialmente muy grande de peticiones on-line de clientes a través de una interfaz www, sería deseable que el tiempo máximo de respuesta del sistema, proporcionando una buena solución, estuviera limitado superiormente de una forma razonable (Delling y Wagner, 2009). Asimismo, debe tenerse en cuenta que las soluciones que quedarían registradas en estos servicios de información de viajes podrían proyectar su influencia hacia los patrones de congestión que fueran utilizados para asesorar futuras decisiones en la determinación de rutas óptimas sometidas a tráfico en tiempo real.

Se denomina enrutamiento al proceso de seleccionar las “mejores” rutas en un grafo $G = (V, A)$, donde V es un conjunto de nodos y A es un conjunto de arcos. La mayoría de los estudios sobre problemas de enrutamiento se han realizado bajo el supuesto de que toda la información necesaria para formular los problemas es invariante en el tiempo (Toth y Vigo, 2014). En muchas aplicaciones prácticas, esta suposición generalmente no se verifica dado que los tiempos de recorrido pueden variar de manera exógena debido a la congestión del tráfico, las condiciones climáticas, etc., o de manera endógena, en función las decisiones que libremente adopte en conductor modificando a su criterio la velocidad del vehículo (por ejemplo, para ajustar el consumo de combustible) o alterando el tiempo de viaje mediante la inclusión de periodos de descanso en la conducción. Una clasificación de los problemas de enrutamiento dependientes del tiempo con respecto a varios criterios puede verse en Pillac et al. (2013).

El cálculo de rutas que ofrece Google Maps, como navegador integrado en las prestaciones de un vehículo, permite que los usuarios puedan conocer el tiempo estimado de llegada al destino seleccionado. Dicho cálculo se supone que se realiza utilizando una serie de parámetros. Entre ellos, la velocidad máxima permitida y la velocidad recomendada en cada tramo. Además, estos tiempos se promedian teniendo en cuenta los datos históricos registrados de las velocidades medias a lo largo de esas carreteras y calles por las que pasan las rutas consideradas, así como los tiempos que han invertido otros usuarios en anteriores ocasiones (si tal información estuviera disponible). Otros datos que suponemos que deben intervenir en este cálculo son, por supuesto, los de tráfico, con la información en tiempo real que afecta especialmente al tiempo estimado. El éxito de las predicciones a futuro obtenidas sobre los tiempos estimados de llegada ofrecidas por Google Maps son muy dependientes de la posible concurrencia de tales incidencias.

En cualquier caso, el resultado de estas predicciones se basa en estimaciones calculadas mediante procedimientos sometidos a confidencialidad empresarial.

Actualmente, hay múltiples operadores que proporcionan información del estado del tráfico basándose en la velocidad observada de circulación de los vehículos a lo largo de los tramos. Sin embargo, esta información no es completa ya que no cubre la totalidad de vehículos circulantes, bien porque existe una porción de vehículos “no conectados” en el parque, o bien porque las fuentes de esta información no cubren la totalidad de navegadores, de los operadores de telefonía o de las flotas de vehículos. Por ejemplo, Google-Traffic e InfoTransit son dos servidores de información de tráfico en tiempo real que operan en España y que se basan en datos de operadores de telefonía, flotas específicas de vehículos (aseguradoras, transportistas, clubes de automovilistas, etc.), sensores fijos de tráfico fijos y sistemas de navegación GPS. Eglese et al. (2006) examinan los problemas relacionados con la construcción de una base de datos de tiempos de recorrido dependientes del tiempo para una red de carreteras y evalúan los beneficios de los sistemas de planificación y enrutamiento de vehículos dependientes del tiempo para una aplicación desarrollada en Inglaterra.

Asimismo, los problemas de enrutamiento dependientes del tiempo se han tratado en el ámbito del denominado Vehicle Routing Problem (VRP) como una variante del mismo en múltiples contextos. Entre ellos (ver Gendreau et al., 2015):

- Planificación de rutas aeronaves, barcos o submarinos en el espacio bidimensional o tridimensional, donde las decisiones incluyen no sólo la determinación del itinerario, sino también el ajuste de potencia. El factor de dependencia del tiempo puede ser causado por las corrientes de aire, oleaje en el océano o el flujo submarino. El objetivo a minimizar suele ser la duración del trayecto, el consumo de combustible (o, equivalentemente, las emisiones de CO2) o una combinación de ellos (Perakis y Papadakis, 1989; Norstad et al., 2011).
- Otras causas de dependencia del tiempo que pueden alterar la duración de recorrido en el VRP sería la necesidad de reabastecer unidades móviles (Helvig et al., 2003), o la necesaria interceptación de trayectorias de otros vehículos (Jiang et al., 2005).
- Finalmente, la presencia de obstáculos en movimiento podría ser también un factor determinante en la planificación del movimiento de robots que puede modificar el tiempo de recorrido de los tramos (Sutner y Maass, 1988; Latombe, 1990; Fujimura, 1995).

2. FORMALIZACIÓN DEL PROBLEMA

Sea el grafo $G = (V,A)$ donde V es un conjunto finito de n nodos o vértices y A es un conjunto finito de m aristas o arcos que conectan los nodos. Cada arco puede ser denotado como el par (i, j) cuando se corresponda con el par de vértices i y j.

En general, para este tipo de problema se considera que los pares (*i*, *j*) son ordenados. Sean *O* (vértice origen o inicial) y *D* (vértice destino o terminal) dos nodos dados de *G*; se define un camino *p* desde *O* hasta *D* en *G* como la secuencia alternada de vértices y arcos:

$$p = \{O = v_0, a_1, v_1, a_2, v_2, \ldots, a_k, v_k = D\} \quad (1)$$

tal que se cumple:

- $a_i \in A, \forall i = 1, \ldots k;\; v_i \in V,\; \forall i = 1, \ldots k-1.$
- $a_i = (v_{i-1}, v_i) \in A, \forall i = 1, \ldots k.$
- $O, D \notin \{v_1, v_2, \ldots, v_{k-1}\}.$

Se define el costo asociado al arco $a = (i, j)$ como el número real positivo $c(a) = c_{ij} \geq 0$. De esta forma, el costo de un camino *p* equivaldrá a la suma acumulada de los costos de los arcos que lo componen: $c(p) = \sum_{(i,j)\in p} c_{ij}$.

Sea P_{ij} el conjunto de todos los caminos de *i* a *j* en el grafo *G*. Siguiendo la notación de Dreyfus (1969), el problema de encontrar el camino más rápido entre los puntos *O* y *D* donde el tiempo de viaje entre el punto *i* y el punto *j* dependa del tiempo de partida del punto j se puede formular como sigue. Denotemos mediante los valores positivos $d_{ij}(t)$ dicho tiempo de viaje invertido y mediante $f_i(t)$ al mínimo tiempo de viaje invertido hasta alcanzar el destino *D* partiendo desde el punto *i*.

El esquema recurrente

$$\begin{cases} f_i(t) = \min_{j \neq i} \left[d_{ij}(t) + f_j(t + d_{ij}(t)) \right] \\ f_O(t) = 0 \end{cases} \quad (2)$$

nos permite diseñar un algoritmo iterativo que, a partir del procedimiento ideado por Dijkstra (1959), proporcione la ruta más rápida en este contexto de tiempos de recorrido en los arcos dependientes del tiempo. Dicho algoritmo se describe más abajo.

2.1 Algoritmo de Dijkstra (entorno estático)

1. **Read** grafo **G=(V,A),** matriz de adyacencia **Ady** y matriz de costes **D** de desplazamiento entre pares de puntos adyacentes.
2. **Construir** vector **f** que almacena los mínimos costes de desplazamiento al origen desde cada nodo de G (inicialmente, sólo los nodos adyacentes con el origen no tendrán valor infinito).

3. **Construir** vector **p** que almacena los nodos sucesores a cada nodo de G en el camino óptimo (inicialmente, sólo los nodos adyacentes con el origen podrán estar determinados).
4. **Inicializar** conjunto **S** de nodos explorados con el origen sólo. **Inicializar** conjunto **LIST** de nodos por explorar dándole el valor complementario LIST=G\S.
5. **While** LIST no sea el vacío:
   5.1 Identificar el índice **j***
   $$j^* = Arg\left[\min\left\{f(j) : j \in LIST\right\}\right]$$
   5.2 Remove índice j* de LIST
   5.3 For each sucesor **k** de j* incluido en LIST:
   If *f(k) > f(j*) + C(j*, k)* **then**
   a. *f(k):= f(j*) + C(j*, k)*
   b. *p(k):= j**
6. **End**.

A continuación, se expone el mismo ejemplo que se usa en Wen et al. (2014) para ilustrar el funcionamiento del algoritmo de Dijkstra y sus limitaciones cuando la red es dependiente del tiempo.

En la Figura 1 se considera una situación estática, donde los pesos de los arcos no varían con el tiempo.

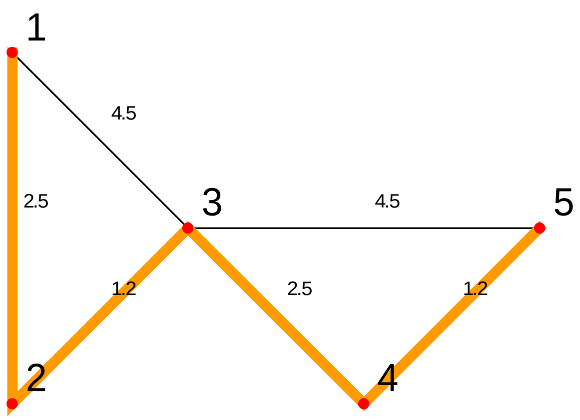

Fig. 1 –Camino más rápido entre nodos 1 y 5 usando el algoritmo de Dijkstra

Como se ilustra en la Figura 1, la solución al problema es el camino 1-2-3-4-5, y el tiempo invertido es 7.4 (2.5+1.2+2.5+1.2) minutos, como puede comprobarse aplicando el algoritmo paso a paso.

Inicio:
Vector f= (0, 2.5, 4.5, infinito, infinito)
Vector p= (- , 1, 1, - , -)

Conjunto S={1}. Conjunto LIST={2,3,4,5}

Paso 1:

j*= 2

Conjunto LIST={3,4,5}. Sucesores de j*= 2 en LIST= {3}

k=3. ¿Es f(3)=4.5 Mayor que la suma de f(2)=2.5 y C(2,3)=1.2? → Sí.

Entonces: f= (0, 2.5, 3.7, infinito, infinito); p= (- , 1, 2, - , -)

Paso 2:

j*= 3

Conjunto LIST={4,5}. Sucesores de j*= 3 en LIST= {4,5}

k=4. ¿Es f(4)=infinito Mayor que la suma de f(3)=3.7 y C(3,4)=2.5? → Sí.

Entonces: f= (0, 2.5, 3.7, 6.2, infinito); p= (- , 1, 2, 3 , -)

k=5. ¿Es f(5)=infinito Mayor que la suma de f(3)=3.7 y C(3,5)=4.5? → Sí.

Entonces: f= (0, 2.5, 3.7, 6.2, 8.2); p= (- , 1, 2, 3, 3)

Paso 3:

j*= 4

Conjunto LIST={5}. Sucesores de j*= 4 en LIST= {5}

k=5. ¿Es f(5)=8.2 Mayor que la suma de f(4)=6.2 y C(4,5)=1.2? → Sí.

Entonces: f= (0, 2.5, 3.7, 6.2, **7.4**); p= (- , 1, 2, 3 , 4)

Paso 3:

j*= 5

Conjunto LIST= Vacío. **END**

A partir del vector de nodos precedentes p= (- , 1, 2, 3 , 4) se puede reconstruir fácilmente el camino óptimo entre los nodos 1 y 5.

Supongamos ahora que el arco 3-5 dependa del tiempo de la forma siguiente:

- Para valores del tiempo entre 0 y 4, el tiempo necesario para recorrer el arco 3-5 es como en el caso anterior (estático) de 4.5 minutos.
- A partir de t=4, como novedad, el tiempo de recorrido del arco decae hasta valer 1,3 minutos.

En ese caso, como se expone en la Figura 2, el camino más rápido entre los nodos 1 y 5 sería la secuencia 1-3-5, siendo el tiempo invertido de 5.8 (4.5+1.3) minutos.

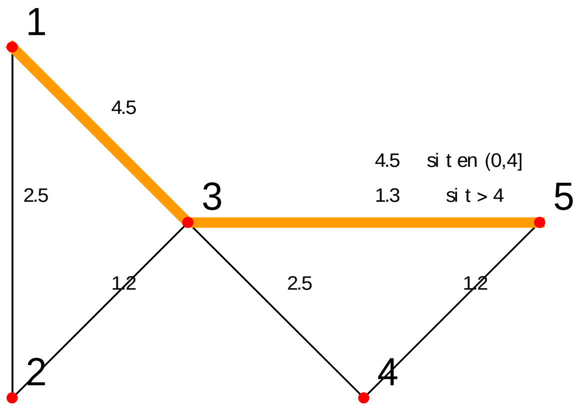

Fig. 2 –Camino más rápido entre nodos 1 y 5 en arcos dependientes del tiempo con prohibición de esperas en los nodos.

Para tratar de adaptar el algoritmo de Dijkstra a este nuevo contexto se debería incluir al menos una referencia temporal que recogiera la hora de inicio del recorrido de cada arco cuando se determina la ruta más rápida. Estas referencias temporales para cada uno de los nodos se deberían almacenar temporalmente como componentes de un vector. El nuevo punto 3 del algoritmo adaptado sería:

> **3'. Construir** vector **p** que almacena los nodos sucesores a cada nodo de G en el camino óptimo y, además, el vector **t** que almacena las horas de comienzo para la validez de esa sucesión.

Habría, asimismo, que modificar la instrucción **5.3** para incluir una actualización del vector t cada vez que se cumpliera la condición $f(k) > f(j^*) + C(j^*, k)$.

Sin embargo, se puede comprobar que la simple introducción de estas dos variantes no serviría para determinar la solución óptima. Aplicando el algoritmo modificado al ejemplo anterior, se puede apreciar que la dependencia en el tiempo del coste asociado al arco 3-5 no tiene efecto en el resultado final del algoritmo porque pasaría inadvertido.

Inicio:

Vector f= (0, 2.5, 4.5, infinito, infinito). Vector t= (- , 0, 0, - , -).
Vector p= (- , 1, 1, - , -).
Conjunto S={1}. Conjunto LIST={2,3,4,5}

Paso 1:

j*= 2
Conjunto LIST={3,4,5}. Sucesores de j*= 2 en LIST= {3}
k=3. Para t=0, ¿es f(3)=4.5 Mayor que la suma de f(2)=2.5 y C(2,3)=1.2? → Sí.
f= (0, 2.5, 3.7, infinito, infinito); t= (- , 0, 2.5, - , -); p= (- , 1, 2, - , -)

Paso 2:

j*= 3

Conjunto LIST={4,5}. Sucesores de j*= 3 en LIST= {4,5}

k=4. Para t=2.5, ¿es f(4)=infinito Mayor que la suma de f(3)=3.7 y C(3,4)=2.5? → Sí.

Entonces: f= (0, 2.5, 3.7, 6.2, infinito); t= (- , 0, 2.5, 3.7 , -); p= (- , 1, 2, 3 , -)

k=5. Para t=2.5, ¿es f(5)=infinito Mayor que la suma de f(3)=3.7 y C(3,5)=4.5? → Sí.

Entonces: f= (0, 2.5, 3.7, 6.2, 8.2); t= (- , 0, 2.5, 3.7 , -); p= (- , 1, 2, 3, 3)

Paso 3:

j*= 4

Conjunto LIST={5}. Sucesores de j*= 4 en LIST= {5}

k=5. Para t=3.7, ¿es f(5)=8.2 Mayor que la suma de f(4)=6.2 y C(4,5)=1.2? → Sí.

Entonces: f= (0, 2.5, 3.7, 6.2, **7.4**); t= (- , 0, 2.5, 3.7 , 6.5); p= (- , 1, 2, 3 , 4)

Paso 4:

j*= 5

Conjunto LIST= Vacío. END

Nótese que efectivamente el vector final p no ha variado (sigue valiendo (- , 1, 2, 3 , 4)), por lo que sería necesario introducir una nueva estrategia para el algoritmo. Proponemos la incorporación de una instrucción en la que se ampliara el grafo de conexiones, replicando cada nodo j* tantas veces como cambios a la baja se produzcan en los valores de los arcos salientes. En la Figura 2, el arco 3-5 toma dos valores, antes y después de t=4 minutos. El primer nodo de este arco que visita el algoritmo es el nodo 3 para t= 3.7 minutos. Este nodo se decide redefinirlo 3a y hereda las conexiones del nodo original (entre ellas, la conexión 3-5 valorada para t=3.7 minutos). Además, se replica un nuevo nodo 3b con las siguientes características:

- El nodo 3a se conecta de forma unidireccional al nuevo nodo 3b con el necesario tiempo de espera t=4-3.7=0.3 minutos.
- El nuevo nodo 3b replica todas las conexiones que tenía el nodo 3 en el grafo original salvo la conexión con el predecesor del nodo 3a en el camino que se está calculando. Los valores de estas conexiones se deberán aplicar en las respectivas ponderaciones a partir del tiempo referenciado de t=4 minutos.

En la Figura 3 se muestra el grafo ampliado según se ha descrito, así como el camino más rápido entre los nodos 1 y 5, que sería ahora la secuencia 1-2-3a (etiquetado como 3)-3b (etiquetado como 6)-5, lo cual implicaría una espera en el nodo 3 de 0.3 minutos, siendo el tiempo total invertido de 5.3 (4+1.3) minutos.

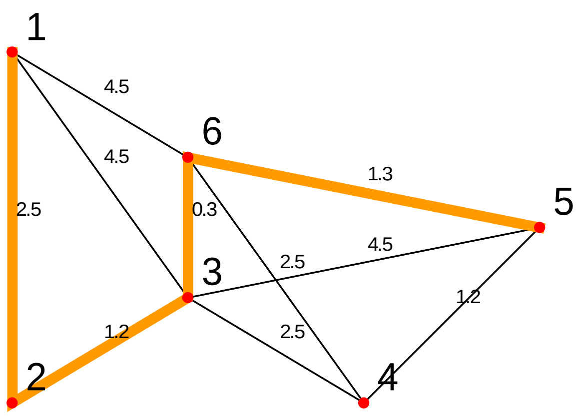

Fig. 3 –Camino más rápido entre nodos 1 y 5 en arcos dependientes del tiempo sin prohibición de esperas en los nodos.

3. UN ALGORITMO ADAPTADO

El algoritmo que se presenta a continuación incluye las modificaciones necesarias para poder determinar caminos más rápidos entre pares de nodos dentro de una red, estando las ponderaciones de sus arcos sometidos a variaciones según horario conocido o pronosticado con antelación.

3.1Un Algoritmo de Dijkstra adaptado a arcos dependientes del tiempo

1. **Read** grafo **G=(V,A),** matriz de adyacencia **Ady** y matriz de costes **D** de desplazamiento entre pares de puntos adyacentes.
2. **Construir** vector **f** que almacena los mínimos costes de desplazamiento al origen desde cada nodo de G (inicialmente, sólo los nodos adyacentes con el origen no tendrán valor infinito).
3. **Construir** vector **p** que almacena los nodos sucesores a cada nodo de G en el camino óptimo (inicialmente, sólo los nodos adyacentes con el origen podrán estar determinados).
4. **Inicializar** conjunto **S** de nodos explorados con el origen sólo. **Inicializar** conjunto **LIST** de nodos por explorar dándole el valor complementario LIST=G\S.
5. **While** LIST no sea el vacío:

    5.1 Identificar el índice **j***

    $$j^* = Arg\left[\min\left\{f(j) : j \in LIST\right\}\right]$$

    5.2 If los arcos de salida del nodo j* no cambian en el tiempo **then**

    5.2.1 **Remove** índice j* de LIST

    5.2.2 **For each** sucesor **k** de j* incluido en LIST:

    If *f(k) > f(j*) + C(j*, k)* **then**

    i. *f(k):= f(j*) + C(j*, k)*

    ii. *p(k):= j**

else

5.3 Por cada arco de salida nodo j* que cambie en el tiempo y por cada modificación de la ponderación del arco:

5.3.1 **Replicar el nodo j* (sea j*'), actualizando** el conjunto V.

5.3.2 **Repetir** para el nuevo nodo j*' las **conexiones** que tenía j* (con las mismas ponderaciones, si no fuera el arco de salida considerado), **excluyendo** la conexión de j* con su precedente en el camino.

5.3.3 **Añadir un enlace dirigido de j* a j*'**, ponderado con el tiempo de espera requerido en el nodo j*.

5.3.4 **Actualizar** el conjunto A según 5.3.2 y 5.3.3.

5.3.5 **Incluir** en el conjunto LIST el nuevo nodo j*'.

6. End.

El bloque de programación que se añade está etiquetado como 5.3, y este se activa cuando se detecte la existencia de arcos de salida que dependan del tiempo. La complejidad del algoritmo depende precisamente del número de arcos cuyas ponderaciones están sometidas a cambios dependientes del tiempo, así como del número de cambios incorporados.

4. CONCLUSIONES

En este artículo se ha analizado el problema de la determinación de caminos más rápidos con arcos dependientes del tiempo en redes de transporte. Son numerosas las contribuciones bibliográficas existentes relativas a esta temática, debido principalmente a la relevancia que adquiere esta cuestión en la planificación logística y de viajes para todo tipo de usuarios.

Se ha estudiado específicamente la metodología presentada en Wen et al. (2014), donde se propusieron dos métodos heurísticos para resolver el problema de la ruta de costo mínimo entre un par de nodos con una red de carreteras que varía en el tiempo y existe además un cargo por congestión.

La herramienta desarrollada por estos autores se basaba en modificaciones del algoritmo de Dijkstra, donde se había establecido una prohibición de espera en los nodos.

La técnica de búsqueda algorítmica de caminos más rápidos con arcos dependientes del tiempo introducida en esta contribución sigue esa línea metodológica de adaptación del algoritmo de Dijkstra a este contexto, lo cual garantiza un alto nivel de eficiencia para el cálculo de soluciones.

En cambio, la contrapartida, como ha quedado constatado en la redacción del procedimiento, está en que el grafo original se deba ampliar convenientemente, tanto en número de nodos como en nuevos arcos (algunos de ellos unidireccionales, que son los que indican el avance del tiempo). Sería posible, no obstante, limitar este crecimiento del grafo contenedor de soluciones, considerando sólo la incorporación de aquellos nodos y arcos que pudieran mejorar la solución actualmente calculada y obviando aquellas otras ampliaciones que claramente derivaran en empeoramientos.

AGRADECIMIENTOS

ABSTRACT

The presence of cyclists on Spanish two-lane rural roads is common, so they have to interact with motor vehicles. Due to the speed differential and vulnerability of cyclists, overtaking is one of the most dangerous and frequent interactions. Therefore, a minimum distance of 1.5 m must be observed. The overtaking manoeuvre depends on road section and cyclist group distribution. Interaction between cyclists and vehicles has been characterized in the past but overtaking to cyclist groups has barely been studied. This study uses a driving simulator to analyse how the presence of cyclists and their group configuration affect traffic operation and safety on two-lane rural roads. A fixed driving simulator has been adapted to incorporate cyclists, using speed and lateral position obtained from field studies. Based on field data, a physical scenario and different traffic scenarios have been recreated, so volunteers can drive the simulator – emulating a motor vehicle – tracking their speed, lateral position, and other variables. These results can be compared to those observed for checking the validity of this methodology. The driving simulator offers some results which are difficult to obtain through other methodologies, enabling a better analysis of the phenomenon. By sorting different bicycle patterns and including several volunteers, the impact of bicycle pelotons on traffic performance and safety can be characterized. This will help in offering recommendations to integrate cyclists and motor vehicles in a safer way.

1. INTRODUCTION

Nowadays, there is an increasing presence of bicycle traffic on Spanish two-lane rural roads, which must be considered when analysing safety and operation of traffic on these roads. Most of the cyclists who use rural roads are sport cyclists, and they usually ride individually or in groups. Due to the differences between cyclists and motorized vehicles, the severity of the accidents registered on rural roads are higher than on urban environment. In fact, in 2019, the 60% of the fatal accidents with cyclists involved were registered in rural roads, despite most of the accidents with cyclists involved (72%) were registered on urban environment (DGT, 2019).

Due to the speed differential and vulnerability of cyclists, overtaking is one of the most dangerous and frequent interactions. The overtaking manoeuvre has been studied in many research using different methods and analysing different variables. Most of these previous studies were focused on the safety point of view, and they analysed mainly the lateral clearance between the overtaking vehicle and the bicycle and the overtaking vehicle speed. Regarding the method used to develop these studies, most of them used instrumented bicycles to collect real data (Llorca et al., 2017; Dozza et al., 2016; García et al., 2019; López et al., 2020). Other studies used naturalistic data (Debnath et al., 2018) or test track data (Rasch et al., 2020). Another methodology that allows obtaining data of the overtaking manoeuvre to cyclists is the use of driving simulators (Bella and Silvestri, 2017; Bianchi-Piccinini et al., 2018; Farah et al., 2019; Mecheri et al., 2020; Goddard et al., 2020; Rossi et al., 2021).

This methodology allows obtaining data from the drivers' point of view, investing relatively short time and in an easy and economical way. All the previous studies, that analysed the interaction between motorized vehicles and cyclists on rural roads using a driving simulator, considered only one cyclist riding alone, and simulated scenarios designed by varying the geometric characteristics of the rural road, the position of the cyclist or the oncoming vehicle presence.

None of them studied the effect of groups of cyclists riding on rural roads, and real geometric and traffic scenarios considering cycle traffic and oncoming traffic were not simulated.

The presence of cyclists on two-lane rural roads not only affects safety, but also traffic operation. Moll et al. (2021) performed a study using a traffic micro-simulator to analyse the effect of cycle traffic on traffic operation on narrow two-lane rural roads. Their results showed that cycle traffic presence decreases motorized vehicle average travel speed and increases percent followers and delays. The use of a driving simulator allows to obtain several performance measures to characterize and analyse the affection on both safety and traffic operation.

Previous studies performed by Llopis Castelló et al. (2016, 2019) proposed a methodology for road safety analysis using driving simulators. Following this methodology, the virtual scenario is designed, recreated and loaded into the driving simulator based on geometric characteristics of the road and surroundings.

Then, a set of driving simulator tests is performed by some volunteers. Finally, the results of the simulator are validated by comparison with the real data obtained on field observations. At last, the results obtained from the simulator can be analysed to obtain conclusions. This methodology can be used not only to analyse road safety, but also to characterize traffic operation (Dols et al., 2021).

The present study aims to simulate a real geometric scenario and three traffic scenarios obtained from field observations. Other innovation of this study is that the traffic scenarios simulated include groups of sport cyclists, riding in different configurations. Using the developed driving simulator will be possible to obtain some results which are difficult to obtain through other methodologies, enabling a better analysis of the phenomenon.

2. METHOD

The first step was to create the road physical virtual scenario. The physical recreation used the methodology developed by Dols et al. (2016) that requires to define the road geometric characteristics (alignment, elevation and cross-section), as well as the environment (side margins, vertical signs, road markings, surroundings, etc.). From this information, the virtual scenario can be recreated and loaded into the driving simulator. In the next step, a group of volunteers (who must be representative), will travel through the virtual scenario using the simulator. Fig. 1 shows the methodology used.

This paper is focused on the first stage. The main objective was to incorporate groups of cyclists inside the driving simulator scenario, and to simulate the real road and traffic characteristics in a realistic way. The traffic scenarios implemented corresponded to real scenarios observed in the segment.

Therefore, the results of the simulator can be validated with field data in order to analyse the behaviour of the drivers in the simulator with respect to that observed in the field. In addition, on the second stage, data from driving simulator test can be used to evaluate safety and traffic operation in the road.

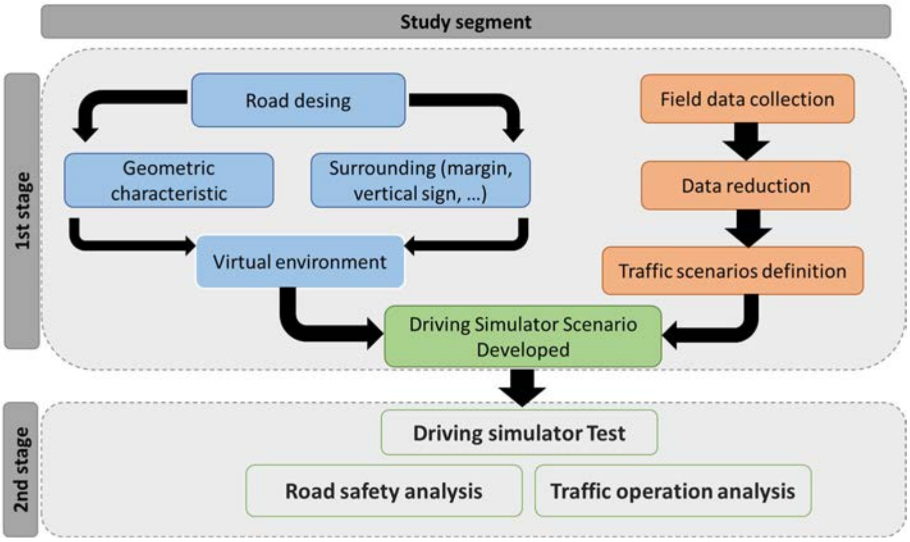

Fig. 1 – Methodology used to develop road segment and cross-section characteristics.

2.1 Study segment description

This study was performed in a segment of two-lane rural road located in the road CV-310, in the region of Valencia (Spain). The study segment is 4,860 meters long, and it has a lane width of 3.2 meters. The road has paved shoulder varying the width between 1.5 and 2 meters. The road has a downward slope of about 7.2% from the beginning to the end of the segment analysed. An important feature of this segment is that the shoulder is coloured in red.

2.2 Field data collection and reduction

Data collection consisted of naturalistic recordings made simultaneously in the extremes of the segment, using small high-definition video cameras. The video cameras were discreetly located so that they could not be noticed by road users. Data reduction beginning with reviewing the videos recorded in the start point of the segment, and the timestamp and the typology of each road user was registered. Finally, the videos recorded at the end point of the segment were reviewed to complete the dataset. This data reduction was realized in both directions of the studied segment. As a result, the time space diagrams considering the trajectories of each road user were obtained and used to select the traffic scenarios with the maximum and the minimum bicycle traffic for the simulations.

2.3 Virtual scenario

The virtual scenario design can be a laborious process. As Dols et al. (2016) indicated, the scenario geometric and traffic characteristics to be modelled will determine the accuracy of the model and therefore the success of the study to be carried out. Modelling the virtual scenario requires a high degree of specialization in many areas (traffic, road design, road safety, among others) as well as graphic simulation techniques and 3D object modelling, to reproduce real-world conditions as good as possible

The present study aims to simulate a real geometric scenario and different traffic scenarios obtained from field observations. To do this, firstly, a physical scenario has to be developed.

The physical scenario has to be similar to the real road segment, so their design is based in real data collected on the road and obtained from computer programs based primarily on satellite imagery. Once the physical scenario has been designed and built, the traffic scenarios have to be designed. The traffic demands considered in each traffic scenario were based on field observations. However, the main challenge is to integrate the groups of cyclists and their observed behaviour in the simulator.

2.3.1 Physical scenario

The physical scenario was designed by the Institute for Design and Manufacturing (IDF) of the Universitat Politècnica de València based on the Multilayer Editing Procedure (Dols et al., 2016, 2021). This methodology implies that the scenario editing procedure of all elements to define the virtual scene are modelled as a multi-layer editing technique in which different data-files are including the types of information needed to model the road and their surrounding virtual scene.

2.3.1.1 Road Design Geometry

The road design was developed using Civil 3D software. Then, the horizontal and vertical alignments, and the cross-section characteristics were provided in an Excel file with the coordinates (x, y, z) of the axis of the road, the edges of the lanes and the platform given at each meter. One of the characteristics of this section is that the width of the shoulder varies between 1.5 m and 2 m, the majority being 1.5 m wide, while the lane width is constant during all the segment To consider the variation in the cross section, the equations of the shoulder width limits were obtained as an input to the physical development of the model for the simulator.

Terrain model of the surrounding area

ASC file with the cartography, downloaded from the website of the National Plan for Aerial Orthophotography (NPAO), and combined with a more precise tachymetry.

Orthophotography of the study area

Also downloaded from the National Plan for Aerial Orthophotography (NPAO) website in Enhanced Compression Wavelet (ECW) format.

Inventory of Elements of the road and the environment

A file in Excel format, with all the elements of the superstructure as vertical signs, road beacons, road markings, lateral safety barriers and lateral walls was completed. Each road and environment element were described and their specific location in the road, referenced to the beginning of the road segment, were registered.

For each observed vertical sign, the location where it appears, referenced to the beginning of the study segment, and the margin where it appears were indicated. In addition, to know the orientation of each of them, the direction of circulation was noted. Fig. 3 show the different vertical signs observed in the study segment, and lately introduced into the virtual physic scenario.

Fig. 2 - Vertical signs observed in the study segment.

In the study segment some road beacons to signalize the curves were observed (Fig. 3). These road beacons were located in the road indications their point location, referenced to the beginning of the segment, and their margin and orientation. The number of signs that formed each beacon (simple or double) was also indicated. The location of them was always out of the road, and of the lateral safety barrier, when it was present. In the study there were also observed a speed radar sign and its corresponding speed radar device (Fig. 3).

(a) (b) (c) (d)

Fig. 3– (a) simple road beacon; (b) double road bacon; (c) speed radar sign; (d) radar box observed in the study segment.

The different types of road markings observed in the study segment are shown in Fig. 5.

The lateral centre lines, which separate the lane and the shoulder, were continuous in all the segment, while the centre line presented the five types shown in Fig. 5. These data were reported considering the points were the lines changed along the segment. In the study segment there are simple and double lateral safety barriers (Fig. 6), most of them are double safety barriers, used to improve the safety for motorcyclists; and there are only two segments with a simple safety barrier.

The locations of the safety barriers were defined indicating the type "Simple" or "Double", and the point of the road and the length where this containment system exists. In addition, it has been differentiated for each of the road margins in an increasing direction of road length, referring to the origin of the study segment. The disposition of the safety barriers will be on the outside of the hard shoulder.

Fig. 4 - Different centre and lateral line types observed in the study segment.

(a) (b)

Fig. 5 - Lateral safety barriers observed in the study segment. (a) simple safety barrier; (b) double safety barrier.

In this section there are several lateral walls whose height, and the initial location and length were provided. The texture and colour of each lateral wall was registered in order to obtain a similar result in the virtual scenario. A CAD file was also generated with the location of environmental elements that cannot be associated with a specific point of the road, such as buildings and vegetation. Two types of trees were defined in the virtual environment, they were orange and pine trees.

2.3.2 Traffic scenarios

As a novelty on driving simulator studies, real traffic scenarios were simulated, considering the same cycle traffic and oncoming traffic than observed on the field. This fact makes the validation process more realistic, so it is possible to validate the simulator results for each traffic scenario simulated in a more exact way. Therefore, the physical appearance of all road users, and their trajectories along the road segment were analysed.

2.3.2.1 Groups of cyclists

The trajectories of the cyclists along the segment depend on the shoulder width at each point. Therefore, the trajectories of the cyclists had to be incorporated in the simulator considering the lane and shoulder width variation. The positions of the bicycles were different considering the direction, as the lane and shoulder widths. The bicycles positions were defined as y_br and y_bl, for the right and left side of the road respectively. Then, for the direction with x positive values, the trajectory of the bicycles, which ride on the right shoulder, was defined by:

While the trajectory of the bicycles in the opposing direction, when they ride in the left shoulder, were defined by:

$$y_{br} = \begin{cases} y_r + \frac{y_{rs}-y_r}{2} & \text{if } y_{rs} - y_r \geq 2.2 \\ y_{rs} - 1.1 & \text{if } 2.2 > y_{rs} - y_r \geq 1 \\ y_r - 0.1 & \text{if } y_{rs} - y_r < 1 \end{cases} \quad (1)$$

$$y_{bl} = \begin{cases} y_l + \frac{y_{ls}-y_l}{2} & \text{if } y_l - y_{ls} \geq 2.2 \\ y_{ls} + 1.1 & \text{if } 2.2 > y_l - y_{ls} \geq 1 \\ y_l + 0.1 & \text{if } y_l - y_{ls} < 1 \end{cases} \quad (2)$$

These trajectories correspond to a single cyclist. When two cyclists ride two-abreast, they are modelled as two bicycles, separated 1 m and centred in the defined positions for one cyclist. To better reproduce the groups of cyclists in the simulator, the different groups were simulated based on a combination of one cyclists and a couple of cyclists riding two-abreast.

The distance considered between cyclists who ride in-line was 1 m. About the speed at which the bicycles ride, there was considered that all the bicycles ride at the same speed, and this speed was considered constant based on the values obtained in filed data.

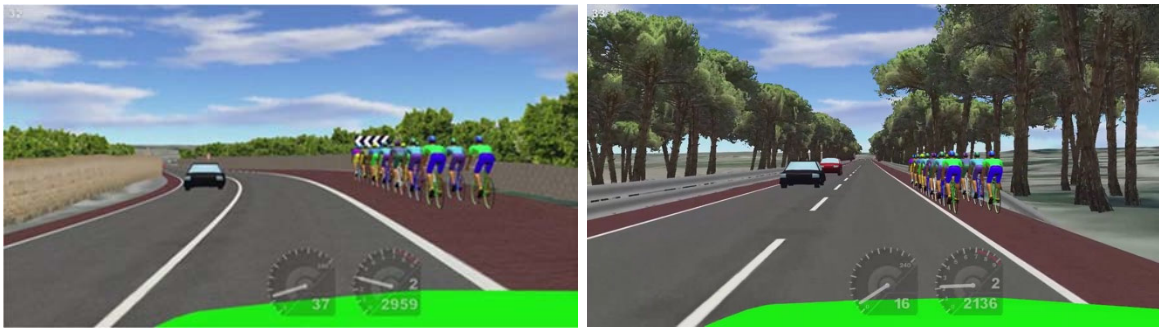
Oncoming motorized vehicles

All the oncoming vehicles were considered to travel at the same constant speed. This speed was obtained from the field data collected in the study segment. Regarding the lateral position, the oncoming motorized vehicles were centred in the lane for both directions, as it was the most common position observed on field.

2.3.2.2 Cyclists and motorized vehicles appearances in the simulator

The vast majority of cyclists who ride on two-lane rural roads are sport cyclist. Therefore, to increase the reality in the simulator experiment, all cyclists introduced in the simulator were equipped by sport cyclist clothes and helmet. To simulate the reality better, different colours and models were considered for the simulation, for both bicycles and motorized vehicles. In that way, the cyclists and the oncoming vehicles that one participant encounters during the test have different appearance selected at random, as it happens in reality. Fig. 7 shows various examples of overtaking manoeuvres of the vehicle driven in a curve or straight lines section of the scene where the traffic of oncoming vehicles appears at the same time.

In the virtual scenario developed, four types of medium-sized vehicles have been reproduced (5-door sedan, 3-door coupe, sports car and van), with dimensions between 3.8 meters to 4.5 meters in length, widths from 1.72 m to 1.91 m and heights from 1.2 m to 1.82 m. The cyclists modelled occupies a length of 1.52 m, width of 0.52 m and height of 1.52 m, where the only difference between the members of the peloton is the clothing colour they wear.



(a) (b)

Fig. 6 – Cyclists and motorized vehicle appearance reproduced in the driving simulator. (a) overtaking manoeuvre of cyclist peloton in a curve; (b) overtaking manoeuvre of cyclist peloton in a tangent segment.

2.3.2.3 Traffic scenarios simulated

Both bicycle and motorized vehicles traffic data were provided for the simulator in an Excel file, which included the direction of the simulation, the Average Travel Speed (ATS) of motorized vehicles and bicycles, and the initial location of each road user when the test starts.

The simulated traffic scenarios were selected from the field dataset. Regarding the time-space diagrams obtained, the vehicle who overtakes a higher number or cyclists had been chosen as the traffic scenario 1. The traffic scenario 2 was selected from the data obtained in the opposing direction, in that way participants changes the direction of travel and so they are less conditioned to the same travel. The traffic scenario 2 was selected considering a vehicle trajectory which encounters a lower cycle traffic. Then, it is possible to compare the effect on the traffic operation considering one scenario with high cyclist demand and another with a lower one. Finally, a third scenario was designed based on the traffic scenario 1 and doubling the cycle traffic. This scenario was not observed on field but can offer results about how a high cyclist demand affect the safety and traffic operation in a rural road. In these scenarios, a similar volume of oncoming vehicles has been considered, in order to compare the condition generated by varying only the cycling volume.

2.4 Driving simulator

The experimental tool used in this study is the SE2RCO driving simulator, designed and developed by the Institute for Design and Manufacturing (IDF) of the Universitat Politècnica de València (Llopis-Castelló et al., 2016). This tool it is based on a fixed-based simulator which provides the capability for implementation different simulation software, data collection and driving assessment in real time. It is composed by simulation computer, three-screen-display monitors with 120 degrees of field of view (FoW) (1.80x0,34 m and Matrox TripleHead2Go graphics card), steering wheel, pedals, and gear-shift lever and adjustable seat based on a Citroen Saxo. It is capable to acquire longitudinal and lateral speed, location and azimuth with a frequency of 10 Hz. It has been instrumented with load cell (brake pedal force), potentiometers to measure displacement in the three pedals, micro-switch to detect gear-lever position, encoder for measuring steering wheel angle and torque sensor for the steering wheel torques.

3. RESULTS AND DISCUSSION

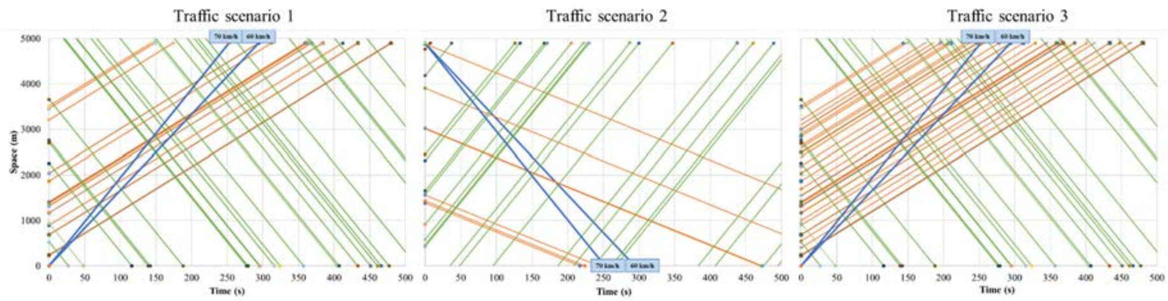
3.1 Field data

The field data collection was carried out on a Saturday morning, since it is when it was expected to see a greater number of groups of cyclists. Table Table 1 shows the main results of the field data collection. According to the results of average travel speeds (ATS) showed in Table 1, the average travel speed of motorized vehicles in both directions for the simulator were considered 70 km/h, while for bicycles a different ATS were stabilized considering the travel direction. Then, for bicycles an ATS of 35 km/h in the direction 1, and of 23 km/h in direction 2 were considered. These average travel speed selected for bicycles in the driving simulator were more realistic than the previous ones considered in other studies which used a driving simulator, since they were obtained from field measurements.

Direction	Initial hour	Duration	Observed bicycles	ATS bicycles (km/h) Mean (SD)	Observed motorized vehicles	ATS motorized vehicles (km/h) Mean (SD)
1	8:20	4:39	287	34.85 (4.72)	777	69.93 (6.78)
2	8:19	4:14	191	22.64 (3.42)	539	68.44 (6.75)

Table 1 – Bicycles and motorized vehicles and their ATS registered during the data collection.

Fig. 7 shows the time-space diagrams for the three traffic scenarios with the trajectories of the bicycles in orange and those of the opposing vehicles in green. The trajectories correspond to straight lines since it was considered that all of them circulated at a constant speed. The trajectories of two hypothetical vehicles that travel the section at constant speed have been represented in blue, one driving at 70 km/h and the other at 60 km/h. It is observed that when a driver travels the section at a higher speed, interactions with more cyclists are produced.



(a) (b) (c)

Fig. 7– Trajectories of bicycles and oncoming vehicles: (a) traffic scenario 1; (b) traffic scenario 2; (c) traffic scenario 3.

3.2 Virtual scenario

According to the scenario design methodology developed by Dols et at. (2021), the total development time of the virtual scenario applied in this study, based on the multi-layer methodology, can be divided into three phases: editing time (obtaining and editing data sources with specific software), programming time (preparation, treatment and adaptation of the data for a specific simulator) and processing time (processing time to generate native files adapted to a specific simulator). Considering that the virtual scenario has been designed for a 4.86 km segment of the road, and according to the hour/km ratios necessary for the implementation of the virtual scenario, the development times results used in each of these three phases have been quantified as follows:

Editing time: 35 hours	Editing time ratio, Rte: 7.2 hours/km
Programming time: 84 hours	Programming time ratio, Rtp: 17.28 hours/km
Processing time: 0.16 hours	Processing time ratio, Rts: 0.034 hours/km

Therefore, the total estimated ratio of development time used in this study is about RT = 24.5 hours/km. This development time can be considered as moderate (between 20 to 35 hours km), compared to other methods of developing scenarios with manual editing, which are usually classified as very high (more than 50 hours / km). The values of the development times of virtual scenarios obtained in this study are consistent with those defined by Dols et al. (2021) in the analysis of virtual scenario development methodologies for the development of road safety audits through the use of driving simulators.

One of the advantages of using this multi-layer scenario design methodology is the fact that it presents the possibility of introducing very rapid changes in the traffic simulation model used. For example, in this work bicycles are moving at a constant speed in each scenario, but if needed, it is possible to modify the behavior model of each independent cyclist, or a peloton as a whole, modifying the specific Excel file with the data required, allowing the analysis to be adapted to more unfavorable or dangerous situations.

In the development of the traffic scenario, the bicycle and vehicle paths have been simulated according to a previously established behavior model. However, the versatility of the method used also allows the introduction of behavior models with variable trajectories for each of the mobile objects on the scene, with only modify the data layer that determines the trajectory of cyclists and vehicles.

One of the limitations of the present study has been the analysis of the physical contacts between vehicles and cyclists. In our work, the modeling of the physics between objects has been carried out without the purpose of studying the effect of the collision between vehicles and cyclists, nor the consequences of the same, since the final objective has been based on determining the behavior of the driver before the appearance of groups of cyclists who have to be overtaken considering oncoming traffic. This current limitation may be the source of future work in which a vehicle-cyclist contact model should be introduced to determine the trajectories and consequences of the collision of cyclists and vehicles circulating on the road. In that case, a contact physics modeling would have to be developed in one of the data layers that allow the generation of the entire virtual scenario.

4. CONCLUSIONS

In this paper the development of a driving simulator integrating cyclists is performed. To recreate the road physical virtual scenario and ensure that it is similar to the real road, naturalistic data was collected by realizing naturalistic observations in the extremes of a two-lane rural road segment. From these recordings, traffic scenarios were obtained, both for motorized vehicles and for bicycles.

Based on field data, both of the road geometry and surroundings and of the traffic, it is possible to recreate the real phenomenon observed on field. Therefore, it is possible to validate the driving simulator results and compared them to field data. Finally, by using the driving simulator it is possible to obtain some results which are difficult to obtain through other methodologies, enabling a better analysis of the phenomenon.

On further research will be possible to analyse the effect of some changes in the safety and traffic operation. These variations can be realized on the geometry of the rural road, as incorporating turnouts, varying the lane or shoulder widths and colours, or varying the speed limit of the road. It is also possible to analyse the effect of variations in the traffic demand.

Future works applying this methodology would allow the analysis of the road safety from both existing roads and others that are in the design phase, by introducing models of traffic behavior of cyclists and vehicles, according to certain cross section configuration or construction, e.g. the introduction of roundabouts, variable widths, slopes, etc.

AKNOWLEDGEMENTS

This study was part of a research project titled "Improvement of safety and operation of two-lane rural roads with cyclists (Bike2Lane)" (TRA 2016-8089-R) subsidized by Spanish Ministry of Science and Innovation. In addition, the authors would like to thank the Road Department of the Valencian Provincial Council, and General Directorate of Traffic of Spain, for their cooperation in field data gathering.

ABSTRACT

In last years, driving simulators have had an increasing use in researching highway geometric design. However, research simulators have high costs. A possible solution to avoid these costs is using videogame simulators. Videogame racing simulators have achieved high quality with a moderate cost. Some of these games include very detailed models that describe very accurately the performance of the simulated vehicles. In addition, they provide very realistic images of the car, the highway and their surroundings.

With the aim of using them as research tools, several of the most popular games have been analysed. Two of them have been selected: rFactor2 and Assetto Corsa. Also, a 3D model of a section of an actual highway has been made and adapted to be used by the aforementioned games. Some tests have been conducted using a custom computer system, and the modelled highway section, with both game simulators. From these tests results, both sim racing software can be used to build a low cost driving simulator useful for road geometric design research.

1. INTRODUCTION

Driving simulators are designed to reproduce situations that occur in actual vehicle driving. Numerous studies establish the usefulness of driving simulators in research on road geometric design, traffic studies, and driver training.

Driving simulation research has a series of advantages compared to research based on actual driving. One of the most important advantages is the capability to create virtual environments with fully controllable parameters that would be challenging and expensive in actual driving (Olstam et al. 2008).

Another advantage of simulators is the relative ease of collecting data about driving parameters. In addition to the speed and acceleration values, which are not difficult to measure in actual driving, there are other parameters such as the position of the vehicle within the lane, the stopping distance from a stop line, or the fixation point of the driver's gaze, which are relatively easy to measure in a simulator and more difficult to measure in actual driving tests (De Winter *et al.*, 2012).

Driving simulators can be classified according to the type of vehicle they simulate: passenger cars, trucks, motorcycles, machinery and others. A distinction must also be made between simulators intended to be driven by one person or those intended to simulate autonomous vehicles. This paper talks about driving simulators for passenger cars driven by a person, which will be called driving simulators.

The use of driving simulators for research dates back to the second half of the last century (Fox, 1960). Currently, driving simulators use computerized systems. Their use has increased in recent years, favoured by the increase in computers' power and the improvement in the quality of image display systems.

Despite this development, the price of a driving simulation system for research on road geometric design is still too high for many research departments at universities. In the low range, a primary research simulator can cost between 30000 and 100000 euros. The most advanced models have complete systems for reproducing accelerations and require a hangar for their installation. Their cost can reach several million euros (BMW Group, 2020).

Allen *et al.* (1995) studied the characteristics that a simulation system based on a personal computer should have to serve as a low-cost simulator for research. The composition of a simulation system remains the same as when Allen *et al.* analyzed it.

However, some of the necessary components have improved performance and availability. A simulator requires various hardware and software components. Also, it is necessary to establish the characteristics of the simulated vehicle and the information necessary to reproduce the scenario in which the simulation takes place.

The simulator hardware includes the reproduction of the driving cabin, the reproduction systems of the images, sounds and accelerations, and the computers that control the entire system. The cockpit is where the driver sits and includes the controls to operate the simulated vehicle. The most basic controls are those to change the direction and speed of the vehicle.

The computer keyboard can be used for these functions in the most straightforward simulators, although today, it is common to have a steering wheel and pedals for the accelerator, brake, and clutch.

The cabin can include other additional controls, such as the gear lever or the handbrake, for example. Automakers sometimes use simulators to test the ease of use of new controls. Most complex simulators reproduce the interior of the vehicle completely. According to Mecheri *et al*. (2017), the absence of a cockpit in the simulator causes drivers to underestimate the vehicle's distance to the right edge of the road. In curves to the right, drivers move further from the centre of the road. This is not the case when turning to the left.

Leaving aside the possible influence that non-driving factors may have on driving, such as the driver's state of mind, the drivers take their actions based on the perceptions they receive through their senses. Of these senses, the one with the most influence is sight, although hearing and the perception of accelerations are also important.

According to Sivak (1996), most of the information used by drivers is visual. In a driving simulator, the image reproduction system consists of one or more screens that reproduce images with a certain cadence measured in frames per second (fps). The images span a certain width of the field of view (FOV). The FOV presented to the users of the simulator greatly influences their driving performance (Shahar *et al.*, 2010). There may be some additional screen to simulate what the driver would see through the rearview mirrors, for the instrument panels' presentation, to control the simulator software or to display the telemetry parameters. In some cases, virtual reality glasses are used instead of screens.

Some authors have pointed out that virtual reality glasses do not provide significant advantages and, on the other hand, increase dizziness problems in simulator users (Kemeny and Panerai, 2003; De Winter *et al.*, 2007, 2009)

One or more speakers reproduce the sounds that the driver heard while driving. The sounds include the engine's noise, the friction of the wheels with the road, the sound produced by other vehicles, the wind, or others.

In most elemental systems, there is no mechanism available to reproduce accelerations. Current models of steering wheels usually include vibration systems, called force feedback, which reproduce the sensations that the driver perceives through the steering wheel while driving, due to impacts with irregularities in the road, due to collisions, wheel slippage or other reasons. More complete systems may include actuators that move the seat in rhythm with the vehicle's supposed movement.

The simulator software runs on one or more computers. It controls all the hardware. The software is in charge of managing the vehicle's controls, performing the calculations related to the physical dynamics of the movement, generating the images and sounds, and maintaining the general operation of the system.

The simulation uses a virtual scenario containing all the information related to the road, its surroundings, the weather, and the traffic of other vehicles and pedestrians. This virtual scenario, together with the physical parameters that define all the scenario elements, constitutes the simulation's data.

One of the factors that most affect the economic cost and consumption of the simulator's resources is the reproduction's fidelity. Trying to replicate the world in all its details is impossible and inefficient.

Furthermore, it is unnecessary to achieve the research objectives. Modelling involves abstraction. The model must extract the aspects of the world that are important so that the tests' results have the required validity. Some authors claim that it is essential that the operation of the vehicle, the visual representation and the behaviour of the objects in the environment are as realistic as possible (Olstam *et al.*, 2008; Allen *et al.*, 2010). Other authors think that greater fidelity does not always positively affect the result. It depends on the objectives that the simulation wants to achieve (De Winter *et al.*, 2009; Tichon and Wallis, 2010)

The video game industry has become one of the leading entertainment industries. The expression 'sim racing' refers to virtual motor racing competitions based on driving simulation games. This expression highlights the difference with the arcade type driving games, which leave aside the driving simulation aspects a bit to delve into other different objectives. There are two hardware platforms for this software: consoles and personal computers (PC). Consoles offer the advantage of immediacy; it is only necessary to turn on the console and start playing. Computers need more preparations, but they also offer the most significant possibilities in terms of customization and modification of games to adapt them to research objectives. Some of the sim racing games simulate circuit car racing, such as Assetto Corsa, rFactor 2, iRacing, Automobilista, Project Cars 2 and F1 2020. Others simulate rallies, such as Dirt Rally, Collin McRae Rally or Richard Burns Rally. There are also others geared towards truck driving, such as Euro Truck Simulator. Currently, almost all have versions available for consoles and PC. They also usually include the ability to compete with other players over the Internet.

Sim racing has undergone significant development in recent years, leading to championships in which professional motorsports drivers participate. Often such tournaments are even televised and lead to significant cash flows from prizes and advertising. This has led large car manufacturers to develop content for such events, providing realistic models of their vehicles, for example. Currently, the main simulation games reproduce the racing circuits with maximum fidelity, using models extracted using LIDAR techniques that reproduce even the most minor details of the track or its surroundings. All this has resulted in some of the existing games reaching very high standards for the quality of the graphics and the fidelity of the reproduction of the physics of the vehicle movement. The widespread use of sim racing video games has led some researchers to question whether their use by young people may have an influence on how they drive actual vehicles in the future (Ruscio, 2018).

Parallel to the development of the sim racing games industry, an industry of hardware components for such games has been developed, including all the components necessary to reproduce the vehicle's cockpit: seats, steering wheels, pedals, gear stick, motion platforms and others. This development has led to lower prices for these components.

There have been experiences in using Sim Racing games for research. Weinberg and Harsham (2009) built a driving simulator using commercial components for the video game industry to reproduce the cockpit. The simulator seat was equipped with a motion platform that allowed to reproduce the vibrations and inclinations experienced during driving due to potholes, acceleration, braking and others. As software for the simulation they used rFactor software (Studio 397 and Image Space Incorporated, 2005). For the creation of the scenarios they used the program Bob's Track Buider (Pywell, 2007). To obtain the telemetry they used plugins from the rFactor game as well as plugins developed by themselves. The result was a simulator that they claim was comparable to a mid-range research simulator and at significantly lower cost. Tiu et al. (2020) analyzed the possibility of using a sim racing game to analyze the driving ability of people who had suffered a stroke. The authors of the study point out several advantages in using sim racing games compared to research simulators: they have a considerably lower cost, provide a wide range of telemetry values and offer greater realism of the images and the operation of the vehicle. One of the drawbacks noted in the study is the difficulty in reproducing real traffic situations with more than one vehicle.

Using a simulator based on a sim racing game for research has advantages and disadvantages compared to using a simulator specifically designed for research. About the cost of the hardware (computers) and the vehicle cockpit, all things being equal, the cost is the same.

However, the cost of simulation software, as already mentioned, is much higher in research simulators. While a simulation software for research can cost between 30000 and 100000 euros, the software cost to create a simulator based on a sim racing game, including all the additional software necessary for creating scenarios and the management of the telemetry, rounds the 100 euros. Another advantage of sim racing games is the realism of the vehicle physics. In general, the realism achieved in the physics of vehicle operation in the latest versions of sim racing programs is superior to that of commercial research simulators (excluding the specific simulators available to large car manufacturers). The quality of the graphics and the scenarios realism is also generally superior to that of the research simulators. However, research simulators have specific tools that make it easy to incorporate the road geometry. In sim racing games, it is necessary developing specific tools or use more artisanal procedures. The simulation of the traffic of other vehicles and pedestrians is possible and relatively easy to incorporate in the research simulators. In sim racing games, it is not possible, or it is not easy.

In general, simulation software has two critical components in simulation: the graphics engine and the physics engine. The physics engine manages the controls inputs, performs the necessary calculations, updates the vehicle and other objects positions and passes the information to the graphics engine, which is responsible for generating the images that appear on the screens. Both the graphics engine and the physics engine use 3D scene data and vehicle data.

The creation of the 3D model of the scenario in which the simulation is to take place is the most time-consuming task in the tests carried out with a driving simulator (Dols *et al.*, 2016; Dols *et al.*, 2021). The possible components of this scenario are:

- Road:
    1. Geometry: Alignment, profile and cross-section
    2. Pavement: physical and visual characteristics of the road pavement
    3. Traffic sign and road marking
    4. Infrastructure associated with the road: guard-rails, lighting columns and other elements
- Environment:
    1. Area of the terrain that is visible while driving
    2. Constructions, vegetation and other elements whose presence may affect driving
- Traffic: other vehicles, pedestrians or animals that may affect the behaviour of drivers
- Weather: wind, rain, snow, fog or other weather effects
- Sound effects

Depending on the type of experiment and the level of fidelity desired, each element needs greater or lesser detail. The simulation software also needs to know the vehicle characteristics in the simulation to reproduce its behaviour.

2. MATERIALS AND METHODS

The start-up of the simulator consists of the acquisition, assembly and configuration of the hardware and software. Then, for each test, the 3D model of the road and its environment must be created in the appropriate data format for use in the selected simulation software.

With this, it is now possible to test by conducting road trips with different drivers while recording telemetry data. Finally, the data from the routes telemetry is analyzed to conclude the research. Below is the description of these phases as they have been carried out in this research work.

2.1 Hardware

The hardware used during this research has been the following:

- Computer: HP Prpdesk, Intel i7, 64 bits, 3.4 GHz, 8 Gb RAM
- Graphic card: NVIDIA GeForce GT 730 2 Gb RAM

- Screen: HP 2009V
- Steering wheel: Thrustmaster T300 RS – GT Edition
- Pedals: 3 metal pedals (accelerator, brake and clutch)

As gearshift stick, the steering wheel's paddles were used, one of them to upshift and the other to downshift.

2.2 Software selection

The first part of this research work consisted of selecting the sim racing games to assess their suitability for use as support software for a driving simulator applicable to the research. For this, the main sim racing programs has been explored and analyzed their fundamental characteristic. A survey was conducted among regular users of sim racing games to obtain additional information about the reviewed games. The survey asks about the graphics quality, the realism of the physics of the vehicle movement and some other questions. The survey obtained 54 valid responses. Figure 1 shows a graph with the results of the survey.

The horizontal axis indicates the quality of the graphics for each game, and the vertical axis indicates the realism of the vehicle dynamic. The program that got the best rating from users for its physics was Richard Burns (RB) Rally. Top rated for graphics quality were Assetto Corsa and Assetto Corsa Competizione. They both score very highly when it comes to physics.

Not all games allow for incorporating actual roads or for using ordinary tourist vehicles. Programs that do not allow such modifications are not helpful for the type of research intended. It is also needed to extract the telemetry of the tests to analyze speeds, trajectories, and other data.

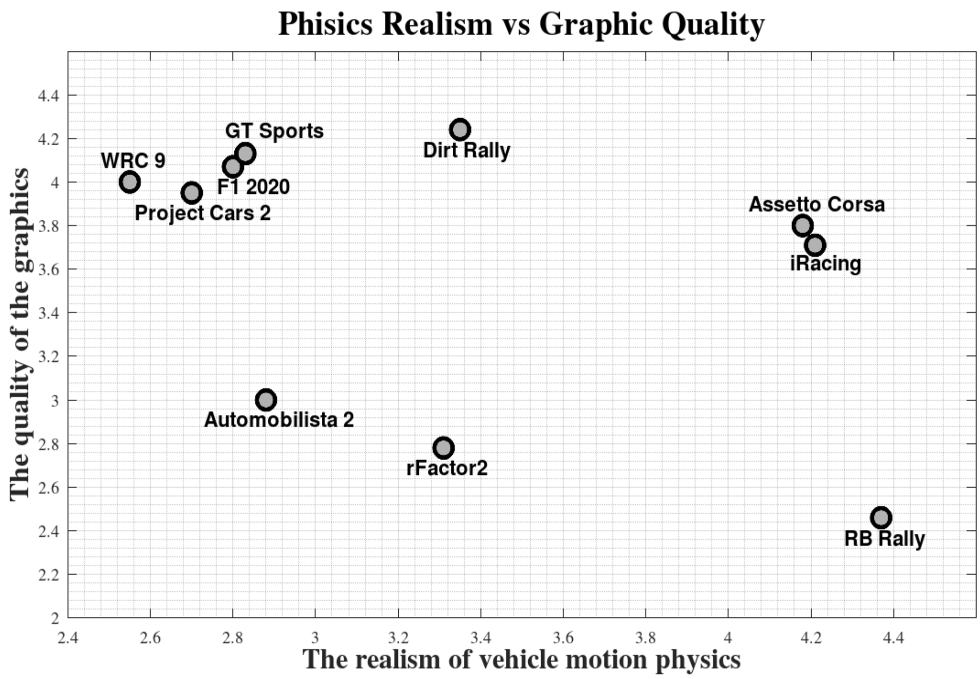

Figure 1 – Summary of survey results about sim racing games: image quality vs physics

Among the sim racing games analyzed, only three meet the conditions to incorporate actual roads, use passenger cars, and allow extracting and analyzing the telemetry: Assetto Corsa, RB Rally and rFactor2. All three have high-quality graphics and very realistic physics. RB Rally is no longer in development, so the decision was to use Assetto Corsa and rFactor2 for research tests (Studio 397 and Image Space Incorporated, 2012; Kunos Simulazioni, 2013).

Sim racing games come with presets adapted to sporty driving. For use in road research, it is convenient to adjust some parameters to increase the realism of driving of a passenger car. One of them is the turning of the steering wheel. In racing cars, a particular turn of the steering wheel produces a more significant turn of the wheels than in passenger cars.

Another parameter that is important to adjust is the driver point of view. The two games selected allow to set the position of the driver seat. The width of the FOV is also essential; an improper setting produces an unrealistic driving feel.

2.3 3D model development

For each road to test, developing a 3D model in the appropriate data format for the chosen simulation software is necessary. 3D modelling software is an adequate tool to create these models. 3DS Max and Blender are examples of this type of software. Modelling software can export their models to the FBX format, but each sim racing game uses its specific format for the 3D model. Some software is needed to convert the 3D model (in FBX format) to the specific format of the sim racing game.

When generating the FBX files, 3D objects and materials need specific parameters to define their characteristics so that later the physics and graphics can be interpreted appropriately by the sim racing game. Each of the games has a different way of defining these parameters.

Hence, it was necessary to develop two different models: one for Assetto Corsa and the other for rFactor2. The Assetto Corsa scenarios use the .kn5 format, which can be obtained from the corresponding FBX file using the KS Editor software (made by Assetto Corsa developers). This format includes the materials and the images of the textures used to display them. However, the rFactor2 scenarios use GMT format files for the geometry of the 3D meshes and the files. It stores the texture images in separate files.

Each of the programs has a set of files where the physics of the materials is defined. Figure 2 shows the workflow used from creating the 3D model for the two sim racing games.

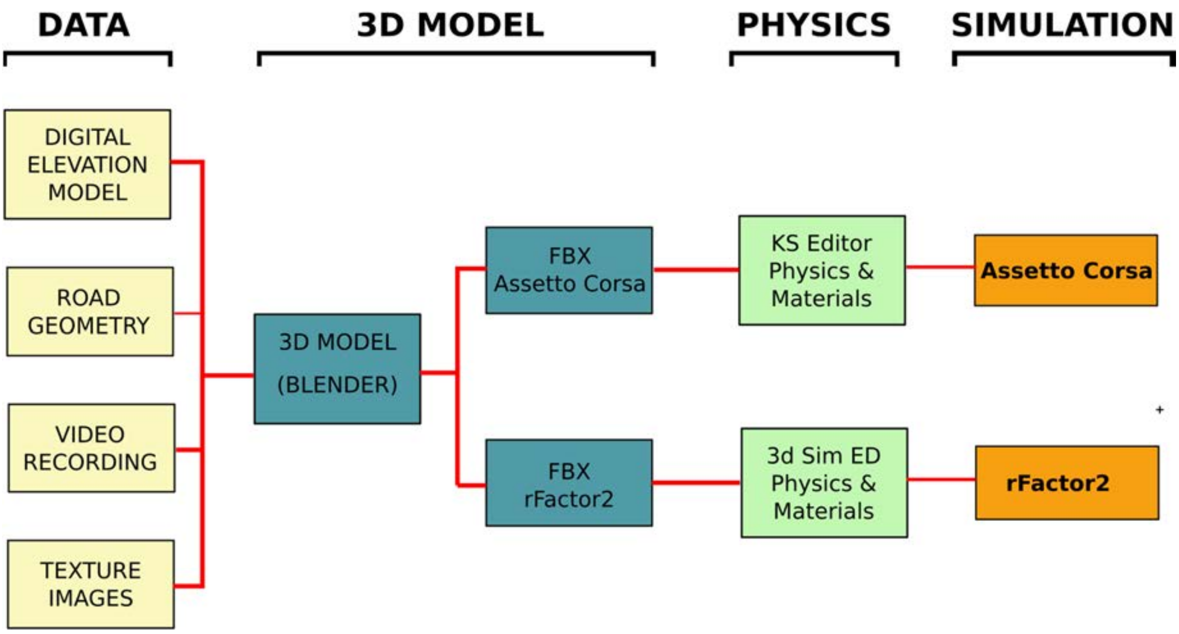

Figure 2 – Workflow for creating simulations using the sim racing games rFactor2 and Assetto Corsa.

This research work studied a 6 km long section of the two-lane rural highway M-607, located between Colmenar Viejo and Cerceda (Madrid). The section chosen is located between stations 36 and 42. The lane width is 3.5 m and the shoulder width is 2.5 m.

Digital elevation model (DEM) from the Spanish *Instituto Geográfico Nacional* (CNIG) was used in GIS format. A 12x3 km rectangle was used, which included the road area. The road centre line geometry was obtained from the definition of its alignments. Using GIS tools and scripts developed for this study, a file was generated with the X, Y, Z coordinates of the centre line points every 10 meters.

For 3D modelling, the Blender v2.91 software with the GIS plugin was used (Blender Foundation 2021, Lyszczarz, 2012). A script developed in Python by the authors was used, allowing reading an XYZ coordinate file and converting it into a 3D Blender curve to incorporate the road centre line in Blender (Higuera de Frutos, 2021). In order to achieve a more realistic 3D model (road markings, traffic signs, etc.) data recorded in the actual highway through RoadRecorder software was used (Higuera de Frutos, 2017). Images with free licenses were used for materials textures (roadway asphalt, shoulders, terrain, vegetation, guard-rails and traffic sign). The final model had 136,156 vertices, 249,947 edges, 118,796 tiles, and 197,039 triangles.

Figure 3 shows two details of the edition of the model with Blender software. The image on the left shows a general view of the scenario: the road mesh and the digital elevation model mesh with the mountains in the background. The image on the right shows a detail of a part of the model.

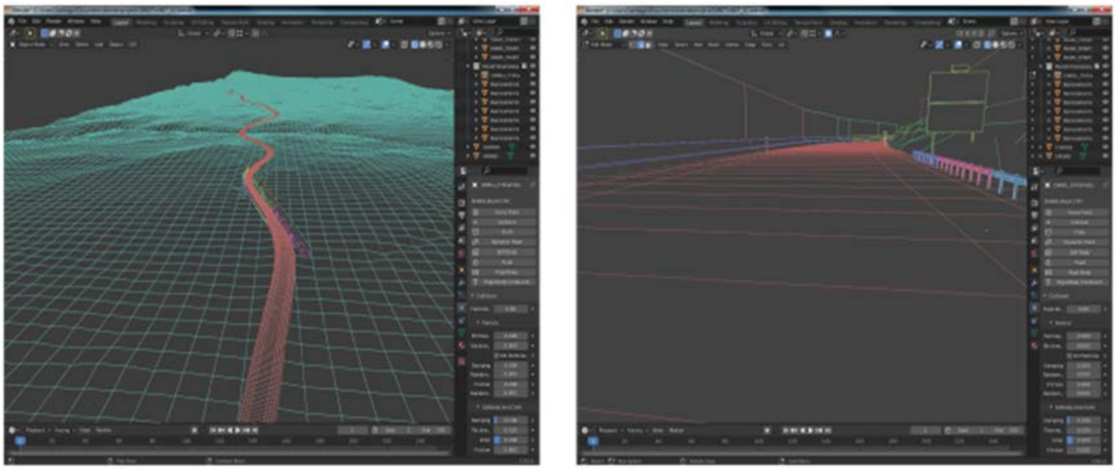

Figure 3 – Edition in Blender. The left image shows DEM and road meshes with mountains on the horizon. The right image shows the mesh detail in some area of the model

2.4 Materials and physics

The 3D model must follow certain conventions regarding the geometries and names of objects and materials. Together with specific parameters defined in the scenarios configuration files, these conventions allow the game engines to correctly interpret the way of visualizing the materials and interpreting the physics. Also, specific objects, called *spawn objects* by Assetto Corsa and *timing objects* by rFactor2, allow games to interpret the position where the simulation begins, the direction of the routes, and what telemetry sections record, among other functions. Each game has its objects and its way of interpreting them.

The lighting characteristics, the properties of the objects materials, and the shaders parameters determine the visual aspect. Each game has its shaders and its collection of parameters to define. Each object, for example, the road surface, uses several superimposed images (several image channels), which, when processed by the shaders, generate the final appearance. It is a complicated process that requires specific knowledge of computer image processing.

Some configuration files define the properties of the objects and their physical behaviour.

The primary interaction is between the vehicle tires and the roadway surface. The gravity force also affects all objects. It is also needed to define if the objects can collide or move in case of impacts. The game engine will interpret the driver actions on the controls and resolve collisions, friction or acceleration of the vehicle.

2.5 Telemetry

The physical parameters of the simulation can be monitored using data acquisition plugins and stored in telemetry files.

The most widely used telemetric data analysis program is Motec (MoTeC Pty Ltd, 2001), a professional system well known in all kinds of actual motorsport competitions. Assetto Corsa and rFactor2 can also use Motec. Each game allows installing a specific plugin to generate data logs that the Motec program can then interpret.

The telemetry files generated offer about one hundred parameters measured while driving every few milliseconds. The parameters include the instantaneous values of position, speeds, accelerations, vehicle inclination angles, engine operation values, parameters about the tires, temperatures, and many more. Also, Motec offers the possibility of generating formulas that, from the existing parameters, allow generating values not contemplated by default.

An interesting feature is generating the track followed by the vehicle from the lateral acceleration values. This option helps analyze the trajectory followed or generate the drawing of the road when the GPS position is not available.

For this study, Motec software was used in order to analyze vehicle telemetry of every test.

3. RESULTS AND DISCUSSION

Creating scenarios was laborious and required knowledge about 3D modelling and image processing, but the results were satisfactory. The generated scenarios can be used, with minor modifications, in either of the two simulators (Assetto Corsa and rFactor2). The imaging of the two simulators was very sophisticated, with highly realistic images. The process of creating scenarios and starting the simulations required a similar workload for both programs. Figure 4 shows the comparison between road actual video frame, the image generated by Blender, and the equivalent frames while driving in each of the simulators.

To carry out the driving tests in the modelled section, five drivers aged between 50 and 60 years collaborate. All drivers had more than 20 years of actual vehicle driving experience.

Each of them did two test runs with each of the simulators on the M-607 road scene. Next, each driver made two tours in each simulator, and the system recorded the corresponding telemetries. Drivers did not found significant differences between the physics of vehicle operation. The driving sensations were realistic with both software.

Figure 4 – Top left: a video recording of the actual road. Top right: image generated by Blender. Bottom left: image from Assetto Corsa. Bottom right: image from rFactor2

Figure 5 shows an example of a report generated by Motec comparing the speed during the same driver trip, once using the rFactor2 simulator and the other time using the Assetto Corsa simulator. The upper part of the graph corresponds to the comparison of the speeds along the route. The black line represents the speeds during the ride with rFactor, and the blue line during the ride with Assetto Corsa. The vehicle speed values are similar. The lower part of the graph corresponds to the road track generated from the geographic coordinate data obtained by rFactor2.

4. CONCLUSIONS

The objective of this study was to analyze the possibility of using sim racing games as driving simulators in research work on road geometry. A comparison has been made between the two existing games that, in the authors' opinion, offer the best features for this purpose: rFactor2 and Assetto Corsa.

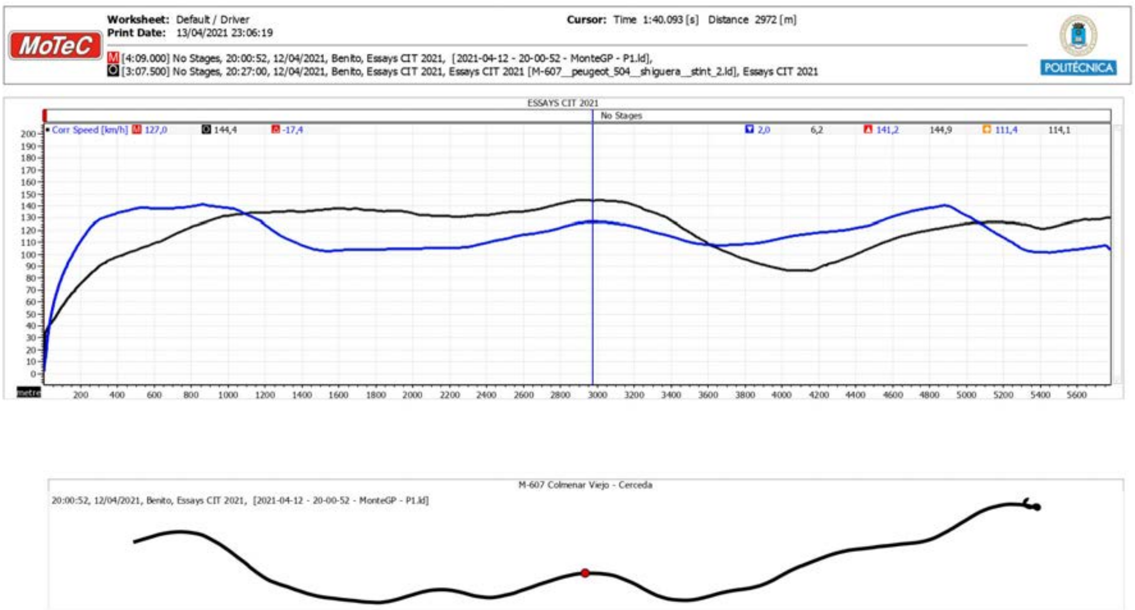

Figure 5 – Motec telemetry report. Comparison between the speed of the same driver in two different simulators ((Assetto Corsa and rFactor2). Up: speed (km/h). Down: road alignment (m)

The use of 3D design software (Blender), GIS information and road geometry to create the 3D scenarios was a time consuming task, but provided results with realistic images. During the driving tests, the drivers found no significant differences between the physics of the vehicles in the two games. Both software offered realistic driving sensations. The telemetries obtained (positions and speeds) had enough information for future research studies on vehicle speeds and road geometry. In next research works, the number of studied roads and the number of drivers will be increased.

In conclusion, both tested software can be used for building a low-cost driving simulator for road geometric research.

ABSTRACT

The aim of this study is to create an intelligent system that improves the efficiency of garbage collection, (cardboard waste, in this particular case). The number of cardboard containers to be collected each day will be determined based on a prediction made on the filled volume recorded in each container. It will be reflected in the cost and fuel savings, reducing emissions and contributing to environmental sustainability. These results will allow planning the sequence of waste removal, which means the optimal collection route considering restrictive parameters such as the type of truck, the location of containers, collection times by zones, and the availability of working staff.

A filling prediction system is proposed based on real historical data provided by the current waste collection company in Algeciras (ARCGISA). To achieve this objective, an intelligent system is designed using predictive analytics and several methods based on machine learning, modelling the collection system as a classification model, comparing the results from a statistical point of view (using sensitivity, specificity, etc.). The results obtained with the best-tested method indicate an improvement average rate of 26% in sensitivity performance index and 67% in specificity performance index.

Currently, waste collection is carried out without predictive analysis. The relevance of an efficient waste collection system is becoming increasingly important. Achieving optimal waste collection will result in improved service to citizens, cost savings for the administration, and significant environmental improvements.

1. INTRODUCTION

This project aims to create a 'smart' system that improves the efficiency of waste collection, in this case, cardboard. This system solves two major problems faced by waste collection companies. On the one hand, to determine which containers should be collected each day according to their filling volume and, on the other hand, to obtain the collection order, i.e. to know which is the optimal route for the collection of the containers. This will save costs and fuel, thereby reducing emissions and contributing to environmental sustainability.

A filling prediction system is proposed based on real data, provided by the company ARCGISA (Agua y Residuos del Campo de Gibraltar, S.A.), from which the optimum collection time will be estimated based on an ideal filling level and the optimum route for collecting the containers will be obtained. A significant reduction in management time, economic savings and an improvement in the quality of the service provided to citizens are expected, increasing urban sustainability. In summary, a dynamic system of container filling predictions is proposed to estimate the optimal filling time and calculate the most favourable route for collection. To achieve these objectives, the project aims to design an intelligent system using predictive analytics and machine learning to improve the planning and efficiency of selective waste collection, based on the use of neural networks.

Each person generates a large amount of waste every day. The life cycle of waste harms the environment. Efficient waste management has become a necessity to preserve available natural resources. For this reason, the objective is to achieve urban sustainability and guarantee the quality of life of citizens. Furthermore, waste treatment offers a business opportunity, since the recycling of products such as cardboard allows them to be reused for the production of new products. The management of this waste for further treatment is a chain that involves the collection, transport, processing, recycling and monitoring of new products.

Increasingly, organisations and companies assume that environmental improvements in their production systems and services are competitive advantages, either by reducing economic costs or by improving the image of the product in the eyes of better informed and aware consumers. To reduce waste generation and improve sustainability, tools and mechanisms such as life cycle analysis (LCA) and eco-design are used.

LCA is a methodology used to assess the potential impact on the environment of a product, process or activity throughout all its stages of existence (extraction of raw materials, production, distribution, use, end of life). At each stage, the energy and resource inputs and potential outputs in the form of emissions, discharges and wastes associated with the system under assessment are quantified.

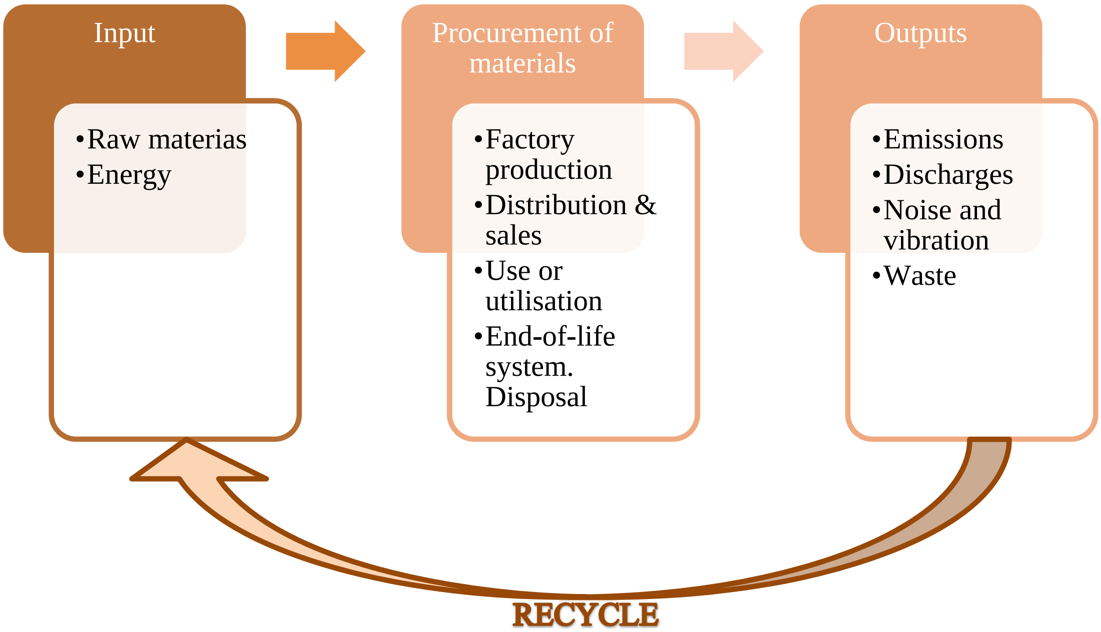

Fig. 1 - The life cycle of a product.

In Spain, around 1.5 million tonnes of domestic plastic, brick, metal and paper/cardboard packaging were recycled in 2019. This figure comes from two main sources of rigorous control to ensure the rigour of the information on waste management; the sources are the municipalities responsible for the selective collection of packaging and the recycling plants responsible for transforming this waste into new raw material. Table 1 shows the recycled packaging waste (in tonnes) by material and area of management (municipal or private) in 2019. The amounts considered have been certified by the local authorities based on the agreements signed by Ecoembes (is a non-profit organization in Spain devoted to sustainable development and recycling).

Quantities recycled (tonnes)	Conventions and Agreements with Public Administrations	Authorised private managers	Total
Plastics	527.949,1	88.786,6	616.735,8
Paper & cardboard	577.319,0	54.364,8	631.683,8
Metals	219.368,2	30.052,0	249.420,1
Wood	0,0	7.821,5	7.821,5
Total	1.324.636,3	181.024,9	1.505.661,2

Table 1 - Amounts recycled in Spain 2019 (source: MITECORD)

Regarding a regional level, Andalusia has 19 light packaging sorting plants and 1,552 Andalusian companies that make the recycling system possible. There are 83,465 yellow and blue containers on public roads, which is 2,046 more than in 2018. In the last five years, the use of the blue bin has increased by an average of 22%. Each citizen deposited 7.5% more paper and cardboard packaging in 2019 compared to the previous year, i.e. each Andalusian citizen deposited 13.2 kg of paper and cardboard per year.

The idea is to predict each container separately, which is more difficult due to the specific characteristics of the state of each container, i.e. its location, the population density of the area in which it is located, the habits of the citizens, etc. And that this prediction serves to subsequently generate optimal collection routes. There are studies to predict waste quantities using time series techniques to predict the quantities of waste generated by an entire city, e.g. Xiamen in China (Xu et al., 2013).

To generate the optimal routing of vehicles, there is still little work directly related to the waste collection problem. There is a study conducted in Portugal, in which collection routes are planned for all days of the month, which are repeated every month and thus minimise the cost of operation. (Teixeira et al.,2004), but it focuses on the routes generated, not on the amount of waste in each container. The objective is to minimise the total distance travelled in the period, which is the sum of the distances travelled by all vehicles on each day.

There is a growing body of literature on the prognosis of the municipal solid waste (MSW) generation. For decades, studies have been conducted using different models, which generally fall into four categories: regression-based models (Daskalopoulos et al., 1998, Sokka et al., 2007, Benitez et al., 2008, Rimaityte et al..., 2012), system dynamics models (Dyson and Chang, 2005, Kollikkathara et al., 2010), computational intelligence models (Jalili and Noori, 2008, Noori et al., 2009, Wang et al., 2010), and time series based models (Chen and Chang, 2000, Navarro-Esbri et al., 2002, Li et al., 2003, Liu and Yu, 2007). Computational intelligence models, such as support vector machines and artificial neural networks, are commonly used due to their high flexibility and non-linear prediction capability. However, these three types of models often use demographic and socio-economic factors that are difficult to identify and quantify (Chen and Chang, 2000; Dyson and Chang, 2005). Time series forecasting models generate future information on MSW generation on a time scale using only historical MSW information.

The authors of this study have previous experience in the use of Artificial Neural Networks (ANNs) in predictive modelling related to transportation engineering and logistics. It is worth highlighting the studies carried out to predict the number of correct inspections at border inspection posts (BIPs). This problem can lead to congestion and bottlenecks within these critical facilities in port or airport systems and can lead to higher costs and delays in the supply chain.

Forecasting of the inspection volume or over freight cargo or maritime traffic can be useful tools to improve the quality of service, operations planning and human resources in ports.

This is also the case of this work where the prediction is about container fill rates and can be useful in the quality of waste collection system (Moscoso-López, J.A et al, 2016; 2020; Ruiz-Aguilar, J.J et al, 2014; 2019; 2020).

Achieving an optimal waste collection will mean an improvement in the service to the citizen, a saving in economic costs for the administration and a significant environmental improvement. The aim is therefore to avoid unnecessary trips to nearly empty containers, as the emissions of pollutants generated by extra trips could harm the environment rather than contribute positively to waste collection.

2. DATA DESCRIPTION

Selective waste management is carried out by the company Aguas y Residuos del Campo de Gibraltar (ARCGISA). It is a public service company owned by the Mancomunidad del Campo de Gibraltar. ARCGISA, as the main company in the agreement for the collection of cardboard, has a limited number of resources to carry out the waste collection. The planning of the current collection system has a wide margin for improvement, as several factors influence in the process, such as the timetables of the staff, the type of vehicle, the type of streets, the situations in the city, the collection timetables, the capacity of the containers themselves, their location, etc. Of the entire collection process, the most important and costly phase of the cycle is the collection procedure, accounting about 70% of the cost associated with waste treatment. This involves the work of many people and vehicles. This project focuses on improving the planning and management of the selective collection of cardboard in the Campo de Gibraltar area.

Campo de Gibraltar consist of seven municipalities, which form one of the three metropolitan areas in the province of Cadiz. In the metropolitan area of the Bay of Algeciras, we find the first industrial pole of Andalusia and the second in Spain and the main port of the national port system in terms of total traffic 5.125.385 TEUS/year . This places the scope of the project at a population of 270,000 inhabitants (INE 2019) and an industrial, commercial and port area of the first national order. It should be noted that Algeciras is the largest municipality in the study area, and is integrated into the National Smart Cities Plan.

In Algeciras, waste collection is currently carried out without predictive analysis. Collection routes are often left to truck drivers. With the growth of cities, the importance of having an efficient waste collection system is increasing. An intelligent waste collection system is therefore proposed to solve the problems faced by the collection services. It will determine which containers need to be collected each day and what is the optimal route for each truck.

The pattern of generation of this waste is fluctuating and does not follow a constant seasonal pattern. This fact makes it difficult to plan the collection, and as mentioned above, it is the operators themselves who manually monitor the filling percentage of the container being collected to estimate when the next collection will take place. This data has to be manually typed in the office, which involves many hours of dedicated staff time. Figure 2 shows the actual annual volume of each container. This is the reason why this project proposes an intelligent system for predicting fill levels based on historical collection data, using predictive analytics and machine learning techniques to estimate which containers are in the optimal range for collection.

3. METHODS

In this work, the objective is to obtain a multiple regression model f:Rn→R for the desired output parameter (the cardboard container volume as a function of the lagged time-series data) using Artificial Neural Networks (ANNs).

3.1 Neural Networks

A Multiple Linear Regression (MLR) model may not be the best fit available. In such cases, a nonlinear regression method like artificial neural networks (ANNs) may provide a better analysis. The most widely used ANN model is the feedforward neural network, based on backpropagation learning procedure (Rumelhart et al., 1986). It models the relationship between X and Y in the form of the equation 1.

$$Y = g\left(\sum_{j=0}^{M} w_{kj} \cdot f\left(\sum_{i=0}^{D} w_{ij} \cdot X_i\right)\right) \tag{1}$$

where *g(x)=x* and *f(x)=tanh(x)*, are proved to be universal approximators (Horni et al, 1988), given the sufficient number of hidden units (M value in the formula). Such networks can, therefore, approximate arbitrarily well any general function, which makes them highly interesting for modelling purposes.

3.2 Experimental Procedure

Thus, the overall system can be viewed as a mapping from a set of input features, to an output variable (the next daily value of cardboard volume in a certain container). The mathematical form of the mapping is determined with the help of the data (training set). Of course, we need to build a system capable of making good predictions on unseen data. In order to measure this generalization capability, crossvalidation using another set of samples (test set) are used.

We adopted crossvalidation to estimate the number of hidden units based on the generalization performance of the model.

We divide available data into 3 distinct groups (training, validation and test sets). Then, we estimate the parameters of each model using one of the groups (the training set). Validation set is used to early stopping and to avoid overfitting. Finally, the test set is then used to test the quality indexes simulating the real performance of the model. This process is repeated 20 times, and the results averaged over these runs. This procedure of resampling simulation has been designed to avoid variation coming from different sources, thus independence and randomness is guaranteed. The different preprocessing methods have been combined with several topologies of backpropagation feedforward neural networks (BPNN) networks.

3.3 Perfomance indexes in classification

To visualise the results obtained with a classification model, the Confusion Matrix (Kohavi and Provost, 1998) is normally used. Each row of the matrix represents the number in actual values for each class and each column represents the number of predictions for each class.

		Prediction	
		Negative	*Positive*
Real	*Negative*	**a**	**b**
	Positive	**c**	**d**

Table 2 - Confusion matrix

True positive and true negative results are a correct classification, while false-negative and false-positive results are two types of errors. It depends on the values:

- **a,** is the correct number of predictions in a negative case.
- **b,** is the number of incorrect predictions in a positive case, i.e. the prediction is positive when the value should be negative.
- **c,** is the number of incorrect predictions that a case is negative, i.e. the prediction is negative when the value really should be positive.
- **d,** is the number of correct predictions that a case is positive.

Some standard indexes are defined: accuracy, precision, true positive rate (TPR), false positive rate (FPR), true negative rate (TNR) and false-negative rate (FNR):

$$\text{Accuracy} = a+d / (a+b+c+d) \quad (2)$$

$$\text{Precision} = d / (b+d) \quad (3)$$

$$\text{Sensitivity} = d / (c+d) \quad (4)$$

$$\text{Specificity} = a / (a+b) \quad (5)$$

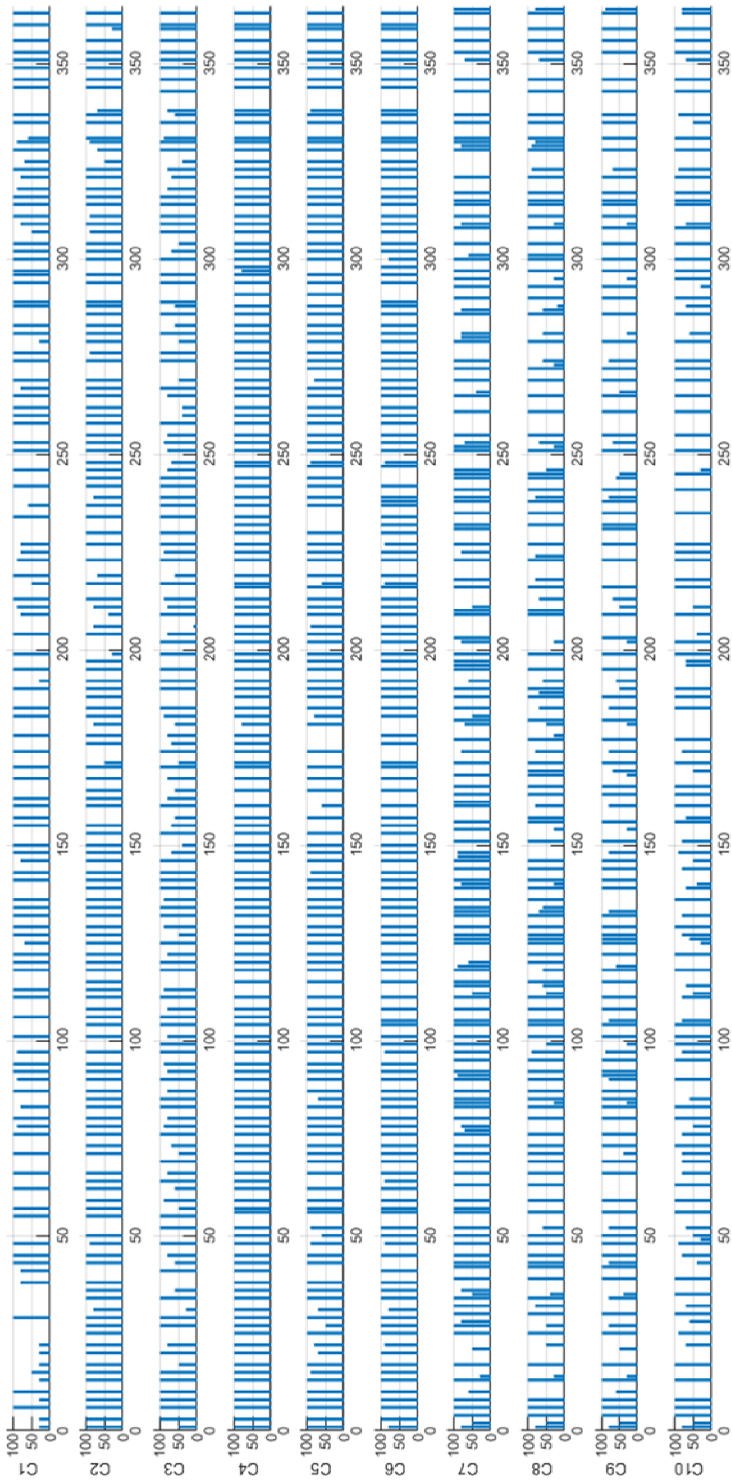

Fig. 2 – Distribution of the actual amount of cardboard collected during the year for each container.

4. RESULTS AND DISCUSSION

This section discusses the most important results obtained in this study. Table 3 shows the real performance of the actual collection system. It is worth mentioning that a lot of inefficiencies were detected. The specificity for each container is really not adequate. This lack of performance means that the actual collection system is very inefficient because there were a lot of times when the truck comes to an empty (or not adequately full) container.

Container	Sensitivity	Specificity	Accuracy	Precision
C1	0,52	0,25	0,4	0,48
C2	0,5	0,05	0,4	0,64
C3	0,61	0,09	0,41	0,53
C4	0,5	0	0,42	0,73
C5	0,51	0,05	0,41	0,65
C6	0,51	0,03	0,42	0,69
C7	0,58	0,16	0,47	0,66
C8	0,57	0,29	0,47	0,59
C9	0,56	0,35	0,47	0,55
C10	0,55	0,33	0,45	0,51

Table 3 - Average performance for each container using the actual collection system.

Table 6 contains the mean correlation coefficients obtained in the random re-sampling experiment with 20 replicates for each container and in function of the number of neurons and the window in the past. The experimental procedure has been applied to a sample of 10 containers of Algeciras, numbered C1-C10. In general, it is worth mentioning that the best performance between the forecasting and the real values were obtained with a certain number of neurons (most of the times, 10 or 20 neurons). This fact indicates that the prediction model is not exactly linear and therefore, methods such as multiple linear regression or ARIMA fails in their predictions. Nevertheless, as Table 6 illustrates, the best results were obtained using a moderate number of neurons and the different number of lags in the past depending on the container. Using too many neurons could improve results in the training stage but can produce overfitting and wrong results in the test phase.

Table 4 compiles the quality indexes of the best models selected in table 6. Especially relevant are the values obtained in sensitivity and specificity because these two indexes indicate how the classifier model works to detect when the cardboard container should be collected (50%-100% of total volume) and also how the truck should not collect a cardboard container (0%-50% of total volume). Both indexes allow us to compare the efficiency of the forecasting model.

There are two cases with two models selected because they have obtained very similar results of forecasting (see Table 4, the case of containers C4 and C8). In these cases, we can adopt two strategies. On the one hand, we can use the Occam’s razor criterium and selecting the simplest model (in this case, with less parameters, i.e. less number of neurons). On the other hand, we can select the model with a lesser distance in the pair (sensitivity, specificity) to the point (1,1). To compare with the actual collection system, we have computed Table 5 reflecting the improvement obtained in each container using the best forecasting model.

Container	Sensitivity	Specificity	Accuracy	Precision	Parameters
C1	0,742	0,910	0,813	0,918	d =3 nhiddens = 10

Table 6. - Mean correlation coefficients in the random re-sampling experiment with 20 replicates for each container as a function of the number of neurons and the window in the past.

5. CONCLUSIONS

In summary, with the experiments done, the R correlation coefficient (over test sets in the best models) yields closer estimates to real values of the collected year 2019 time-series. It was clear from our experiments that some of the neural models are much better than others (see Table 4). For example, the R correlation coefficient (average) between BPNN best model (nhiddens = 10, d = 4) is 0.936 in the container C4, better than the rest of models (over test sets).

We have tested the potential of shallow ANNs as a predictive tool in this application. ANNs require no priori assumptions about the model in terms of mathematical relationships or data distribution. We have used multilayer perceptron models (MLPs) with a backpropagation learning rule. The designed procedure of resampling simulation avoid variation, thus independence and randomness is guaranteed. Determination of the model which fits better the prediction of each cardboard container volume time-series can be possible. The improvements in the performance indexes have been quite relevant and the new predictive system should be easily applied to save costs and fuel, thereby reducing emissions and contributing to environmental sustainability.

In summary, this work provides an effective and alternative way to compute predictions with the hypotheses used in the study, obtaining a new forecasting system that allows us to improve efficiency and it should be useful to better garbage collection planning.

ACKNOWLEDGEMENTS

This work is part of the research project RTI-2018-098160-B-I00 supported by 'MICINN. Programa Estatal de I+D+i Orientada a 'Los Retos de la Sociedad'. Data used in this work have been kindly provided by ARCGISA. Colaboration between ARCGISA and University of Cádiz was supported with Fundación del Campus Tecnológico de Algeciras (FCTA).

ABSTRACT

The main aim of this work was to measure the influence of the volume of shipping over the Sulphur dioxide (SO2) concentration in the air pollution in two monitoring stations located at Algeciras city and Alcornocales Park developing the same analysis in these two locations.

The target is to demonstrate the assumption that Algeciras is more affected by SO2 than Alcornocales Park which is 30 km far away from Algeciras Port. A multiple regression approach has been applied using wind data: wind direction (degrees) and wind speed (km/h) recorded in two weather stations, together with the volume of the gross tonnage per hour (GT/h) of vessels in the Bay of Algeciras to estimate SO2 concentration values in the two stations Algeciras and Alcornocales. The database contains records of hourly samples of these variables during the year 2019. Different artificial neural networks (ANNs) models were compared and the results showed that SO2 in Algeciras station could be better explained than the same pollutant in Alcornocales station. On the other hand, ANNs produced better results than linear models which means that nonlinear models fit best the data. A cross- validation procedure has been applied in order to assure the generalization capabilities of the tested models. The results showed that in Algeciras a more reliable estimation could be done reaching a correlation estimation between the model and the target (real) values of SO2. This fact highlights the major influence of maritime transport in the Bay of Algeciras

1. INTRODUCTION

The importance of cities outdoors in pandemic times has increased substantially since people are doing their lives in streets, parks, and common zones.

It is now, more than ever, when the air surrounding cities becomes essential to develop secure sports activities and their day to day life. This is what motivates this study, in order to gain knowledge about how ports can affect towns. Algeciras city is highly populated with a total of 123,000 inhabitants in 2020, and the Bay of Algeciras is a big exchange site of winds, which makes it interesting analysing this area in concordance with a pollution scenery. For this reason, this study is developed in this location due to its connection with chemical and steelmaking industries, Gibraltar airport, and Algeciras Port, one of the most important ports of goods in Europe, which is a hub of economic activity. Maritime traffic has experienced a massive increase in Europe, and in the whole Globe. The low offer of public transport in the bay makes this zone full of constant private traffic which decreases the air quality. All the transportation sources contribute to a complex pollution scenario, although we focus on Algeciras Port. As one of the main ports in Spain and Europe, the relevance of maritime traffic evinces not only goods movement but also air pollution.

Therefore, the appearance of particulate matter is higher in port zones (González et al., 2011, Viana et al., 2014) often motivated by the ineffective maintenance of vessel engines that makes them unnecessarily consume and waste more fuel (Moreno-Gutiérrez et al., 2015). High rates of the total ships' emissions can be dispersed to 400 km inland (González et al., 2011). Worldwide estimations suggest that vessels are responsible for 15% of NOx and 8% of SO2 emissions all around the Globe, involving 20- 28% of the total emitted gases in the transport sector (Corbett et al., 2007). Besides, other estimations calculated that vessels produce 3% of the total human greenhouse gases, double of aviation (IMO). Not only do navigating ships discharge fumes to the atmosphere but also docked vessels, which can be considerably reduced by switching to lower-sulphur fuel in the ECAs (Emission Control Areas) (Wan et al., 2019). Some pieces of research estimated that 172,000 vessels consumed during voyages about 47 million metric tons of heavy fuel oil and emitted about 2.4 million metric tons of SO2 (Wang et al., 2007). The database provided by Algeciras Port Authority showed that about 29,000 vessels berthed during the year 2019 in the Bay and, while berthing only the auxiliary engine (AE) is functioning to generate electricity onboard what produces lower emissions than cruising (Durán-Grados et al., 2020). Lee et al., (2020) estimated other emissions from several types of ships (general cargo, cruise, container, and tankers vessels) facing the docking process.

Calculations in SOx emissions in the Strait of Gibraltar went from 8.20 ton/km2/year in 2007 (Moreno-Gutiérrez et al., 2015) to 11.60 ton/km2/year in 2017 (Nunes et al., 2020). As a curious fact, Durán- Grados et al., (2020) estimated how Ro-Pax passenger-ships affected the atmosphere in the Strait of Gibraltar during the 90 days of COVID-19 pandemic lockdown while all vessels were berthed in the port of Algeciras taking into account the auxiliary engine and, they obtained a reduction of 12% of emissions. Several studies present an overview of air quality in Europe and port cities (Guerreiro, et al., 2014; Wagner 2019).

Others, the relationship between transport-related air pollutant concentrations to integrate new models for sustainable mobility of vehicles (Catalano, et al., 2016) and the usage of different methods to predict peaks of pollution in critical meteorological situations, particularly in the Bay of Algeciras (Muñoz et al., 2014). Due to huge vessels with engines run on heavy fuel oil (2,700 times higher than road fuel), the shipping emissions are tackled in many manuscripts (Corbett et al., 2007; Liu, et al., 2014; Nunes, et al., 2019; Puig, et al., 2020; Bilgili, et al., 2021; Moreno-Gutiérrez and Durán-Grados (2021)).

Nunes, et al., (2019) evaluated four important ports in Portugal in terms of environmental, social, and economic criteria to evaluate the implementation of policies for in-port emissions. Other authors have studied four types of marine fuels on the environment and human health and concluded that IMO 2020 Sulphur Cap are not at a desirable level yet (Bilgili, et al., 2021). Sanchez et al., (2020) detailed methods to reduce traffic emissions and to implement policy interventions in cities.

In terms of meteorological events that affect pollution, winds seem to be important. Meteorology contribution to pollution events together with forecasting models are faced by Muñoz et al., (2014); Gonzalez-Enrique et al., (2019b); Vellalassery et al., (2021).

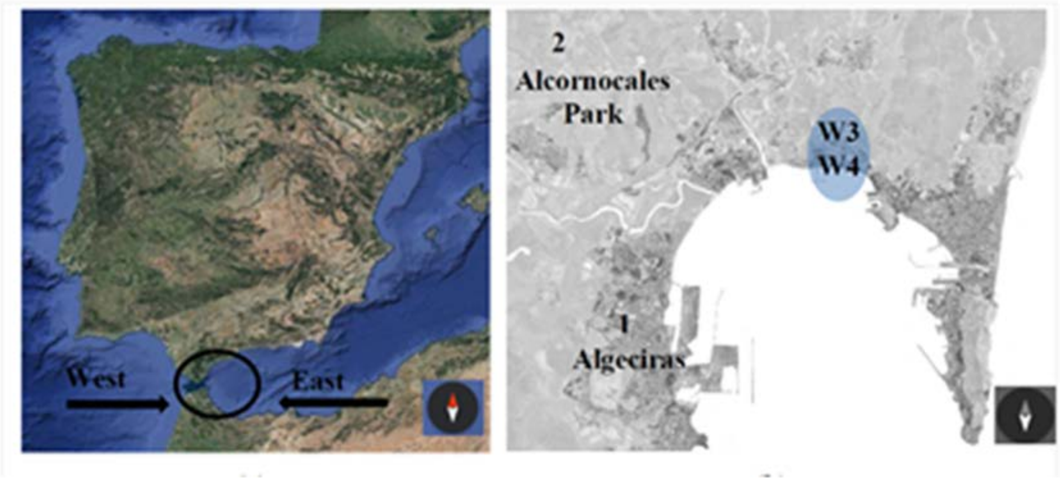
Estimations related to urban areas are tackled in Hu et al., (2021) and in Johnson et al., 2020). The evolution of the interaction between ports and cities is shown in Hesse (2013) adapted from Hoyle (1988). Sustainable cities are related to green transport but Wagner (2019) revealed also multiple factors such as economics, planning development, civil engineering, geography, and of course, transportation.

In this work, the best estimation model of SO2 concentrations in Algeciras and Alcornocales Park is achieved using historical data resolving an input-output fitting problem with feedforward artificial neural network (ANNs). Linear regression models are applied and compared as a benchmark. The rest of this manuscript is organised as follows.

Sect. 2 describes the study case, the database and the methodology. Sect. 3 presents the experimental procedure and the different tested approaches. Sect. 4 discusses the obtained results, and finally, Sect. 5 states the main conclusions.

2. MATERIALS AND METHODS

The Bay of Algeciras is located in the south of Spain, Figure 1(a), and the port of Algeciras is shown in Figure 1(b). The strategic position of the port due to its specific orographic location and the two main directions of wind, East winds (Levante) and West winds (Poniente), affect this area. Figure 1(b) highlights the monitoring stations over the Bay, described in Table 1. Weather stations were denoted using Wn (W3- 4) and listed Algeciras and Alcornocales Park correspond to pollutant monitoring stations



(a) **(b)**

Figure 1 – (a) Bay of Algeciras location and its frequent winds; (b) Monitoring stations (air pollution 1- 2, and meteorological W3- 4)

This study area was chosen due to the importance of maritime transport in this bay. As well, road traffic that moves the goods from this point to the rest of Spain has increased substantially during the last ten years in Algeciras. The two monitoring stations tested, Algeciras and Alcornocales Park are located in Figure 1(a). Alcornocales Park was chosen because it is a remote unspoilt green area where, theoretically, pollution does affect less.

The hypothesis is that Algeciras city is more affected by maritime transport than Alcornocales station. Therefore, a prediction model in Algeciras should be better explained than another in Alcornocales station, due to the effect of maritime transport.

Looking at Figure 1(b), the localization of the Bay of Algeciras is clear and also the different monitoring stations spread over the region. The two dominant winds in the bay are shown in Figure 1(a), Levante (East) and Poniente (West). These peculiar ways in which the wind blows are due to the funnel factor of the bay contained by the Rock of Gibraltar and due to the connection between the Atlantic Ocean and the Mediterranean Sea.

Code	Monitoring/weather station	Latitude	Longitude
1	Algeciras (EPSA)	36º8'11.7" N	5º27'11.44" W
2	Alcornocales	36º13'35" N	5º31'11.44" W
W3	Cepsa (60 m high)	36º11'37.66" N	5º24'1.24" W
W4	Cepsa (15 m high)	36º10'54.7" N	5º25'43.42" W

Table 1 – Location of the meteorological and SO2 monitoring stations

2.1. Materials

Andalusian Government and Algeciras Bay Port Authority (APBA) have provided to the University of Cádiz the recorded values of SO2 concentration, wind, and GT (Gross tonnage) of vessels. The database was recorded hourly for SO2 concentration and wind speed and direction. Then, a new data imputation procedure was performed to complete the missing values. Here, missing data values have been included using a data imputation algorithm considering the measured values in other monitoring stations close to each station, following a proceeding previously used in other works by authors (Turias et al., (2006), Turias et al., (2008), Martín et al., (2008), Moscoso-López et al., (2016), González-Enrique et al., (2019a), Ruiz-Aguilar et al., (2020)). Figure 2(a)(b) shows SO2 concentration time-series and Figure 3(a) shows the wind rose representation of W3 station (Cepsa at 60 m high) and Figure 3(b) the wind rose of W4 station (Cepsa at 15 m high).

The vessel database provided by APBA contains a register for each vessel in the Bay in 2019 (with corresponding timestamps of arrival and departure). The database was transformed into a GT/h (Gross-tons per hour) computing the number of vessels in an hour and the total of Tons of those registered ships. Therefore, each hour a certain number of vessel-tons are located into the Bay, and theoretically affecting the air pollution.

The pollutant data are collected in two monitoring stations in Algeciras and Alcornocales Park, and the weather data are collected in two meteorological stations located in Cepsa refinery at 60 m high (W3) and 15 m high (W4) (see Figure 1b). The SO2 concentration (μg/m3) is recorded in Algeciras city and Alcornocales Park to verify the initial hypotheses (that Algeciras is more affected by SO2 than Alcornocales Park). The weather variables used in this research are the two components of the wind; wind speed (km/h) and wind direction (degrees).

Code	Variables	Measurement	Station
Output1	SO_2	$\mu g/m^3$	Algeciras (EPSA)
Output2	SO_2	$\mu g/m^3$	Alcornocales
Input1	Vessels	GT/h	-
Input2	WS (Wind speed)	Km/h	Cepsa (60 m)
Input3	WS (Wind speed)	Km/h	Cepsa (15 m)
Input4	WD (Wind direction)	Degrees	Cepsa (60 m)
Input5	WD (Wind direction)	Degrees	Cepsa (15 m)

Table 2 – Variables of the study

2.2. Methods

Artificial Neural Networks (ANNs) have been tested in this work together with the use of vessel and wind information in order to predict SO2 concentrations. In this sense, this system could be seen as a virtual sensor SO2 concentrations as a function of maritime transport and wind variables. ANNs require no prior assumptions about the model in terms of mathematical relationships or data distribution. Feedforward ANNs based on a backpropagation learning rule has been used (Rumelhart et al., (1986)). The output was the hourly SO2 concentrations, and the inputs were the gross tons of vessels summed each hour in the Bay of Algeciras, and the wind speed and wind direction in a certain timestamp.

Furthermore, different models were built, some of them using only the pollutant information and the rest considering exogenous variables (vessel and wind information).

The purpose of this modelling approach is to establish a quantitative relationship between a group of predictor variables, X, and a response Y (in this case, the SO2 concentration to be predicted). ANNs have found many applications on air pollution (Jorquera et al., (1998); Nunnari at al., (1998); Gardner et al., (1999); Balaguer, et al., (2002); Perez et al., (2001); Perez et al., (2002); Viotti et al., (2002); Kukkonen et al., (2003); Turias et al., (2003); Turias et al., (2006); Turias et al., (2008); Martín et al., (2008); González-Enrique et al., (2019a)).

For feedforward ANNs, a pattern is formed by inputs together with the pollutant concentration to be forecasted, named real or desired output. There is no way to determine the optimum although Hornik et al., (1989) show the capabilities of backpropagation feedforward networks. An experimental procedure has been used to determine the best ANN configuration.

A standard Multiple Linear Regression (MLR) model has been used as a benchmark in this study.

3. EXPERIMENTAL PROCEDURE

A procedure of resampling simulation was designed to select the model with the best generalization capabilities. First of all, data were selected to create and train the network.

Then its performance was evaluated using mean square error and regression analysis. A feedforward artificial neural network with sigmoid hidden neurons and linear output neurons can fit multi-dimensional mapping problems arbitrarily well, given consistent data and enough neurons in its hidden layer. Authors have successfully used similar procedures in other problems (Ruiz-Aguilar et al., (2014); Moscoso-López et al., (2016); Gonzalez-Enrique et al., (2019b); Ruiz-Aguilar et al., (2020)). Besides, in this problem, the best ANN model using 1000 replications was chosen. ANNs were trained with the Levenberg-Marquardt backpropagation algorithm. Finally, the obtained results were statistically analysed and compared in order to select the model with the best generalisation capabilities.

ANN models with different hidden units were compared to determine the effect of the addition of non-linear processing capabilities on model performance. The resampling procedure was found to reduce test set prediction error and to mitigate the effects of overfitting.

The strategy split randomly the database into three portions (training 70%, validation 15%, and test 15% sets) and the performance results were collected only for the test set in order to estimate the generalization error of each model using unseen data as .

Approach	**Input variables**	**Wind direction**
1	Vessels	Levante (East Wind)
2	Vessels	Poniente (West Wind)
3	Vessels, WS, WD	Levante (East Wind)
4	Vessels, WS, WD	Poniente (West Wind)

Table 3 – List of the tested approaches in the experimental procedure

The approaches 1 and 2 are represented in Equation (1):

$$\hat{SO}_2(t) = f(vessels(t)) \quad (1)$$

The approaches 3 and 4 are represented in Equation (2):

$$\hat{SO}_2(t) = f(vessels(t), wind\ direction(t), wind\ speed(t)) \quad (2)$$

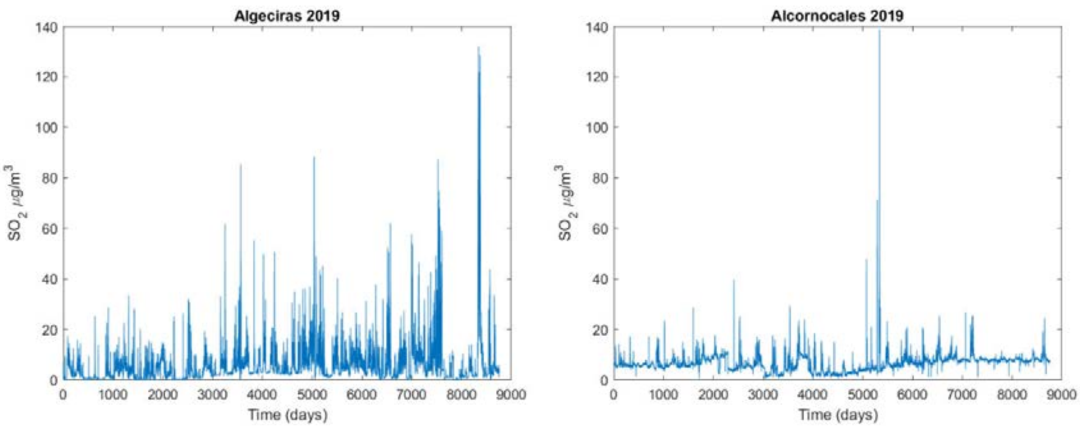
where vessels(t) are the hourly sum of the gross freight in tonnes of all the vessels in the Bay.

The output in each approach is the concentration of SO2 recorded in every station (Algeciras or Alcornocales Park). The models have been subdivided into three submodels: the first one for wind patterns of "Levante" (East wind), the second one for wind patterns of "Poniente" (West wind), and the last one for the rest of the examples in the database. Figure 3(a)(b) shows the winds of roses where these two main wind scenarios can be seen

4. RESULTS AND DISCUSSION

The Bay of Algeciras supports a mean of tons of vessels of one million tons per day as we can see in Figure 4. Moreover, Figure 2(a) shows the large variability of SO2 concentrations in Algeciras and higher concentration values. In contrast, Figure 2(b) indicates a low variability in Alcornocales Park and lower data.
The simulations were run in MATLAB environment. A complete experiment using shallow.

ANNs was developed to prove the efficiency and reliability of SO2 concentration estimation in two monitoring stations in the Bay of Algeciras (Spain) as a function of the total gross tons each hour. Levenberg-Marquardt was used as optimization algorithm and early stopping to avoid overfitting.



(a) (b)

Figure 2 – Hourly SO2 data from stations in 2019 (a) Algeciras; (b) Alcornocales Park

Figure 2 shows a considerable number of concentration peaks of SO2 pollutant in Algeciras than in Alcornocales Park monitoring station, also these values in Algeciras station fluctuate considerably more and in Alcornocales Park the values are significantly more stable. Table 4 shows their means and standard deviation.

Station	Mean Value	Standard deviation
Algeciras	5.8168	8.5573
Alcornocales Park	6.7610	3.6223

Table 4 – Descriptive statistics of SO_2 monitoring stations

Characteristic winds in the Bay of Algeciras are drawn in the wind roses in Figure 3(a)(b). Both clearly show pure East winds 90º (Levante) and pure West winds 270º (Poniente), although in the Bay the West encompasses an angular range of 270º ± 30º approximately.

Most of the winds are normally lower than 54 km/h (15 m/s) and only a few episodes a year are higher than 70 km/h (20 m/s).

Figure 4, shows the 2019 vessel database provided by APBA. This data contains a register for each vessel in the Bay in 2019 (with corresponding timestamps of arrival and departure). In order to check if this data leverage SO2 concentrations, the database was transformed into a GT/h (Gross-tons per hour) calculating the number of vessels in an hour and the total of tons of those registered ships. Thus, a certain number of vessel-tons are located into the Bay each hour. In Figure 4(b), a data histogram is shown. The most frequent data is about 1E+06 GT/h. This amount of vessels produces emissions that can affect a certain area of influence

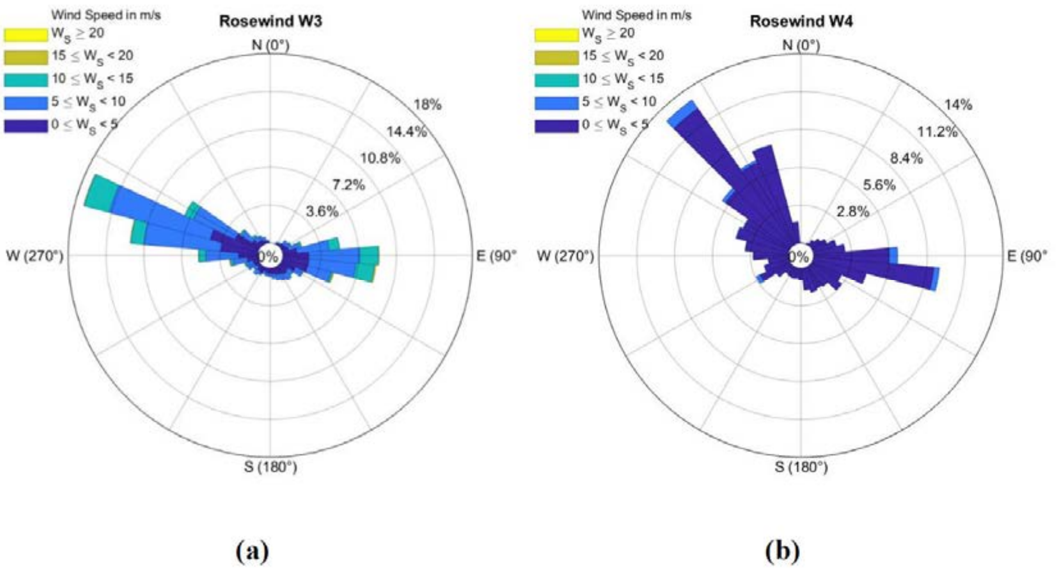


Figure 3 – Wind roses year 2019 (a) station W3 at 60 m high; (b) station W4 at 15 m high

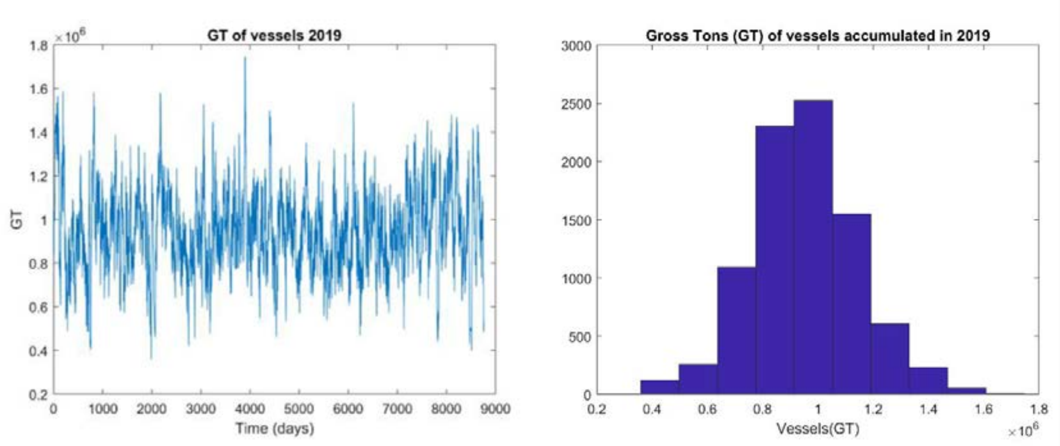

Figure 4 – Hourly vessel data 2019 in Gross Tons recorded in the port of Algeciras

In Tables 5-6 the results of linear regression models are exhibited for every approach. The highest regression coefficient (r = 0.4499) using the linear model is obtained in Algeciras for approach 4 (vessels + West wind) compared to r = 0.2432 in Alcornocales, which indicates a better explanation of the linear model in Algeciras. Analysing Table 6, approaches 1 and 2, it is observed that if we consider only the vessels as input, the model seems to show more leverage in Alcornocales in the case of East wind conditions. In the case of Algeciras, the linear model produces better results when Poniente conditions are registered. This fact could be explained due to in these specific conditions the SO2 concentration values show lower values in Algeciras and they are easier to model linearly.

Approaches 3 and 4 get better results than approaches 1 and 2, which means that input variables affect more strongly if interactions are considered.

Tables 7-8 show the results of ANN models. It is worth mentioning that ANN models fit better the database than MLR models. This fact is explained due to nonlinear behavior of the pollutant dispersion around the study area. One more time, the best results were found when approaches 3 and 4 were used. In the case of Alcornocales, better estimation results were obtained in Levante conditions, and the case of Algeciras, the best estimation model was found in Poniente conditions. The highest result is obtained in Algeciras with 20 hidden neurons (r = 0.7810) compared to the highest coefficient (r = 0.6356) in Alcornocales for approach 4 and only 1 hidden neuron.

Globally, the results show a poor linear relation amongst variables which means that, in comparison to ANNs models in Tables 7-8 with better regression coefficients, the inputs do not follow linear relations. ANNs models work better in general when exist non-linear behaviors and this fact is observed in the obtained results.

Besides, better results were obtained when wind variables are also used. Furthermore, a differentiation between Poniente models and Levante models improves the obtained results as we can see in Tables 5-8.

Figures 5-8 show the different variables used and also show the training examples in order to analyse how in each case, different conditions appear. Figures 5-8 show data after applying normalisation. The training examples of SO_2 are shown in green evidencing

Poniente and Levante events in both monitoring stations, Algeciras and Alcornocales Park. Ingeneral, West winds (Poniente) produce lower SO_2 situations and the reverse occurs with East winds (Levante). In both stations, West winds (Poniente) events models produce a better fitting in training data for SO_2 (green crosses) than in East wind due to the fluctuating nature of the SO_2 time-series in Levante conditions. Generally, in Poniente conditions, SO_2 data are more stable.

5. CONCLUSIONS

The SO2 database is better suited to non-linear models as we can see from the results in Tables 5-8. ANNs models show better results than linear models, going from 0.7810 with 20 hidden neurons to 0.4499 in linear models in Algeciras. Although East winds are supposed to fit better the data in Algeciras, the results show that West winds produce a better fitting training data for SO2 due to the stability of SO2 data in Poniente conditions.

Once the study is developed, several conclusions can be extracted:

ANNs models deeply improve results of MLR revealing a strong non-linear behavior.
The usage of separated models for the two dominant winds (Poniente events and Levante events) also enhances the results of an individual model.

Future researches will focus on the usage of non-supervised clustering algorithms such as Kohonen's self-organising (SOMs) maps to produce patterns to which separate models can be applied and also deep learning approaches.

The analysis presents promising results to be used afterward in SO2 forecasting models . together with historical data of the time-series of SO2. In this research, the SO2 data were only used as outputs. Therefore, using a wind separation stage (Levante and Poniente), a robust estimation was developed and the obtained results have allowed us to confirm that this approach can serve as a support decision tool to citizens and/or institutions.

ACKNOWLEDGEMENTS

ABSTRACT

The selection of the preferred alternative in a parking facility project is usually made in a state of uncertainty. Decision-making methods are a useful tool to systematically arrive at a final decision between different alternatives and reduce subjectivity in decision making by creating a series of filters. However, the selection of the appropriate variables to be considered in the analysis may be problematic as well. Performing sensitivity analyses on entry variables is a key feature to ensure that the final choice is stable when initial conditions experience changes. This paper suggests a methodology to select the best alternative when considering parking facilities. The methodology compares the results from two different sensitivity analyses techniques. The changes in preference experienced as the applied weights change through the process are analyzed and the most critical criteria are identified.

1. INTRODUCTION

Urban mobility planning is a fundamental aspect of sustainable development. Sustainable mobility is thus understood as a transport system that allows the movement of people and goods in better conditions of functional quality (travel time, punctuality, comfort, safety, etc.), with more rational use of resources (energy, space, etc.) and a lower environmental impact (reduction of emissions derived from these consumptions. Parking facilities planning is a very significant element of urban transport system planning and sustainable city development, both at local and strategic levels.

A parking facilities policy can be an appropriate strategy to address congestion problems (Ibeas et al., 2014). In general, proper parking management will result in less search traffic and a better use of available parking space (European Union, 2005). On average, a car can spend up to 23 hours a day parked and uses several parking spaces each week (Litman, 2016). Problems related to parking planning are among the most common problems faced by designers, planners, operators and public sponsors. These problems often materialize as a lack of supply (few spaces are available, more need to be built) or deficient management (available facilities are used inefficiently and need to be better managed). Also, parking facilities come at a high cost to society, (Litman, 2016). Therefore, proper planning of parking facilities is necessary and new alternatives need to be studied taking into account all the variables that determine their efficiency and sustainable development.

Multicriteria decision-making (MCDM) methods are tools used regularly for the selection of infrastructure alternatives. The main advantage of MCDM is the simplicity of application and the versatility it offers to solve any problem where there is a known limited number of alternatives. The construction of the decision matrix itself helps to analyse the problem and synthesise the possible solutions, as well as the relative importance of the different requirements (Mullur et al., 2003). However, they have some drawbacks that need to be highlighted: Firstly, potentially optimal alternatives may be discarded because they never receive the highest total score, yet they are the alternatives that best meet the main requirements; Secondly, depending on the method used for weighting criteria, this process has a subjective component and is influenced by the preferences of the decision-maker.

Furthermore, the usefulness of any model depends on the accuracy and reliability of its results. Therefore, it is highly desirable to develop MCDM methods that are less sensitive to the relative importance of the criteria (weighting), or to build strategies that help to assess the sensitivity of the model and the uncertainty of the outcome, (Maliene et al., 2018).

In this research, the results provided by a MCDM for the selection of alternatives in parking facilities projects are analysed by comparing results from the application of two different methods, that are based on sensitivity analysis. For this purpose, the changes in the ranking of alternatives by varying the weights in the selection criteria are analysed and the most critical criterion is determined.

2. LITERATURE REVIEW

MCDM methods are tools that have been extensively used for the selection of infrastructure alternatives. Practitioners often rely on simple decision methods such as the weighted sum method or the Pattern method (Sigford and Parvin, 2013), (Suarez Galarza, 2015).

These methods are characterized by a direct assignment of weighting criteria, which is very subjective. Similarly, sensitivity analysis is limited to changing the weighting of criteria to determine how the ranking of alternatives changes, without analysing the critical criteria or threshold values that determine changes in the ranking.

In the academic literature, there is a broad body of knowledge focused on the selection of alternatives in infrastructure projects in different fields. MCDM methods are applied with different objectives: to assess the sustainability of the different alternatives (Penadés-Plà et al., 2016), (Sierra et al., 2018), (Zavadskas et al., 2018); to take into account the correlation between input variables, (Mardani et al., 2015); to obtain a ranking of suitable alternatives to optimise and/or prioritise investments in early stages of infrastructure planning; (Belošević et al., 2018); to assess risks, (Mohsen and Fereshteh, 2017); to determine the optimal location, (Wu et al., 2019).

MCDM methods have many advantages because they allow complex problems to be solved systematically and simply. Nevertheless, the results of the different decision methods are affected by a certain degree of uncertainty. It is therefore important to identify and understand the different sources of uncertainty and to quantify, as far as possible, the uncertainty and its influence on the results of the decision method. However, recognising and quantifying uncertainty is a complex and multifaceted issue, (Azzini et al., 2020). The uncertainty in the data, procedures and approaches used for its resolution justify making a study of the behaviour of the decision-making process as complete as possible, (Moreno-Jiménez et al., 1998). In this sense, the analysis of the behaviour should be carried out at three levels that respond, respectively, to the effectiveness, efficacy and efficiency of the decision process: (1) the approximation (validity); (2) the modelling (robustness); and (3) the solution (stability), (Moreno-Jiménez et al., 1998).

Sometimes the concepts of uncertainty analysis, sensitivity analysis and robustness analysis of the decision method are confused due to their similarity. All these concepts target the quality of the decision method, but there are differences between them, (Azzini et al., 2020), (Song and Chung, 2016). Uncertainty analysis aims to quantify the uncertainty in the solution provided by the decision method due to the uncertainty in the inputs (criteria and alternatives) of the method, (Azzini et al., 2020). To determine the robustness of the methods, an analysis of the behaviour of the solution is usually performed, assessing the possibility of change in rank between alternatives when relevant aspects (alternatives, criteria, dependencies, etc.) are added or removed, (Moreno-Jiménez et al., 1998). Finally, sensitivity analysis measures the stability or behaviour of the solution to small changes in preferences that occur during the resolution process, or to small changes in the values of the parameters. Thus, sensitivity analysis is a process of investigating the behaviour of an uncertain system, process or method, (Medeiros et al., 2017).

Different types of sensitivity analyses can be grouped into three main categories: mathematical, probabilistic and graphical (Frey and Patil, 2002). Among the sensitivity analyses applied, two stand out: weight variation of the criteria in a given interval and the most critical criterion method. The first method allows to determine independently the effect of each criterion on the solution. For this, the weight of each criterion is modified (increasing and decreasing) by a small percentage - for example, 5%- and by a large percentage – for instance 50%-, while maintain the weight of the rest of the criteria. In this way, the relative sensitivity coefficients of each criterion can be calculated as the number of changes in the ranking of alternatives due to these changes, (Davies et al., 2012). The most critical criterion method is a sensitivity analysis method to assess the impact of uncertainty on the determination of the most critical criterion and on the results, (Triantaphyllou and Sánchez, 1997). In addition to these two sensitivity analysis methods, there are other methods based on uncertainty analysis by optimising the distance metric, (Hyde and Maier, 2004).

3. MATERIALS AND METHODS.

3.1 MCDM methods.

First of all, it should be noted that not all MCDM are perfect for all decision problems. MCDM can be classified into the following groups, (Penadés-Plà et al., 2016), (Hajkowicz and Collins, 2007), (de Brito and Evers, 2016):

- Methods based on a utility/value function or Multi-attribute Utility Theory (MAUT). The objective of these methods is to find an expression through which the decision-maker's preferences are reflected by using a utility/value function.
- Paired comparison methods. These methods allow different alternatives to be assessed according to qualitative criteria by comparing them two by two. They can also be used to establish the relative importance and weighting of criteria, by paired comparisons of the criteria, i.e. the question of how much more important criterion A is compared to criterion B.
- Methods based on the concept of distance. These methods determine a classification of the alternatives according to their distance from an ideal solution. An ideal solution is the hypothetical alternative that is obtained from the combination of the different alternatives, choosing the variables that "behave" best concerning each criterion.
- Outranking methods. This term includes all those MCDM that revolve around the theoretical concept of overcoming relationships.

3.1.1 SAW Method

The Simple Additive Weighting (SAW) method, also known as the weighted sum method, is the simplest and most widely applied method, (Kittur, 2015). For ech alternative, it obtains the weighted sum of the performance ratings for all criteria, (Br Sembiring et al., 2019), (Wira Trise Putra and Agustian Punggara, 2018).

The overall performance rating of each alternative, P_i, is given by the expression:

$$P_i = \sum_{j=1}^{n} w_j * x_{ij} \tag{1}$$

Being w_j the weight of each decision criterion, C_j, and x_{ij} the normalized value of the evaluation of alternative A_i concerning criterion C_j, i.e. the element a_{ij} of the decision matrix after normalization. The alternative that obtains the highest value of P_i is considered the best alternative.

Normalization of the decision matrix's elements is necessary to evaluate the different alternatives concerning decision criteria that have different units of measurement. In this way, normalization converts the elements of the decision matrix into dimensionless values.

In the SAW method, the normalized values are obtained by summing the values of each row of the transposed decision matrix and then dividing each element of that row by that sum, (Ginevičius, 2008). For the normalization of the elements of the decision matrix it is necessary to take into account whether the criterion is a beneficial criterion or a cost criterion, so that the normalized values are obtained according to the following expressions:

$$x_{ij} = \frac{a_{ij}}{\sum_{i=1}^{m} a_{ij}}, if\ C_j\ is\ a\ beneficial\ criterion \quad (2)$$

$$x_{ij} = \frac{1/a_{ij}}{\sum_{i=1}^{m} 1/a_{ij}}, if\ C_j\ is\ a\ cost\ criterion \quad (3)$$

Being m is the number of alternatives of the decision problem.

3.1.2 AHP Method

The Analytic Hierarchy Process (AHP), was developed by the mathematician Thomas Saaty in the late 1970s, (Saaty, 1990). It is a MCDM based on paired comparisons that allows the decision-maker to express his or her preferences for weighting the different criteria. To do this, the Saaty scale (Saaty, 1990) is applied and the criteria are compared two by two. The differences between these two elements are established verbally and these descriptive preferences are represented by numerical values. In this way, when two elements are equally preferred or important to the decision-maker, the pair of elements will be assigned a "1"; a "3" when there is moderate importance of one element over another; a "5" indicates strong importance of one element over another; a "7" indicates very strong importance of one element over another; and finally a "9" indicates extremely preferred or importance of one element over another. Even numbers are used to express intermediate situations, (Saaty, 1990).

The weight eigenvector is calculated for the criteria that determines which is the most ideal solution. This is done by making a paired comparison of them for each project (Martínez Rodríguez, 2007), (Yepes et al., 2015). It must be taken into account that the weight eigenvector is not the same for each project, since certain criteria may have bigger importance in comparison to the others, depending on the characteristics of the project. It is necessary to remember that AHP measures the global inconsistency of the views by the Consistency Proportion, calculated by dividing the Consistency Index and the Random Index, and it should be less than 10%. The Consistency Index measures the consistency of the comparison matrix, (Saaty, 1990):

$$CI = \frac{\lambda_{max} - n}{n - 1} \quad (4)$$

Being λ_{max} the biggest value of the paired transposed comparison matrix, and n the matrix range. The Random Index is an index that measures a random matrix, whose values are given in Table 1.

Matrix range	2	3	4	5	6	7	8	9	10
Random Index	0,00	0,58	0,90	1,12	1,24	1,32	1,41	1,45	1,49

Table 1 – Random Index, AHP method.

Therefore, this allows for an acceptable level of confidence that the decision process has been carried out correctly. On the other hand, through AHP we can establish the ‘behaviour’ of each alternative for each of the qualitative criteria that are part of the decision making processes, to obtain a quantitative assessment for qualitative criteria.

3.2 Sensitivity analysis

The two main methods of uncertainty analysis in which decisions are made are the weights variation of criteria in a given interval and the most critical criterion method. In the first method, the objective is to independently determine the effect of each criterion on the results of the MCDM. For this purpose, the weight of each criterion is increased or decreased by 5% (small change), 50% (large change) and 95% (very large change). The weights of the remaining criteria are similarly increased or decreased to ensure that the sum of the weights of all criteria remains equal to 1. This results in relative sensitivity coefficients calculated as the number of changes in the ranking of alternatives due to changes in the criteria weights.

In the most critical criterion method, the impact of uncertainty is assessed by determining the criterion whose effect produces the greatest changes in the results, (Triantaphyllou and Sánchez, 1997). To do this, it calculates the minimum change (δ) to the weight of a criterion (w_k), to reverse the ranking of the alternatives. It is calculated for each pair of alternatives A_i and A_j for each criterion C_k, as follows:

$$\delta_{k,i,j} = \frac{P_j - P_i}{x_{jk} - x_{ik}} \quad (5)$$

Being P_j and P_i the positions occupied by alternatives A_j and A_i in the ranking and x_{jk} and x_{ik} the normalized ratings of each alternative concerning criterion C_k. The condition $\delta_{k,i,j} \leq w_k$ must be satisfied for the change in the ranking of the alternatives by changing the weights of the criteria to be feasible. Sometimes, it may be impossible to reverse the existing ranking by changing the weights of the current criteria. However, when the conditions are met, the modified criterion weight, w_k^*, can be calculated from the following equation:

$$w_k^* = w_k - \delta_{k,i,j} \quad (6)$$

The percentage change of the criteria weights can be calculated as:

$$\%w_k^* = \frac{w_k^*}{w_k} * 100 \quad (7)$$

The criticality degree of each criterion C_k, D_k, is defined as the minimum absolute value of $\%w_k^*$. From here, the sensitivity coefficient of each criterion, $sens_k$, can be defined as a measure of the sensitivity to the change in the weighting of the criterion C_k as follows:

$$sens_k = \frac{1}{D_k} \quad (8)$$

So the most critical criterion will be the one with the highest sensitivity coefficient.

3.3 Data collection

In this paper, a case study is developed applying to the construction of parking facility in Cordoba City’s centre the two sensitivity analyses previously described. The problem of parking in the historic centre and its periphery was outlined in the Advance of the Sustainable Mobility Plan for the city of Cordoba, drafted in April 2011, (Cordoba City Council, 2011).

In the historic centre there are different types of parking for different usages: private parking for residents, blue zone parking for visitors and loading and unloading parking for good delivery.

On Cordoba’s periphery the implementation of regulated or blue zones is insufficient for the proper management of parking, making it is necessary to limit traffic and better manage mobility.

Three alternatives for a new parking facility are evaluated, (Vimcorsa, 2010):

- Alternative 1: Parking on Gran Vía Parque Ave. on the corner of Manolete Ave. The parking consists of one floor above ground level, uncovered and landscaped, and two floors below ground level.

- Alternative 2: Surface parking in Gran Vía Parque Ave. on the corner of Manolete Ave. in the same location and conditions as alternative 1, but building only the surface level, surface parking.
- Alternative 3: Surface parking in the street Pintor Racionero. Due to the limitations to underground works due to the existence of important archaeological remains, the installation has only the surface parking level.

Ten selection criteria have been considered for the evaluation of the alternatives: C1, Number of parking spaces; C2, Utility value to the user (relationship between users' willingness to pay to save time looking for a parking place and the tariff parking); C3, Number of current parking spaces in the target area; C4, Ratio of inhabitants to existing residential parking spaces in the area; C5, Intermodality; C6, Cost of parking (construction cost and maintenance cost); C7, Environmental impact; C8, Population; C9, Proximity to commercial areas, C10, Proximity to administration areas and offices.

Table 2 includes the evaluations of each alternative concerning each selection criterion, and table 3 shows the normalized decision matrix, according to equations (2) and (3).

Criteria	Alternative 1	Alternative 2	Alternative 3
C1	508	218	246
C2	0.618	0.618	0.653
C3	527	527	688
C4	6.18	6.18	3.82
C5	1005	1005	1970
C6	8525.57	2709.3	2485.16
C7	0.6753	0.0817	0.2431
C8	15275	15275	7540
C9	97532	97532	27139
C10	30150	30150	6797

Table 2 – Evaluations of each alternative concerning each selection criterion

	C1	C2	C3	C4	C5	C6	C7	C8	C9	C10
A1	0.055	0.067	0.023	0.013	0.019	0.017	0.017	0.063	0.012	0.008
A2	0.024	0.067	0.023	0.013	0.019	0.054	0.146	0.063	0.012	0.008
A3	0.027	0.070	0.018	0.008	0.010	0.059	0.049	0.031	0.003	0.002

Table 3 – Normalized decision matrix.

The vector of weights is determined according to the AHP method as described in section 3.1.2. The weight vector obtained is $w = (0.1056, 0.2037, 0.0638, 0.0350, 0.0475, 0.1310, 0.2124, 0.1559, 0.0270, 0.0181)$. It is important to remember that the consistency of the comparison matrix must be identified. After determining the consistency following equation (4), we obtain CI = 0.0953. Since the Consistency Proportion is under 0.1 the assessments made can be considered as consistent.

To determine the best solution, the SAW method is applied as previously described, resulting in alternative 2 as the best ranked alternative, followed by alternative 1, and finally alternative 3.

4. RESULTS AND DISCUSSION.

To determine the stability of the solutions obtained by the MCDM, a sensitivity analysis is performed as described above. First, the most critical criterion is determined using equations (5) to (8). For this purpose, the alternatives are compared in a pairwise manner, obtaining the degree of criticality of each criterion and the corresponding sensitivity coefficients (Figure 1).

	C1	C2	C3	C4	C5	C6	C7	C8	C9	C10
1-2	-424.50	N/F	N/F	N/F	N/F	N/F	N/F	N/F	N/F	N/F
1-3	61.83	-466.29	N/F	N/F	N/F	-41.88	-56.13	55.59	N/F	N/F
2-3	-4975.18	-2496.73	N/F	N/F	N/F	-3084.47	N/F	N/F	N/F	N/F

Table 4 – Criticality degree of each criterion (minimal values). N/F: no feasible change

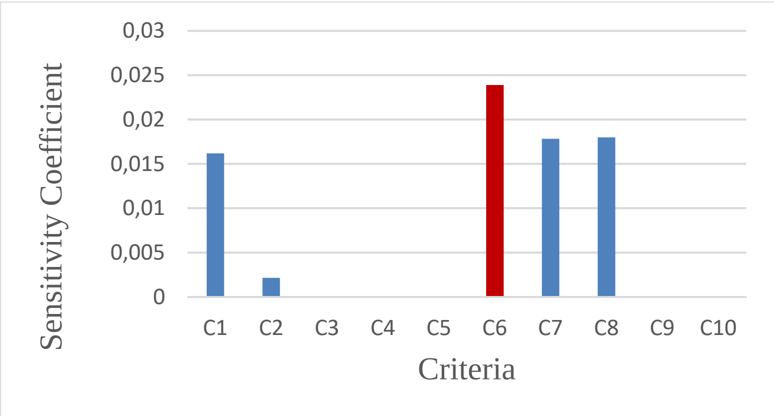

Fig. 1 – Sensitivity Coefficient of each criterion

The results obtained are shown in Table 4. It can be determined that alternative 2 remains the best alternative in almost all cases. Alternative 2 could only be surpassed by alternative 1 if the weight of criterion C1 is increased by 424.50%, and by alternative 3 if the weights of criteria C1, C2 and C6 were increased by 4975.18%, 2496.73% or 3084.47% respectively. However, the most likely changes in the ranking of alternatives 1 and 3.

Relatively small changes in the weights of the criteria can produce changes in the second best alternative. Moreover, it can be deduced that criterion 6 is the most critical criterion, followed by criterion 8, because for the smallest change in the weight of this criterion (41.88%) a change in the ranking of alternatives occurs, which is also reflected in Figure 1.

Next, independent changes in the weight of each criterion are introduced (5%, 50% and 95%). The relative sensitivity coefficients are obtained, that is, the number of changes that occur in the ranking of alternatives due to these changes. The results obtained are included in Table 5.

	Increase (%)			**Decrease (%)**		
	5%	**50%**	**95%**	**5%**	**50%**	**95%**
C1	0	0	0	0	0	1
C2	0	0	1	0	0	0
C3	0	0	0	0	0	0
C4	0	0	0	0	0	0
C5	0	0	0	0	0	0
C6	0	1	1	0	0	0
C7	0	1	1	0	0	0
C8	0	0	0	0	0	0
C9	0	0	0	0	0	0
C10	0	0	0	0	0	0

Table 5 – Relative sensitivity coefficients calculated as a number of changes in the alternative ranking due to change of criteria weights.

The results obtained confirm that changes only occur in one position of the ranking of alternatives. Alternative 2 remains for these weights the best alternative. It is also confirmed that for relatively small changes in the weight of criterion 6 the largest changes in the ranking occur, together with criterion 7. However, criterion 7, according to the analysis of the most critical criterion, has a lower sensitivity coefficient value than criterion 8, which has the second-highest sensitivity coefficient value after the most critical criterion. Given these results, it can be stated that the uncertainty and stability analysis of the solutions of the MCDM must be performed with two different techniques to verify the results because there may be small discrepancies depending on the method used.

5. CONCLUSIONS

MCDM are a very useful tool for the selection of alternatives in a simple way. The decision process however takes place in an environment of uncertainty, because the input variables may vary. Moreover, the results obtained depend on the nature of the selection criteria and, especially, on the weights assigned to these criteria. In most cases, the assignment of weights to the criteria is done by experts, so there is a subjective component and the results may change depending on these weights. Therefore, it is necessary to analyse how the variation in the relative importance of the decision criteria influences the solution of the MCDM. In this paper, we have analysed how changes in the weighting of the selection criteria can influence the solution of the MCDM by using two different sensitivity analysis and comparing the results. It is proposed that whenever possible these sensitivity analyses are carried out to confirm the results and to study the effect of the weights of the criteria on the selection of alternatives. Although the sensitivity analyses carried out have some limitations since they study each criterion independently and do not apply to all MCDM, they are a simple first approximation that allows determining the robustness of the solution obtained and can be the basis for a more exhaustive study of those criteria.

RESUMEN

En la actualidad, en todo el mundo la tendencia está concentrada en lograr Ciudades Accesibles usando un patrón de movilidad basado en un transporte masivo sostenible y accesible para personas con movilidad reducida, con las respectivas implicaciones de tener que adecuar el contexto urbano y de tener que integrar movilidad peatonal y transporte público, en una sinergia que tiene el objetivo principal de devolver los espacios públicos a los ciudadanos.

Del PMUS de Majadahonda se sabe que el reparto modal de todos los viajes diarios en la ciudad, alrededor del 20% son viajes no mecanizados, la gran mayoría a pie. La cuota de reparto modal que tienen los desplazamientos a pie en Majadahonda se sitúa por debajo de las ciudades españolas que suele rondar el 30%.

En esta comunicación se presentan los resultados del Plan de Accesibilidad Peatonal realizado por los autores en la ciudad como consecuencia de una iniciativa del equipo municipal. Incluye:

- Análisis y diagnóstico
- Propuestas

Las propuestas son de tres tipos y van más allá de las comunes de accesibilidad, teniéndosetambién en consideración otros aspectos:

- Creación de Itinerarios Accesibles: Prever actuaciones en calles que generen itinerarios accesibles.
- Zonas de calmado de tráfico: El estudio de accesibilidad tiene en cuenta los problemas que existen actualmente en relación con la seguridad de los peatones en la vía pública y los problemas que surgen como consecuencia de la excesiva

velocidad de los vehículos a motor, por lo tanto, se deben proponer medidas o soluciones a estos problemas, para ello se propondrán calles, zonas o actuaciones decalmado de tráfico.

- Urbanismo táctico: Se proponen medidas de urbanismo táctico, estas medidas son económicas y a corto plazo, de manera que la ciudadanía pueda ver el cambio en su ciudad casi desde los inicios de la implantación del estudio de accesibilidad.

1. ENFOQUE

La ciudad es el espacio en el que los individuos adquieren la condición de ciudadanos, estoes, la condición de ser personas titulares de derechos políticos, sociales y culturales. Tal virtud comporta permitir el acceso a las personas a múltiples servicios y equipamientos, posibilitar el contacto con otros y favorecer la libertad de elección; y todo ello en igualdad de condiciones.

Una ciudad debe ser capaz de dar a sus habitantes la capacidad de realizar todas las actividades que en la misma se desarrollan del modo más independiente y autónomo posible.

El espacio público urbano es un elemento dinamizador y fundamental en la sociabilización de las personas, donde se generan espacios de interacción entre los habitantes de la ciudad.El espacio público tiene una clara incidencia y contribución a la calidad de vida social y material en la ciudad, particularmente de los sectores de la población en riesgo de exclusión.

Majadahonda, por su configuración física, sus condiciones climáticas y las previsiones de planeamiento, se presta a la movilidad peatonal para que esta constituya un pilar básico en la construcción de un nuevo modelo urbano. Casi la totalidad del municipio (exceptuando las urbanizaciones situadas más al sur) se sitúa a una distancia de 2,5 kilómetros del centro urbano, una distancia que puede fácilmente ser cubierta andando en unos 30 minutos. Del PMUS se sabe que el reparto modal de Majadahonda indica que, de todos los viajes diarios en Majadahonda, alrededor del 20% son viajes no mecanizados, su gran mayoría son viajesa pie. La cuota de reparto modal que tienen los desplazamientos a pie en Majadahonda se sitúa por debajo de las ciudades españolas.

Existen una serie de factores o de problemas que frenan el avance de la movilidad peatonal y casi todos se engloban en una causa común: lafalta de accesibilidad universal. Por este motivo el Ayuntamiento decidió elaborar el Plan de Accesibilidad Peatonal del casco urbano de Majadahonda:

"*Un Plan de Accesibilidad es un plan de actuación, cuyo objetivo es hacer accesible gradualmente el entorno existente, con el objetivo de que TODAS LAS PERSONAS lo pueden utilizar libre y autónomamente*" Real Patronato de prevención y de atención a personas con minusvalía.

Por lo tanto, un plan de accesibilidad:

- Es un modelo sistemático que se realiza en un entorno concreto con el objeto de encauzar las acciones a acometer: Dirige y organiza
- Es un instrumento dinámico y sujeto a modificaciones: Carácter abierto.
- Las propuestas se definen en estrategias que se estructuran en acciones y proyectos a desarrollar con posterioridad: Precisa de un desarrollo posterior.

2. METODOLOGÍA

La **metodología** aplicada se estructura en tres fases: análisis, diagnóstico y propuestas, quese desarrollan a continuación:

FASE 1 Análisis	Interno	Visitas técnicas
		Toma de datos
		Participación pública
	Externo	Normativa de aplicación
		Benchmarkig
FASE 2 Diagnóstico	Causas	Problemas estructurales
		Problemas de diseño urbano
		Problemas de mantenimiento y conservación
		Problemas de control y concienciación
FASE 3 Propuestas	Tipo, Específicas y Complementarias	Presupuesto
		Priorización

3. ANÁLISIS Y DIAGNÓSTICO

A partir de la información disponible, las visitas técnicas, la toma de datos y la participación ciudadana, se ha realizado el análisis de la situación actual que se estructura en tres bloquesfundamentalmente:

- Análisis funcional: Estudio funcional de las diferentes áreas de actividad en los itinerarios peatonales. Las tres acciones principales (transitar, descansar y cruzar) seestructuran en los siguientes bloques:
    - Vías de tránsito
    - Zonas estanciales

- Puntos de cruceAnálisis tipológico: Este segundo análisis aborda los diferentes elementos urbanos de forma individual, describiendo sus tipologías y características desde la perspectivade la accesibilidad.
- Análisis sectorial: Un estudio por áreas globales del entorno urbano, abordando la realidad concreta de ese ámbito con la complejidad que motiva la superposición de itinerarios puntuales

El diagnóstico de la accesibilidad en Majadahonda recoge una reflexión, una síntesis y una clasificación de todos los elementos que se han analizado y que se han detectado en la tomade datos realizada previamente, de manera que se puedan valorar y establecer las prioridadesde actuación.

Se ha realizado un **diagnóstico en función de las causas**, ya que diferentes causas provocandiferentes barreras urbanísticas y esto da lugar a diferentes soluciones:

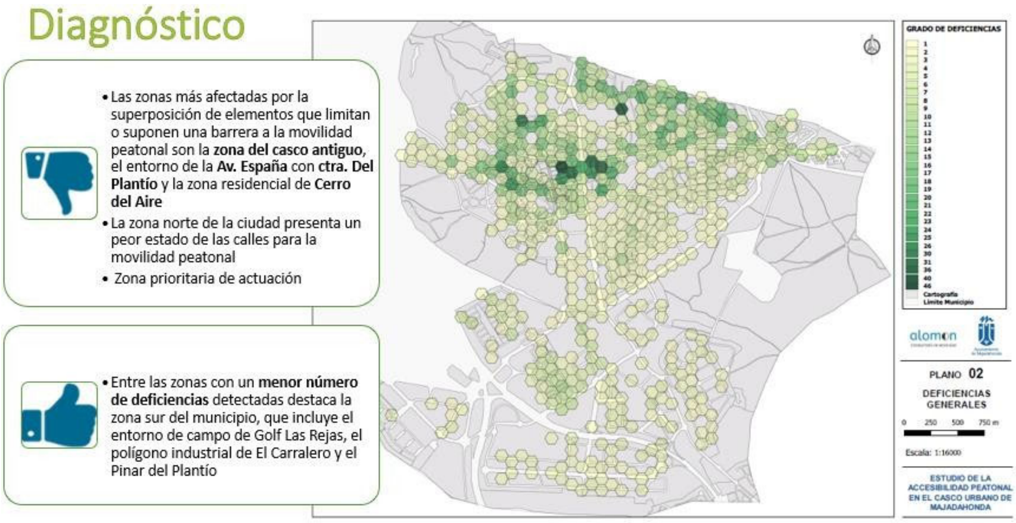
De esta forma, el diagnóstico se ha estructurado en problemas de cuatro tipos diferentes:

- Problemas estructurales: Son problemas que no se pueden cambiar, pero podemos convivir con ellos y ofrecer recursos para que la accesibilidad se mejore, el más destacable es la topografía en la zona histórica y la barrera que supone la M-503.
- Problemas de diseño urbano: Son consecuencia de errores de diseño o de ejecución. En este aspecto destaca la falta de accesibilidad de los itinerarios principales del municipio (acerados insuficientes), la discontinuidad de los mismos debido a los puntos de cruce no adaptados, los elementos urbanos mal

localizados (alumbrado y arbolado interrumpe el paso) y las plazas de aparcamiento reservadas a PMR con un diseño incorrecto.

- Problemas de mantenimiento y conservación: Son derivados de la falta de mantenimiento, conservación y limpieza del espacio urbano. Lo más llamativo es el pavimento en mal estado en algunas aceras.
- Problemas de control y concienciación: Derivados de malas conductas por parte de algunos ciudadanos y que precisan del control por parte de las autoridades competentes. Destacan los elementos comerciales invadiendo la acera, en especial las terrazas de bares y restaurantes y los vehículos mal estacionados.

La siguiente ilustración muestra **diagnóstico global de la accesibilidad** según el número deincidencias detectadas:



4. PROPUESTAS

En función del tipo de problemática detectada en el diagnóstico de la situación actual de la movilidad peatonal se han considerado **dos tipos de mejoras**:

- Las **propuestas de mejora tipo** se desarrollan para aspectos o problemáticas que sehan detectado de una forma generalizada en el municipio:
-
    - Red de itinerarios peatonales accesibles.
    - Pasos peatonales accesibles.
    - Estacionamientos reservados para PMR.
    - Mobiliario urbano.
    - Escaleras y rampas.
    - Vados vehiculares.
    - Conexión a paradas de autobús.

- Sin embargo, hay muchas otras deficiencias de accesibilidad detectadas que son concretos en determinadas calles y que requieren de un análisis pormenorizado, en estos casos se realizan las propuestas de soluciones específicas.

En ambos casos, se incluyen fichas resumen de las actuaciones necesarias que incluye un breve diagnóstico, las características de la actuación planteada, una estimación del coste deejecución de las mismas, el diseño correcto en base a la normativa de aplicación y la priorización de las actuaciones. Se muestra una ficha de actuación específica a modo de ejemplo:

Avenida de España-1		
Itinerario peatonal no accesible		
El tramo de la Avenida de España comprendido entre la Av. Rey Juan Carlos I y la Calle Mare Nostrum, tiene un ancho de acera que no cumple con la normativa, debido a la existencia de alcorques en el itinerario peatonal. Con esta actuación se plantea el disponer de 1.80 metros de acera desde el alcorque, eliminando la superficie de jardín que sea necesaria para garantizar la accesibilidad del itinerario. En este ámbito se han registrado un **alto índice de siniestralidad vial**	 	
Diseño de propuesta 	**Presupuesto estimativo:** 1. **Demolición y movimiento de tierras:** - m3 de desbroce de tierra vegetal. - m2 de demolición de solera de hormigón y pavimento hidráulico. 2. **Pavimentación:** - ml de suministro y colocación de bordillo de hormigón. - m2 de suministro y colocación de solera de hormigón y pavimento hidráulico.

Una vez creada una red de itinerarios peatonales accesibles es necesario impulsar la movilidad peatonal en el municipio a través de medidas informativas y de concienciación: Elaboración de un plano "Metrominuto" de itinerarios peatonales accesibles y campaña informativa, Medidas de vigilancia y sanción para el estacionamiento ilegal, Medidas de vigilancia y control de terrazas, Elaboración de un estudio de iluminación en el ámbito de los itinerarios peatonales accesibles, Elaboración de un proyecto piloto de mejora del acceso al CEIP El Tejar con medidas de urbanismo táctico.

5. CONCLUSIONES

En la actualidad, hay una clara tendencia, en todo el mundo, a lograr ciudades más amables, más sostenibles y más inclusivas. Ha llegado el momento de modificar la estructura urbanística, edificatoria y del transporte en nuestras ciudades y pueblos, potenciando las medidas que facilitan la información, orientación y comunicación para todos los colectivos, suprimiendo las barreras arquitectónicas existentes y buscando la accesibilidad universal; contribuyendo con ello a que todas las personas disfruten de un confort y una calidad de los servicios ofrecidos, y facilitando el desplazamiento y la integración de las personas con discapacidad, al conseguir una mejora de sus propias cualidades y posibilidades, evitando el aislamiento y la marginación a que se ven sometidos hoy en día.

ABSTRACT

The objective of this paper is to present a detailed descriptive analysis of the influence of the mobility restrictions during the COVID-19 pandemic lockdown in Spain on the wellbeing of people. In this paper, we focus on the wellbeing of walkers and drivers during that period.

The dataset used for this study was collected through a web-based survey during April of 2020, in which 1870 valid responses were obtained. In this study a subpart of the survey is used, including data related to travel characteristics during the lockdown and information collected regarding several wellbeing metrics.

The total mobility of people was reduced more than half during the lockdown, and modal share was also altered substantially. Women increased walking by 44% and men by 48%.

The use of car was reduced by 24% in the case of men, and by 11% in the case of women.

Younger and older people are those who walked more during lockdown. Although walking was the predominant travel mode during the lockdown, those who walked more are related to lower values of wellbeing.

Implications for the development of transport policies to improve the wellbeing of people are derived from the results of this study.

1. INTRODUCTION

The lockdown of Spring 2020 to reduce the spread of the Covid-19 pandemic reduced the economic activity and restricted the mobility of people dramatically all over the world. Using phone data, it was estimated a reduction of weekday mobility between 50% and 60% of vehicles-km in Spain (MITMA, 2020). This reduction was high as 80% during weekends.

Travels between 0.5 and 2 km decreased between 40% and 50%, and those trips longer than 10km decreased between 70% and 80%. According to that study, personal mobility during the lockdown period reduced more than half. The limitation of mobility particularly impacted on public transport. Reductions of 90% of riders were registered in all public transport modes during the lockdown.

Among the negative effects of the limitation of mobility during the lockdown, we are interested in its influence on the wellbeing of people. Staying at home for long periods of time, the need for tele-working and attending classes on-line, and the prohibition of carrying out any out-door activity (except walking the dog), could possibly led people to experience negative feelings. Who was more affected? How (limited) walking and driving influenced wellbeing? What transport planning measures can be implemented to alleviate a lockdown impact on the wellbeing of people? The objective of this study is to answer these questions.

2. WELLBEING AND TRAVEL

Human beings seek to maximize their pleasure experiences, which is achieved through the satisfaction of preferences and minimization of pain with the aim of upgrading gratification in terms of happiness. This is the hedonic or subjective approach of wellbeing (Nordbakke & Schwanen, 2014).

On the other hand, wellbeing can also be achieved recognizing that living consistently with the true self is what inspires and gives meaning to one's life. This eudaimonic, objective or psychological wellbeing occur when the individual lives in congruence with his own value system, and eudaimonic discomfort will occur in the opposite case (Vázquez, Hervás, Rahona & Gómez, 2009).

How the use of each travel mode influence SWB has been extensively studied. For example, a literature review carried out by Ettema et al. (2016) indicates that using active travel modes results in higher travel satisfaction than using the car and in particular public transport. In this line, Morris and Guerra (2015) found that bicyclists present higher values of positive affect, followed by car passengers and car drivers. They also found that users of bus and train experience the most negative emotions.

Singleton et al (2019) found that walking/bicycling is associated with high values of health, confidence, and positive affect. Cycling commuters scored higher on distress, fear, and lower on security. On the contrary, results from the study of Zhu et al. (2019) indicate that the SWB of residents who commute walking or cycling was lower than that of those who commute by other travel modes. Respondents in this study lived in rural areas and cities with low urbanization, which could partially explain these results.

They also found that the longer the commute time, the lower the SWB, which is in line with results from Stutzer and Frey (2008), who found that people with longer commuting time report systematically lower SWB among public transport users. Lunke (2020) has also found that train commuters present highest levels of SWB.

During the Covid-19 pandemic only general studies of wellbeing have been carried out (Cheng et al., 2020; Zacher and Rudolph, 2020; Foa et al., 2020; Kimhi et al., 2020; Sibley et al., 2020; Anglim and Horwood, 2020; Suso-Ribera and Martin-Brufau, 2020). This study aims to fill this gap.

3. SURVEY DESCRIPTION AND DATA COLLECTION

The dataset used for this research was collected by a web-based survey that was designed ad-hoc for this study. The main aim of the survey was to gather information regarding the characteristics of out-of-home activities and the associated mobility during the lockdown in Spain, PWB indicators and positive and negative affect of people. The survey started on April 10, 2020 and ended on April 26, 2020. Respondent recruitment was done using two e-mailing lists including professional and personal contacts of the researchers, and senior students of the Universitat Politècnica de València. Besides, the web-survey was disseminated through personal and institutional on-line social media. Participants live in the Valencian Region of Spain.

The survey was divided in three parts. In the first part of the survey, respondents were asked to estimate their daily, weekly or monthly number of times they left home to perform each of the following out-of-home activities: working, grocery shopping, caring tasks, walking the dog, visiting the doctor, other shopping, and other activities (e.g., bank business). The usual travel mode associated to each activity, average time spent traveling and carrying out each activity per week were also collected. The second part of the survey includes questions to characterize PWB and positive and negative affect. Sociodemographic information is collected in the third part of the survey.

The variables included in the analyses are presented in Table 1. Continuous variables are used to measure walking and car use during the lockdown.

Variables	Description	Type
Sociodemographic		
Age	Age of the respondent	Continuous
Gender	0= male; 1 = female	Categorical
Education	1=none; 2=Primary; 3=Vocational; 4=Secondary; 5=Baccalaureate; 6=Non-university; 7=University	Categorical
Household size of respondents	Number of members in the house, including the respondent	Continuous
Household members > 70	People over 70 in respondent's household	Continuous
Household members < 6	People under 6 in respondent's household	Continuous
6 <= HH members < 12	People between 6 and 12 in respondent's household	Continuous
12 <= HH members < 18	People between 12 and 18 in respondent's household	Continuous
Household disable members	People with functional limitations in respondents' household.	Continuous
Type of housing	1=Apartment; 2=Detached or semi-detached house without garden nor private open-air space; 3= Detached or semi-detached house with garden and private open-air space; 4=Other	Categorical
Occupation	1=Student; 2=Employed, 3=Self-employed; 4=Student and employed; 5=Unemployed; 6=Retired; 7=Homemaker; 8=Other	Categorical
Changes on Internet use	1= I do not use it; 2= Less than before; 3=Same as before; 4= More than before; 5=Much more than before	Categorical
Working at home before the lockdown	1=Yes; 2=No	Categorical
Working at home during the lockdown (different from housekeeping)	1=Yes; 2=No	Categorical

Degree of work organization at home	Likert scale: 1=Very bad; 5=Very good	
Home location	1=Center of a big city (>100.000 inhab.); 2=Suburbs of a big city; 3=Mid size city (10.000-100.000 inhab.); 4=Small town (2.000-10.000 inhab.); 5=Village (<2.000 inhab.); 6=Low density city area; Other	
Net monthly income	1=None; 2=Less than 1.000 Euro; 3=1.000-2.000 Euro; 4=2.000-3.000 Euro, 5=3.000-4.000 Euro; 6=More than 4.000 Euro	
Mobility during the lockdown		
TRIPS	Number of times living home per week	Continuous
P_WALK	Percentage of walking when exit from home per week	Continuous
P_CAR	Percentage of car use when exit from home per week	Continuous
TIME_TRAVEL	Time traveling per week (minutes)	Continuous

Table 1. Definition of sociodemographic and mobility variables

Satisfaction and frustration of the three basic psychological needs were collected using the Spanish version for adults of the general Basic Psychological Need Satisfaction and Frustration Scale (BPNSNF) (Chen et al., 2015). This scale includes six four-item subscales to measure autonomy satisfaction (e.g. “I feel a sense of choice and freedom in the things I undertake”), autonomy frustration (e.g. “Most of the things I do feel like I have to”), relatedness satisfaction (e.g. “I feel that the people I care about also care about me”), relatedness frustration (e.g. “I feel excluded from the group I want to belong to”), competence satisfaction (e.g. “I feel confident that I can do things well”) and competence frustration (e.g. “I have serious doubts about whether I can do things well”). Respondents were asked to use a five-point Likert scale to declare if they totally disagree (1) or totally agree (5) with each statement.

Information regarding positive and negative affect were collected using the Positive and Negative Affect Scale (PANAS) (Watson et al., 1988) translated to Spanish by the authors of this research. PANAS includes 20-item self-report measure of positive and negative affect. High negative affect represents subjective distress and unpleasurable engagement, and low negative affect represents the absence of these feelings.

On the other hand, positive affect symbolizes the extent to which and individual experiences pleasurable engagement with the environment. For example, emotions such as enthusiasm and alertness are related to high positive affect, whilst lethargy and sadness characterize low positive affect. A five-point Likert scale was used in this scale as well.

4. SAMPLE CHARACTERISTICS

1,827 respondents provided valid data to all parts of the survey after validations and cleaning. The distribution of the sample according to gender is reasonable balance (Table 2). However, those whose age is between 45 and 64 are overrepresented in the sample. Similarly, those who are working (employed, self-employed and students that also work), are overrepresented in the sample as well.

One third of respondents belong to households that share with only another person (household size = 2) (Table 3). Respondent's household size equal to three are 24.7% of the sample, slightly higher than those equal to four (23.1%). Those who live alone are 12.1% of the sample. And those who live in households of five or more people are 7.3% of the sample.

Respondents living in apartments are most of the sample (78.8%). Those living in attached or semi-detached with garden and private open-air space are 16.0% of the sample.
Those living in big cities (100.000 or more inhabitants) are overrepresented in the sample; they are 60.3% of the sample. Respondents living in mid-size cities (10.000-100.000 inhabitants) are 20% of the sample.

	Respondents	**Percentage**
Gender		
Male	908	49,7%
Female	919	50,3%
Age		
18-25	265	14,5%
26-35	319	17,5%
36-45	301	16,5%
46-55	372	20,4%
56-65	378	20,7%
>65	192	10,5%
Occupation		
Employed	924	50,6%
Retired	293	16,0%
Student	223	12,2%
Student and employed	130	7,1%
Self-employed	115	6,3%
Unemployed	67	3,7%
Other	54	3,0%
Homemaker	21	1,1%

Table 2. Sample sociodemographic characteristics

	Respondents	**Percentage**
Household size		
1	221	12,1%
2	600	32,8%
3	451	24,7%
4	422	23,1%
5+	133	7,3%
Type of housing		
Attached or semi-detached with garden and private open-air space	293	16,0%
Attached or semi-detached without garden nor private open-air space	38	2,1%
Other	71	3,9%
Apartment	1425	78,0%
Home location		
Low density city area	109	6,0%
Center of a big city (>100.000 inhab.)	690	37,8%
Small town (2.000-10.000 inhab.);	151	8,3%
Mid-size city (10.000-100.000 inhab.);	366	20,0%
Other	20	1,1%
Suburbs of a big city	412	22,6%
Village (<2.000 inhab.);	79	4,3%

Table 3. Sample residence characteristics

5. MOBILITY DURING THE LOCKDOWN

The average number of times respondents left home to carry out any of the allowed activities during the lockdown was 4.9 per week, and the median value is 2.25.

Considering that the sample is overrepresented in those with age between 45 and 64, and those employed, the real value of mobility during the lockdown will be somehow lower. In any case, that value contrasts with the estimated mobility before the Covid-19 pandemic in the Valencian Region of Spain: average of 2.5 daily trips per person (Generalitat Valenciana, 2018). Therefore, the mobility during the lockdown was approximately half than before. This is in line with the study carried out by Ministerio de Transportes in Spain using cellphone data (MITMA, 2020), who reported reductions between 40% and 53% of vehxkm on the weekdays of the second half of March 2020.

Mobility during the lockdown was a slightly higher for men than for women and increased with age. Men left home a median value of 2.5 times per week, and women 2.25 times per week. On the other hand, those with age less than 26 presented the lowest mobility, leaving home only 1.5 times per week. Respondents between 26 and 45 years old left home 2.25 times per week. The highest mobility during the lockdown were performed by those between 46 and 65 years old, who left home 3.0 times per week. And the older respondents presented a mobility during lockdown of 2.0 exits from home per week.

The median value of time spent traveling per week during the lockdown was only 20 minutes for those younger than 26. This value increased to 33 minutes for respondents between 26 and 35 years old, and the value is a slightly higher for those between 26 and 45 years old. Participants between 46 and 55 years old spent the maximum time per week traveling: 58.7 minutes. Those between 56 and 65 years old spent a median value of 55 minutes traveling per week. And those older than 65 spent 38.1 minutes per week during the lockdown.

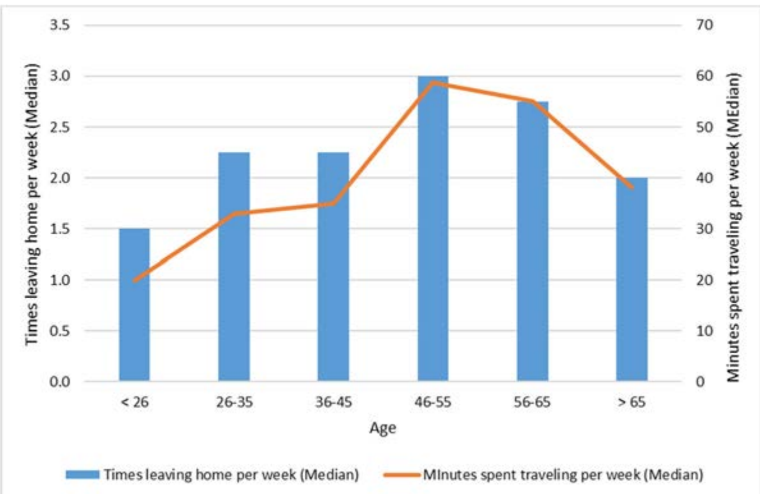

Fig. 1. Degree of mobility during the lockdown by age

The mobility was relatively high for self-employed respondents, who left home a median value of 3,25 times per week. Employed respondents left home 2,5 times per week. Students who also work left home 2 times per week, and students only left home 1,5 times per week. Those who do not work, nor study left home 2 times per week during the lockdown.

Self-employed participants in the study spent the maximum time traveling per week during the lockdown: a media value of 90 minutes. Employed respondents spent a much lower amount of time traveling per week: 45 minutes. Those who studied and were employed part-time spent 25 minutes per week traveling. Students spent the minimum amount of time traveling per week during the lockdown: a median value of 24.3 minutes.

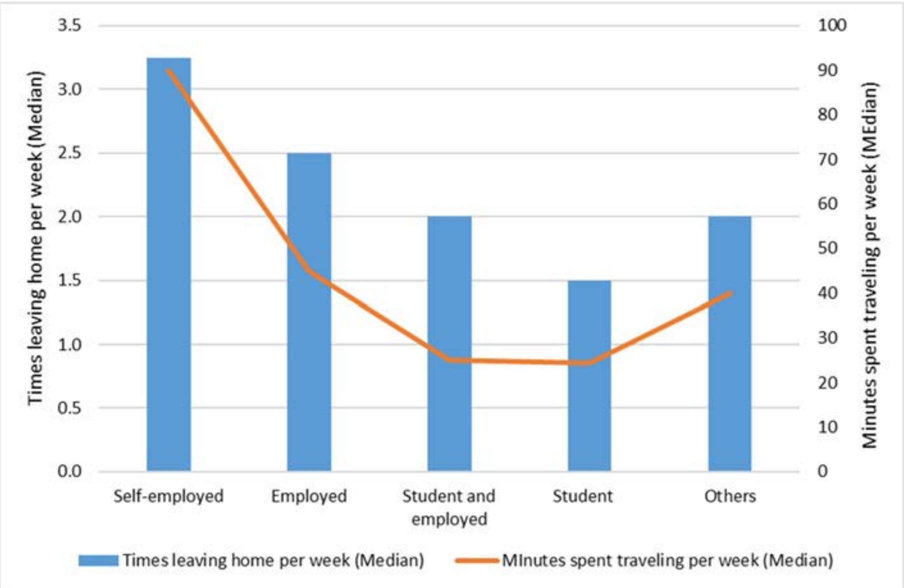

Fig. 2. Mobility during the lockdown by occupation

The travel mode most used when the participants of the study exit from home during the lockdown was walking: the percentage of walking was 77.5%. The second travel mode more used was car, but with only 18.9% of all times respondents left home. The rest of travel modes was hardly used: public transport (2.0%), Bicycle (0.8%), Others (0.8%). It is important to note that almost half of the individuals 849.2%) in the sample only walked when exit from home during the lockdown. In the case of those who used car, 29.7% did not used other travel mode.

Women walked a little bit more than men when leaving home during the lockdown (FIG 4). They also used less the car. Public transport was used by 3% of males, but only by 1% of females.

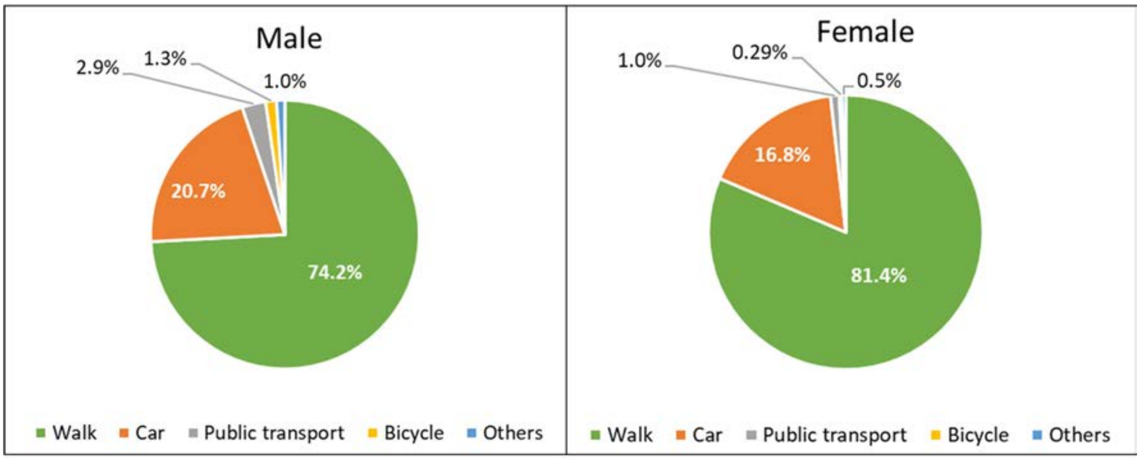

Fig. 3. Travel mode used by gender

The high percentage of walking is due to the consideration of home exits for walking the dog, an out-door activity allowed during the lockdown: more half of the number of times respondents left home walking was to take their dog for a walk (53.3%). The second most important motive for exit home walking is grocery shopping (26.7%). On the other hand, when respondents left home using the car during the lockdown was mainly for going to work (46.6%). Grocery shopping (32.3%) and caring others (14.4%) are the following motives to exit home using car in order of importance.

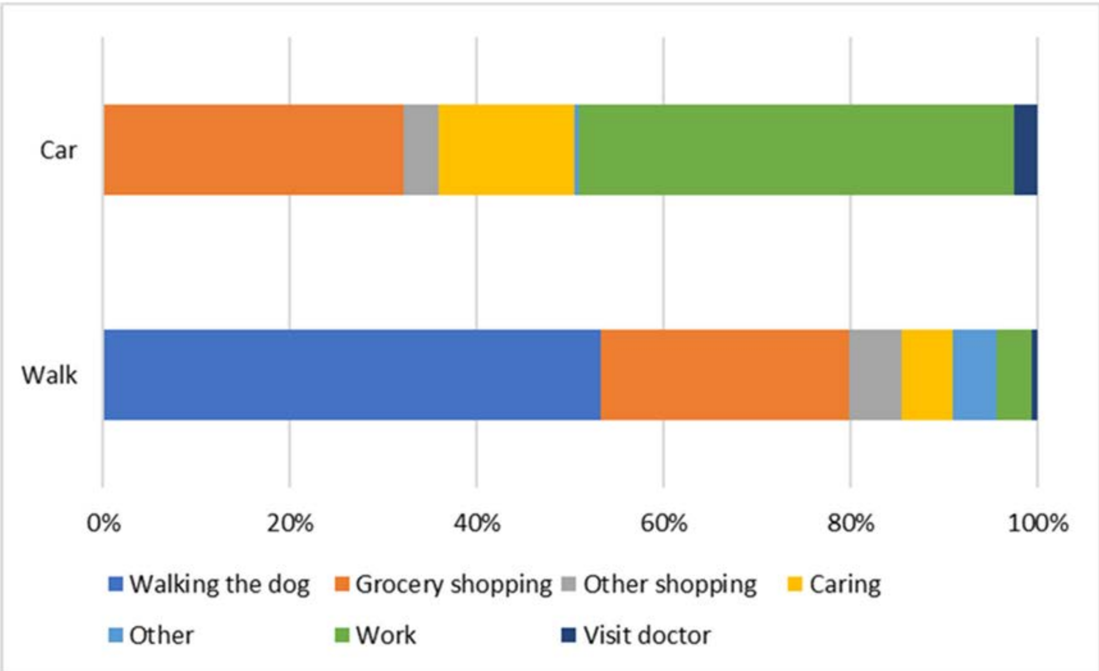

Fig. 4. Motives for leaving home by car and walking during the lockdown

When leaving home during the lockdown, the youngest respondents were those who walk the most (87.9%). In contrast, the walk share of those between 36- and 45-years is 69.8%.

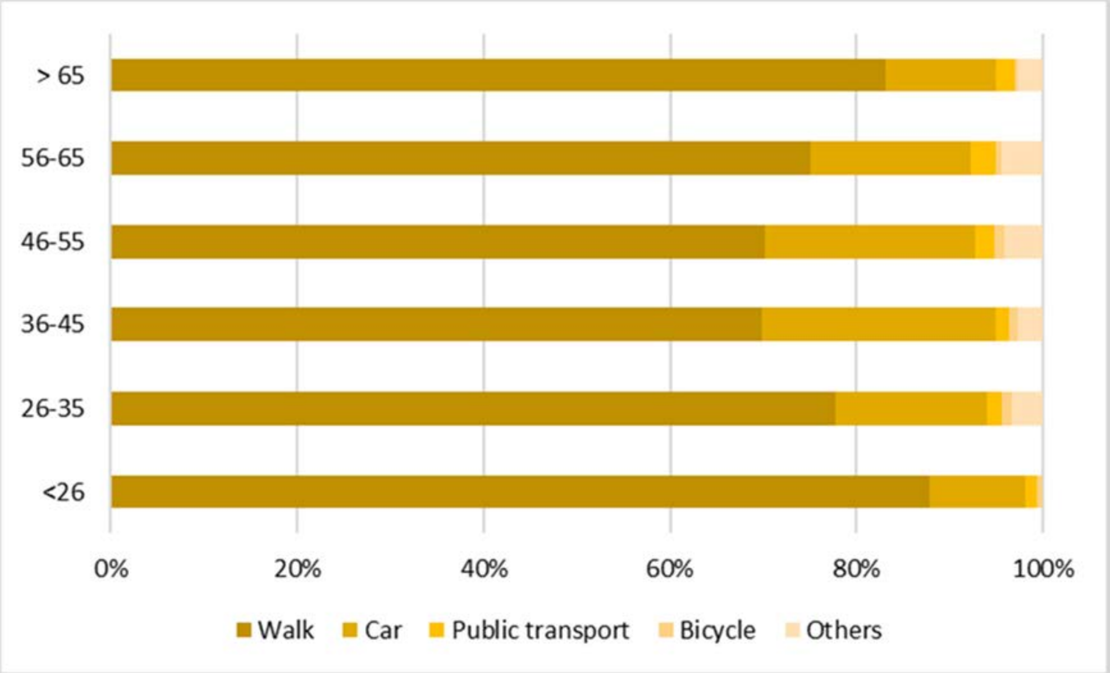

Fig. 5. Travel mode used by age

Mann-Whitney tests are used to find statistically significant differences among median values of PWB variables and Positive and Negative affect according to the characteristics of mobility during the lockdown.

Those who had a low degree of mobility during the lockdown (a median value of times leaving home per week lower than 1.25), and a percentage of walking higher than 66%, present statistically significant higher values of Positive affect (Z=-1.998, Sig=0.046) and lower values of Negative affect (Z=-2.139, Sig=0.032) than those with a percentage of walking between 33% and 66%.

On the other hand, participants who had a high degree of mobility during the lockdown (a median value of times leaving home per week between 2.25 and 6.00) and a low percentage of walking, present statistically significant higher values of Competence satisfaction (Z=-2.523, Sig=0.012) and lower values of Competence frustration (Z=-1.990, Sig=0.047) than those with a percentage of walking higher than 66%.

Similarly, respondents who had a very high degree of mobility during the lockdown (a median value of times leaving home per week higher than 6.0) and a percentage of walking between 33% and 66%, present statistically significant higher values of Positive affect (Z=-2.353, Sig=0.019) than those with a percentage of walking higher than 66%.

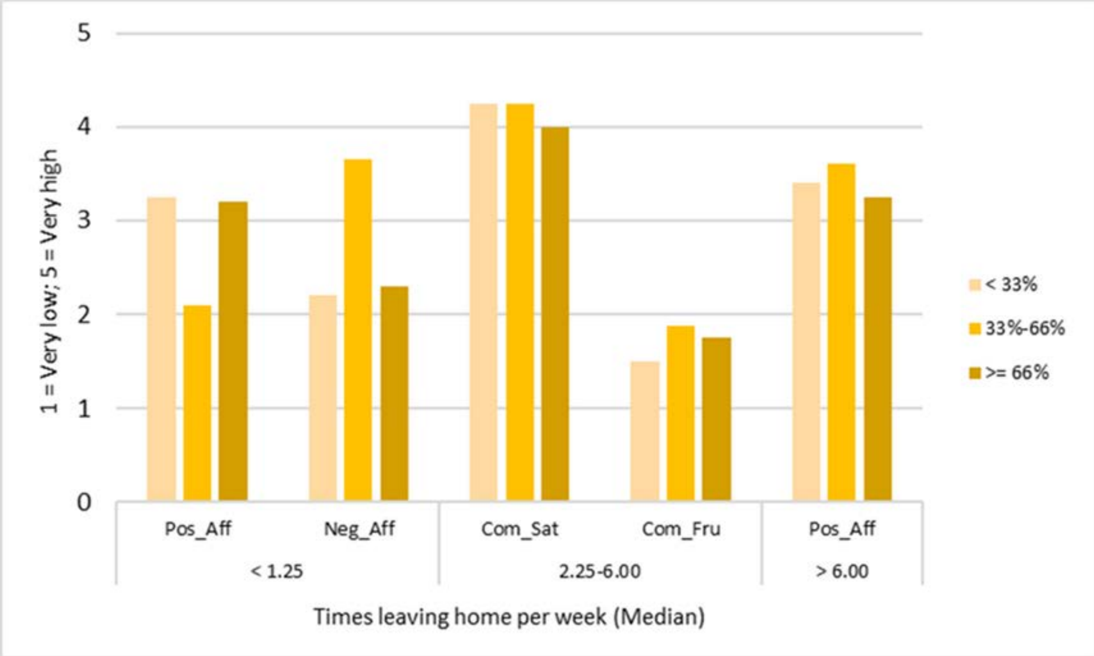

Fig 6. Significant differences of PWB indicators and Positive affect by degree of mobility and % of walking during the lockdown

Those who had a high degree of mobility during the lockdown and a low percentage of car use, present statistically significant lower values of Competence satisfaction (Z=-2.257, Sig=0.024) and Positive affect (Z=-2.289, Sig=0.022) than those with the higher percentage of car use.

Respondents who had a very high degree of mobility during the lockdown and a low percentage of car use, present a statistically significant lower values of Competence satisfaction (Z=-2.616, Sig=0.009) and Positive affect (Z=-3.961, Sig=0.000) than those who use the car between 33% and 66% when leaving home. They also have statistically significant higher values of Negative affect (Z=-2.206, Sig=0.027) than those with higher percentage of car use.

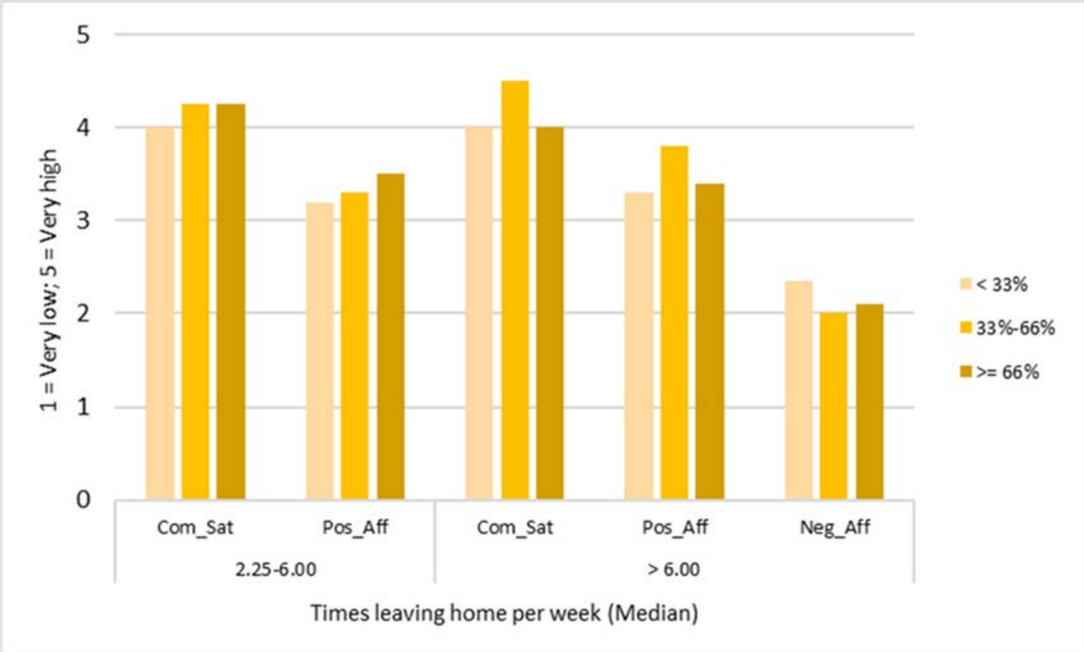

Fig 7. Significant differences of PWB indicators and Positive and Negative affect by degree of mobility and % of car use during the lockdown

Respondents who only walked when leaving home during the lockdown (n=899) present statistically significant lower values of Competence satisfaction (Z=-3.201, Sig=0.001) and Positive affect (Z=-2.215, Sig=0.027) than those who only used car (n=208). They also present statistically significant higher values of Competence frustration (Z=-2.817, Sig=0.005).

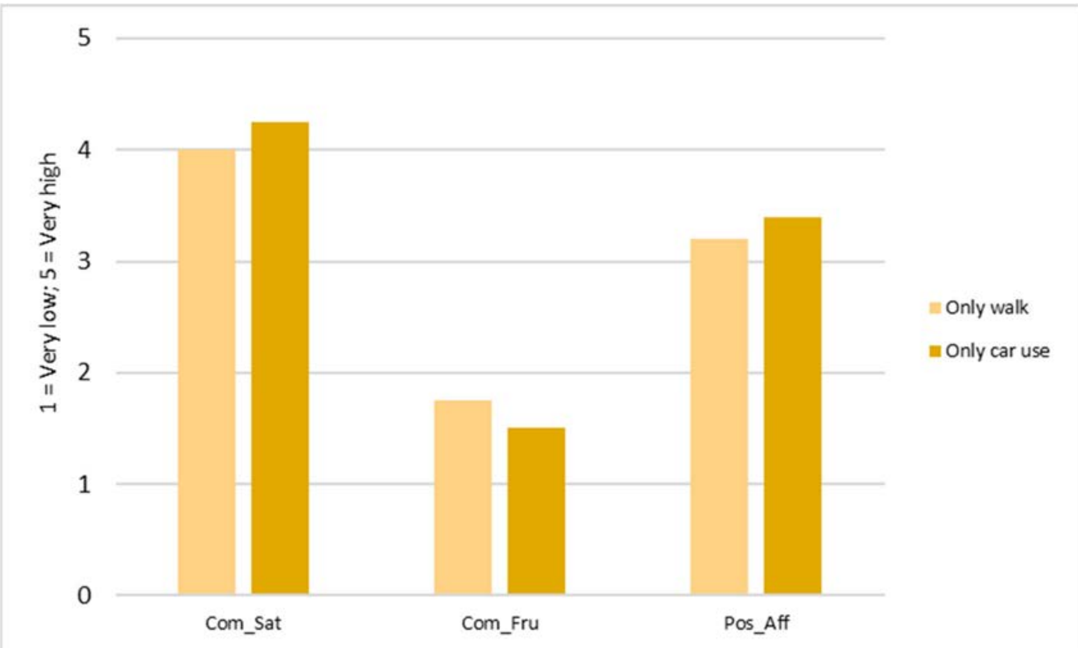

Fig 8. Significant differences of PWB indicators and Positive affect by only walkers versus only car users during the lockdown

Male respondents who only walked when leaving home during the lockdown (n=399) present a statistically significant lower competence satisfaction (Z=-2.506, Sig=0.012) than those who only used the car (n=199). Coherently, male only-walkers present higher competence frustration (Z=-2.995, Sig=0.003) than male only-car users.

Those between 25 and 44 years of age and only walked when leaving home during the lockdown (n=476) present a statistically significant higher competence frustration (Z=-2.672, Sig=0.008) than those who only used the car (n=83). On the other hand, respondents with 65 years old or more who only walked (n=476) present a lower relatedness frustration (Z=-2.272, Sig=0.023) than those who only used the car (n=83).

Self-employed respondents who only walked (n=40) present a higher competence frustration (Z=-2.190, Sig=0.028) and lower positive affect (Z=-2.177, Sig=0.029) than their only car users' counterparts.

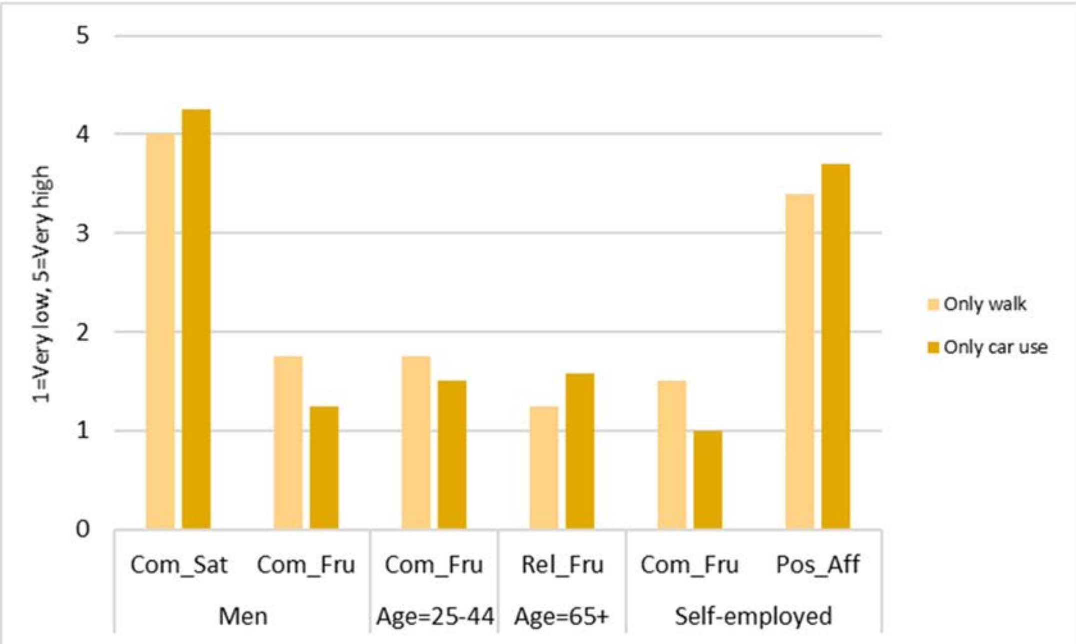

Fig 9. Significant differences of PWB indicators and positive affect of only walkers versus only car users during the lockdown by sociodemographics

Those living in an apartment who only walked when leaving home during the lockdown (n=769) present a statistically significant lower competence satisfaction (Z=-2.520, Sig=.012), and higher competence frustration (Z=-2.468, Sig=0.014) than those who only used the car (n=98).

Similarly, respondents who lived in attached or semi-detached houses with garden and private open-air space and only walked (n=70) present lower competence satisfaction (Z=-2.278, Sig=0.023) and higher competence frustration (Z=-2.780, Sig=0.005) than those who only used the car (n=88).

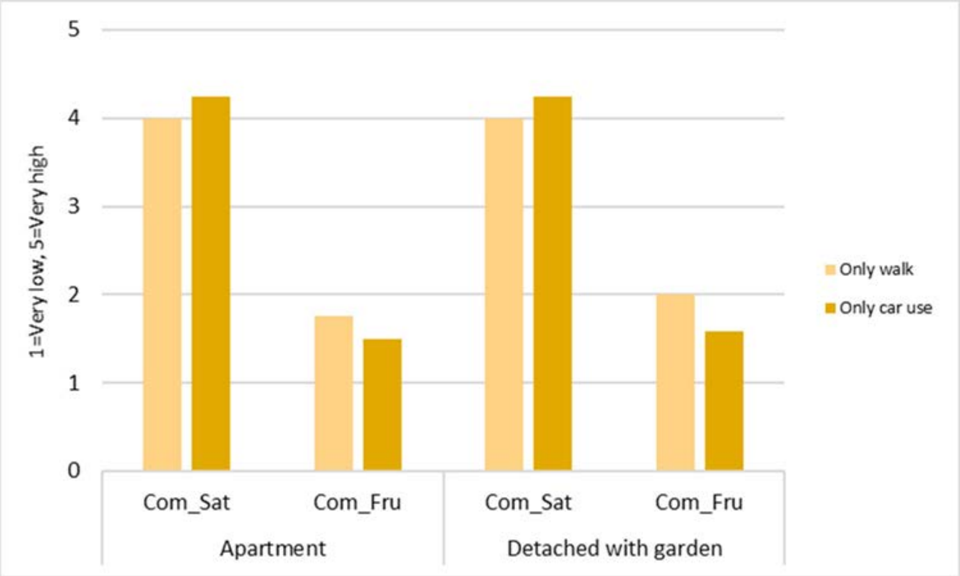

Fig 10. Significant differences of PWB indicators and positive affect of only walkers versus only car users during the lockdown by type of housing

Respondents living in 2-member households who only walked when leaving home during the lockdown (n=314) present a statistically significant a higher competence frustration (Z=-2.201, Sig=0.028) than those who only used the car. Logically, those living in 4-member households who only walked (n=173) present a lower competence satisfaction (Z=-2.448, Sig=0.014) than those who only used the car. And those living in 5+-member households who only walked (n=57) present a lower relatedness satisfaction (Z=-2.075, Sig=0.038) than those who only used the car.

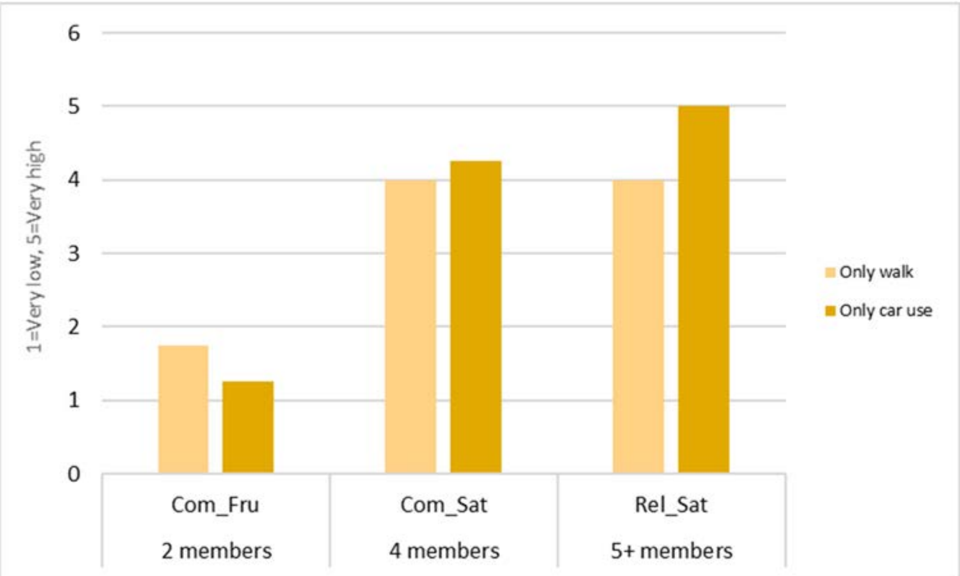

Fig 11. Significant differences of PWB indicators and positive affect of only walkers versus only car users during the lockdown by household size

Those living in the suburbs of a big city who only walked when leaving home during the lockdown (n=219) present a statistically significant lower competence satisfaction (Z=-2.070, Sig=0.038) and higher competence frustration (Z=-2.803, Sig=0.005) than those who only used the car. Respondents living in mid-size cities and only walked (n=161) present a higher competence frustration (Z=-2.490, Sig=0.013) than those who only used the car.

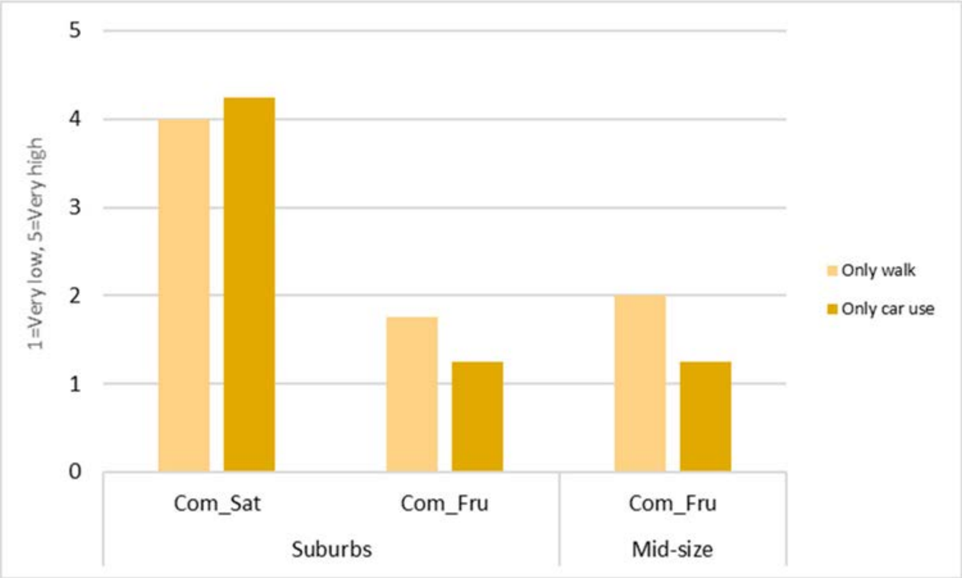

Fig 12. Significant differences of PWB indicators and positive affect of only walkers versus only car users during the lockdown by home location

6. CONCLUSIONS

This paper presents a study of wellbeing of people during the lockdown of March and April 2020 cause by the Covid-19 pandemic in the Valencian Region of Spain. Descriptive and confirmatory analyses are used to study the influence of sociodemographic characteristics of the participants in the research and their mobility attributes on their satisfaction and frustration of basic psychological needs and positive and negative affect.

Mobility was characterized by the percentage of walking and car use when leaving home during the lockdown. For those with a higher the percentage of walking present a lower competence satisfaction and a higher the competence frustration. Moreover, those with the highest degree of mobility during the lockdown and a percentage of walking between 33% and 66% present statistically significant higher values of positive affect than those with a percentage of walking higher than 66%. Only those with a low degree of mobility during the lockdown present statistically significant higher values of positive affect and lower values of negative affect when walking more. These results contrast with the findings related to walking and SWB elsewhere.

During the lockdown people felt more insecure when walking because of the possibility of contagion, which was amplified in urban areas with insufficient pedestrian infrastructure. Besides, walking along complete empty streets increase the sense of insecure (Ferrer et al., 2015).

Some statistically significant differences are found when considering the percentage of car use. Results from the Mann-Whitney test reveal that the more car use, the better the feel in terms of competence satisfaction and positive affect, and present lower values of negative affect. Using car during the lockdown was perceived by people as more secure. During the first weeks of the lockdown, authorities recommended to use private vehicles to those that had to leave home. This fact emphasized the sense of security associated with car, but deteriorated the health security perception of public transport, which persist until today.

Using a subsample of those who only walked or only used car when leaving home during the lockdown, Mann-Whitney tests confirm previous findings: those who only walked felt somewhat worse than those who only used car in terms of competence satisfaction, positive affect and relatedness satisfaction. In particular, men, those living in apartments and attached or semi-detached houses with gardens, those living in 4-member households and those living in the suburbs of big cities, present lower competence satisfaction and higher competence frustration if they only walked. Those self-employed who only walked present lower positive affect. And those living in 5+-member households who only walked present lower relatedness satisfaction. Many people who only walked when leaving home during the lockdown were not used to do it, and they had to walk threaten by the pandemic.

On the other hand, most of those who only drove just kept doing the same thing than before but with the sense of being safer from contagion.

Despite the participants in the research walked a lot during the lockdown, results of this study indicate that those who walked more and those who only walked when leaving home felt somewhat worse compared with those who only used car. There is a need to improve pedestrian infrastructures to provide enough space for people to walk, considering not only the level of service but also health security, which is a factor that should be considered in all transportation planning studies from now on.

ANALYSIS OF UNIVERSAL ACCESSIBILITY AT PUBLIC TRANSPORT STOPS IN THE CITY OF CÁCERES

Montaña Jiménez-Espada
Department of Construction, School of Technology, University of Extremadura
Rafael González-Escobar
Department of Construction, School of Technology, University of Extremadura

ABSTRACT

When dealing with the problems of urban transport, in many cases only the supply and demand, number of users and urban design are analysed, i.e. aspects that influence the operational functioning of the concession of this public service.

The study proposed in this article aims to analyse the situation of public transport stops in the city of Cáceres following the criteria required by current legislation on universal accessibility, trying to identify the architectural barriers encountered by users of the service who have some physical limitation.

Once the existing regulations have been evaluated and the technical requirements to be met have been defined, a critical study of compliance with the legislation in force at the existing bus stops is carried out. Subsequently, solutions are provided in the event of non-compliance in order to solve the adaptation of urban transport in terms of accessibility and the proposal of specific solutions for improvement in various areas under study is formulated. In addition, the main operational problems detected in the accessibility infrastructures for this means of transport are indicated.

After analysing the problems presented by the network of public urban transport stops, it could be pointed out that most of them are the result of a lack of coordination between the general urban development plan and the mobility plan, which prevents the adequate provision of public services.

1. INTRODUCTION AND OBJECTIVES

The city of Cáceres is a medium-sized municipality with deep-rooted habits, one of which is the use of private vehicles for daily commuting and also for mobility from the outskirts to the city centre, which until now has allowed free surface parking, unintentionally facilitating an increase in the use of private vehicles. According to the Infrastructure Plan for Sustainable Urban Mobility (PIMUS) of Cáceres approved in 2014, 55% of the overall mobility of the municipality is carried out by private vehicle.

In this sense, in comparison with other Spanish cities of similar average size, the use of soft modes of transport is low, which can be attributed mainly to two aspects: 1) the topographical conditions of the city and 2) the behaviour of the user who opts for motorised mobility as an indicator of their quality of life.

In relation to public transport, which represents a small percentage of the total number of journeys made by residents in Cáceres (around 9%), the Local Administration is working to increase its share of daily mobility. In order to make the use of public transport more attractive, awareness campaigns are being carried out to promote public transport to the detriment of private transport within the concept of sustainable urban mobility.

The degree of satisfaction shown with the quality of the urban public transport service by users leads to the conclusion that a service is being provided that is adjusted to the particular needs of the city, promoting sustainable mobility and adapting to the economic resources allocated to the financing of this service (Jiménez-Espada, 2016).

A drawback of the current planning and development model of the city of Cáceres is the lack of reserved lanes for public transport, as well as the lack of bans at bus stops, issues that delay the frequency of bus stops, making the use of public transport less attractive and reducing the number of users.

Numerous actions and initiatives have been carried out in the field of universal accessibility, which have been recognised with the following awards: Queen Sofia Accessibility Award 2012 (a distinction that recognises those city councils that stand out for their ongoing work in the field of universal accessibility for people with disabilities) and the Best Accessible Tourism Destination Award 2014 in Spain (promoted by the company ThyssenKrupp, which recognises the efforts of institutions to eliminate architectural barriers and the fight for equality for people with disabilities). To date, there is still much work to be done in Cáceres to achieve universal accessibility for people with reduced mobility.

In (Fernández-Nicolás, 2019), the current urban accessibility in the intramural area of the historic centre of the city of Cáceres is addressed, setting out actions carried out and proposals for future interventions presented to the competent bodies for approval, applying a model for the promotion of urban accessibility to try to achieve tangible universal accessibility for all types of users, sometimes very limited by the existing conditions but which, even without reaching regulatory compliance, could undoubtedly improve the critical points detected.

In urban transport, accessibility depends on the distance and ease of travel from the home to the interchange point and from there to the final destination, including access on the way up and down, as well as the planning of the overall route.

Making public bus transport more attractive and increasing the quality of the service in terms of accessibility can have a positive effect on the main actors involved:

1) For disabled people and people with reduced mobility, who will directly benefit from the improved accessibility of buses. Accessible public transport offers a greater degree of safety for these users.
2) For the service concessionaires, who, by increasing the number of potential users, will improve their bottom line; an adapted bus with accessibility systems (ramp, low floor, etc.) will give security and confidence to people with disabilities, enabling them to shorten boarding and alighting times. In general, there will be greater efficiency in the management of services, which will benefit the companies' objectives.
3) For society as a whole, which will see a general improvement in public transport; this will attract a greater number of users who, in many cases, will abandon the car, helping to increase the environmental quality of the city by reducing pollution, traffic congestion and accidents. Accessible transport ensures safe and comfortable access for all passengers (Vega, 2006).

Transport will be accessible when it allows people to meet their travel needs independently. To achieve this, stations or stops must have the appropriate characteristics to enable all people with disabilities, both physical and sensory, to travel. In addition, vehicles must have the necessary design conditions and technical solutions to allow communication between all persons.

The idea of accessibility and the way it has been promoted by the different public administrations over the last two decades has come to be best expressed in the form of new concepts and approaches such as Design for All or Universal Design and Integrated Accessibility (Alonso, 2002).

The aim of the study proposed in this article is to analyse the situation of public transport stops in the city of Cáceres in accordance with the criteria required by current legislation on universal accessibility and to offer solutions to the existing problems in the event of non-compliance in order to solve the problem of adapting urban transport in terms of accessibility.

2. ACCESSIBILITY IN PUBLIC TRANSPORT

2.1 The bus network in the city of Cáceres

The city of Cáceres has a population of 96,126 inhabitants, according to the latest data consulted at the National Statistics Institute (INE). The municipality has three districts: Rincón de Ballesteros, Valdesalor and Estación Arroyo-Malpartida, which are also served by the city bus. The company SUBUS (belonging to the VECTALIA group), is the concessionaire of the public passenger transport service in the city. It currently has a fleet of 37 vehicles (29 conventional 12-metre buses, 6 articulated 18-metre buses and 2 minibuses). All buses have a low floor, kneeling system (kneeling) and manual ramp. In addition, two thirds of the bus fleet has a double electric ramp, which is backed up by a manual ramp in the event of a breakdown.

The current bus service in the city of Cáceres has a total of 218 bus stops, distributed around 12 regular lines and 2 occasional lines. Of the 218 existing public transport stops, only 138 of them have a bus shelter.

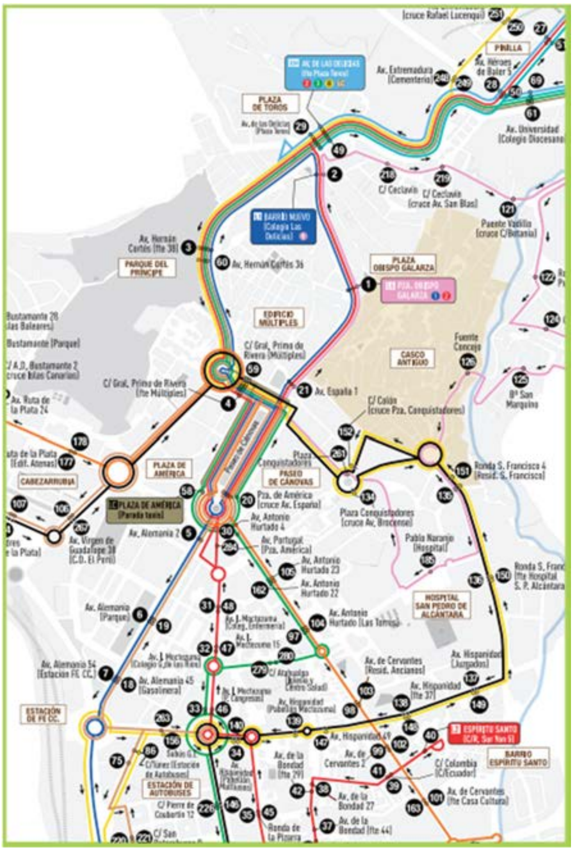

Fig. 1 – Network of bus lines in the city centre (SUBUS, 2020)

With regard to the number of users of this service, it should be noted that in recent years there has been an overall increase in passengers on the lines, which may be due, among other factors, to the management carried out by the representatives of the local administration, who have made a firm commitment to campaigns to publicise the benefits of public transport and have worked in coordination with the concessionary company to implement improvements to the service.

In this regard, efforts have been directed towards modernising and upgrading the urban transport service by contemplating the following measures:

1) Implementation of operating aid systems (SAE) to know the waiting time, mobile applications, recharging of vouchers via internet, installation of USB connections for charging mobile devices on board.
2) Increase in the number of vehicles in the fleet and their integral renovation, as well as the restructuring of lines and the construction of a new city bus station in the city centre.
3) Modification of fares and creation of new types of transport tickets (combined ticket, vouchers for large families, IMAS (Municipal Institute of Social Affairs) social vouchers).

Figure 2 shows the evolution of urban transport passengers over the last 6 years in the city, showing a gradual increase of users using the bus from 2015 to 2019, gaining 355,115 passengers, an increase of just over 8% in 5 years. However, in 2020, ridership plummeted due to the COVID-19 pandemic, with a decrease in ridership of almost 40% compared to 2020.

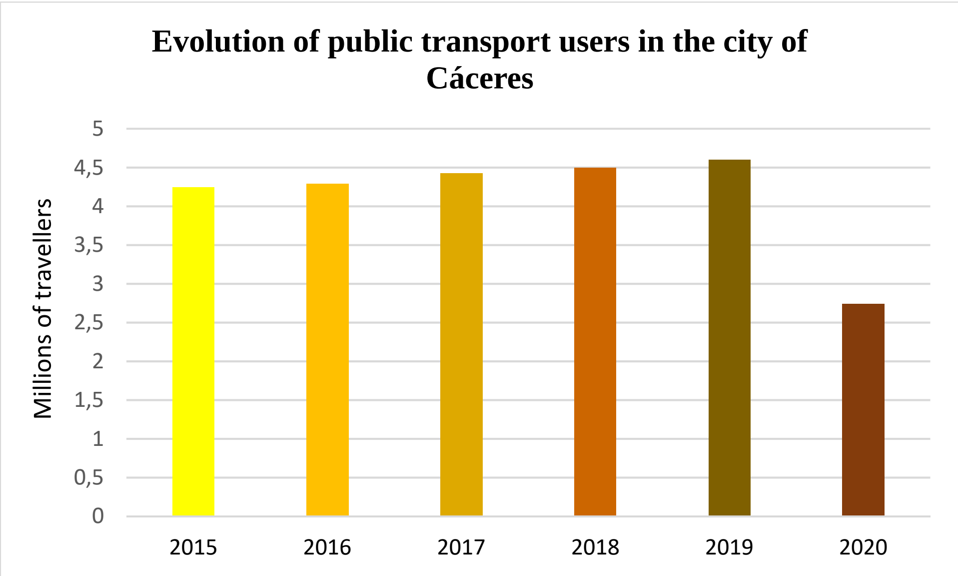

Fig. 2 – Bus passenger registration in Cáceres

2.2 Accessibility issues

According to the Green Paper (Alonso, 2002), the main accessibility problems in urban buses are: the relationship between the pavement and the vehicle, as well as the availability of easy and comfortable boarding systems for all types of users. In addition, other aspects are mentioned such as: space, layout and anchorages for wheelchairs or pushchairs in the vehicles. As basic accessibility indicators, the number of low-floor buses and their proportion of the total are used, and as support indicators, the number of vehicles with ramps and kneeling systems in use and their proportion of the total. In addition, in (Alonso, 2003) White Paper, a series of social and institutional aspects are included, such as: driver training, child buggy access rules and traffic discipline.

The key factors of universal accessibility in transport are usually considered around 4 lines of work: infrastructure, rolling stock, the link between the two and the provision of the service. The guarantee of accessible mobility through public transport is based on the achievement of and compliance with the accessibility conditions set for each of the spaces and moments in the passenger mobility chain. In order to facilitate universal accessibility in rolling stock, (Álvarez, 2011) proposes buses with a low floor and tilting systems for the vehicle that, together with the deployment of small mobile ramps, make it possible to overcome the almost inevitable differences in level with the environment. Buses depend both on the human factor (drivers) and on external factors such as improper parking of vehicles in the vicinity of stops, which make it difficult for the vehicle to get as close to the stop as possible.

Urban transport systems have specific accessibility needs that are determined by the characteristics of these modes of transport, in which there is a large influx of passengers and a frequency that determines the stopping time. These services meet the mobility needs of a population centre and have pre-established routes, subject to specific timetables. They are characterised by seating and standing room and frequent stops. Stops and bus shelters must be accessible to people with reduced mobility and have accessible equipment and furniture (Díaz, 2018). In addition, it is necessary to ensure access to the vehicle by means of low floors, platform lifts, drop-down ramps and kneeling systems. The driving of the vehicle is also important when it comes to guaranteeing the safety of users, who must drive at the appropriate speed for each type of road and avoid driving abruptly. Inside the vehicle there must be spaces reserved for wheelchair users with their corresponding anchorages and safety belts. Likewise, spaces must be reserved for people with reduced mobility.

As indicated in (Alonso, 2010), bus shelters must have information corresponding to the identification, name and route diagram of the lines, as well as a screen that informs users of the location and incidents of the buses on the lines corresponding to that stop.

In Europe, since the early 1990s, the use of low-floor buses on urban transport routes has become widespread (Dols and Vázquez, 2016). According to the information provided in the latest report of the Metropolitan Mobility Observatory (Monzón et al., 2019), it can be said that all of the 14 urban public transport lines in the city of Cáceres have a fleet of buses fully accessible for people with reduced mobility (PRM), the bus being the most accessible means of urban transport for this group, with 100% coverage in operating assistance systems (SAE) and e-ticketing and 10 stops with real-time information panels.

However, public transport stops should be equipped with shelters and perfectly delimited, which in practice is not the case in the vast majority of cases. This fact leads to the appearance of badly parked vehicles that prevent the bus from approaching the bus properly for the boarding and alighting of passengers with reduced mobility and the deployment of the access ramp.

In order to assess the degree of accessibility at public transport stops in the city of Cáceres, the considerations of Royal Decree 1544/2007 are used, whose scope of application in urban buses extends to: stops and rolling stock (vehicles for collective urban transport and with a capacity of more than nine seats, including the driver).

This regulation states that public transport stops and waiting shelters shall be connected to the accessible pedestrian route (IPA) and shall not encroach on it, establishing basic conditions for accessibility in urban transport.

3. RESULTS AND DISCUSSION

The aim of the study proposed in this article is to improve universal accessibility at regular public transport bus stops in the city of Cáceres. In this chapter, taking as a reference the existing regulations that define the technical requirements to be met, a critical study of compliance with the legislation in force (Royal Decree 1544/2007) of all existing bus stops is carried out. Subsequently, solutions are provided in case of non-compliance in order to solve the adequacy of urban transport in terms of accessibility and the proposal of specific solutions for improvement in various areas under study is formulated. In addition, the main operational problems detected in the access infrastructures to this means of transport will be pointed out.

3.1 Bus stops with operational problems

Taking as a reference the regulatory development of RD 1544/2007, of the 218 bus stops currently in service in the city of Cáceres, problems have been detected in 91 of them in terms of universal accessibility, and an inventory has been drawn up, in which the deficiencies are defined on the basis of a series of criteria that help to detect and recognise them.

In the 91 public transport stops analysed, the main errors detected were summarised according to the source of the problem. Thus, the main difficulties were as follows:

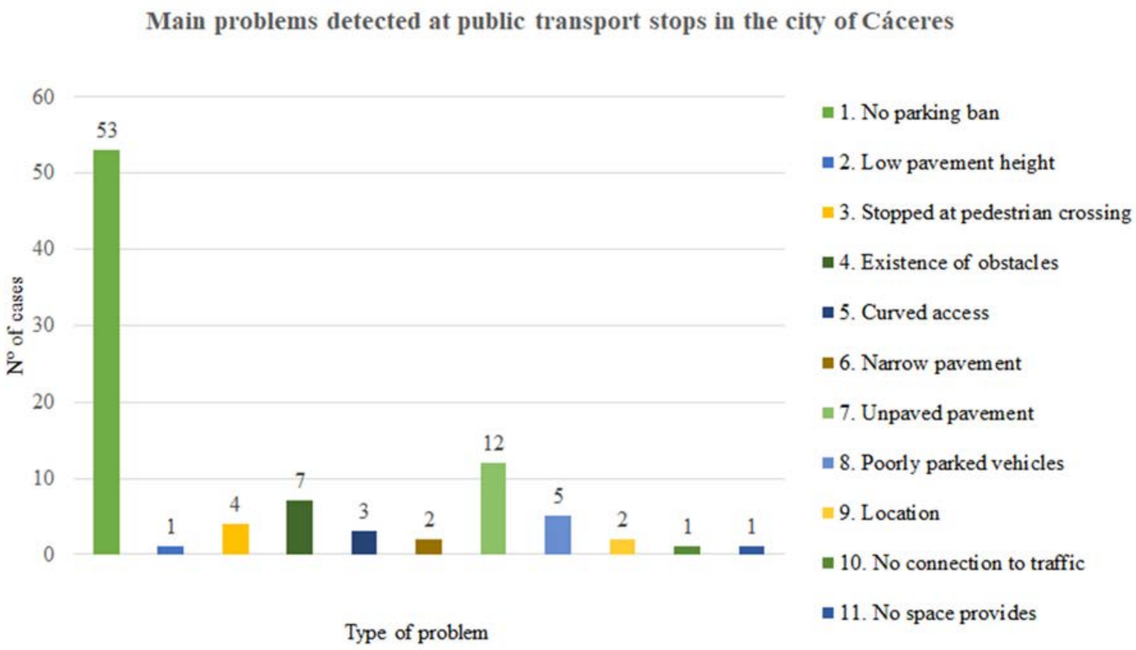

Fig. 3 – Type of problem

The most frequently repeated problem is the lack of parking bans (58% of cases) or, if they exist, they are not correctly signposted. The study shows that a large part of the non-compliances found are due to a lack of planning, as a result of the successive extensions of the network itself in order to solve the problems that have arisen over time in each neighbourhood.

3.2 Proposals for change to improve bus accessibility for people with disabilities

Next, corrective measures are proposed for some specific stops with operational problems of the kind described above, in an attempt to provide standard solutions that can make these stops viable from the accessibility point of view.

By resolving each type of difficulty, the door is opened to propose standard solutions, with the aim of improving journey times and line frequencies, quantitatively reducing the boarding and alighting times of users, thus improving the quality of the service offered to these potential passengers with accessibility problems.

Fig. 4 – Problems type 1, 2, 3

The picture above shows problem typologies 1, 2 and 3. The photograph on the left shows a stop on the university campus with no parking ban for private vehicles, which means that this space is not usually available for buses to approach. It is proposed that the corresponding vertical and horizontal signage be installed to identify the space reserved for public transport. The central image shows a common problem in many cities: the pavement is not high enough for the bus to kneel down. In this case, it is proposed to increase the height of the pavement to 20 cm by means of an anti-slip pavement. The photograph on the right (at 54 Bondad Avenue) shows an undesirable image, the bus stop is located in the middle of a pedestrian crossing. It is felt that it would be appropriate to dispense with the two adjacent parking spaces, widening the pavement in that area and moving the bus shelter away from the zebra crossing and allowing pedestrians to move freely.

Fig. 5 – Problems type 4, 5, 6

The previous figure on the left shows the impossibility of approaching urban transport to the pavement, which is not accessible to people with reduced mobility. The problem is solved by raising the raised kerb to the edge of the road, gaining the necessary area for the location of the stop, which is connected to the pedestrian route by means of a small ramp.

The central image shows that the public transport access is curved. In order to allow the correct approach of the bus, parking is prohibited in the adjacent area, which provides extra space for the vehicle's turning manoeuvre. In the upper right image, a pavement is evaluated that does not comply with the regulations (it is less than 120 cm wide) and does not have a connection for people with reduced mobility. The proposed redefinition of the stop consists of widening the pavement by building a much wider cantilevered platform that connects to the lower level by means of an accessible ramp.

Fig. 6 – Problems type 7, 8, 9

The top left image shows a green area between the pavement and the road, making it impossible for a person with reduced mobility to access the bus. To solve the problem, the pavement should be extended to the edge of the road, thus creating a platform that would allow guaranteed access to urban transport. The central image shows a common inconvenience at bus stops, the indiscipline of the private vehicle driver. The construction of a raised reserved area extending from the pavement to the road would solve the problem. On the other hand, the upper right image shows an example of a poor location of a bus stop immediately after a curve and without a pedestrian crossing nearby, the solution to which is to move it just before the curve (in a straight area), allowing the construction of a bus shelter before a pedestrian crossing.

Fig. 7 – Problems type 10, 11

Figure 7, left-hand side, shows a disconnection with traffic, which could be solved by completing the pavement in the stop area and moving the bus shelter to the centre of this area. On the right-hand side of the image there is no space specifically designated for public transport stops. A rearrangement of the area is proposed, defining an entrance area where the minibus providing the service can stop and turn around by means of a semi-curve. In this way, the bus will not stop in the middle of the street and there will be an area for pedestrians from which the bus can be properly accessed.

Incorrect parking at zebra crossings or bus stops is reduced when there are accessibility features such as low thresholds or platforms. Therefore, it is of particular importance to carry out all those adaptation works at public transport stops that improve accessibility in compliance with the guidelines of RD1544/007.

There are people with reduced mobility who decide to buy non-approved electric scooters to be able to use public transport and who subsequently find that their mobility is reduced because they are unable to use this type of vehicle on the bus. It would be advisable to carry out public information campaigns on accessibility systems on buses.

4. CONCLUSIONS

For the correct development of this work, regular urban passenger transport in the city of Cáceres has been analysed and, specifically, the situation regarding the accessibility of the bus stop network.
Firstly, the conditions of access to public transport stops have been assessed, a service that currently has a total of 218 stops.

Based on the universal accessibility regulations applicable to urban passenger transport (RD 1544/2007), 91 stops have been identified as having accessibility problems for people with reduced mobility and an inventory of these has been carried out, identifying 11 common problems.

Subsequently, corrective measures have been provided for some specific stops that have been adopted as examples and that presented different problems in order to make them accessible.

Having analysed the problems with the network of urban public transport stops in the city of Cáceres, it could be said that most of them are the result of a lack of foresight of new needs, and that they could have been avoided by planning the network in parallel with the development of the new neighbourhoods that have generated these needs.

RESUMEN

En noviembre de 2018, se puso en marcha Madrid Central, una zona de bajas emisiones en la ciudad que tiene como objetivo favorecer al peatón, la bicicleta y el transporte público, limitando el acceso de una gran parte del parque de vehículos privados, en una superficie de 472 ha. La medida ha resultado ser de gran relevancia para la opinión pública y se espera que haya modificado de manera sustancial los patrones de movilidad en el centro de Madrid y sus alrededores.

El objetivo de este trabajo es estudiar los cambios producidos en el tráfico por la implantación de Madrid Central, tanto dentro del perímetro de la zona de bajas emisiones como en su área de influencia, y analizar si existen tendencias que correlacionen con variables socioeconómicas de la ciudad o tendencias espaciotemporales. Para lograr este objetivo, se analizan datos públicos de tráfico del Ayuntamiento de Madrid (Sistema Integral de Control de Tráfico de Madrid, SICTRAM).

En concreto, se analiza la intensidad de tráfico, el número de vehículos por hora que circulan por las calles. Se han descargado datos desde enero de 2018 hasta diciembre de 2019, lo que permite realizar un análisis de su evolución temporal y espacial, tanto en el área de bajas emisiones como en los distritos colindantes, y relacionarla con la implantación de Madrid Central.

Asimismo, se analizan variables socioeconómicas de la población directamente afectada por la medida (población y renta anual neta). Este análisis se realiza de manera gráfica, visualizando los resultados espacialmente y temporalmente. Los resultados del análisis muestran una disminución general en el tráfico de la ciudad, aunque esta no se distribuye homogéneamente.

1. INTRODUCCIÓN

Disminuir la contaminación atmosférica en las ciudades es una de los mayores retos ambientales actuales, ya que allí es donde encontramos las mayores densidades de población (Gakidou, 2017; Santiago et al., 2021). La contaminación perjudica seriamente la salud de las personas, aumentando los riesgos de enfermedades respiratorias y cardiovasculares, (Chiusolo et al., 2011; Medina-Ramón, 2006; Santurtún et al., 2017) o el riesgo de cáncer (Vineis et al., 2006). Diferentes ciudades europeas han iniciado acciones para reducir los efectos negativos de la contaminación en los últimos años, como: Berlín, Paris, Viena, *etc*. (Viana et al. 2020). El municipio de Madrid es la ciudad más poblada y con mayor tráfico de España. Existe actualmente una importante preocupación en relación a la calidad del aire y la mejora de la configuración urbana. Con el objetivo de mejorar esta situación, desde el ayuntamiento se han estado poniendo en práctica diferentes medidas de gestión del tráfico. En el año 2004, se comenzaron a implantar en Madrid un nuevo conjunto de restricciones al tráfico para limitar la circulación por diferentes zonas, denominadas Área de Prioridad Residencial (APR), siendo la primera en el Barrio de las Letras (Ayuntamiento de Madrid, 2007). Este proceso de delimitar el tráfico en el centro de la ciudad ha ido incluyendo nuevas zonas hasta culminar con la creación de la zona cero de emisiones de Madrid central el 30 de noviembre de 2018, y siendo el 15 de marzo de 2019 cuando se hizo realmente efectiva, al comenzar las sanciones por incumplir las restricciones impuestas. Las medidas impulsadas buscan priorizar el movimiento peatonal, el uso de la bicicleta, el transporte público y los vehículos eléctricos o de bajas emisiones.

Esta área permanente cumple con los criterios que autores como Laña et al. (2016) proponen como solución para la ciudad de Madrid por sus características. El área limitada coincide aproximadamente con los límites del distrito centro de Madrid (Figura 1).

Entre los objetivos que planteaba el Ayuntamiento de Madrid en el Plan A de Calidad del Aire (Ayuntamiento de Madrid, 2017), se pueden destacar los siguientes: (i) mejorar los niveles de calidad del aire para partículas en suspensión (PM) según las recomendaciones de la OMS (Organización Mundial de la Salud); y (ii) cumplir el compromiso de reducción del 50% de las emisiones causadas por la movilidad urbana en 2030 con respecto a 2012.

Estos objetivos se pueden relacionar directamente con la cantidad de tráfico en la ciudad.

Actualmente, el Plan A de Calidad del Aire, ha sido sustituido por la Estrategia de Calidad Ambiental Madrid 360 (Ayuntamiento de Madrid, 2019a), que amplía en un 15% sus objetivos de reducir las emisiones y añade otras medidas como el servicio de varias líneas de autobús gratuitas.

El impacto de la medida de Madrid Central ha sido estudiado previamente. Salas et al. (2021) se centraron en el análisis de indicadores de los niveles de contaminación: la evolución de las emisiones de NO_2 entre 2015 y 2019); Izquierdo et al. (2020) estudiaron el aumento entre 2012 y 2020 del NO2, PM2.5 y O3, y su correlación con la disminución de muertes relacionadas con la contaminación); y Santiago et al. (2021) investigaron la incidencia de la contaminación en puntos clave de la ciudad, obteniendo unos resultados que relacionan de manera positiva las medidas tomadas con una reducción de la contaminación. Este trabajo complementa estos resultados previos, aportando un enfoque diferente, centrado en la evolución del tráfico el año previo a la implantación del Madrid Central y el año posterior, como se ha realizado previamente en otros trabajos (Vidal, 1990; Gutiérrez y García, 2005).

Fig. 1 – Límite de la zona de cero emisiones de Madrid Central (Elaboración propia a partir de los datos del MTN50)

2. MATERIAL Y MÉTODOS

El Ayuntamiento de Madrid dispone de un dispositivo de muestreo del tráfico (Sistema Integral de Control de Tráfico de Madrid, SICTRAM) donde se recogen los datos de intensidad, carga y ocupación del tráfico, cada 15 minutos desde el año 2013. Se trata de un dispositivo móvil donde las estaciones pueden variar a lo largo de los meses.

Aproximadamente se toman datos en 4500 estaciones de forma mensual.

Para evaluar el impacto de la medida implantada, el análisis se ha centrado en la intensidad de tráfico (vehículos/hora) al ser la variable más relacionada con la calidad del aire y la contaminación acústica de las disponibles en las estaciones de medición del tráfico. En total, se han seleccionado un total de 3561 estaciones de medición, incluidas dentro de la zonificación definida y con datos a lo largo de todo el alcance temporal establecido (Figura 2)

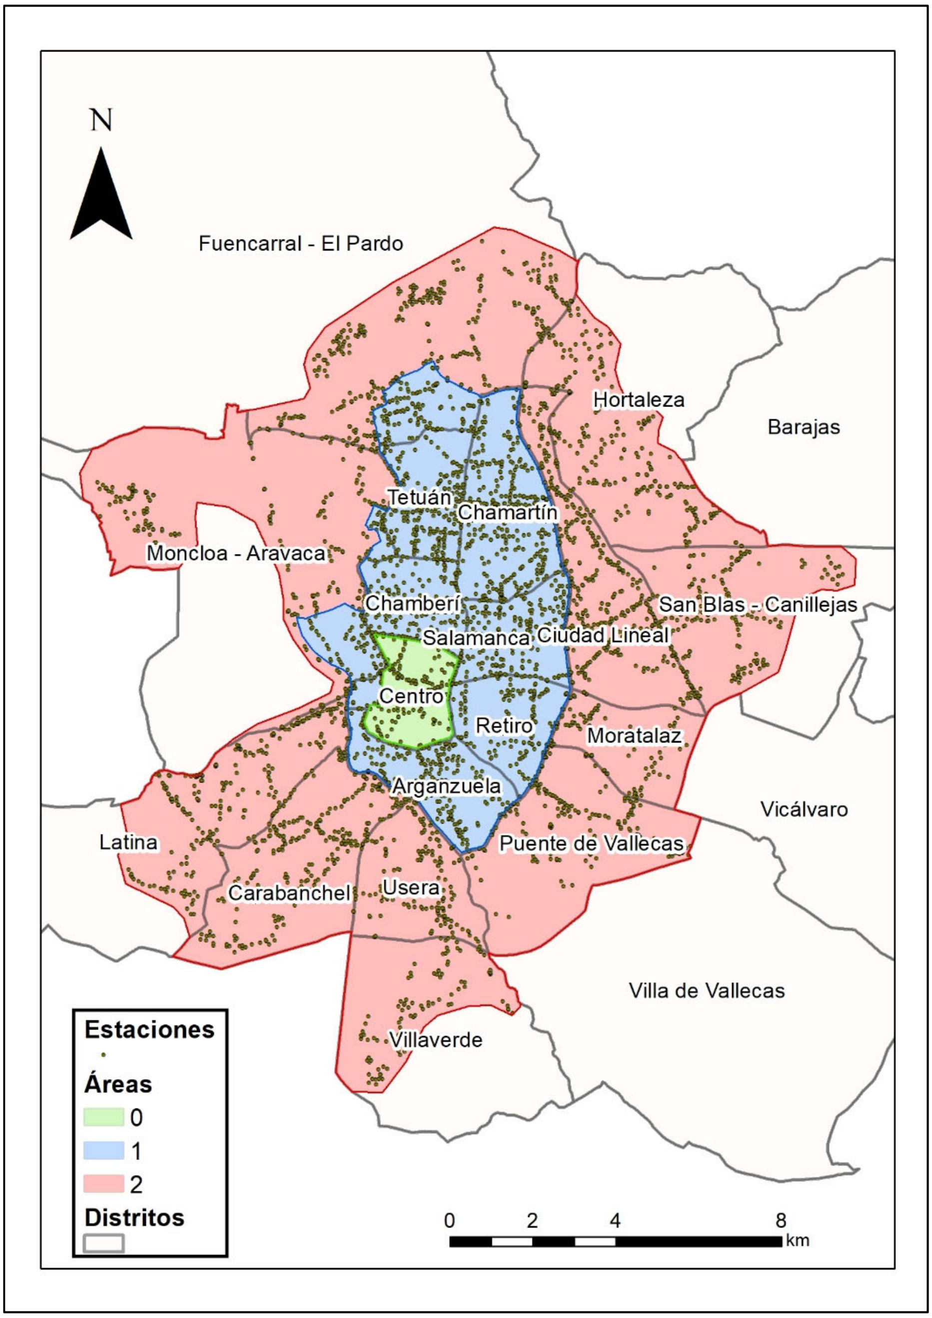

Fig. 2 – Áreas de estudio delimitadas y estaciones de medición del tráfico del SICTRAM seleccionadas en la ciudad de Madrid

2.1 Análisis espaciotemporal de la intensidad de tráfico

Los datos de intensidad de tráfico se han clasificado en función de la posición espacial de las estaciones de medición y la fecha y hora en las que el dato de intensidad se ha tomado. Los datos de intensidad de tráfico han sido promediados de manera conjunta para: cada mes, cada área de estudio, cada distrito y cada franja horaria. Este análisis de datos se ha realizado utilizando un programa desarrollado en los lenguajes de programación de C++ y R.

2.1.1 Análisis espacial

Para visualizar la distribución espacial del impacto de la medida, se han establecido dos divisiones geográficas. Una primera división en tres zonas concéntricas al centro de la ciudad, para estudiar el impacto de la medida por proximidad a la zona cero de emisiones, y una segunda división siguiendo los límites administrativos de los distritos de la ciudad de Madrid.

Las zonas concéntricas elegidas están ilustradas en la Figura 2, y son:

· Área 0, que se corresponde con el lugar de implantación de la zona cero de emisiones de Madrid Central, dónde se han excluido las calles del perímetro exterior, al no existir restricciones para su circulación.

· Área 1, que coincide con el actual servicio de estacionamiento regulado (SER), conocida también como almendra central, excluyendo su perímetro exterior que incluiría gran parte de la M-30.

· Área 2, correspondiente con la zona más periférica de la ciudad, hasta donde se disponía de un mínimo de datos de tráfico. Por este motivo, los distritos de Villa de Vallecas, Vicálvaro y Barajas han sido excluidos totalmente, y otros distritos como Fuencarral - El Pardo, Hortaleza, Villaverde, Latina o Moncloa – Aravaca se incluyen parcialmente.

2.1.2 Análisis temporal

A nivel temporal, se ha considerado que los datos de intensidad de tráfico tienen un carácter estacional anual, por lo cual, se ha decidido comparar los datos de las estaciones entre el año previo a su implantación y el año posterior (2018 y 2019). La capacidad de análisis y la falta de información de los siguientes años no ha permitido ampliar el horizonte temporal.

Para comparar entre ambos años, se ha agregado la información de los datos obtenidos de intensidad de tráfico en cada una de las estaciones de manera mensual.

Por otro lado, también se ha considerado que los datos de intensidad de tráfico también tienen un carácter estacional horario (Monzón et al., 1999), por lo que se ha agrupado los datos de intensidad de tráfico, de cada una de las estaciones, en cuatro franjas horarias: a lo largo de todo el día (00:00 – 24:00), por la mañana (7:00 – 19:00), por la tarde (19:00 – 23:00) y por la noche (23:00 – 7:00); siguiendo la misma clasificación establecida por el Ayuntamiento de Madrid para la evaluación del ruido.

2.2 Datos socioeconómicos

Para abordar el análisis socioeconómico, se ha usado la división administrativa de los distritos de Madrid. Para evaluar el impacto de la medida, se ha correlacionado la variación en la intensidad de tráfico media mensual en cada distrito con (i) los datos de población, como indicador de cuánta gente se ve afectada por la medida, y (ii) la renta anual media, como indicador de la distribución social del impacto. Ajustando una primera regresión lineal a la variación en la intensidad con la población y una segunda regresión lineal con la renta anual media. Los datos se han tomado del año 2019, en el portal web de estadística del Ayuntamiento de Madrid (2020).

3. RESULTADOS

En este apartado, se incluyen los resultados obtenidos del análisis de tráfico de forma general y agregados en las diferentes categorías espaciotemporales establecidas. Después se incluye la relación observada entre la variación en la intensidad de tráfico y los datos socioeconómicos.

3.1 Intensidad de tráfico

Los datos medios anuales de intensidad de tráfico muestran un impacto positivo de la medida en la disminución del tráfico. En cada una de las zonas concéntricas de estudio (Tabla 1), se observa que hay una tendencia radial, siendo el área con una mayor disminución el Área 0, después el Área 1 y por último el Área 2, siendo notable la diferencia entre el Área 0 con las demás. En cuanto a las diferencias por franja horaria (Tabla 2), la disminución es muy similar por la mañana y por la tarde, equiparable a la media de todo el día. El impacto de la medida ha sido menor en el tráfico nocturno.

Área de estudio	**Variación en la intensidad de tráfico media anual (2018 a 2019)**
Área 0	-6,95%
Área 1	-2,49%
Área 2	-1,82%

Tabla 1 – Variación de la intensidad de tráfico media anual entre 2018 y 2019 en las tres áreas de estudio concéntricas establecidas en todo el día (00:00 – 24:00).

Horario	**Variación en la intensidad de tráfico media anual (2018 a 2019)**
Día (00:00 -24:00)	-2,10%
Mañana (7:00 - 19:00)	-2,15%
Tarde (19:00 - 23:00)	-2,07%
Noche (23:00 - 7:00)	-0,54%

Tabla 2 – Variación de la intensidad de tráfico media anual entre 2018 y 2019 en las cuatro franjas horarias establecidas en toda la zona de estudio.

3.1.1 Diferencias espaciales 2018 - 2019

Las tres zonas establecidas para el análisis de la intensidad de tráfico muestran una tendencia en los valores a lo largo del año 2018 y 2019, dándoselos mayores datos de intensidad de tráfico en ambos años el Área 2, seguidos del Área 1 y significativamente más bajos en el Área 0 (Figura 3).

Las disminuciones las diferencias observadas en las medias anuales (Tabla 1) se mantienen al valorarlas de manera mensual, observándose mayores disminuciones en el Área 0 y luego en el Área 1 y el Área 2, las cuales tienen un comportamiento más parecido a lo largo del año. La variación de la intensidad en diciembre es superior en el Área 2 respecto al Área 1, lo cual rompe la tendencia general observa en el resto del año.

Al analizarlo de forma mensual y por zonas concéntricas (Figura 3), se aprecia que solo el Área 0 presenta una disminución de la intensidad de tráfico en el mes de marzo y sin embargo en el mes de julio solo en el Área 0 se produce un aumento del tráfico entre 2018 y 2019.

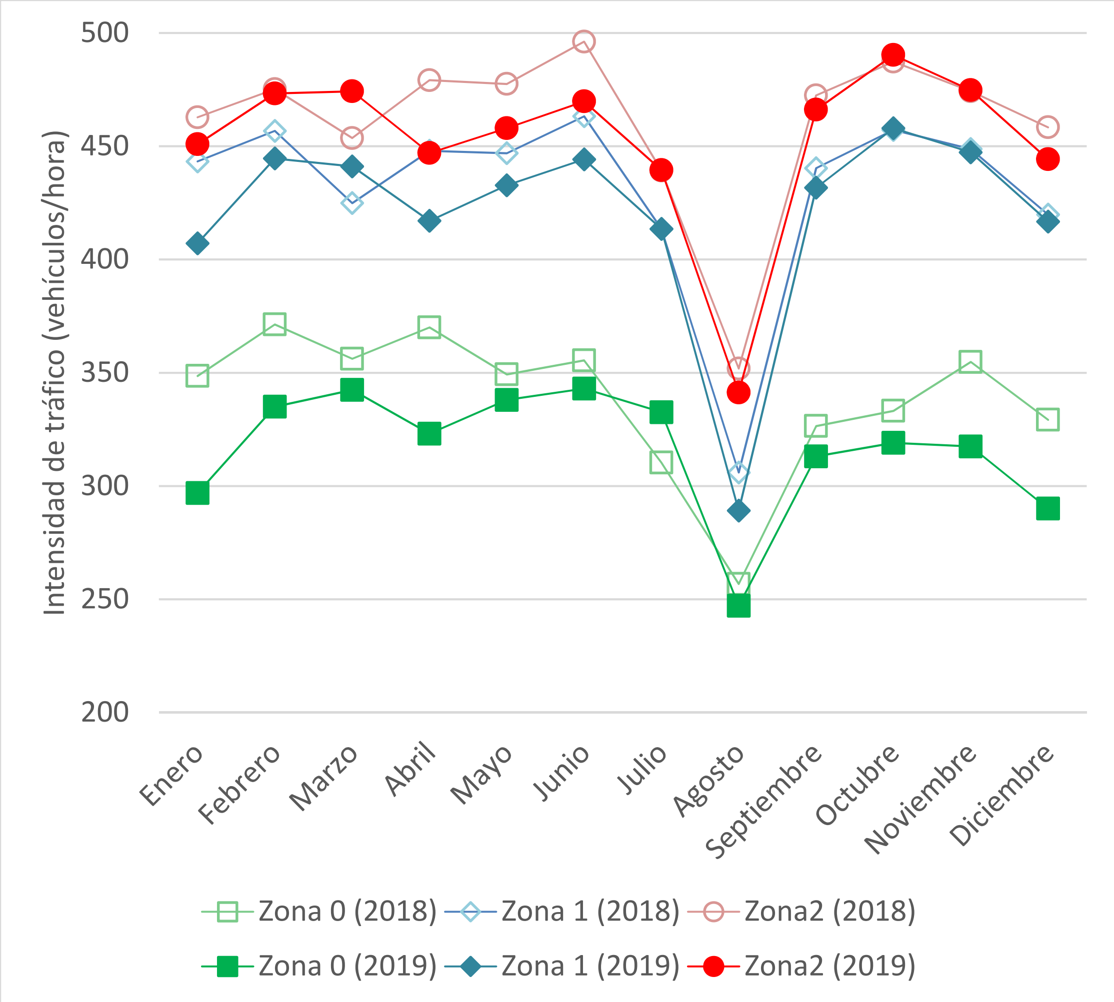

Fig. 3 – Comparación de la evolución de la intensidad de tráfico mensual media en los años 2018 y 2019, durante todo el día (00:00 – 24:00) en las tres áreas de estudio delimitadas (Área 0, Área 1 y Área 2) en Madrid

3.1.2 Diferencias temporales

La intensidad de tráfico tiene una fuerte componente estacional en el tiempo. A lo largo del año se observa un patrón que varía de forma proporcional a lo largo de los meses, ya que en verano disminuye drásticamente la intensidad de tráfico en comparación con el resto de meses tanto en 2018 como en 2019 (Figuras 3 y 4).

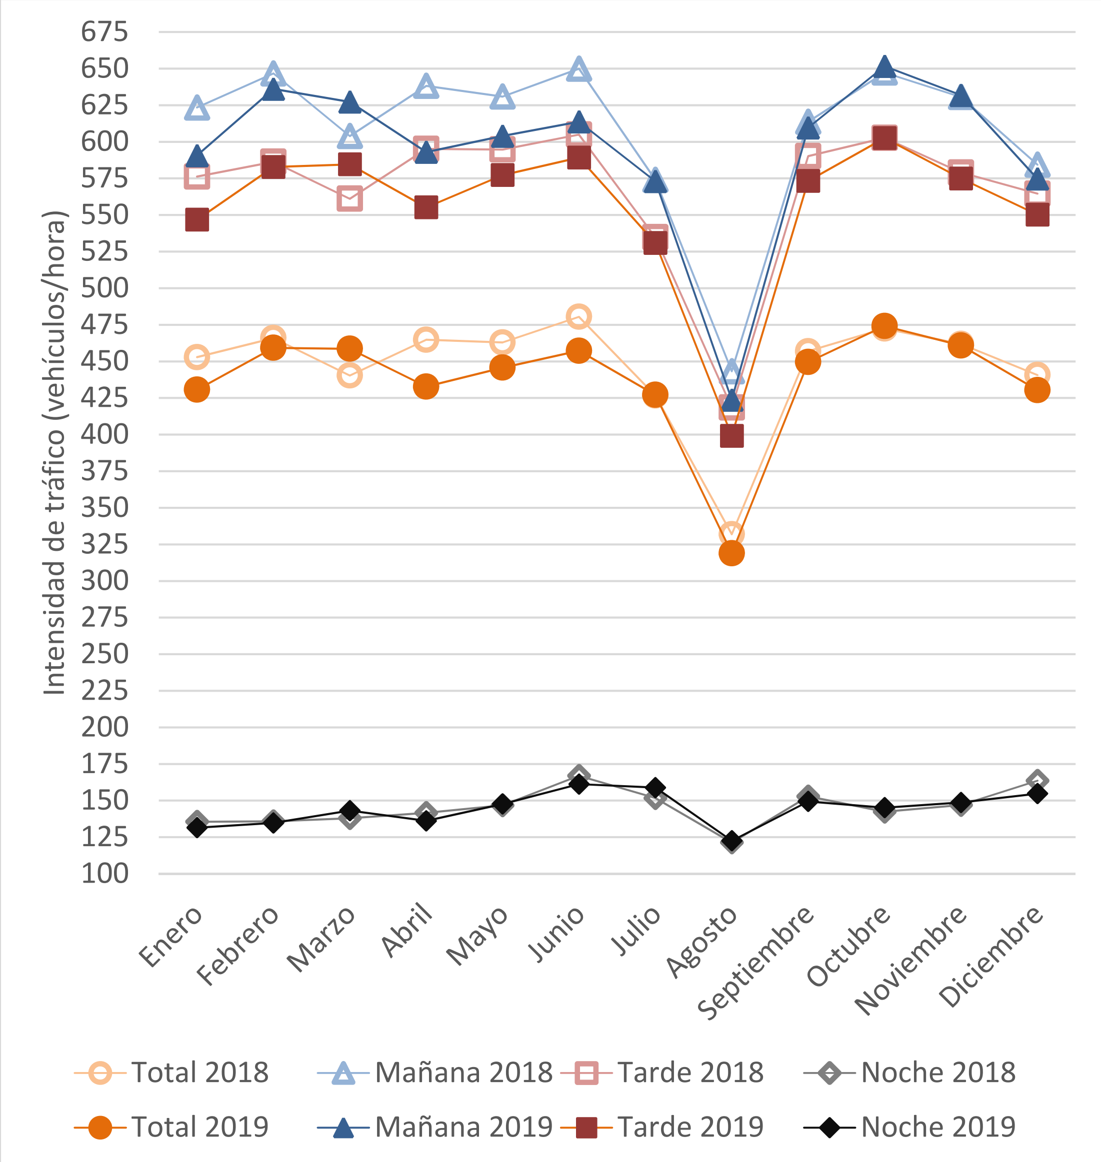

Fig. 4 –Comparación de la evolución de la intensidad de tráfico mensual media en los años 2018 y 2019, durante todo el día (00:00 – 24:00) y en horario de mañana (7:00 – 19:00), tarde (19:00 – 23:00) y noche (23:00 – 7:00), en la zona de estudio

Comparando la intensidad de tráfico media de manera mensual en la franja horaria de día (00:00 – 24:00) entre 2018 y 2019 se matiza la disminución en la intensidad de tráfico, ya que no todos los meses disminuye de manera homogénea (Figura 4). Los meses con una mayor disminución de intensidad son abril, mayo y junio. En el resto de meses, se aprecia una también una disminución en la intensidad de tráfico, aunque menor, y en el caso de marzo llega a aumentar la intensidad de tráfico de 2019 a 2018.

Comparando las diferentes franjas horarias se observa también que cada periodo sigue una tendencia propia, teniendo el periodo de noche significativamente menos intensidad de tráfico que las franjas de por la mañana y por la tarde tanto en 2018 como en 2019 (Figura 4).

Las franjas horarias de la mañana y la tarde, al acumular la mayor parte del tráfico siguen una distribución similar a lo largo del año en el impacto de la medida, mientras que en la franja horaria de la noche las diferencias son menores y, aparte de haber un aumento en la intensidad de tráfico en marzo, también se produce un aumento del tráfico en julio, octubre y noviembre.

3.2 Análisis socioeconómico 2018 -2019

Los datos de población y renta media mensual no han mostrado que tengan correlación con las disminuciones observadas en los diferentes distritos de Madrid estudiados (Figuras 5 y 6). Distritos con rentas anuales bajas, presentan resultados muy diferentes: Villaverde (-7,46%; 26.599 €); Puente de Vallecas (+0,36%; 24.688€). En los distritos con mayor población también aparecen resultados dispares: Puente de Vallecas (-0,36%; 246.021 hab.); Latina (-6,67%; 238.154 hab.).

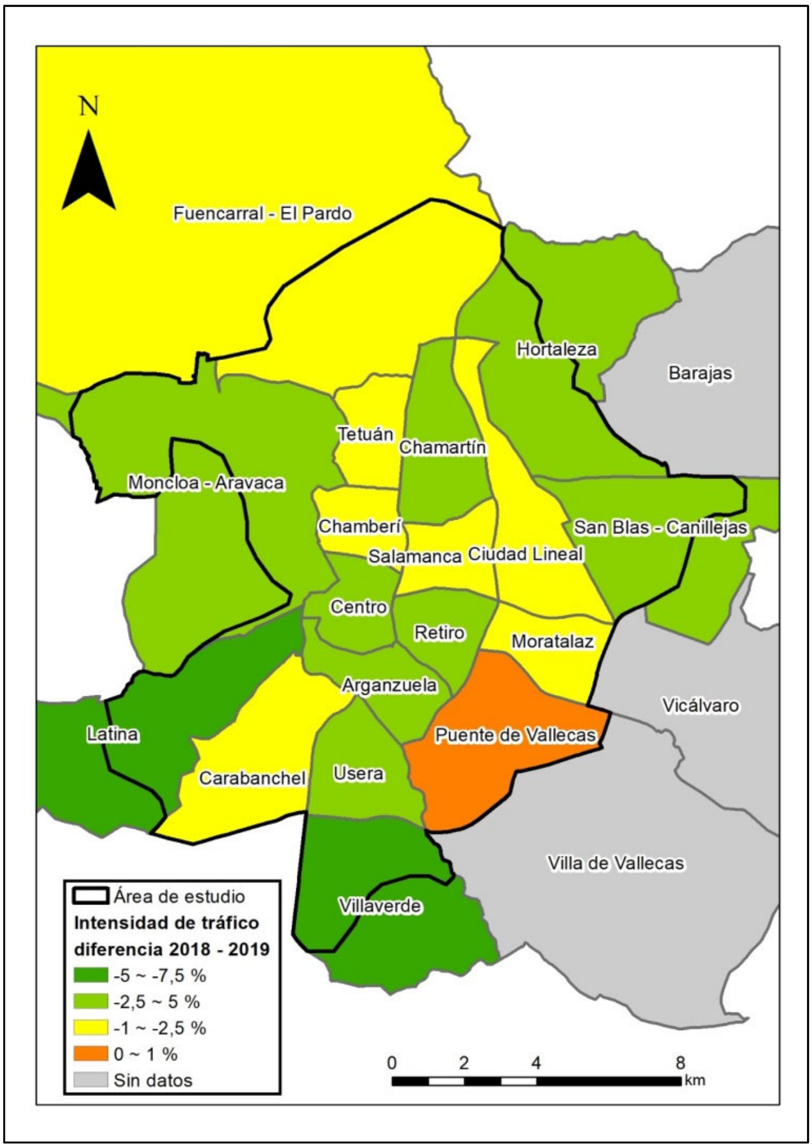

Fig. 5 – Variación porcentual de la intensidad de tráfico en los distritos de Madrid entre 2018 y 2019

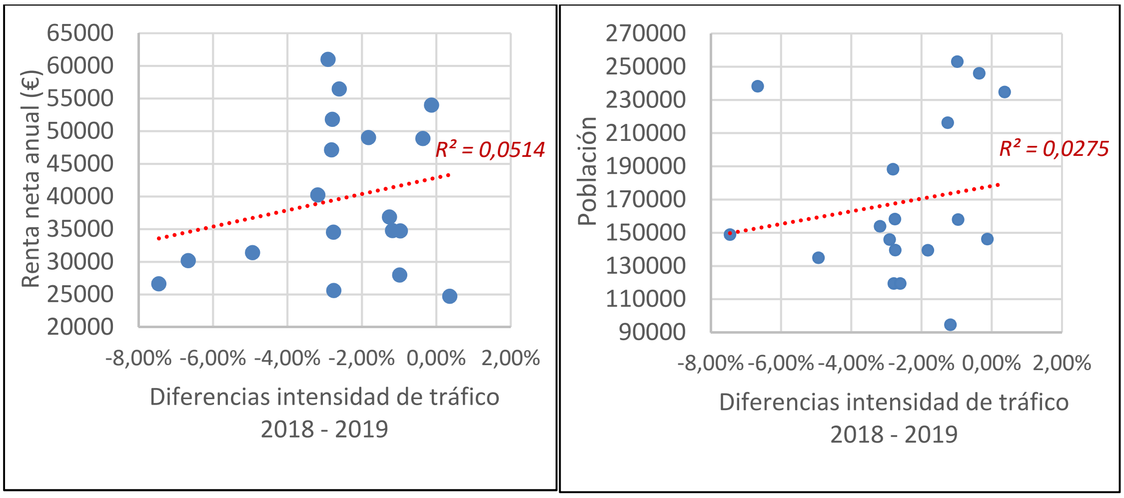

Fig. 6 – Correlación por distritos sobre los datos socioeconómicos (Población y Renta anual media) con la variación de intensidad de tráfico media mensual observada entre 2018 y 2019

4. DISCUSIÓN

El análisis del impacto de la medida de la zona de cero emisiones de Madrid Central es complejo y existen múltiples interpretaciones de los resultados. Por un lado, clasificando temporalmente los resultados, el impacto de la medida en los meses de verano, así como en el periodo nocturno es mucho menor, posiblemente al tratarse de periodos en los que la intensidad de tráfico es más baja y los viajes sobre los que se aplican las restricciones seguramente sean porcentualmente menores. Mientras que el impacto en el horario de mañana y tarde cuando se producen los mayores niveles de tráfico es mayor.

Es importante señalar que, aunque la implantación del Madrid Central se realizó a finales de noviembre de 2018, las sanciones no comenzaron hasta marzo de 2019 y se estableció un periodo cautelar, por lo que puede haber un sesgo en los meses de diciembre, enero, febrero y marzo. Este efecto posiblemente limite el impacto de la medida, y por tanto es posible que comparando con el siguiente año disminuya más la intensidad de tráfico y podría explicar la anomalía encontrada en el mes de marzo, donde se produce un aumento en la intensidad de tráfico entre 2018 y 2019. También se produjo un acuerdo que supuso la suspensión temporal durante una semana a principios del mes de julio de 2019 (Ayuntamiento de Madrid, 2019b) que posteriormente fue anulada por sentencia judicial (Ayuntamiento de Madrid, 2019c), lo cual podría también explicar porque se presenta una anomalía en el mes de julio en el Área 0, donde a diferencia de las otras áreas se produce un aumento del tráfico entre 2018 y 2019.

Por otro lado, clasificando espacialmente los resultados, no existe un impacto homogéneo en todas las zonas de la ciudad. Se observan distritos como Villaverde, donde la medida llega a reducir un 7,46% la intensidad de tráfico, y otros como Puente de Vallecas donde aumenta un 0,36%.

Los resultados parecen indicar que los distritos ubicados en las entradas sur y oeste a Madrid son los que presentan una mayor reducción del tráfico y podrían ser las vías de entrada más afectas por la medida (Figura 5).

La ubicación de las estaciones de medida del tráfico del Ayuntamiento no es homogénea, en dos aspectos: están sobrerrepresentadas las calles con un mayor ancho de calle y la densidad de estaciones por distrito no es homogénea. Está distribución de las estaciones excluye las calles con menor tráfico, siendo necesario matizar que las disminuciones observadas están referidas a calles principales que son donde se acumula el mayor tráfico.

A diferencia del enfoque centrado en las estaciones de medición de contaminación de la ciudad de Madrid (Salas et al. 2021; Izquierdo et al., 2020), existe un mayor número de estaciones de medida del tráfico, y esto ha permitido un análisis espacial más detallado del impacto de la medida. Al analizar directamente los datos de contaminación, la influencia meteorológica puede sesgar los datos (Katsoulis, 1996; Buchhoolz et al., 2010; Grundström et al., 2015; Laña et al., 2016; Chen et al., 2017), por lo que un análisis desde diferentes perspectivas ayuda a unos resultados más precisos.

En el análisis de la intensidad de tráfico no se ha tenido en cuenta la evolución del parque automovilístico de la ciudad, el cual se renueva año a año. Los vehículos más modernos presentan mejoras para disminuir sus emisiones contaminantes, especialmente los vehículos eléctricos e híbridos, que no tienen restricciones de acceso a la zona de cero emisiones. En relación a la intensidad de tráfico, Santiago et al. (2021) señalan que el aumento en la economía genera un aumento en el tráfico de la ciudad, por lo que los resultados observados en la disminución de la intensidad de tráfico pueden haberse visto minimizados al existir una tendencia creciente en la economía de la ciudad en este periodo.

Al igual que se ha relacionado la disminución del tráfico con beneficios a la contaminación, es posible que también haya asociado un impacto negativo a la economía de la ciudad. En el futuro es posible que el efecto de la medida se estabilice y no siga reduciendo el tráfico de la ciudad, aunque es posible que en los próximos años se produzcan efectos inducidos en la reducción del tráfico, ya que reducir la intensidad de tráfico, favorece el uso de transporte público como el autobús, al reducir los tiempos en los trayectos (Higgins et al., 2018), y esto a su vez, favorece la disminución del tráfico.

Basándonos en la información disponible en el Ayuntamiento de Madrid, se podría ampliar el horizonte temporal hasta 2013, ya que se disponen de datos de intensidad de tráfico e incluir los años 2020 y 2021 en el análisis, esto ayudaría a precisar mejor los resultados al distinguir mejor el efecto de la medida respecto a una tendencia general, y también podrían utilizarse otros indicadores del tráfico como la carga y la ocupación para poder relacionar mejor el tráfico con la contaminación.

Por último, en nuevos estudios, sería interesante combinar la evolución del tráfico con trabajos como el realizado por Cárcel-Carrasco et al. (2021), que analizan el impacto en la contaminación de las restricciones a la movilidad en el conjunto de la ciudad, derivadas de la pandemia del COVID-19.

5. CONCLUSIONES

El impacto del Madrid Central ha sido disuasorio para el tráfico de la ciudad, existe una disminución en el uso del vehículo privado como medio de transporte de forma general en toda la ciudad. Este resultado es compatible con trabajos anteriores que han detectado niveles inferiores en la contaminación atmosférica de la ciudad.

Se observan principalmente dos tendencias en la distribución del impacto de la medida: las zonas más próximas al área de Madrid Central son las más beneficiadas por la medida, llegando a una disminución del tráfico del -6,95% dentro del área con restricciones; y los ejes de entrada oeste y sur a Madrid han sido las más beneficiadas.

No existe una tendencia general que indique que la medida no afecta más a las zonas de mayor población o con una situación económica más frágil. Aunque el distrito de Puente de Vallecas (2º en población y último en renta anual media) presenta un aumento de la intensidad de tráfico.

AGRADECIMIENTOS

Este estudio está enmarcado en el proyecto DESPACIO" (TRA2017-88058-R), financiado por el Ministerio de Economía, Industria y Competitividad de España en el "Programa Estatal de I+D+i Orientada a los Retos de la Sociedad". Los autores también quieren agradecer al Ayuntamiento de Madrid por la información del tráfico proporcionado.

CITIES AT HUMAN SPEED: A FAVORABLE WAY TO REDUCE THE PACE OF MODERN LIFE. PULL AND PUSH MEASURES FOR CHANGE.

Cristina López García de Leániz
Investigadora en el Centro de Investigación del Transporte (TRANSyT, UPM)

ABSTRACT

Walking is the wealthiest and fairest, healthiest, safest and strongest, smartest and greenest form of transport (Government of Scotland, 2014). Since Walking is part of the daily life of most people, that is why it is often taken for granted.

To achieve a city for pedestrians, urban planners must reflect on how to stop designing cities with dispersed, discontinuous, and car-centric urban models, because it will be impossible to reverse this trend of development. Currently, contemporary cities must face the stress of its population, due to the speed of urban life, traffic congestion, long travel distances, etc.

This research is underpinned by how pedestrian's scale contributes to better urban environments and for the welfare of citizens through the development and implementation of policies and strategies for encouraging walking. To address this issue, it tries to identify the factors that determine walking, and it explores some existing strategies at three administrative levels: local, regional, and national. In this regard, it proposes push and pull measures as the potential to help more people to walk. The city of Pontevedra is selected as a case study because it is considered a case of success. The results indicate that there is necessarily a transversal organization of mobility in the administration, adequate combinations of pull and push measures have shown to have the greatest effect, and interventions tailored to different parts of the city.

1. THE INVISIBILITY OF WALKING

Walking characterizes the most accessible and greenest way of mobility (International Transport Forum, 2018). Furthermore, people walk to get fit and feel good, and because it is appropriate and social (City of London, 2018).

On the contrary, physical inactivity is responsible for over 5 million deaths annually through its effects on multiple non-communicable diseases (such as heart disease, stroke, cancer, etc.) (Sallis et al., 2016) and it is the second biggest cause of global mortality (Government of Scotland, 2014).

However, walking trips have been largely ignored as a mode of urban transport (CEOs for Cities, 2009; ITF, 2012; Rietveld, 2000), or that walking is treated as the 'Cinderella of transport modes' (Paroah, 2003) despite being the most important of all. Since walking is part of the daily life of most people, it is often taken for granted, which Goodman (2003) calls 'the invisibility of walking'.

The understanding of nonmotorized modes of transport - walking and cycling - is extremely complex. However, in the existing literature, walking is often presented along with cycling (Litman 2017; Buehler & Pucher, 2017; Active Living Research ALR ,2016; Krizek, Forsyth & Baum, 2009; Ogilvie, 2004; Saelens et al., 2003; Tolley, 2015, 2003; Rietveld, 2000). Although there are complementary, greener and sustainable modes, each mode has its distinctive features, and they should be separated in data As Nadal said, it is crucial to promote active mobility, but also 'smart mobility' understood as the one that each person needs in each circumstance and at each moment of their life (Nadal, 2020).

Walking can be characterized along the four 'As' adapted from Carruthers, Dick & Saurka (2005) to understand urban transport: i) Affordability is very high since walking is a universal mode for all citizens, except in some cases of mobility impairments. It does not require any vehicle, it is free; it only requires capable legs and energy to cover the distance; ii) Availability is high since other modes are limited through routes, schedules, and frequencies. Walking is the most available mode of transport, limited only by potential difficulties to walk for long distances, safety concerns, or barriers along the route; iii)

Accessibility is high, most people can reach a certain place on foot. iv) Acceptability depends on the pedestrian; external factors or some individual perceptions, such as personal security, can boost or deter from walking. Citizens are all pedestrians, but they don't have the same conditions to walk (physical, economics, etc).

The study of pedestrian mobility is difficult to address since it is challenging to explain the pedestrian behaviour and the interactions between urban structure, mobility habits, and other factors (Krizek, 2000). Walking is often overlooked as a mode when measuring transport behaviour for the purposes of planning. (ITF,2017).

Walking can be used for different purposes (Paroah, 1996): i) as the sole mode to go from one place to another. In London, it includes a quarter of all daily trips (City of London, 2018); ii) as a means of reaching other modes, e.g., for going to the metro station, to the bus stop, to a parked car. In the US, there is a major reason to walk (Besser and Dannenberg, 2005); iii) as a means of using public space, e.g., to meet other people or window shopping; iv) as a recreational and leisure medium, like long walks without a specific reason or destination or playing in the streets (tend to be longer).

Most surveys only collect the first and second purposes, and it is difficult to obtain reliable data on walking. Their methodology focuses exclusively on car travel and public transport, without taking into account the share of pedestrian trips, even when it is an important component (ITF, 2018; Litman, 2017; Pozueta, 2007; Rietveld 2000; Socialdata, 2013; Trolley, 1990) and excluding walking journeys of less than ten minutes (Litman 2017; Paroah, 1996; Sanz 2004) or it goes together with bike. Consequently, this will limit the comparison of the share of walking between different sources (European Road Safety Observatory, 2006).

Indeed, 63% of all urban trips are less than 5 km in length (ITF, 2018). Thus, it opens a great opportunity to encourage walking in urban areas. Likewise, slightly more than two-thirds of Europeans walk every day (68%) while half use a car every day (50%). However, roughly one in ten Europeans (12%) never uses a car (European Commission, 2013). The weight of the pedestrian mode in many cities is not to be underestimated: in central Paris, the walking modal share is 47%, followed by Barcelona with 44%, New York City with 39%, Mumbai with 33%, London with 32%, Madrid with 30%, Berlin with 29%, Vienna with 27% and Shanghai with 27% (ITF, 2017). Consequently, as Litman (2019) said, “Improving travel options and reducing vehicle traffic tends to benefit everybody in a community”, since inadequate mobility is an important element of social exclusion that determines the level of urban poverty (UN-Habitat 2013).

The present research aims to reflect on the current accelerated pace of life in cities and how to reduce it through the possibilities offered by pedestrian mobility. It starts identifying factors that determine the choice of walking. Secondly, it analyses some examples of policies and strategies for encouraging walking that have launched in three administrative levels: local, regional, national, and presents a review of push and pull measures for increasing walking. Finally, the city of Pontevedra provided the empirical focus. It has been selected because it is considered a case of success and a worldwide reference.

2. CHANGING SPEED OF URBAN LIFE: PEDESTRIAN SCALE

With the outbreak of the coronavirus pandemic in March 2020, cities suddenly stopped, mobility and noise ceased; citizens became more aware of the speed at which they were living and the way of life that was had acquired. Many of the drawbacks of the current urban model have provoked new debates on the need to favor the proximity of daily activities at the neighborhood level, density, and the lack of public quality space. In European cities, by 70-80% public space is occupied by the car (EU, 2020).

Before this health crisis, the climate emergency was giving signs that it was not possible to continue living at this rate of energy consumption and with these environmental repercussions.

On the other hand, people living in larger cities with high urbanization and increasingly sedentary work, are more likely to be physically inactive, to have a higher prevalence of depression and stress, because of the accelerated urban environments and lifestyles.

Now more than ever, humans need to walk to be in contact with others and they need to share public open spaces. In this regard, the quantity and quality of pedestrian public space determines the urban quality. Today, people are full-time interconnected, but at the same time it’s seems to be the most disconnected time from their environment. Outdoors’s environment can reduce stress and aid recovery from stressful conditions (Thompson et al., 2011).

As Gelh (2014) said, the public space is good when there are many nonessential activities in it, when people go out into the public space as an end in itself, to enjoy it and spend time in it (Monheim, 2003). It gives a sense of belonging. Walking not only depends on the pedestrian facilities but is also highly dependent on the built environment (Krizek et al., 2009; Adkins et al., 2012). Monotonous and uninteresting scenarios can deter walking on foot. Conversely, attractive, safe, socially animated scenarios stimulate people to walk more (Pozueta et al., 2013; Saelens & Handy, 2008). Indeed, in many cities, creating attractive walking environments has increased retail turnover and pedestrian flow (Tolley, 1990; TEST, 1988, Government of Scotland, 2014).

Pedestrian mobility implicates highly competitive travel time over short distances, but competitiveness decreases as distance increases, compared to other modes (Pozueta et al., 2013). The travel time per pedestrian per trip that is acceptable by a person is established between 20 and 30 minutes. Distance, real or perceived distance, is a barrier for walking (Krizek et al., 2009) and is one of the key factors influencing the choice of walking (ITF, 2018; Adkins, et al., 2012; Greenwald & Boarnet, 2001; Handy, 1996). However, it is not easy to determine what is the acceptable distance to walk because travel distance is also dependent on the age, physical conditions, the state of the pavement, and urban environment, but mainly on the size of the urban centres (Gelh, 2014).

In the last decades, the design of the city, the public space, and the location of activities have been done with a car-centric planning, which has resulted in a greater consumption of land and energy, causing problems in the environment and inaccessibility to many sectors of citizenship. Some urban planners focus their interest on density but forget to change diversity and design (Cervero & Kockelman, 1997).

To change this trend, urban planning is essential and must avoid the monofunctionalism of urban areas, promoting the balanced diversity of the main functions of the city such as living, working, shopping, recreation and education (Paroah, 1996). This is so called ‘proximity urbanism’, which creates proximity and autonomy.

As seeing above, walking varies a lot depending on the trip purpose (Tolley, 1990; Monheim, 1979). Proximity to employment is the variable that most influences travel distance and modal choice, rather than the existence of commerce and services in the residential area (Cervero & Radisch, 1996; Gainza & Etxano, 2014), especially among women (Cerin et al., 2007). Furthermore, proximity to destinations is the element that most positively influences walking as a mode for nonrecreational travel, more than aesthetic quality, infrastructure, or security (Saelens & Handy, 2008; Cervero & Duncan, 2003).

Less intensity of urban activity implies a greater use of the car and vice versa (Litman, 2019; Newman & Kenworthy, 1989).

There are multiple factors that influence walking. The following is a brief selection of them built upon the impact on the individual places and infrastructure related to walking.

2.1. Pedestrians individual

The individual decision to walk is not only conditioned by personal needs, but several different factors interfere in personal choices and attitudes (ARL, 2016). The walking behaviour is very different among the age and life-cycle stages (Van der Hoorn & Van Wee, 2013, Pozueta, 2007), social status –education level and household characteristics-, gender, (Tolley, 1990), the perception of safety and security, etc. However, income, travel time, and transport costs (in terms of individual expenditure on transport), influence on the choice to walk or not; or pedestrian travel habits are influenced by cultural factors such as societal values (ITF,2012). For instance, in southern European countries, walking 'is part of the lifestyle, is a basic aspect of daily life' (Lamíquiz, 2011).

2.2. Places where people walk

More than two-thirds of the European population live in urban areas and they continue to grow: by 2050, 82% of Europe's population will be urban (European Union, 2011).

This opens a large field of action for pedestrians, above all in many small and medium sized cities. The bigger the city, the more complex the trajectories and the longer the distance. In Spain, according to the Metropolitan Mobility Observatory data (OMM, 2017), small areas have the highest percentage of walking and cycling, followed by large areas and medium ones, as it can be seen in Table 1, by purpose of the trip (obligatory or non-obligatory mobility) and in the main cities:

	Large areas*			Medium areas**			Small areas***		
	Obligatory	Non-Obligatory	Main city	Obligatory	Non-Obligatory	Main city	Obligatory	Non-Obligatory	Main city
Walking & cycling	22,4	47,5	**49,9**	25,3	47,1	**49,5**	24	54,9	**51,9**
Public Transport	19	18	23,1	11	4,7	14,6	9,1	10,4	10,4
Car & motorbike	57,9	34,1	25,8	62	47,2	34,6	66,2	34,2	37,1
Others	1,3	0,9	2,8	1,8	2,7	1,7	1,6	1,7	1

* 7 large metropolitan areas: more than a million of inhabitants
** 7 medium metropolitan areas: more than 500.000 inhabitants
*** 8 small metropolitan areas: less than 500.000 inhabitants

Table 1. **Modal share in Spanish cities. Source: OMM, 2017**

Compact areas can reduce the number of motorized trips and boost the nonmotorized ones (Cervero & Kockelman.,1997), especially for non-work trips. By contrast, sprawl, as the physical pattern of low-density expansion of large urban areas, is one of the major challenges facing urban Europe (EEA, 2006). Sprawl has an "unmistakable and profound influence on travel" and makes public transport services in good condition (frequency, number of lines, etc.) unviable and increase the use of cars. This situation generates the growth of vulnerable population groups that live in the periphery and have to travel great distances (UN- Habitat, 2013).

Moreover, the urban structure and its subsequent transformation by planning have a great influence on human behaviour and the way the city's function (Gelh, 2014). There are some good examples of old compact urban structures with quality urban spaces resulting in lively streets, such as Barcelona, Copenhagen, or Paris. Some street layouts are preferable to others. "*Most old cities have a complex and fine-grained street pattern and that makes them more interesting*" (Hass-Klau, 2015). It can be said that people living in areas with dense, mixed-use, integrated buildings, and with good access to public transport are more likely to walk (City of London, 2018). Moreover, Cervero & Duncan (2003) highlight that urban design influences the choice of walk: curved and cul-de sac street layouts discourage walking. On the contrary, well-connected streets, mixed land use, and small blocks favour short distances and walking.

Rarely in the literature, the data of pedestrian mobility distinguishes among central, inner, or outer cities, and the difference in modal distribution in different parts of the city can become notorious. For example, walking is the most common mode of transport in central and inner Madrid by 40% and 32%, but this percentage decreases by 29,2% in the outer cities (Consorcio Regional de Transportes Madrid, 2020). London strategy outlines different approaches for central, inner, and outer London, where 41% of all trips are made on foot in the central and inner cities and 29% outer (City of London, 2018).

Additionally, the existence of a larger metropolitan area greatly influences the modal shift. In Spain, in cities with less metropolitan development, the percentages of trips on foot are generally higher (Sanz, 1998). For example, the city of Vitoria Gasteiz does not have a metropolitan area and it has the highest walking modal share in Spain. Ewing (2005) found a strong correlation between metropolitan development patterns and walking.

2.3 Infrastructure for walking

Nowadays, the sheer scale of many cities makes a multimodal system necessary, since the majority of the trips require the combination of several modes (Southworth, 2005).

However, *walking is a key element in most multimodal trips* (ITF, 2012) and may be more important than it seems. Likewise, a critical factor supporting walkability in larger cities is accessibility to public transport for longer trips and it is necessary to improve the connectivity and ease of transfer between modes (ITF, 2018; Krizek et al., 2009) and to see if public transport services can be reached on foot (Paroah, 1996).

Any increase in transport modal share is because there is a shift to another mode (Paroah, 2003). In most cases, cycling increases at the expense of walking (Krizek et al. 2009); motorised modes at the expense of nonmotorised modes and public transport at the expense of private transport (Werner et al., 2003). The challenge is to shift users away from the car.

Good walking conditions are considered the following five ‘Cs’ (Paroah, 1996): i) Connected: in a comprehensive network, with short street blocks instead of less permeable large blocks (Pozueta et al., 2013). ii) Convenient: with direct routes without detours. iii) *Comfortable*: adequate surface and pavement, enough widths, non-obstacles, with good lighting. iv) *Convivial*: diversity of public spaces to stay and mix of buildings and activities. v) *Conspicuous*: clear routes in terms of design and signing.

There is no defined average distance to walk. The radius of action of a walking trip, taking as a reference the travel time between 20 and 30 min, is between 1.5-2.5 km. (Pozueta et al., 2013), but to spend a great value of time is often a reason against walking. It is considered as a means of transport that takes a longer time, compared to other mechanized modes (Goodman et al., 2003). The walking speed is also one of the main conditions against other modes, since it varies, under normal conditions, between 4- 5 km/h. Other factors influencing walking speed are the quality of pedestrian facilities, the age and physical state of the pedestrian, the crowd on the streets, or the weather (Gehl, 2014). Improving the quality of the infrastructure, e.g., to include more footways, provide wider pavements with smoother surfaces, making walking spaces more enjoyable (ITF, 2018), and prohibiting cyclists on pavements, have a positive influence on walking (Walcying, EU Project). Providing more infrastructure may not in itself change behaviour.

One of the most important measures is to reverse the hierarchy of public spaces (Government of the Basque Country, 2016), to put pedestrians in the first place and bring them the best conditions to walk. Likewise, ‘intermodality spaces’ are convenient if it is possible to share the space by different means of transport. The ‘coexistence’ between modes is a matter of speed and it would be possible, but not under spatial equality conditions (Gehl, 2014; Monheim, 2003) because it depends on the volume of car traffic, not above 250 cars/h, or either on the speed of cars between 10km/h and 20km/h.

3. POLICIES AND STRATEGIES FOR ENCOURAGING WALKING

Several cities have opted to promote pedestrian mobility, with different purposes such as: for reasons of the health of the population (improving the health of citizens and preventing diseases); for a first step for a mind shift by urban development model on a human scale and proximity; for a requirement to be another means of transport and highlight its importance and benefits, etc.

To establish some principles or objectives, strategies or plans for walking have been launched at different levels, mostly at the city level, but there are also examples at the regional (e.g Scotland) and national (e.g Norway) level. Table 2 shows some selected examples, indicating their main objectives.

Country/Region/ City	*Strategy/Plan*	*Main goals*
City of London (2018)	Walking action plan. Making London the world's most walkable city	i. 80 per cent of all journeys to be made on foot, by cycle or using public transport by 2041. ii. Londoners have to do at least 20 minutes of active travel every day by 2041. iii. Efficient use of street space, improving the experience of walking on London's streets.
Paris (2017)	Stratégie "Paris piéton"	i. Facilitate pedestrian continuity and new sharing of the road. ii. Promote the diversity of street uses. iii. Raise the comfort standards of public spaces. iv. Rethink the orientation of pedestrians. v. Consolidate the pedestrian culture of Paris.
Scotland (2014) Scotland launched in 2003 its first physical activity strategy 'Let's Make Scotland More Active' (LMSMA).	Let's Get Scotland Walking The National Walking Strategy	i. Create a culture of walking where everyone walks more often as part of their everyday travel and for recreation and well-being. ii. Better quality walking environments with attractive, well designed and managed built and natural spaces for everyone. iii. Enable easy, convenient, and safe independent mobility for everyone.
Norway (2014)	The Norwegian Walking Strategy: "Walking for life"	i. Walking should appeal to everyone. ii. More people should walk more.
City of Copenhagen (2007)	More people to walk more. The pedestrian strategy of Copenhagen	i. 20% increase in pedestrian traffic by 2015 compared to 2009 ii. By 2015, Copenhageners walk 12 minutes a day

Table 2. Walking strategies.

The most effective strategies for encouraging walking seem to be "those that are multidisciplinary and include a mix of top-down and bottom-up approaches with buy-in from government and non-government organizations, academic institutions, professional and commercial groups, and passionate citizens" (Walk21, 2017), in short, when they involve all stakeholders of the city.

Some existing strategies (e.g., Scotland) not only establish measures that promote walking, but also connect sectoral policies with each other (for instance, health, transport, urban planning, environment, social, etc.), achieving a comprehensive approach that reinforces each action, and across a range of policy areas at national, regional and local levels (Government of Scotland, 2014).

4. PULL AND PUSH MEASURES FOR INCREASING WALKING.

Before any intervention or action, each city must make a careful diagnosis and it would be wise to start by asking why people do not walk, as London did when it developed the walking strategy. The main reasons they found were: i) time to spend in travel (24%); ii) high traffic (21%); iii) personal security (20%); iv) other travel preferences (18%); v) bad pedestrian facilities (14%); vi) not being fit enough (14%); vii) safety and fear of traffic (12%); viii) having a disability and the state of pavements (10%) (City of London, 2018). If policy makers do not know how people move, it is very difficult to be efficient in the management of measures.

Pull measures to increase walking refer to all incentives that discourage some attitude or habits and promote a modal shift. In this research, it concerns deterring strategies that discourage driving. On the other hand, push measures are considered as enabling strategies (policy, infrastructure investment, or actions) that boost walking (Piatokowski et al., 2019).

Nevertheless, push measures for sustainable modes such as walking, which is necessary but not sufficient to extend a sustainable urban mobility model (Sanz, 2007). Piatkowski et al., (2019) in their study in 4 American cities in which they carried out the *Non-motorized Transportation Pilot Program* revealed that establishing a joint action between actions that boost active transport (push measures) and those that discourage car use (pull measures) is more effective than doing them separately.

They also point out that attention must be paid to the measures applied to deter driving because they can harm the promotion of walking, so it is not only necessary to be careful when carrying out the intervention but also the capacity to implement it.

Combining measures can cause nondesirable effects such ‘Suction effect’, but between sustainable modes instead of subtracting the car, for instance, a new policy that promotes scooters can attract people walking; or ‘Rebound effects**’,** for example, measures that improve the environmental effectiveness of a vehicle also translate into greater use of it; or ‘migratory effect’, the application of measures in the inner city, for example a streets pedestrianization can drive traffic to edge areas (Sanz, 2007).

There are countless of measures to act on, but not all measures are the same in terms of magnitude.

For instance, ‘hard measures’ (big investments in more convenient crossing and redesigning intersections for pedestrians, renovation of the urban streetscape, park & ride outside the city centre, etc.) or ‘soft’ measures like information and promotion campaigns etc. Although it may happen that ‘soft’ measures can enhance the effectiveness of ‘hard’ measures (W21, 2019). Table 3 presents a review of pull measures and Table 4 push measures, both used in walking policies and strategies.

	Type of measure	***Example***
Pull measures	*Car traffic restraint*	Creation of a traffic control center by the city council to give preferential pedestrian use in the centre
		Reducing the speed of vehicles
		Reallocating road space, reducing road space.
		Targeted restrictions on vehicles better than a simple ban
		Parking duration and parking turnover
		Reduction of search traffic
		Car limited zones
		Decrease parking spaces
		Ban pavement parking
		Parking charges
		Park & Ride outside the city centres
		Parking penalties for improper parking
		Permanent or time-of day car bans
		Congestion management
	Road safety	Reducing speed, reducing accidents & injuries
		Separate cycle path from footpath
		Crossing at street levels (no skywalks & subways)
		Reduce road danger
		Speed humps in the carriageways
		Traffic calming: 30 km/h, 20 km/h or 10 km/h
	Enterprise and trip generation pole Coordination:	Promotion of shoft mode of transport to access at work
		Support staff to change employee’s mobility patterns
		Change bonus ‘company cars’ for other economic or tax incentives
		Teleworking or desksharing schemes
		Shuttle bus lines to the main transport nodes of the city. Connect the main attraction / generation points to all the transport networks
	Public transport	Providing convenient, punctual, frequent, and well-connected public transport systems
		Attractive pedestrian connections
		Placing bus stops at shorter intervals
		Improving security and accessibility to the most vulnerable groups: elderly, children and those with mobility constraints.
		Transport mode transfers simple, quick, efficient, safe and confortable

Table 3. Pull measures to encourage walking.

	Type of measure	***Example***
Push measures	*Improving environment for walking*	Pavements fit for walking
		Increase the width of pavements
		Better lighting, with priority to pedestrians
		Construction and improvement of side walks
		Street furniture well placed
		More convenient crossing: redesign the intersections for pedestrians
		Better signing
		Making more attractive places for everybody
		Removed obstructions and obstacles
		Walking routes were clear, connected and well signposted
		Flush dropped kerbs
		Increase the frequency of pedestrian phases in the traffic light cycle
		Removal barriers for disabled people
		Improvements in public spaces: sidewalks, terraces, outdoors activities: cultural, animation, ephemeral art installations, artist and street performers
		Prevent invasion of sidewalks by parked cars or bikes or electric scooters
		Protection from inclement weather
		Avoid elevated and underground pedestrian crossings
		Green and nature in the streets
		Publish walking route maps
		Technology like apps and devices will play an important role in the walkable futures of cities
		School pedestrian routes
		Footway free from litter and dog mess
	Land use planning	Integrating walking into transport and land use planning
		Pilot projects school streets with timed road closures
		Minimise the need to travel
		Improved retail vitality
		Promotion of mixed-use neighbourhoods
		Increase density
		Activity in the ground levels of buildings walls
		Street markets.
	Promotion campaigns The most effective campaigns are those that combine information, education, service developments, legislation and changes to the physical environment (Tolley, 2003).	School mobility programs
		Leisure walking routes
		Information, awareness and communication Campaigns
		Supporting a culture change

Table 4. Push measures to encourage walking

Hereafter, the Spanish city of Pontevedra has been chosen as a case study to analyse push and pull measures for increasing walking in cities and their combinations, because it is considered a word reference for the success in the implementation of the measures, are more focused on enabling (push measures) strategies than on deterring strategies. In addition, the passage of time allows to evaluate the results after almost 20 years of action.

5. RECOVERY OF THE CITY FOR PEOPLE: THE CASE OF PONTEVEDRA

Pontevedra is a small city in Galicia, the capital of the same name province, with a population of 83,209 inhabitants in the capital and 945,408 inhabitants in the metropolitan area. It is located on the Spanish northwest coast.

In 1996, the city monitored the traffic situation (The traffic in the centre of Pontevedra was three times greater than the traffic intensity in the centre of Madrid and 5 times greater than in the centre of London, 74,000 cars entered in 5 km2), which had an impact on poor air and life quality for citizens, the city council decided to carry out an urban reform for improving the quality of the environment for people living, both in regulation and design.

Local authorities analyzed proposals made in other cities to reflect upon what might or might not work as following: congestion charging, improvement of public transport, pedestrianization of the city centre, traffic calming, traffic restrictions on the appearance of license plates, crossings at high or below levels like skywalks and subways, etc.

While most cities focused on trying to solve the problem of urban traffic (pull measures), the actions taken in Pontevedra focused on recovering the city and public space for people (push measures). The city council tried to influence any potential side effects in a positive way rather than negative.

5.1. Pull and pull measures

The decision was made to reverse an unsustainable traffic situation and poor urban quality, and it was important to properly select the measures so that they would be effective from the beginning because any mistake would put even more against the sectors most sensitive to change.

In order not to delay the transformation, it was decided to start acting and in turn adapt the Sustainable Urban Mobility Plan (SUMP), since it had previously been studied in depth what and how to do it. It was a participated and consulted process. The main measures were basically implemented in 4 scopes (Concello de Pontevedra, 2016): i) pedestrian priority; ii) accessibility; iii) drastic reduction of traffic in the city; iv) road safety. Figure 1 shows various actions carried out in Pontevedra during the period between 1999 and 2015.

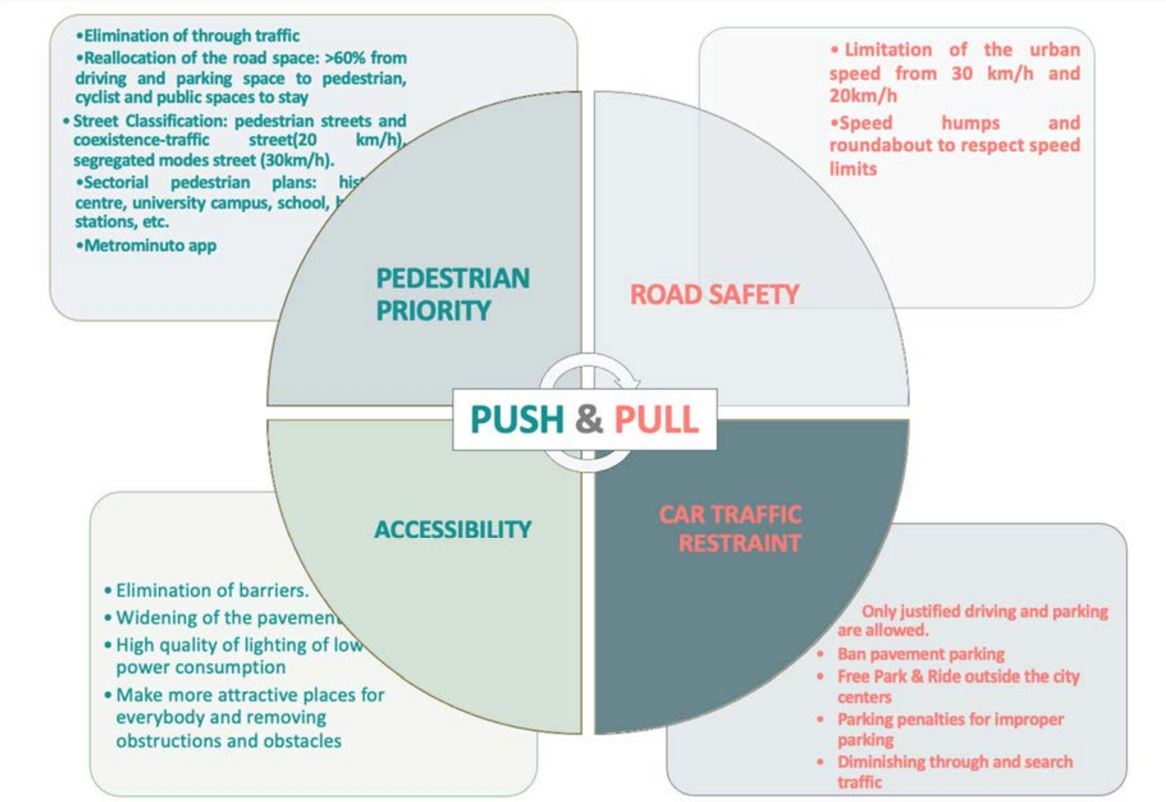

Figure 1. **Pull and push measures applied in Pontevedra (1999-2015).**

Once the implemented measures have been shown, the foremost results are presented below.

5.2 Main outcomes

It can be said that Pontevedra recovers the city for the people for several reasons. First, because the space for cars was reduced to give it to the pedestrian, the ratio was changed from 75-80% for cars to 75-80% for the pedestrians; cars are not prevented from entering the city, but through-traffic is gradually being excluded from the city centre (30% of vehicles); residents and various necessary activities that generate traffic are allowed such as: loading and unloading, access to garages, messaging, public transport and private services (with a maximum of 15 minutes of parking); pedestrianization actions were jointly carried out with cultural actions and events; underground car parks have been increased and since 2010, the speed has been reduced to 30 km/h throughout the municipality; and universal accessibility has been achieved throughout the public space, getting a safe public space, and where children play in the squares and go to school alone. Consequently, in 9 years, accidents have dropped to 0 and air quality has improved and is within WHO limits.

Additionally, the city has a parking system in which free spaces are contemplated to carry out small errands, free parking on the urban edge, and rotating paid parking lots throughout the city.

It is important to ensure that the benefits of change are noticeable. It seems that this has been the case because citizens are proud of their city and the population has been increasing. Decision-makers believe that the success was due to several factors (Concello de Pontevedra, 2016): i) a strong will to achieve the objectives: public spaces for all, accessibility for all; ii) starting with a phase of deep and conscientious reflection on how to act, learn from the successes and errors of other cities and permanent collection of information; iii) comprehensively understanding decision making on the urban space as a whole; iv) global solutions of overall problems instead of isolated and small actions, with imperceptible outcomes; v) outline the actions specifically for each neighborhood or urban area vi) successful political and inter-administrative coordination; vii) weighted use of the car reasoned and optimized, with the consequent change of habits. The car is used only when active modes are not competitive; viii) traffic reduction measures are gradually more intense in the centre than in other parts of the city (in 18 years, a third of the traffic in the center has been reduced); ix) overcome opposition through good information; x) instead of doing a few big festivals or events, more small and diverse actions were carried out in the streets contributing to an improvement in the quality of life for citizens.

6. CONCLUSIONS

A favorable way to reduce the pace of modern urban life is to design cities at human speed, moving at the pace of the person but not the car. Pedestrian mobility adds multiple benefits, first for the individual: it is healthy, it is active, reduces the level of stress and allows him to perceive more details through the human eyes, and normally, it increases the sense of belonging; secondly for the environment: it contributes to reach clean air, it is noiseless, takes up less space than any other mode of transport and no vehicle or device is needed to move (except disable people) and finally, pedestrian infrastructure or facilities are affordable than any road or rail infrastructure.

Reclaiming space for the pedestrian means taking it off to another mode, mainly to the car. This does not mean to ban cars, but to use them only when it is necessary and sustainable modes are not competitive. Initially, it may be an unpopular measure and less impressive than the inauguration of an infrastructure. That is why courageous politicians are needed to push for a more humane urban model and they who know how to achieve it.

Although an important variety of measures has been presented, unfortunately each city must contextualize and find its own way to establish which are the most appropriate combination of measures and how to succeed in their implementation.

It is not a matter that is achieved in the short term, not in one stage. A global action is more efective than the sum of isolated actions. As has been seen in the city of Pontevedra, the combination of pull and push measures maximize the benefits of both.

It is advisable to prevent possible side effects between measures and a different approach in different parts of the city. New projects need to be designed according to the unique urban areas, and for different cycles of life and groups of age (children, youth, older) adapting the concept aforementioned of ‘smart mobility’. In addition, it will be a form of not only to establish measures that promote walking, but also to connect sectoral policies with each other (for instance, health, transport, social and cultural, etc.). Thus, the transversal organization of mobility in the administration is desirable and it contributes to a comprehensively understanding of mobility.

COSTS AND BENEFITS OF GENDER POLICIES IN TRANSPORTATION. STATE OF THE ART OF QUANTITATIVE APPROACHES

Oscar Martínez Alvaro
Transport Professor (UPM). Transport Researcher (Transyt). Managing Partner (Tool Alfa). Ph. D. Civil Engineering. M. Sc. Economics

Project Manager. Tool Alfa. M. Sc. Civil Engineering

ABSTRACT

The transport sector has been a pioneer in the quantification and even monetization of complex issues, such as the value of life or the value of time. Gender issues are more and more in the core of many policies, but its analysis is usually qualitative at most. The objective of this paper is to review current quantitative approaches, and highlight their advantages, their drawbacks and their gaps.

The transport sector can be analysed with a gender perspective, either considering its workers or its users. In both cases, men and women show different attitudes and behaviours. To begin with, workforce in transport is predominantly male, while public transportation is used mostly by women.

There are numerous studies with a gender perspective in the transport sector. Most are qualitative and simply describe the problem or the project in question. More and more are using quantitative approaches, but mostly for describing interventions, not for assessing impacts. In many respects, such as gender violence, there have been notable advances, despite methodological difficulties. In others, almost nothing can be found. In any case, evaluations are far from systematic and important gaps remain.

The large experience of the transport sector when dealing with intangible impacts should facilitate the development of quantitative assessments and evaluations, but the lack of quantitative ex-post analyses makes it difficult to assess gender-oriented projects.

1. GENERAL FRAMEWORK

In the transport sector, impacts as diverse as the cost of accidents and life loss or the benefits due to time savings have been quantitatively evaluated for decades. However, the gender approach, which is currently the axis of many policies, is frequently assessed from a merely qualitative point of view.

This article provides a review of quantitative analyses related to the gender approach in the field of transport. Three large analysis groups have been identified, each of which subdivided as follows:

- Regarding women as employees of the transport sector, where two types of impacts arise:
  - Direct ones, either related to labour costs (which include salaries, absenteeism and productivity) or derived from accidents.
  - Indirect ones due to the female participation gap.
- Regarding women as transport users, two types of impacts can be considered:
  - Direct ones related to gender-related violence when using public transport.
  - Indirect ones linked to the mobility of the users.
- In addition, there are other highly important impacts, of indirect nature and delayed over time, derived from female empowerment.

Most these issues may be considered from the point of view of costs, whose reduction are benefits. In the following paragraphs, this distinction is not dealt with and must be taken for granted.

2. WOMEN AS EMPLOYEES

2.1. Labour costs for companies

From a managerial point of view, labour costs in general (men or women) are highly relevant in the transport sector. In Spain, in the freight transport by road, the cost of drivers (without subsistence allowances) ranges between 54.7% of total operating costs for a van and 16.7% for a refrigerated trailer in international transport (Ministerio de Transportes, Movilidad y Agenda Urbana, 2020a). In road passenger transport, the equivalent value varies between 55.8% for a minibus with 10 to 25 seats and 28.8% for a bus with more than 55 seats (Ministerio de Transportes, Movilidad y Agenda Urbana. 2020b).

The wage gap is the difference in salaries between men and women with the same position and performance. In Spain, the harmonized wage gap (isolating the effect of differences in age, seniority, educational level, working hours, etc.) in the transport and storage sector was 10.5%, as an average value for the 2002 - 2014 period. As a comparison, the value of this indicator in the education sector was 5.5%, in the Public Administration 6.7%, in commerce 11.8%, in construction 14.0% and in manufacturing 19.5% (PWC, 2019). Transport is, therefore, in an intermediate position.

A study of direct differential monetary costs for hiring a woman instead of a man in several Latin American countries showed that they are less than 1% of the total labour cost of female employees. The additional cost for companies in Argentina for hiring a woman was 0.39%, in Chile 0.92% and in Uruguay 0.50% (Abramo and Todaro, 2002).

In Spain, and particularly in Andalusia, before the increase in paternity leave, maternity leave represented an extra cost for women of between 0.24 and 0.36% of salary (Junta de Andalucía, 2010).

Productivity refers not to the input cost but to the cost of the input relative to the output. A study carried out with a wide series of data in industries in the United States (data from 1974-1978), Sweden (data from 1990) and Norway (data from 1990) found negative differences of 2%, 1% and 3%, respectively, in the productivity of women compared to men, although it was indicated that it could be due to factors that had not been considered (Trond and Vermond, 2006). In studies related to specific sectors, such as agriculture in various Central American countries and in Mexico, levels of female productivity are very similar to those of men (CEPAL, 2011).

Regarding absenteeism, no specific data has been found for the transport sector, but there are some results of interest for other sectors and certain geographical areas:

- Absenteeism due to family reasons is higher in women with small children, although if absenteeism due to illness or other reasons is taken into account, it may become higher in the case of men (Álvarez, 2000).
- In different Australian companies 84.2% of employees had taken at least one time off during the year for a reason not anticipated by their employer. The absence rate was slightly higher for women (2.7%) than for men (2.3%) (VandenHeuvel and Wooden, 1995).
- In the UK, the average absenteeism rate for the entire population was 3.7%. If only absenteeism due to illness and accidents was considered, this rate dropped to 2.4%. The difference between these two measures was much higher for women than for men. The average total absenteeism rate for women was 5.2% and 2.9% for illness and accidents, respectively. For men, these values were 2.4% and 2.0%, respectively (Bridges and Mumford, 2000).
- In a major metropolitan area in the United States, women were absent more frequently than men, but with a difference that was not very significant (2.88% of women versus 2.14% of men) (Scott and Mabes, 1984).
- In Andalusia (Spain), female absenteeism explains an extra cost of between 0.83% and 0.87% of the average salary with data from 2006 (Junta de Andalucía, 2010).

Regarding accidents, in the transport sector it is relevant to make a distinction between two types of accidents:

- Accident at work, common to any other sector, considering all kinds of accidents.
- Traffic accidents, due to vehicle handling, as a case of accidents in general.

In Spain, and referring to all types of accidents by gender, the "incidence index" is used. It is defined as the number of accidents that occur at work in a given period for every 100,000 people on the workforce. For 2015 the values were as follows (INSHT, 2016):

- For all sectors, the index value was 2,088.9 for women and 4,313.6 for men.
- For the transport and communications sector, the value was 3,331.2 for women and 5,561.2 for men.

About traffic accidents by gender, there is information from several countries, always very favourable for women:

- In Spain, an investigation carried out in Andalusia found that, taking into account the travel time as an indicator of the degree of exposure, the risk of injury in a traffic accident was lower for women: in serious injuries 23.6% less than men and in deaths 35.1% (González, 2019).
- In the United States, an analysis carried out in the road freight sector showed that, compared to a female participation rate of 5.0% of total drivers, women were 2.0% of drivers involved in accidents without injuries and 2.7% of those involved in accidents with injuries (TRB, 2016).
- In Jordan and for an average annual driving distance for women of 12,000 km and for men of 17,000 km, the results regarding the adjusted accident rate per 1,000 drivers and per km travelled was 2.42 times higher for men (Al -Balbissi, 2003).

2.2. Gender gap

The "gender gap" describes any difference between the values of one variable for men and for women. The "wage gap" has already been discussed, as a difference in remuneration between men and women for the same position and performance. The "participation gap" is the difference between men and women in share of the labour force.

The participation of women in the "transport and logistics sector" has increased in the EU countries in recent years, although there are still clear differences between countries. France and Germany show female participation rates of over 25%, while other countries, including Spain, are still around 20-21% (Eurostat, 2019).

Country	2013	2017
France	25.83%	26.23%
Germany	25.48%	25.26%
United Kingdom	19.28%	20.95%
Italy	20.23%	20.22%
Poland	20.73%	19.31%
Spain	17.96%	19.02%

Table 1 – Percentage of women over the total number of people between 15 and 64 years employed in the transport and logistic sector in several EU countries

As a comparison, the percentage of female participation in the transport, storage and communication sector in 2014 in the set of 18 countries in Latin America and the Caribbean was 20.9% (CEPAL, 2017).

If the analysis is carried out in specific subsectors, it is found that in road passenger transport Spain was the EU country with the highest percentage of female drivers: 15% compared to the European average of 12% (IRU, 2019). This is one of the results of the huge growth of women in obtaining a bus driver's license between 2012 and 2018: 60.51% (DGT, 2020).

3. WOMEN AS USERS

3.1. Gender violence

Public transport is one of the environments where women can feel a greater feeling of lack of security, although values vary largely (International Transport Forum, 2018):

- A national survey in the United States found that one in four women had experienced sexual harassment situations on public transportation.
- In Paris (France), 100% of women using the regional public transport system had experienced situations of harassment according to a recent survey.
- In Mumbay (India) a survey of 1,000 users at seven metropolitan railway stations found that 54% of respondents had experienced sexual harassment.

On the other hand, in 2014 a survey of more than 6,500 users of public transport in 16 of the world's most populated metropolitan areas, found that the public transport systems of Bogotá, Mexico City, Lima, Delhi and Jakarta were the areas with the worst overall value in the city, but this problem also stood out, although to a lesser degree, in London and New York (Thomson Reuters Foundation, 2014).

However, an adequate official quantification frequently faces problems of lack of representativeness.

The number of complaints is usually very low, especially in countries with weak police and legal support. Continuous perception and victimization surveys, with adequate preparation of the personnel who ask the questions, could make it possible to assess the evolution gender-specific violence (UN Women, 2017; Galiani and Jaitman, 2016).

Going one step further, it is possible to calculate the monetary value of violence by means of methods closely similar to those used in transport economics:

- For the direct costs related to medical, police and legal care, both of the criminal act itself and of the judicial and penitentiary process in the event of the offender's arrest, the so-called accounting method is used, based on the budgets of the departments of health, police and the judiciary, along with the number of complaints made.
- For the valuation of indirect costs (productivity lost by companies, loss of income of victims, etc.), the results of surveys of companies and victims are often used.
- And, as expected, the valuation of intangibles is complex, due to difficulties in monetizing aspects such as pain and suffering, along with other aspects such as the loss of social capital.

Some examples found consider tangible and intangible costs, but others are limited to tangible ones. In the table that follows, the first four countries include tangible and intangible costs, while the last two take into account only health loss costs (health services, lost economic output and physical and emotional impact).

Country	Crime	Unit cost	Note	Source
United Kingdom and EU	Homicide Injuries Common assault Sexual violence	1,733,192 € 14,209 € 2,316 € 52,486 €	Values in € 2012	EIGE, 2014
USA	Homicide Rape Sexual assault	4,474,501 US$ 103,560 US$ 32,780 US$	Values in US$ 1996	Clark et al., 2002
Canada	Homicide Rape Sexual assault Sexual harassment	7,951,145 C$ 50,007 C$ 14,225 C$ 630 C$	Values in C$ 2009	Canada Department of Justice, 2014
Australia	Sexual violence	26,780 A$	Annual value per victim in A$	PWC, 2015
Guatemala	Homicide Rape	94,604 US$ 6,570 US$	Values in US$ 2005	Balsells, 2006
El Salvador	Homicide Rape	181,510 US$ 5,453 US$	Values in US$. 2007	Acevedo, 2008

Table 2 – Unit costs for crimes of gender violence

3.2. Mobility

The first observation regarding mobility is that, due to their different social roles, men and women move differently. All data lead to the same conclusion: women walk more and use public transport more. With data from the Basque Country (Spain), more than half of trips of women are walking, while for men walking represents just over a third of trips (Emakunde, 2013).

Mode	Women	Men
Car	27.5%	44.8%
Walking	51.7%	37.3%
Bike	1.4%	2.5%
Railway	7.6%	5.3%
Bus	8.0%	3.9%
Motorcycle	0.3%	1.6%
Multimodal	1.3%	1.1%

Table 3 - Distribution of trips according to the main modes of transport in the Basque Country

Improving mobility is the essence of the functionality of a transport system. The benefits of improving women's mobility can be classified into two types:

- The direct benefit is this related to the reduction of travel times, easily monetizable in transport economics.
- The main indirect benefit is associated with the increase in opportunities that the improvement of mobility brings: a greater number of possible jobs, educational premises, places of social interaction, health services, etc.

Regarding the reduction of travel times, most surveys carried out in recent years in metropolitan areas already include the gender perspective in the assessment of travel time according to the trip purpose, the transport mode, etc. Analysis with data from Sweden (Börjesson and Eliasson, 2019) found no general differences in the valuation of travel time according to gender, despite the fact that they had detected different valuations in access to public transport in relation to perceived personal safety (Börjesson, 2012). However, in societies with greater gender inequality, it seems that the social valuation of time is different for men and women, both in terms of travel for work and other reasons. In particular, in Spain it seems that women value travel time between 43 and 50% more than men, as shown in the table below.

Scope and date	Hourly travel time value for women	Hourly travel time value for men	Source
Santander. Bus (2003). Under 24 years and 1,200 Euros/month	3.25 Euros	2.17 Euros	IDAE (2010)
Santander. Bus (2003). More than 24 years old and less than 1,200 Euros/month	13.75 Euros	9.19 Euros	IDAE (2010)
Santander. Bus (2003). Less than 24 years old and more than 1,200 Euros/month	3.59 Euros	2.51 Euros	IDAE (2010)
Santander. Bus (2003). Over 24 years and 1,200 Euros/month	15.19 Euros	10.61 Euros	IDAE (2010)
U. de La Laguna (2000)	8.91 Euros	6.13 Euros	Amador (2005)
Teide National Park. Private and rental car (2016)	12.30 a 13.86 Euros	9.58 a 11.0 Euros	Marina (2017)

Table 4 – Economic valuation of travel time differentiated by gender in Spain

Regarding the benefit for access to opportunities, an interesting study in Buenos Aires obtained the following results (Peralta et al., 2014):

- The need to minimize travel times in order to combine work and domestic activities means that women must look for job opportunities at shorter distances from home. In the workforce, women with children must look for jobs within a 20% shorter distance than men.
- The average distance travelled by men on each trip is much higher than that travelled by women: 6.72 km compared to 4.77 km.
- Regarding the speeds of these trips, tit is 8.62 km/h for women and 10.93 km/h for men. This difference is due to the larger use of public transport by women.

In Spain, a study carried out in Madrid and Barcelona (Matas et al., 2010) stands out. It assessed accessibility in public transport and its impact on women compared to men in terms of labour market. For the metropolitan areas studied, better access to employment in public transport increases the probability of working. The distinction according to educational level shows that the effect is greater for those women with a lower level of education and, probably, with less car availability. Thus, if accessibility by public transport increases:

- Women without studies in Barcelona would see an increase in employment ratio from 34.3 to 40.8% and those in Madrid from 30.7 to 34.0%.
- In the case of women with primary education, the increase would be from 45.0 to 48.0% in Barcelona and from 37.7% to 39.1% in Madrid.

Other studies show that more than 70% of the women surveyed at some point in their life rejected or gave up a better job due to the distance they travelled, while only 40% of men had to do the same. The results also show that the level of exclusion is higher for low-income women (Fédération Internationale l'Automobile, 2014).

4. EMPOWERMENT

Empowerment is defined as the “process of access to resources and development of personal capacities to be able to actively participate in shaping one's life and that of their community in economic, social and political terms” (European Commission, 1998). Therefore, most of the benefits discussed above on women as users also lead to greater empowerment.

A first type of empowerment can be classified as “economic empowerment” and is related to time savings and increased opportunities, as well as increases in income, savings and consumption. It has already been discussed previously, particularly about improving mobility, but it may include other aspects such as increased disposable income if transport costs decrease. In addition, there may be issues of more complex monetization, such as improving access to schools or healthcare facilities.

“Social and political empowerment”, related to participation in the public sphere is an area where the existence of numerous intangibles makes it difficult to find significant examples of impact quantification, let alone monetization. The most complete references found of ex post analyses are related to rural areas in poor countries, and the role of women employed in road and highway improvement and maintenance tasks. Although they are of utmost importance, they provide information only about some isolated indicators, without any consolidation:

- Following the implementation of a rural road improvement program in Bangladesh with active female participation, the results showed a decrease from 31% to 16% of poverty, while girls' school enrolment increased by 5.7% and the number of jobs healthcare coverage doubled (Quader, 2011).
- Various rural road improvement programs in Peru between 1995 and 2013 with female participation entailed an increase in school enrolment of 19.2%, while the number of health consultations increased by 17.8% in the communities that benefited from the project (World Bank, 2017).

5. ECONOMIC EVALUATION

In the research carried out, no manuals or guides with quantitative methods of evaluation of the gender approach have been found, not to mention specific ones in the transport sector.

In terms of women as employees, the economic assessment of the gender gap has not been found for the transport sector, but there are various estimates for the economy as a whole. In Spain, a recent analysis with data from 2018 and 2019 showed that Spanish GDP would increase by more than 200,000 million euros, equivalent to 16.8% of GDP in 2018, if the gender gap was eliminated (PWC, 2019). In any case, the value of impacts and the low cost of implementation make it obvious that the overall balance is neatly positive.

When it comes to women es users, there are interesting efforts to define its main impacts of (Inter-American Development Bank, 2016) or to establish systematic evaluation methods, but they are usually limited to stating general principles, without providing the typical default values that help evaluators so much in other fields of transport (García-Calvente et al., 2016).

Some efforts have been made in several sectors in order to assess gender-oriented projects, but very few in the transport sector, where most analyses are simply valuation of impacts, which in this context is no minor feat. In transportation, some ex-post studies give information on the impact of measures oriented towards the reduction of gender-based violence and the difficulties of valuing it simply:

- The “Viajemos Seguras” (Let's Travel Safely) Program in Mexico City, in operation since 2008 and recently strengthened, is a set of actions that range from prevention to care actions. The impact of the measure to have specific subway cars for women has been evaluated and the results have been mixed: sexual violence disappears but physical violence increases. (Soto et al., 2017).
- The “Bájale al Acoso” (Come Down to Harassment) strategy in Quito (Ecuador) in the main bus and trolleybus corridors began in 2014 and in 2017 it was structured as a program of actions. The latest references obtained from a continuous impact evaluation showed a decrease of 34.5% in situations of sexual harassment, considered to be the result of more than 2,500 complaints and the conviction of 20 harassers (Banco Inter-American Development, 2018).

When it comes to mobility, the higher speed of the private vehicle compared to public transport in Buenos Aires means that, when women have access to the car, the average speed of their trips increases by 5.76 km / h. If the travel speeds of women were compared to those of men (keeping the number of trips), their opportunities in the labour market would open between 20 and 80% (Peralta, 2014). In this case, incidentally, the reflection might be whether, for other social and environmental considerations, the transfer from public transport to private vehicle is desirable.

More structured analyses comparing costs and benefits are very few. Two notable cases in relation to assessing gender-violence related projects have been found. Both have in common the use of the benefit to cost ratio as an indicator.

- Ratios of B/C up to of 17 have been obtained for reducing violent assaults, regardless of the gender of the victim (Copenhagen Consensus Center, 2016).
- A B/C ratio of 9.25 was estimated in an evaluation of five years of actions established by the Violence Against Women Act of 1994 in the United States (Clark et al., 2002).

6. CONCLUSIONS

In a context where gender-responsive policies are ubiquitous, data related to women as a part of the workforce in the transport sector are relatively abundant. Common measures such as the wage gender gap are well established, as it happens in any other sector. Even some specific aspects, such as traffic accidents are well documented. Most indicators are either similar for men and women, or positive in favour of women. This reinforces the need to increase the role of women in the transport sector as employees. Be it from the strict point of view of the operating companies or from the point of view of the whole society, it becomes obvious that the reduction of the gender gap is positive and its social and economic impacts are huge.

But from the point of view of women as transport users, information is not as clear. Some projects in different sector have assessed quantitative impacts of gender-based projects, but in the transport sector experiences are scarce and figures less available. Violence reduction or time savings have been valued, and its final impacts even monetised. But many other aspects are simply not analysed with quantitative tools. More often than not, results are shown in terms of resources spent (investment done, for instance) or, at most, in terms of direct results (such as number of complaints). Concepts such as empowerment, which may be considered the backbone of many policies, are rarely quantified and probably have never been assessed.

If economic evaluation is systematically used in other types of transport projects, including so sensitive issues such as the value of human life, one could expect that actions with a gender focus might be also assessed using, at least, a quantitative approach, but this is the exception to the rule. The main barrier to this improvement is the lack of ex post data: although costs may be well defined, values of benefits (or reduced costs) are unknown.

Rational priority setting requires information of high quality. If such information is not available, governments may be making inefficient decisions. The transport sector is used to dealing with intangibles: well-planned, quantitative ex-post assessments of the many recent and planned actions should be high on the gender agenda.

ABSTRACT

Recent developments in the transport and mobility sectors are radically altering mobility patterns; these include digitization, smart mobility applications, and local digital services, which offer a wide range of innovations that are adaptable to rapidly-evolving lifestyles. However, many services currently are offered as an "online" mode or incorporate digital elements, and the lack of adequate digital literacy or of specific competencies / skills can be expected to generate situations of exclusion.

The DIGNITY project (https://www.dignity-project.eu/), a European initiative in the European Union's H2020 framework, aims to promote an ecosystem of digital mobility services that is sustainable, integrated, and user-friendly, and which improves accessibility, social inclusion, daily mobility experiences, and everyday life of all residents. The project selected four pilot studies in five EU countries (Spain, Italy, Belgium, the Netherlands, and Germany) for their innovative proposals in sustainable and inclusive mobility. The case studies apply the DIGNITY approach, which is based on conducting workshops, interviews, and surveys.

Here, we specifically address the study based in Barcelona, which is at the forefront in smart urban transformation. The digital divide in mobility in the Barcelona Metropolitan Area was evaluated using a mixed approach of combining literature review with a quantitative survey. The results reveal the needs and perceptions of people about local mobility, as well as the gaps in the use of technology products and services.

1. INTRODUCTION

Digital transformation has a great impact on the daily lives of people. Public products and services are becoming more interactive and are being increasingly offered online. Nevertheless, some groups in society do not fully benefit from the opportunities of digitization (Loos, E. et al., 2020; Groth, S., 2019), (for instance, women, people who are older or have functional impairments, low education, low income, as well as short-term migrants and ethnic minorities) and are more likely to be excluded from many services and facilities (Durand, A. and Zijlstra, T., 2020).

In the transport and mobility sector, advances such as digitalization, availability of smart applications, and locally-based digital services are disruptive for mobility patterns and offer a range of mobility innovations that respond to rapid changes in lifestyles. New mobility concepts can include a wide variety of elements, such as novel products, data-based processes, and services inspired by new transport dynamics (e.g., mobility-as-a-service [MaaS] and on-demand public transport), as well as new business models, such as pay-as-you-go. However, technology has not yet contributed to universal access, as most of the new transportation technologies have more greatly benefited a specific demographic: urban, young, tech-savvy, and usually well-off (Vandycke, N., 2018).

Therefore, commuting and mobility produces new challenges for the political agendas and the development of the public and private sectors, with a strong presence of information and communication technologies. In this context, synergies appear that can produce social exclusion in the field of mobility and the use of new technologies. More and more studies are examining the digital divide and transport poverty in greater depth; even so, the growing relationship between mobility and the use of new technologies, as well as the tendencies of governments and companies to move towards digitization, require further studies that relate the two concepts and give a precise overview of social exclusion and situations of inequality that are being generated in this area.

2. THE OPPORTUNITY OF THE DIGNITY PROJECT

The DIGNITY project (DIGital traNsport In and for socieTY; https://www.dignity-project.eu/) is a European initiative funded by the European Union's Horizon 2020 Program. DIGNITY aims to contribute to the development of a transport system that is inclusive, digital, and interconnected, and that meets the needs of all residents. The project has fourteen partners from six European countries.

The overall objective of DIGNITY is to foster a sustainable, integrated, and user-friendly digital travel ecosystem that improves accessibility, social inclusion, travel experiences, and daily life of all inhabitants.

The project thoroughly examines the digital mobility ecosystem to understand the full range of factors that could lead to disparities in the adoption of digitized solutions for different user groups in Europe. The idea is to support public and private mobility providers in their conception of general digital products or services, to make these accessible and usable by the largest possible number of people, regardless of their income, location, social or health situation, or age. Further, results from DIGNITY should help policymakers formulate long-term strategies that promote innovation in transportation while responding to global social, demographic, and economic changes, including the challenges of poverty and migration. Four case studies on implementing inclusive mobility solutions have been selected as pilot projects, based on their ambition of working towards these types of solutions: Ancona (Italy); Barcelona (Spain); Flanders (Belgium), and Tilburg (the Netherlands) (for more information on DIGNITY pilot projects, see https://www.dignity-project.eu/pilots/).

This article is specifically based on the case study of the Barcelona Metropolitan Area (*Àrea Metropolitana de Barcelona*, AMB). The objectives are to: i) characterize the context of digital exclusion with respect to mobility in the AMB, and ii) to understand the patterns of use of digital technologies by residents for their daily mobility.

3. METHODS

The proposed objectives of this study are based on i) a bibliographic review collected in an academic study of a Master's thesis (Bella, R., 2020), as its considerations and recommendations advance the knowledge of the current situation in the field of study; and ii) the preliminary results of a quantitative survey carried out in November and December, 2020.

The fieldwork of collecting interviews was entrusted to the GESOP Institute (*Gabinet d'Estudis Socials i Opinió Pública*, Cabinet of Social Studies and Public Opinion) of Barcelona. The questionnaire with 96-questions/variables is divided into eight parts, each of which addresses specific issues related to mobility and technologies and includes several questions and variables, such as: access to and use of technology; technology for public transportation; general computer and mobile device activities; attitudes toward technology, technology symbols, and interfaces; personal abilities / skills; demographics; and specific questions about daily mobility. The work presented here is mainly focused on specific topics of the survey:

- Technology access and use: related to the access to and frequency of use of different devices;
- Technology for public transport: addresses issues related to the use of digital public transport services;

- Demographics: describes characteristics of the population (e.g., social, educational, residential, etc.);
- Questions about daily mobility.

Although two subsamples were defined (one for the city of Barcelona, and the other for the remaining metropolitan area), this article only presents grouped data. Interviews were stratified by district, and the potential interviewees were selected randomly after taking into account gender, age, and nationality quotas.

4. RESULTS AND ANALYSIS

The bibliographic analysis (Bella, R., 2020), provides essential information to understanding the context of the digitization of mobility in the AMB. The population of Barcelona is uniquely situated with respect to the use of digital tools. In the comparison of the Digital Economy and Society Index (DESI) regarding internet access, use, and connectivity, the city of Barcelona is positioned among the European leaders, well above the average for Europe, Spain, and Catalonia (DESI, 2019). Despite this evaluation, an analysis of the aspects of i) mobility and social exclusion; ii) digital divide; and iii) digital exclusion detects groups that are of special interest due to their vulnerability and/or discrimination:

- Women;
- Older people (e.g., ≥65 years old);
- Individuals who are unemployed, retired, or exclusively dedicated to unpaid household work;
- People with lower levels of education;
- Individuals with high degrees of functional impairment and wheelchair users.

Residents who belong to one (or more) of these groups are seen to have a higher risk of social exclusion in terms of mobility.

The results of the survey highlight interesting characteristics in the use of digital technologies and mobility services, as well as the main limitations and concerns of the main groups analyzed in the Barcelona metropolitan area.

The information on the use of digital technologies in mobility, with respect to the different groups identified as vulnerable, is shown in Figure 1. The importance of using of digital services to find travel information is noteworthy. In general, a considerable percentage of the population (82.2%) uses digital sources to find travel information with women using them slightly less (80.1%). On the other hand, the groups with the lowest educational levels and the older population are the ones that are less likely to use these methods to gather information when planning a trip (62.7% and 56.3%, respectively).

Among older people, there is a higher distrust in the use of digital services for trip planning; approximately one out of three older people feels insecure about planning a trip on public transport using a mobile phone. Furthermore, about 60% of people with a lower level of education experienced similar limitations. A much higher level of trust was observed for the group of women (71.5%). In total, around 75% of the population feels quite confident in using a smartphone to plan a trip. The remaining 25% include people who have access to digital technologies but do not feel comfortable using them, which may lead to exclusion from mobility.

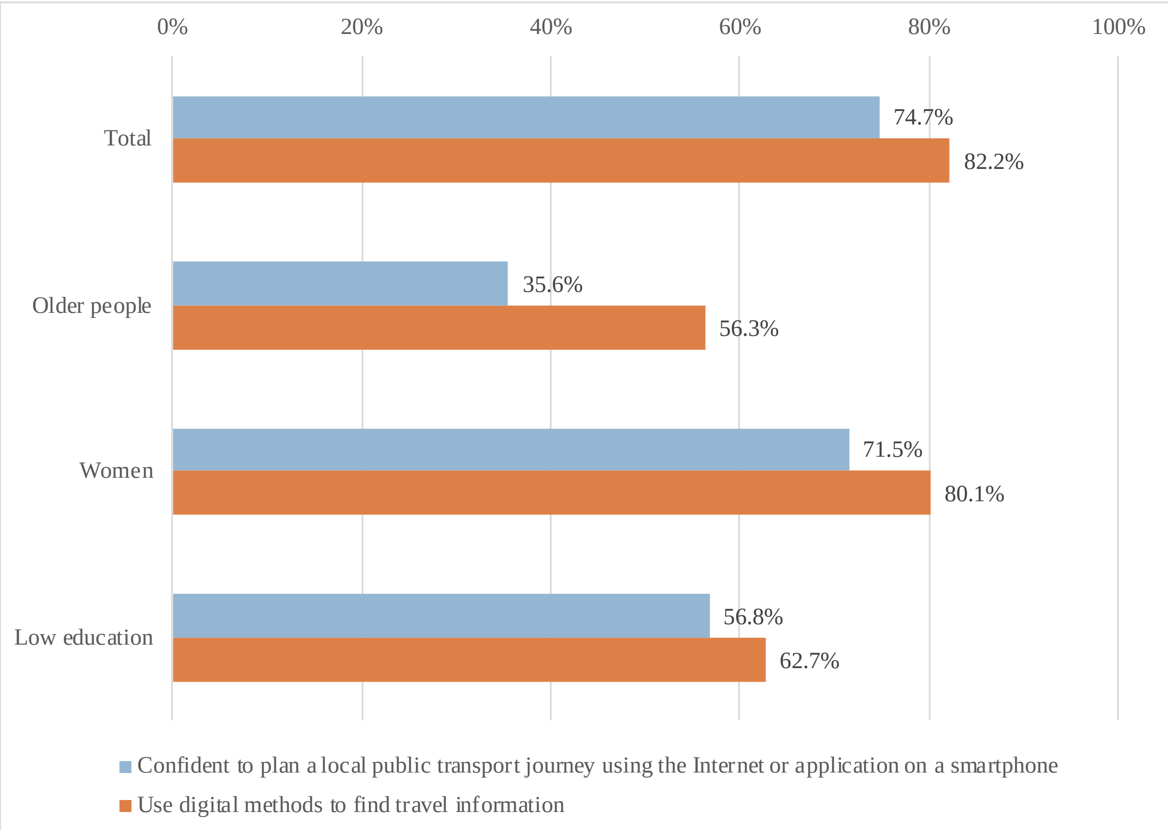

Figure 1. Use of technology for digitally-supported mobility, separated by groups identified as vulnerable

The use of digital transport services by each vulnerable group (Figure 2) revealed that, in general, the percentage of use among all groups is low. The highest percentages are for digital payment for parking and mobile taxi booking. The use of carpooling, carsharing or on-street scooter/motorbike hire services is very low, which shows that these new forms of shared transport remain unpopular among the general population.

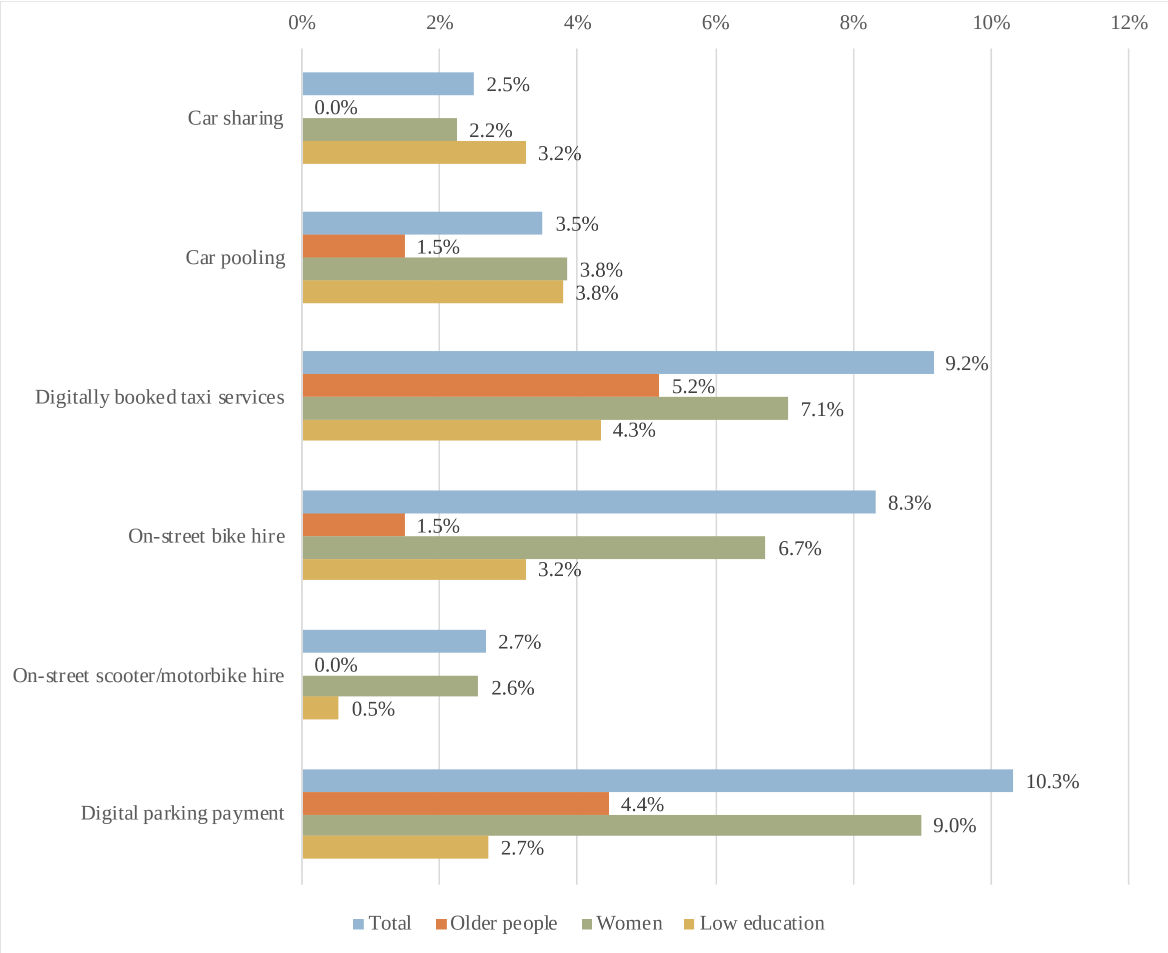

Figure 2. Use of digital transport services per group identified as vulnerable in the past three months (at the time of questionnaire)

Figure 3 analyzes the perceived limitations in regular mobility among the different groups identified as vulnerable. In general, more than 50% of the responses indicate that no particular limitations on mobility are perceived. Of the perceived limitations, safety is among the most important, with a higher percentage of women (50%) and older people (48.1%) perceiving this as a limitation. The cost of transport represents the second-most perceived limitation, cited as the most important one for the groups of the women (47.4%) and the one with the lowest education level (47.0%). Limitations due to lack of digital knowledge are currently less important, although more significant in the case of older and lower-income people.

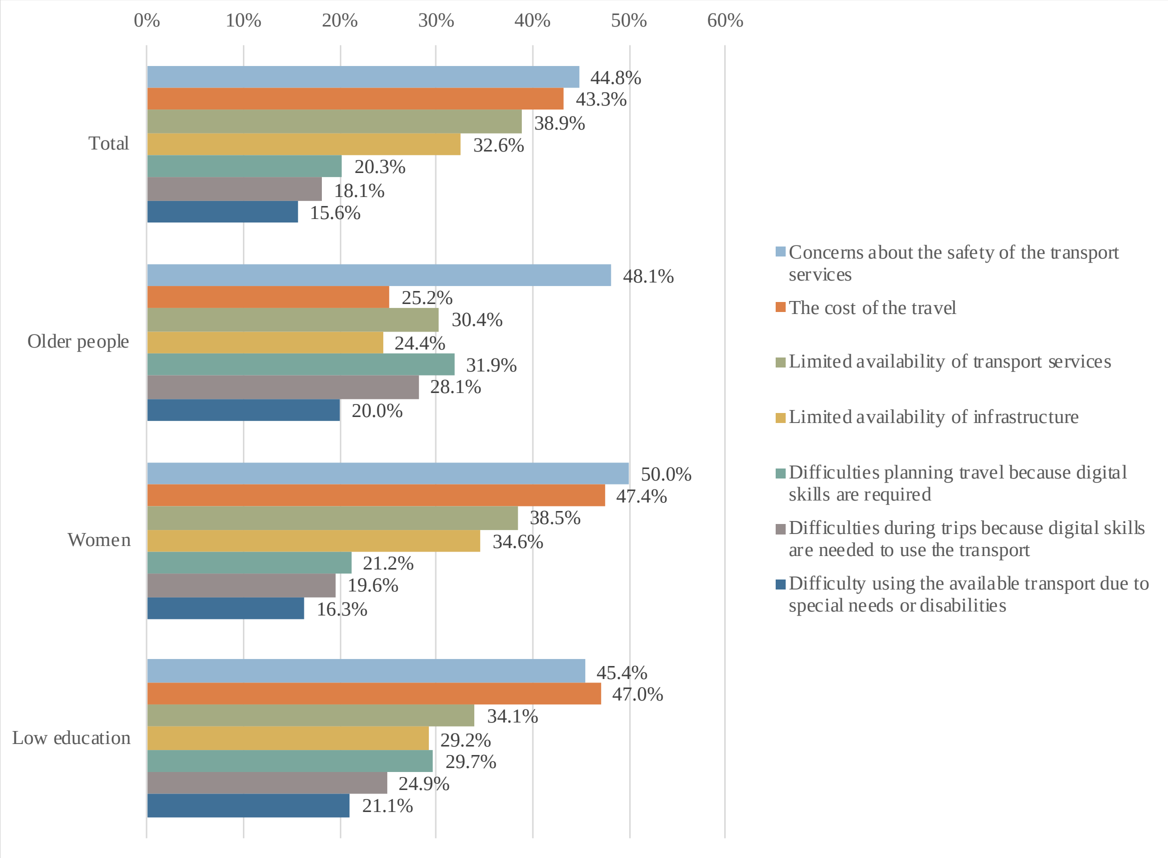

Figure 3. Limitations on regular mobility, per group identified as vulnerable

Figure 4 shows the global perception of the importance that the interviewees assigned to the promotion of different future actions, taking into account that the survey was taking during the COVID-19 crisis of 2020. The post-COVID measure that was indicated as the most important was to an increase in the provision of public transport to avoid congestion (83.5%). This measure is mainly related to perceived safety at the health level and concerns about the risk of contagion, which will be an important issue from now on in the context of public transport that has to be addressed with adequate measures, in order to regain the trust and reliability of this fundamental public service, which is essential for a sustainable urban ecosystem. Notably, the interviewees assigned a high importance to measures that address working conditions—specifically, the flexibility of working hours (75.7%) and an increase of teleworking (73.2%). Promotion of actions such as the implementation of contactless transport tickets or the expansion of pedestrian areas are also considered important for the future of cities, with percentages above 60%. Less importance was assigned to measures such as the expansion of bike lanes (54%) or the promotion of new shared electric vehicle systems (51.4%). Finally, the measure with the lowest perceived importance is the ease of driving to work by car (40.4%).

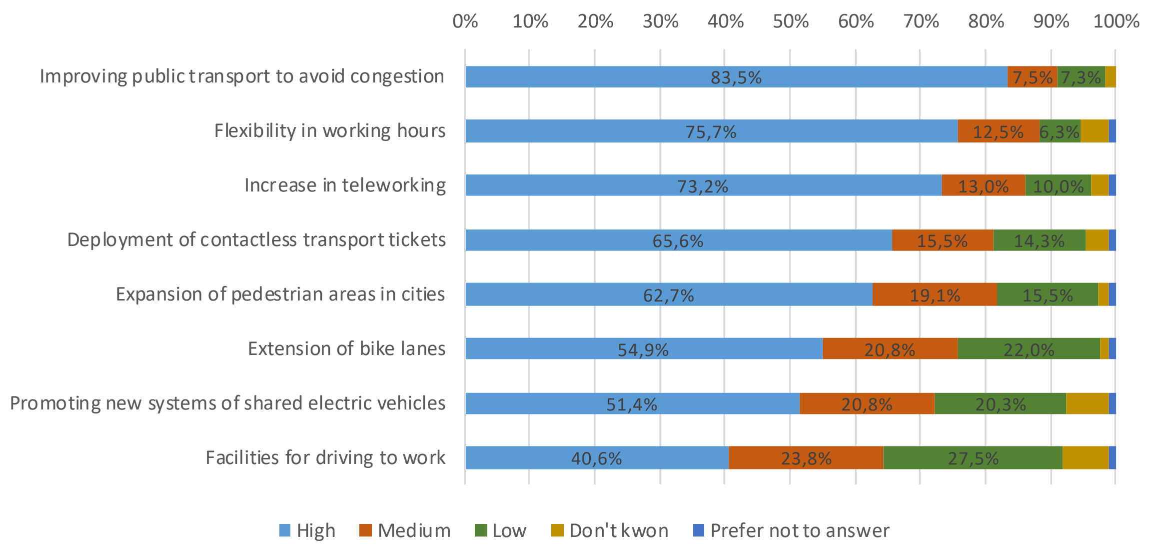

Figure 4. User perceptions about the need to promote specific actions (note that the survey was taken during the COVID-19 crisis in 2020 in Spain)

6. CONCLUSIONS

This study confirmed the problem of potential exclusion related to the mobility of certain social groups in the AMB and recommends that specific studies are carried out to promote a better understanding of the phenomenon, as well as to promote more inclusive policies that better integrate social and technological aspects. In the coming years, an increasingly accelerated development of digital tools focused on mobility—from MaaS to autonomous cars—is likely lead to a total paradigm shift in the way of understanding travel. Therefore, it will be necessary for the entire population to be able to correctly use it, to avoid generating greater social inequalities that strongly limit social development in all its senses. In addition, it will be important to address certain aspects, such as improvement of public transport—with particular attention to categories such as women and older persons, who represent a significant percentage of users—as well as the promotion of working conditions that recognize the flexibility of working hours and the possibility of working remotely. These factors will in turn lead to important changes in the conception of services to be offered and in the conditions of provision of the public transport service.

ACKNOWLEDGEMENTS

This research was done as part of the Dignity project which received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement number 875542.

EL RECIENTE CAMBIO DE PARADIGMA DE LA MOVILIDAD EN EL ÁMBITO EUROPEO

Pedro Saldaña Alegre
Consultor de transporte, Ineco, España
Javier Martínez Boada
Consultor de transporte, Ineco, España

ABSTRACT

Durante décadas, los pilares "teóricos" de la sostenibilidad, -el medioambiente, la economía y la sociedad-, han articulado la planificación de las Administraciones en el ámbito de las infraestructuras y del transporte. En "la práctica", el principal esfuerzo inversor se ha destinado al crecimiento del stock de infraestructuras para superar los déficits de capacidad de las redes.

Recientemente, la rápida digitalización, las nuevas pautas de movilidad y la mayor concienciación social sobre la preservación de nuestro entorno y la urgente lucha contra el cambio climático, han provocado la necesidad de que las Administraciones se replanteen el enfoque con el que afrontar sus políticas de transporte.

El cambio de paradigma pasa por incorporar la movilidad como un concepto más amplio que engloba no sólo a aquello que es inherente al transporte desde una perspectiva tradicional, –el desplazamiento de personas o bienes, entre un origen y un destino, consumiendo recursos cuantificables–, sino que además incluye todos aquellos condicionantes, motivaciones y percepciones de los individuos, situando al usuario y sus necesidades en el centro de todo el sistema.

Tanto la Unión Europea como los Estados miembros están en un proceso de transformación de sus políticas orientándolas hacia la movilidad cotidiana de toda la ciudadanía. Proceso de transformación que se ha visto fuertemente influenciado por la irrupción de la pandemia de la Covid-19 en el año 2020.

Este artículo hace un recorrido a través de las políticas de movilidad europeas más representativas del mencionado cambio de paradigma y en relación con las materias identificadas como más novedosas, con el objetivo de identificar el denominador común de todas ellas. Los ejemplos destacados deben de entenderse siempre en sus correspondientes marcos competenciales y territoriales.

1. INTRODUCCIÓN

La evolución tecnológica surgida desde finales de la década pasada, la concienciación ciudadana y la mayor ambición de las Administraciones públicas por la descarbonización de la economía y la concentración de la población entorno a grandes núcleos urbanos ha motivado un cambio de paradigma en las políticas de movilidad y cambios en las pautas de movilidad, tanto de personas como de mercancías a nivel global. Una mayoría de países han adaptado sus políticas de movilidad, pasando de una política de inversión en infraestructuras y servicios a una nueva manera de proveer un sistema de movilidad más adaptado a las necesidades reales de la ciudadanía, bien a través de la implementación de medidas específicas o de legislación en materia de movilidad y transporte.

Es notorio que la irrupción de la pandemia global provocada por el COVID-19 ha acelerado más si cabe este proceso de adaptación de las políticas públicas a esta nueva realidad. Por un lado, la pandemia ha confirmado ciertas urgencias y ayudado a concienciar más a la población sobre la necesidad de descarbonizar y digitalizar la economía. Por otro lado, la Administración, en este camino hacia la transformación, se encontrará los próximos años con el reto, además, de recuperar la economía. En todo caso, se ha puesto de manifiesto la necesidad de una colaboración entre Administraciones competentes y resto de agentes del sector en materia de movilidad, antes difícilmente pensable, y que es la base sobre la que asentar un sistema de movilidad resiliente y resistente ante futuras crisis por venir.

La coordinación administrativa e institucional parte desde el más alto consenso internacional como es la Agenda 2030 sobre el Desarrollo Sostenible de la ONU (2015), el Acuerdo de París (2015) hoy ratificado por 187 Estados, el “Pacto Verde Europeo” (European Green Deal) anunciado por la Comisión Europea en diciembre de 2019, la Estrategia Europea de Movilidad Sostenible e Inteligente que se describe en mayor detalle en el siguiente epígrafe, así como otra serie de iniciativas de ámbito internacional, y más concretamente europeo, a través de las cuales se suscita decididamente el cambio de paradigma en la movilidad.

En este artículo se hace un recorrido de las políticas novedosas en el ámbito de movilidad de distintos países europeos, fundamentalmente entorno a las vertientes del uso de datos en la movilidad, de la conducción conectada y autónoma, los combustibles alternativos, los sistemas de gestión y financiación de infraestructuras y la integración de urbanismo y movilidad. Destacan las experiencias en estados como Francia, Finlandia, Alemania, Noruega o Países Bajos, de la misma forma que, en un contexto nacional, se tienen en cuenta las políticas de la Administración General del Estado, sobre todo por parte del Ministerio de Transportes, Movilidad y Agenda Urbana y en el marco de su Estrategia de Movilidad Segura, Sostenible y Conectada 2030 y la Ley de movilidad sostenible y de financiación del transporte que la complementará.

2. LA NUEVA ESTRATEGIA EUROPEA Y LAS URGENCIAS TRAS PANDEMIA

Como reacción a los nuevos retos que se plantean en el sector del transporte y la logística, la Unión Europea, y en concreto la Comisión Europea, ha aprobado recientemente estrategias y planes de acción que se enmarcan en esta nueva forma de hacer política del transporte, priorizando ya no tanto la provisión de infraestructuras sino el aprovechamiento de las herramientas digitales y la consecución de objetivos medioambientales y climáticos.

Sobre la base de que la provisión de infraestructuras ha sido y seguirá siendo un elemento clave e imprescindible para la cohesión socioeconómica y territorial, así como para la creación y consolidación de un mercado único competitivo, las prioridades del sector de la movilidad han cambiado ahora hacia:

- El aprovechamiento de las oportunidades que suponen la aplicación de nuevas tecnologías y la digitalización para el sector de la movilidad.
- La consecución de objetivos medioambientales y climáticos, ahora bajo una perspectiva más ambiciosa fruto del Acuerdo de Paris de 2015 y del consecuente Paco Verde Europeo del año 2019. Esta prioridad se alinea fielmente y tiene como soporte las políticas energéticas de la Unión Europea, ámbito profundamente estratégico de la Unión desde su fundación. Dentro del plan de acción del Pacto se incluyen numerosas acciones, que han ido ampliándose en los últimos dos años, entre las que se incluyen una propuesta de una Ley del Clima europea que consagre el objetivo de alcanzar la neutralidad climática en 2050 (y una reducción de emisiones de GEi del 55% respecto a 1990 en 2030), la puesta en marcha del Pacto Europeo por el Clima, la Estrategia de Movilidad Sostenible e Inteligente o la revisión de la Directiva 2014/94/UE sobre la infraestructura para los combustibles alternativos y del reglamento sobre las Redes Transeuropeas – Transporte.

Y todo ello se tendrá que llevar a cabo en un contexto actual e imprevisto como es la pandemia de la Covid-19 y haciendo frente simultáneamente a sus efectos inmediatos y posteriores a corto, medio y largo plazo. Esta pandemia ha traído consigo dos consecuencias al sector del transporte:

- Por un lado, la necesidad de incluir como otro pilar básico además de la digitalización y la sostenibilidad ambiental y climática a la resiliencia. Los efectos devastadores sobre la sociedad y economía de la pandemia en el año 2020 han situado en el foco político a todas aquellas estrategias, acciones y medidas encaminadas a mejorar la capacidad de reacción de los sistemas económicos y sociales. Por suerte, los mismos objetivos de digitalización y sostenibilidad del transporte son piezas clave para lograr esta resiliencia de la movilidad.
- Por otro lado, la creación de los fondos europeos supone una oportunidad histórica para invertir en movilidad que todos los agentes no pueden dejar pasar.

> La inversión en movilidad sostenible y conectada traerá consigo la creación de empleo de calidad, de redes de investigación, la descarbonización de la economía y una mayor cohesión social y territorial, entre muchos otros efectos.

Todas estas necesidades surgidas tras la crisis sanitaria se han tenido en cuenta a la hora de diseñar el paquete de fondos “Next Generation EU”, con motivo del cual cada Estado miembro ha creado sus correspondientes planes nacionales para la gestión de dichos fondos enfatizando las áreas sobre las que incidir en cada territorio. En el caso español, el Plan de Recuperación, Transformación y Resiliencia establece cuatro directrices: la sostenibilidad ambiental, la digitalización, la igualdad de género y la cohesión social e inclusión.

En este contexto surge la Estrategia de Movilidad Sostenible e Inteligente de la Comisión Europea. La estrategia sienta las bases de cómo el sistema de transporte de la UE puede lograr su transformación verde y digital ganando en su capacidad resiliente ante futuras crisis, tratando de conseguir una reducción del 90% en las emisiones para 2050, gracias a un sistema de transporte inteligente, competitivo, seguro, accesible y asequible. Este impulso para transformar el transporte llega en un momento en que todo el sector aún se está recuperando de los impactos del coronavirus. Con una mayor inversión pública y privada en la modernización y ecologización de flotas e infraestructuras, y reforzando el mercado único, se tiene una oportunidad histórica para hacer que el transporte europeo no solo sea más sostenible sino más competitivo a nivel mundial y más resiliente.

En un sentido amplio, la Estrategia de Movilidad Sostenible e Inteligente de la CE ha tenido una buena acogida por los Estados miembros y el sector. Sin embargo, también ha sido foco de algunas críticas relevantes a tener en cuenta. Entre otras, se ha puesto en juicio el excesivo papel de los biocombustibles al tiempo que se echan en falta una mayor importancia de los electrocombustibles y el hidrógeno verde, se demandan compromisos de reducciones de emisiones más ambiciosos o se echan en falta hitos específicos para el uso de la bicicleta (Parlamento Europeo; 2021).

Es necesario resaltar, además, que las políticas europeas se han regido desde hace una década por documentos estratégicos como el “Libro Blanco del Transporte: Hoja de ruta hacia un espacio único europeo de transporte: por una política de transportes competitiva y sostenible”, de 2011, que recogen objetivos no vinculantes y “declaraciones de intenciones” sin haber resultado en acciones concretas. Los retos que recogía aquel Libro Blanco y el diagnóstico que se hacía de la movilidad, salvo los efectos inesperados de la Covid.19, siguen siendo, a grandes rasgos, los mismos que en la Estrategia de Movilidad del año 2020. Desde ámbitos del sector se demanda una mayor ambición de la Comisión Europea.

Sin embargo, bien es evidente que el papel de la Unión Europea en la consecución de los objetivos de descarbonización y digitalización de la movilidad es políticamente limitado.

La movilidad, con efectos sobre la economía mundial e impactos en todo el planeta, está también presente en el día a día de ciudadanos y empresas, por lo que se necesita del compromiso de Autoridades locales, regionales y por supuesto, de los Estados. Por ello, bajar del nivel europeo al nivel local, pasando por el nacional y el regional, resulta clave, y la labor de planificación y gestión de la movilidad en contacto con el territorio resultan determinante.

3. EJEMPLOS DE POLÍTICAS NOVEDOSAS EN EUROPA

A la hora de abordar el análisis de las políticas de movilidad de los Estados miembros de la Unión Europea, es preciso tener en cuenta que la movilidad es un sector transversal a la organización política, administrativa o competencial de los territorios. Para un correcto entendimiento de las distintas aproximaciones relativas a la movilidad deben tenerse en cuenta, por tanto, las distintas Administraciones con competencias en transporte y movilidad, conocerse el régimen competencial en que se engloban y su margen de acción en el ámbito de la movilidad sostenible. Las acciones en el ámbito de la movilidad se pueden dividir en dos vías: la legislativa y la no legislativa. Son pocos los ejemplos encontrados de territorios con legislación global en materia de movilidad, que regule a la vez el ámbito urbano e interurbano y todos los modos y segmentos. El análisis se enfocará también en los otros instrumentos y herramientas de planificación de la Administración (estrategias, planes, etc.)

A nivel de los estados miembros, previo y posterior a la crisis sanitaria, destacan las labores de ciertos gobiernos, por novedosas y por bien ejecutadas, a juicio de los redactores. Estas acciones se han clasificado en 5 ámbitos de actuación que son tendencia actualmente:

- Uso de datos en la movilidad
- Conducción conectada y autónoma
- Combustibles alternativos
- Sistemas de gestión y financiación de infraestructuras
- Integración de urbanismo y movilidad

3.1 Uso de datos en la movilidad

La digitalización en el transporte en particular, pero en toda la economía en general, ha dado suma importancia a un elemento en todo el sistema de movilidad: el dato.

Los datos son ahora el centro de muchas soluciones e incluso modelo de negocio de empresas de movilidad. Por otro lado, la digitalización (sobre todo la telefonía móvil) ha creado un elevado, incluso inabarcable a veces, volumen de datos, de cuyo almacenamiento, gestión y análisis depende el presente y futuro del sector.

Las empresas y Administraciones han detectado la importancia del uso eficiente de los datos y su transformación en información relevante para el desarrollo del negocio y la mejora en la eficiencia. Las herramientas de explotación masiva de datos o big data hacen en este sentido su labor desde hace unos años. Por otro lado, desde la Administración se pretende fomentar el uso de datos abiertos, fiables y de calidad en el sector de la movilidad, que sirvan para desarrollar un sistema competitivo de empresas, servicios y aplicaciones de movilidad amigables para el beneficio de los usuarios.

Muchas Administraciones, tanto del ámbito estatal como regionales o locales, por todo el mundo, están lanzando portales de acceso a datos abiertos actualizados, como pueden ser en el caso de la Unión Europea, los Puntos de Acceso Nacionales. Es el caso de, por ejemplo, el portal “transport.data.gouv.fr” en Francia o “mdm-portal.de” en Alemania.

Además, la publicación de estos datos permite la consulta de los ciudadanos. Sobre la base de la disposición de mejor información se fomenta la transparencia y la participación pública libre e interesada en debates y consultas.

Esta difícil labor de fomento del uso del dato abierto se debe realizar, no obstante, garantizando los derechos de los usuarios. El reto del sector público en el ámbito de la regulación, pero también en el ámbito de la técnica, pues muchas veces adolece un cierto retraso frente al sector privado, más avanzado y disruptor, es muy grande.

En este sentido, cabe destacar la labor del Gobierno de Finlandia, que en julio de 2018 aprobó una nueva Ley de Servicios de Transporte (LVM; 2021), acción que corresponde a uno de sus 26 proyectos estratégicos y que está englobada dentro del eje llamado “Digitalización, experimentación y desregulación” de su programa de gobierno. Se trata de una norma innovadora cuyo objetivo es eliminar las barreras de acceso al mercado y fomentar nuevas formas de servicio basados en la digitalización de la información y la tecnología. Al mismo tiempo, digitalización y tecnología son motivo y fin de la ley. Entre otras cuestiones, la ley obliga a los operadores a aportar al usuario información en plataformas abiertas y formato-código legible, de manera accesible a todos, utilizando interfaces abiertas que permitan al resto de proveedores la venta de *tickets* combinados y obligando a la Administración a incorporar también la información de los servicios que preste directamente.

Por otro lado, la Ley de Orientación de la Movilidad francesa, LOM, (Légifrance; 2019), aprobada en diciembre de 2019 y que, a diferencia de la ley anterior de Finlandia, sí que es una ley global de movilidad, también regula el uso de datos compartidos en el sector de la movilidad.

Compartiendo el mismo objetivo de promover nuevas soluciones de movilidad, la ley, al igual que incluye artículos para favorecer el desarrollo de la conducción autónoma o la movilidad compartida, dedica un capítulo a la aceleración del uso de datos abiertos (Capítulo 1, Título III).

Mediante la norma se garantiza que el 100% de la información sobre la oferta de servicios sea accesible en tiempo real al usuario, a más tardar a finales de 2021. De esta manera Administraciones y empresas podrán desarrollar aplicaciones y ofrecer servicios innovadores, dando la posibilidad de que se puedan ofrecer servicios y viajes puerta a puerta, con un único billete (movilidad como servicio MaaS).

Conviene destacar que la LOM es el fruto de un amplio proceso de participación ciudadana, consulta con grupo de expertos y consenso con las diferentes Administraciones territoriales. Todo ello coordinado en las Conferencias Nacionales de Movilidad entre septiembre y diciembre de 2017, que constituyen un gran ejemplo de gobernanza de la política de movilidad de un gobierno y que derivó no sólo en la elaboración de la LOM sino en la elaboración de otras estrategias.

3.2 Conducción conectada y autónoma

La conducción de vehículos de manera conectada, en el corto-medio plazo, y autónoma, en el largo plazo, son posibles y están siendo desarrolladas gracias a tecnologías emergentes como los sensores, las redes de comunicación 5G o el uso masivo de datos. Se trata de elementos tecnológicos ampliamente desarrollados hoy en día, pero de los que se prevé un mayor auge en la próxima década cuando el uso de la Inteligencia Artificial e *Internet of Things* pueda ser masivo en el transporte en particular y en la economía en general.

Según la Asociación Europea de Fabricantes de Automóviles, ACEA, los sistemas de conducción se basan en vehículos e infraestructuras conectadas entre sí de tal manera que los vehículos pueden "sentir" (percibir), pensar y actuar (ACEA; 2019). En últimas etapas de desarrollo de la tecnología, los vehículos serán capaces de hacerlo sin control humano alguno, mientras que inicialmente se deberá acompañar a los equipos de un cierto grado de interacción hombre-máquina. En función de ese grado de automatización existen, según la Sociedad Internacional de Ingenieros de Automoción, SAE, 5 niveles de conducción conectada y/o autónoma. Solamente en el Nivel 5 el sistema toma el control total en todas las situaciones de tráfico y a cualquier velocidad. El humano es exclusivamente un pasajero, su intervención en la acción de conducir ya no es necesaria (SAE International; 2018).

Las ventajas de la automatización y de la conducción autónoma, y conectada, de vehículos son muy numerosas. La conducción autónoma revolucionará el tráfico rodado mitigando las externalidades actuales, especialmente reduciendo los accidentes (el factor humano es el responsable del 90% de los accidentes de tráfico (PARLAMENTO EUROPEO; 2020) y reduciendo la contaminación y la congestión (el vehículo autónomo se demuestra más eficiente en la conducción).

Además, mediante un uso masivo y una gran penetración de vehículos autónomos y asequibles en las carreteras y ciudades puede contribuir a una movilidad más inclusiva, haciendo posible que personas que no pueden conducir (algunas personas de edad avanzada o con discapacidad, menores o personas sin carné) puedan desplazarse en estos vehículos sin necesidad de depender de otra persona. Se pude concluir que el empleo de altos niveles de automatización puede ser fuente de una mejor calidad de vida tanto en ámbitos urbanos como rurales.

Pero resulta imprescindible destacar el gran número de retos a los que se enfrenta la sociedad a la hora de desarrollar y asentar esta tecnología. Estos desafíos que se plantean no son únicamente tecnológicos (relativos tanto a los vehículos como a la infraestructura física por la que circulan, así como la infraestructura digital) sino que el uso sostenible de la conducción autónoma implica también la consideración de un gran abanico de aspectos éticos, regulatorios, laborales y socioeconómicos.

Los aspectos regulatorios y legislativos serán importantes también en el desarrollo tecnológico a corto plazo, pues solamente con el marco normativo adecuado se puede acometer la gran labor experimental que se requiere para poder hacer frente a estos retos y lograr los objetivos deseados. Es por ello por lo que muchos Estados están trabajando en adaptar sus marcos normativos para permitir y dar cobertura legal a pruebas piloto. Es el caso de los llamados *sandbox* regulatorios, marcos jurídicos específicos que permiten la prueba controlada de proyectos innovadores para testear, por ejemplo, nuevas tecnologías, nuevos modelos de negocio, aplicaciones o procesos para la prestación de servicios de movilidad y transporte. En definitiva, espacios experimentales en los cuales se pueden testear soluciones para las que no hay todavía un marco normativo, o que suponen cambios tan disruptivos que impiden prever adecuadamente el impacto final que pueden tener en el ecosistema de la movilidad.

En este sentido destaca la labor que está llevando a cabo actualmente el Gobierno Federal de Alemania, principal productor automovilístico de Europa, que prevé la aprobación de una nueva ley de conducción autónoma, como parte del pacto del gobierno de coalición (GOBIERNO FEDERAL ALEMÁN; 2021). Ya ha desarrollado un borrador de ley para introducir vehículos autónomos de Nivel 4 en áreas operativas concretas de la red de carreteras. Desde el Gobierno Federal se defiende que este marco regulatorio ofrecerá a Alemania la oportunidad de avanzar en la investigación y el desarrollo y de hacer que la movilidad del futuro sea más versátil, más segura, más respetuosa con el medio ambiente y más orientada al usuario. Numerosos fabricantes de vehículos alemanes aprovecharán este marco regulatorio para acelerar la investigación en el campo y seguir posicionándose estratégicamente en el mercado.

Es el caso de la reciente alianza estratégica entre Volkswagen y Microsoft (Microsoft; 2021).

La Ley de Conducción Automatizada actual, en vigor desde el 21 de junio de 2017, regula el funcionamiento de los vehículos altamente automatizados, que en determinadas condiciones pueden asumir la tarea de conducción de forma autónoma, pero siempre con un conductor. La nueva ley federal regulará el uso de vehículos autónomos sin conductor hasta Nivel 4 en los siguientes escenarios:

- transportes de lanzadera, de corto recorrido (people movers)
- conexiones sin conductor entre centros logísticos (transporte Hub2Hub)
- servicios de transporte orientados a la demanda en horas valle en las zonas rurales,
- vehículos de doble modo, como en el "Automated Valet Parking" para la búsqueda de plaza y aparcamiento de vehículos en modo autónomo en parkings.

La ley crea las condiciones para el uso de vehículos de motor autónomos en todo el Estado federal, aunque en zonas de funcionamiento definidas previamente por las autoridades competentes en cada estado federado. Se regulan también las obligaciones de los propietarios y de los fabricantes.

La creación de sandboxes regulatorios es práctica extendida también para otros ámbitos de la movilidad internacionalmente, como puede ser el desarrollo de soluciones de movilidad compartida, aunque no como ejemplo en Europa, si es relevante en Japón (HBR; 2020), o el desarrollo de sistemas de movilidad aérea urbana Urban Air Mobility en el Reino Unido (CAA; 2020).

La LOM de Francia también creó el marco regulatorio para el desarrollo y la investigación en el ámbito de la conducción autónoma mediante la definición de un programa nacional de experimentación, el seguimiento de la percepción ciudadana o la realización de un estudio del impacto sobre el empleo.

En España, el Ministerio de Transportes, Movilidad y Agenda Urbana prevé en el Documento para el Debate de su futura Estrategia de Movilidad Segura, Sostenible y Conectada la creación de estas figuras normativas para facilitar la experimentación en el campo de la conducción autónoma (MITMA; 2020)

En cualquier caso, mediante avances normativos y/o tecnológicos, la conducción conectada y autónoma está en todas las estrategias de movilidad a nivel internacional. Y ya es una realidad en ciertos ámbitos. Así, por ejemplo, sin ser referencia europea pero sí especialmente relevante, en Guangzhou, China, se despliegan taxis autónomos como parte de una nueva plataforma multimodal de MaaS (Intelligent Transport; 2021). En Europa existen numerosas pruebas piloto en sistemas de transporte público. En concreto en España destacan las dos experiencias hasta la fecha de puesta en marcha de autobuses autónomos en Madrid (“Alsa pone en marcha el primer autobús autónomo en España que circula en tráfico abierto”; 2020) y Málaga (“Avanza e Irizar 'conducen' en las calles de Málaga el primer autobús autónomo eléctrico”; 2021).

3.3 Promoción de combustibles alternativos

El futuro de la movilidad es un futuro descarbonizado y para el año 2050 ha fijado la Unión Europea el plazo para la tener una economía climáticamente neutra. Para lograr este objetivo de descarbonizar la movilidad es crucial el desarrollo de la movilidad eléctrica en paralelo a la producción de energía eléctrica mediante fuentes de energía renovables.

Pero no solo la electricidad ayudará a mover los vehículos, sino que otros combustibles alternativos pueden contribuir a reducir la dependencia del carbono en el corto y en el largo plazo. Se trata sobre todo de los biocombustibles y los combustibles sintéticos. Los primeros están ampliamente desarrollados y en uso, son útiles en el corto plazo para avanzar hacia la descarbonización, pero su uso masivo es insostenible a largo plazo por gran consumo de recursos asociados a su producción. Por otro lado, el propio hidrógeno verde (producido mediante electricidad proveniente de fuentes renovables) y los combustibles sintéticos, (producidos a base de hidrógeno verde) son combustibles todavía en desarrollo, aunque en creciente uso y que sí que se prevé que sean esenciales para descarbonización de sectores como el aéreo o el marítimo que no pueden ser descarbonizados eléctricamente. Además, en el medio plazo, los vehículos de pila de combustible de hidrógeno verde pueden competir con los vehículos de batería eléctrica y sobre todo suponer una gran oportunidad para descarbonizar el tráfico pesado en las carreteras o el ferrocarril.

Actualmente, por tanto, el consenso en los Estados miembros de la Unión Europea es desarrollar ampliamente la movilidad eléctrica fomentando la adquisición de este tipo de vehículos e instalando puntos de recarga, mientras se continúa avanzando en el aumento de las cuotas de renovables en la producción eléctrica.

3.3.1 Flota de vehículos

Las matriculaciones de vehículos electrificados que publica la Agencia Europea de Medioambiente, EEA por sus siglas en inglés (European Environment Agency) son todavía escasas y hay mucho camino por recorrer todavía si se quiere alcanzar el objetivo de la Estrategia Europea de Movilidad, donde se fija en 2030 la existencia de 30 millones de vehículos de cero emisiones (5 millones en España según el PNIEC 2021-2030) (MITECO; 2020). Las cifras publicadas por la agencia para el año 2019 incitan, sin embargo, al optimismo al compararlos con el año anterior (EEA; 2020).

En el entorno europeo (UE-27, Islandia, Noruega y Reino Unido), como se muestra en la Figura 1, en el año 2019 se registraron 534.583 nuevos turismos eléctricos, un 81,6% más respecto al 2018 y un 464,9% más que en 2010. Pero la penetración en el mercado es todavía baja, pues los coches eléctricos suponen solo un 3,5% del total. Las 20.000 furgonetas eléctricas registradas en 2019 suponen un todavía más reducido 1,3% (EEA; 2020).

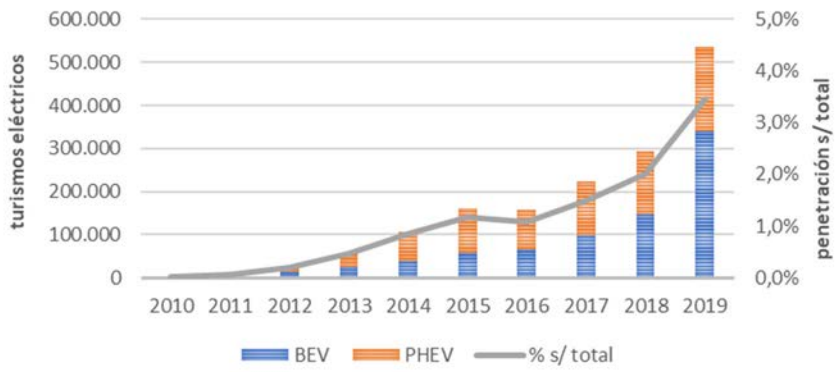

Fig. 1 – Matriculación de turismos (EU-27, Isalndia, Noruega y Reino Unido). Años 2010 – 2019; Fuente EEA

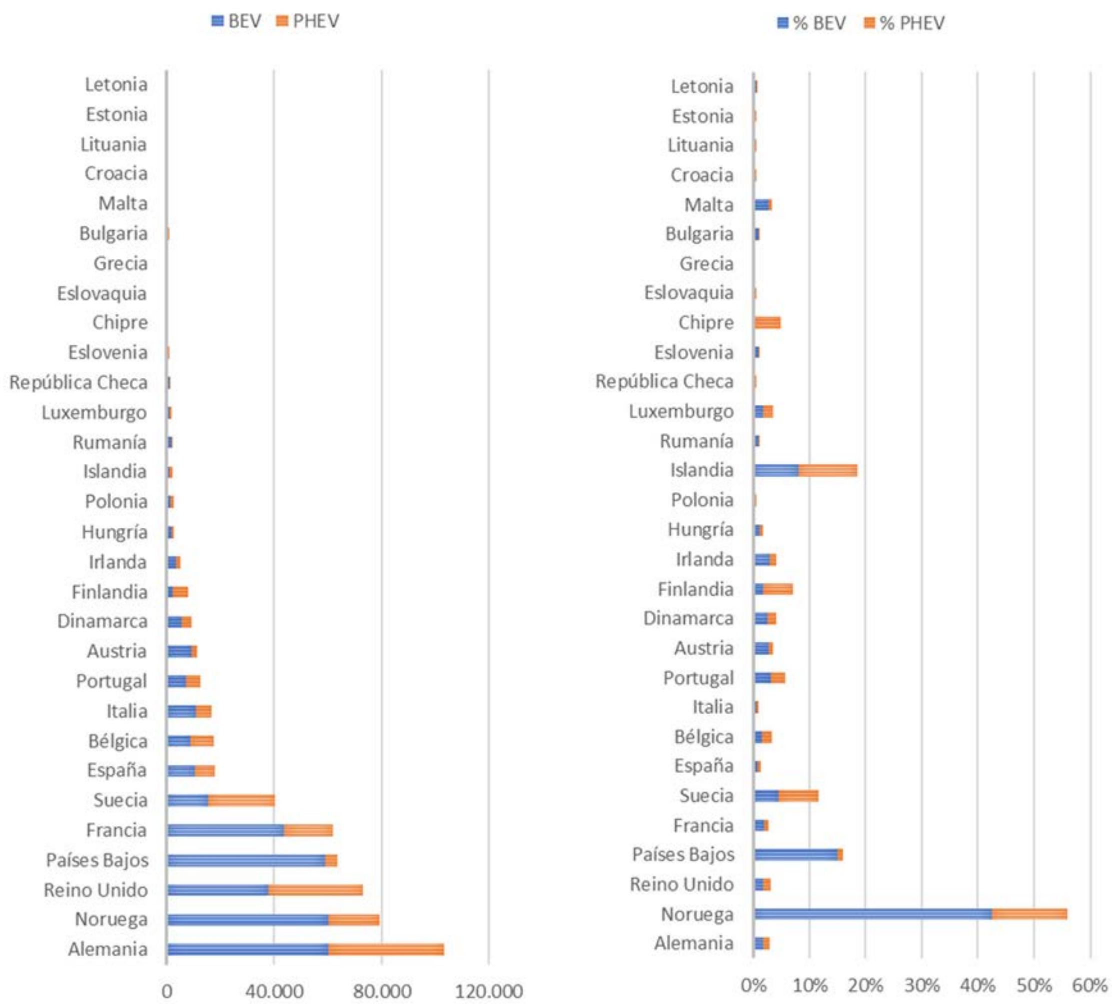
En la siguiente Figura 2 se observa como existe una gran disparidad entre los grados de penetración de turismos eléctricos en los países del ámbito de estudio. En países con un elevado volumen de matriculaciones de turismos como Alemania, Reino Unido o Francia, existen penetraciones cercanas al 3% del vehículo eléctrico. Los datos en Italia o España son todavía peores con el 0,8% y el 1,3% respectivamente. Destacan los Países Bajos y países nórdicos Noruega, Suecia e Islandia por tener altos grados de penetración, en el entorno del 20% analizando los cuatro países conjuntamente, mientras que en el resto de los países el porcentaje medio es tan solo del 2,4%. La media de todo el ámbito de estudio se sitúa en el 3,5% (EEA; 2020).



*. BVE: Battery Electric Vehicles (vehículos de batería eléctrica); PHEV Plug-in Hybrid Electric Vehicles (vehículos eléctricos enchufables o vehículos híbridos enchufables)

Fig. 2 – Turismos matriculados (Valores absolutos –izquierda- y relativos -derecha- por país (EU-27, Islandia, Noruega y Reino Unido) (*). Año 2019; Fuente: EEA

A continuación se detallan algunas de las mejores prácticas que, según informe elaborado por el Ministerio Federal de Transporte y Digitalización de Alemania (BMVI; 2018), han llevado a cabo países pioneros en la incentivación a la compra de vehículos eléctricos como Noruega o Países Bajos:

En Noruega, los conductores de BEVs y los vehículos de pila de combustible de hidrógeno (Fuel Cell Electriv Vehicles FCEV), no siempre los PHEV, tienen los siguientes privilegios:

- No pagan ni peajes de autopista ni urbanos.
- También tienen acceso a aparcamientos públicos gratuitos y a plazas de aparcamiento designadas exclusivamente para vehículos eléctricos.
- El uso de los puntos de recarga públicos es gratuito
- Los vehículos eléctricos tienen derecho a utilizar los carriles bus en algunos municipios siempre que haya al menos dos personas en el vehículo.
- La exención del IVA (25%), del impuesto sobre vehículos y del impuesto sobre vehículos nuevos hace que los BEV sean más baratos que los vehículos de combustión comparables en Noruega. La exención del IVA y del impuesto sobre vehículos nuevos está limitada hasta 2025.

En los Países Bajos los privilegios que se introdujeron en el sistema en los últimos años han ido abandonándose por considerarse que podrían provocar el colapso de determinadas infraestructuras y por considerarse contrarios a la igualdad de todos los usuarios de la vía pública. Sin embargo, sí que ha habido una apuesta fuerte por la electrificación de sistemas de transporte público, flotas de taxi y vehículos de reparto. Para 2025, todo el sistema de transporte público se convertirá en vehículos electrónicos, y en las grandes ciudades sólo los autobuses electrónicos estarán en funcionamiento a partir de 2022. Los operadores de flotas comerciales reciben subvenciones de 3.000 euros del Ministerio de Infraestructuras y Medio Ambiente para la compra de e-taxis y vehículos de entrega electrónica.

También existen incentivos a la compra de vehículos eléctricos, pero solo a los BEV, con una exención del impuesto de matriculación y del impuesto sobre vehículos de motor.

Pero el éxito del caso holandés radica sobre todo en el despliegue de infraestructura de recarga pública y semipública. Entre otros factores, destacan:

- El uso de un protocolo de punto de carga abierto en todos los puntos permite la interoperabilidad del hardware y el software, así como el uso de una única tarjeta de usuario para todos los proveedores
- Un sistema de carga inteligente permite evitar cuellos de botella y una mejor gestión de la energía renovable utilizada

3.3.2 Infraestructura de recarga

La infraestructura de recarga es sin duda, como bien demuestra el caso holandés, uno de los elementos clave para el desarrollo de la movilidad eléctrica.

La Directiva 2014/94/UE sobre el despliegue de la infraestructura de combustibles alternativos (AFID por sus siglas en inglés – Alternative Fuel Infrastructure Deployment) es la normativa europea en esta materia. Exige a los Estados miembros que elaboren Planes Nacionales o Marcos de Acción para el desarrollo del mercado de los combustibles alternativos y su infraestructura. También pretende servir de base para el uso de especificaciones técnicas comunes para los puntos de recarga y ofrecer información adecuada al consumidor sobre localización de puntos de recarga, tipos de combustibles y precios.

Un informe reciente de la Comisión Europea (EUR-LEX; 2021) analiza el nivel de despliegue de estas infraestructuras en la Unión Europea y las acciones incluidas en cada plan nacional de despliegue. La conclusión es que el efecto de la directiva ha sido positivo, pero también destaca el informe que existe gran disparidad en el avance hacia la movilidad eléctrica entre todos los países motivo, en parte, de la falta de una metodología detallada y vinculante por parte de la UE, así como de la disparidad de objetivos y las políticas de los Estados miembros.

La infraestructura de recarga actual en la Unión Europea es suficiente para el escaso parque automovilístico existente. Sin embargo, no existe una red global en toda la Unión Europea y tampoco se prevé que con el actual marco legislativo europeo se pueda desarrollar la red necesaria para alcanzar en el 2030 el objetivo de la Comisión de reducir las emisiones de GEI en un 55% respecto a las del año 1990.

En el ámbito nacional, el Ministerio para la Transición Ecológica y el Reto Demográfico, en colaboración con el Ministerio de Transportes, Movilidad y Agenda Urbana, acaba de presentar la tercera edición del programa MOVES de incentivos a la movilidad eficiente y sostenible que incluye ayudas para instalación de puntos de recarga y a la adquisición de vehículos electrificados (MITECO; 2021)

3.4 Sistemas de gestión y financiación de infraestructuras y servicios

En cuanto a las políticas europeas de gestión y financiación de infraestructuras y servicios públicos, la UE desde sus inicios ha mantenido una política de transporte clara enfocada a unificar las regulaciones de los Estados miembros, con el fin de favorecer el mercado común y la liberalización de la competencia entre modos de transporte. Este hecho surgió desde el Tratado de Roma en 1957 y se vio fortalecido a partir del Tratado de Mastrich el año 1992 donde se estableció una base jurídica cuya adopción sería de obligado cumplimiento.

El libro blanco de la Comisión Europea “curso futuro de la política común de transportes” publicado en 1922, fundamentaba el hecho de que los usuarios no asumieran de manera completa los costes derivados de su propia actividad como una de las razones principales que suponían el desequilibrio modal y la ineficiencia del transporte. Desde entonces han sido distintas Directivas como la Directiva 1993/89/CE, la Directiva 2006/38/CE las que han ido ampliado la cobertura a las políticas europeas para la evaluación de un modelo de cálculo de todos los costes externos para todos los modos de transporte (Liechti y Renshaw; 2007). Igualmente favorecer una unificación en materia de fiscalidad y de tarificación en pro de una mayor eficiencia en el sistema de transporte de Europa (Comisión Europea, 1998) y la recuperación a través de un peaje, permitir a las

Administraciones externalización de costes por el uso que realizan los usuarios de las infraestructuras, así como el control de que ese cobro sea realizado de modo exhaustivo, justo y fiable (Saldaña y Vassallo; 2012).

Es a partir de este momento cuando algunos países de Centroeuropa comenzaron a operar sus redes de carreteras mediante peajes o mediante la introducción de tasas sobre el transporte de mercancías. Entre los países más significativos se encontraron Austria, Alemania, Francia, Suecia, Bulgaria, República Checa, Hungría, Polonia, Rumanía y Eslovaquia (Saldaña, et al; 2012).

Son dos los principios fundamentales que la UE promueve en su actual política de transporte, "el pago por uso" de infraestructuras y "quien contamina paga". En este sentido, dependiendo del tipo de infraestructura modal, los modelos de gestión y financiación son similares en Europa en torno al modo ferroviario y aeroportuario, que se financian fundamentalmente a través de cánones que los distintos operadores que sufragan el coste del uso de las infraestructuras a través de un canon, mientras que aun en la actualidad existen divergencias en cuanto al modelo de gestión y financiación de las carreteras. En este último caso hay que diferenciar aquellos países que tarifican de manera mayoritaria su red de carreteras de alta capacidad, de aquellos otros que no lo hacen y ofrecen a los usuarios el uso de las carreteras sin coste, o bien recuperando una parte de este a través de gravámenes fiscales a los hidrocarburos:

- En el caso de los primeros, más propio de Centroeuropa, tarificando la red principal de carreteras a los vehículos pesados, como es el caso de Alemania, la República Checa o Eslovaquia,
- y en el caso de los segundos, una mayoría de países periféricos que consideran que este tipo de modelos de financiación pueden restar su competitividad en el mercado común, al ser países generalmente destino y no de paso de mercancías. No obstante, países como Portugal, Italia o Francia cuentan con notables redes de autopistas de peaje directo a los usuarios, con el fin de amortiguar los costes de sus inversiones o del mantenimiento de estas.

El ejemplo **alemán** es uno de los más relevantes, quien en el año 2002 decidiera optar por la implementación de un modelo de pago por uso que posibilitara la tarificación de vehículos pesados, principalmente para atender el continuo crecimiento del volumen global en transporte de mercancías que suponía una considerable carga para las autopistas alemanas y conllevaba importantes inversiones en materia de mantenimiento y ampliación de carreteras.

En el año 2002, el consorcio Toll Collect, fue designado por la autoridad alemana como adjudicatario del contrato que instalaría un novedoso sistema electrónico de cobro de peajes basado en tecnología de flujo libre, más conocido como free flow, que calcula y recauda el peaje proporcionalmente al trayecto recorrido (Toll Collect; 2021). Así, tras repetidos retrasos en la implementación de la tecnología en la red objeto de tarificación, TOLL COLLECT completó el despliegue del sistema a finales de 2004, comenzando a operar en enero de 2005 (Haan J. et al; 2011) en aproximadamente 12.000 km de vías de alta capacidad, estimándose que el número de kilómetros recorridos por vehículos pesados, sujetos a tarificación, se estiman en aproximadamente 22.700, de los que el 35% se corresponden a los efectuados por vehículos extranjeros (Ullber F.; 2005). Desde mediados de la década pasada se ha suscitado un debate en Alemania en cuanto a la posibilidad de extender la tarificación no sólo a los vehículos pesados sino al conjunto del parque automotor, aunque sin éxito hasta la fecha presente (BMVI; 2021).

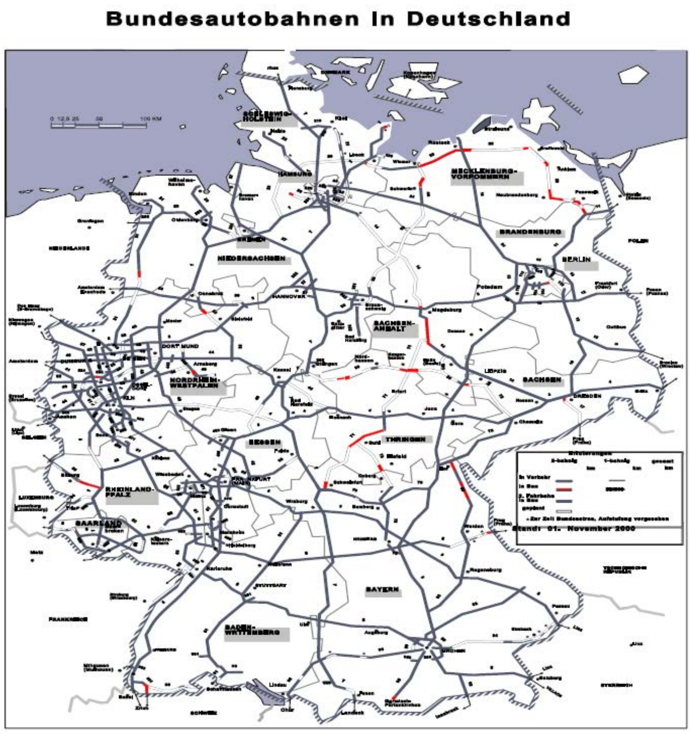


Fig. 3 – Red federal alemana tarificada; Fuente: Ullber; 2005

La tecnología y modalidad de cobro del sistema de peaje establecida por las autoridades alemanas y Toll Collect estableció un sistema de peaje que combinaba por primera vez, a nivel mundial, la técnica de localización mediante satélites (GNSS) y la tecnología de telefonía móvil (GSM). Las tarifas se establecen proporcionalmente al trayecto recorrido por el vehículo pesado, su número de ejes y su categoría, según las emisiones de gases que genera. La introducción de este nuevo sistema en Alemania supuso una tarificación por uso de infraestructuras más justa y equitativa.

La **República Checa** es otro ejemplo de país que ha recurrido a la tarificación de su red, principalmente desde su entrada en la UE en el año 2004 cuando, fruto del dramático estado de conservación de sus carreteras secundarias, el gobierno checo en el año 2008, aprobó un proyecto piloto de free flow híbrido, a partir del cual se aprovechase el sistema de tarificación existente, basado en pórticos DSRC, con un nuevo sistema de tarificación basado en tecnología satelital (GNSS), cuyo alcance posibilitara una mayor flexibilidad y la tarificación de las carreteras consideradas como de ámbito rural (KAPSCH; 2008).

Actualmente la República Checa cuenta con aproximadamente 1.200 km de vías tarificadas mediante el sistema free flow DSRC, que con la última modificación de la Regulación checa No. 240/2014 Coll and Decree No. 470/2012, de enero de 2021, pasa a incluirse la contaminación del aire y del ruido de los vehículos pesados, en el cómputo de la tarificación vial. (MYTO CZ; 2021)

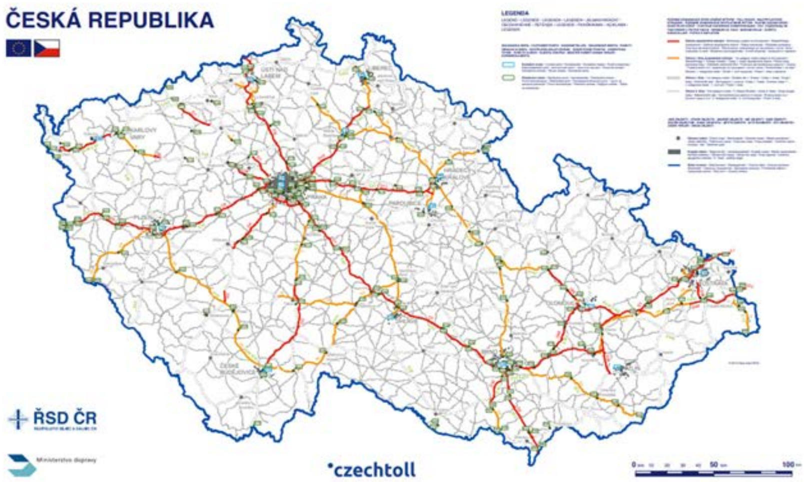

Fig. 4 – Red de carreteras tarificadas CZ; Fuente: MYTO CZ

En el caso checo, el país cuenta con un sistema electrónico de cobro de peajes interoperable basado en tecnología free flow satelital GNSS y de pórticos DSRC. El uso compartido de ambas tecnologías ha posibilitado ampliar el alcance de la red tarificada, englobando no sólo vías de gran capacidad, sino también carreteras de segundo orden. Asimismo, la madurez del sistema previamente existente ha contribuido al éxito del nuevo modelo en su conjunto.

El modelo de pago por uso de infraestructuras **portugués** tradicionalmente ha distinguido entre vías de alta capacidad, autopistas de peaje y las autopistas conocidas como SCUT libres de pago, y la red de carreteras de segundo orden. Las autopistas de peaje se gestionan mediante contratos de concesión establecidos entre la Administración contratante (Estradas de Portugal) y los concesionarios adjudicatarios de los contratos. En cuanto a las autopistas SCUT (libres de pago), su gestión se estableció inicialmente a través de la figura del peaje en sombra, aunque desde 2008 y especialmente en el año 2010, como consecuencia de la insostenibilidad presupuestaria motivada por las cuantiosas necesidades económicas que requirieron la explotación y mantenimiento de la red de utopistas SCUT, el gobierno portugués decidió expandir el pago por uso de las mismas, expandiendo el sistema de cobro electrónico free flow (DSRC) a toda la red de autopistas

SCUT. Cabe subrayar que más de la mitad de la partida de mantenimiento de carreteras del presupuesto portugués ha llegado a estar destinado al pago de los peajes SCUT, situación claramente insostenible.

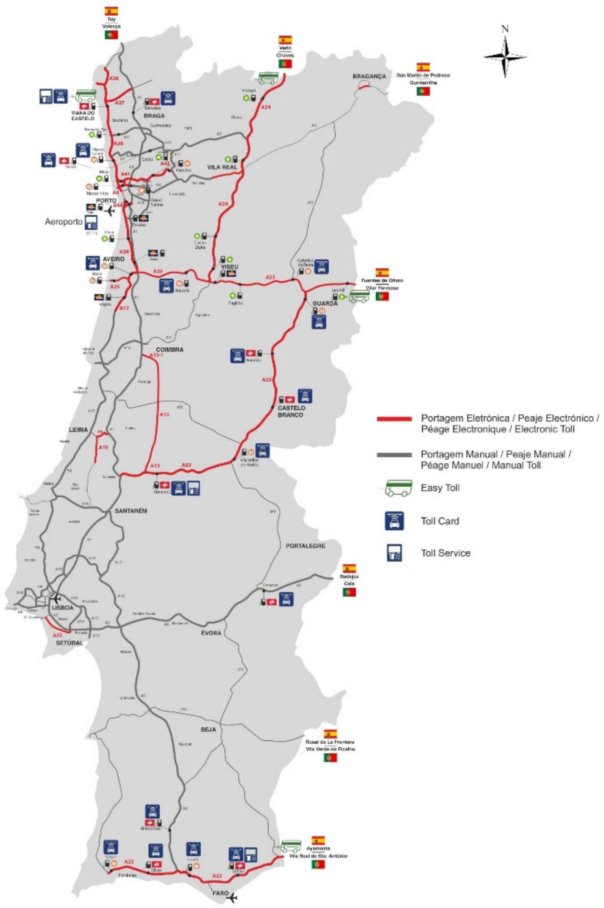

Fig. 5 – Alcance de la red tarificada; Fuente: Portugaltolls

El sistema de cobro de peaje portugués se distingue entre las tradicionales autopistas de peaje con barrera y las exSCUT en el que las autoridades portuguesas han instaurado pórticos DSRC que registran el paso de los vehículos y se categoriza la tarifa correspondiente.

Países como España, Francia e Italia cuentan con una amplia red de vías de alta capacidad, en el que conviven autopistas de peaje con las de tipo gratuito. Cuentan con estándares similares unas y otras si bien la diferencia principal es el modelo de financiación. Así, mientras que, en las vías de alta capacidad gratuitas, tanto la inversión y los costes de mantenimiento corren a cargo del presupuesto público, en las de peaje se financian generalmente a través de la participación público-privada en la que un privado adelanta los costes de su inversión y el mantenimiento durante un plazo que será recuperado a través del pago de una tarifa durante todo el periodo concesional por parte de los usuarios que recorran estas. Existen otras modalidades de financiación en el caso de las autopistas de peaje, bien a través de las modalidades de peaje en sombra y de pagos por disponibilidad, que, aunque resultan inicialmente gratuitas para los usuarios, son igualmente desarrolladas por empresas privadas que adelantan su financiación.

Con el nuevo cambio de paradigma son cada vez más países, entre ellos España ("El Gobierno se compromete con la UE a cobrar en autovías para financiarlas"; 2021), quienes reconocen la limitación del erario público, no solo para invertir en nuevas infraestructuras, sino también para mantener y conservar las existentes, por lo que se ha abierto un debate público en torno al fin de la gratuidad de las infraestructuras viales y la conveniencia del establecimiento de un nuevo modelo de gestión y de financiación que permita la tarificación de estas, permitiendo sufragar el coste de mantenimiento e internalizar el impacto ambiental del tráfico. Por ello España a través del MITMA y bajo el paraguas de su Estrategia de movilidad segura, sostenible y conectada (MITMA; 2020), ha puesto de manifiesto la necesidad de trabajar en pro de:

- una priorización de las inversiones desde una perspectiva de rentabilidad social y de una metodología expost de las infraestructuras,
- una mejor panificación y gestión de la red vial estatal, haciendo hincapié en la fiscalidad de las carreteras y el estudio de los modelos de gestión y financiación,
- la planificación y gestión de la red ferroviaria de interés general, principalmente a través de la Estrategia indicativa ferroviaria,
- del impulso de una fiscalidad verde, tanto del transporte urbano como del interurbano
- y, finalmente, del impulso de nuevos mecanismos de gobernanza, bajo los pilares de la transparencia y de la participación.

El impacto de la pandemia a nivel europeo ha acelerado este debate, dado que los presupuestos públicos, cada vez más exiguos, son insuficientes para poder acometer las necesidades actuales de los ciudadanos, más en un momento en el que es necesario la priorización de otro tipo de equipamientos a gran escala como los de tipo sanitario o la dotación de grandes partidas de gasto público al amparo de los efectos de la crisis sanitaria y los efectos económicos y sociales que esta ha producido.

3.5 Integración de urbanismo y movilidad

Como se ha comentado inicialmente, uno de los mayores retos que afronta el sector de la movilidad es hacer frente a la creciente urbanización. Según el Banco Mundial (Banco Mundial; 2021) a fecha abril de 2020 cerca del 55 % de la población mundial, 4.200 millones de habitantes, vivían en ciudades. Esta tendencia continuará acentuándose hasta alcanzar previsiblemente en 2030 una población urbana de 5.500 millones de habitantes.

En 2050 el Banco Mundial prevé que 7 de cada 10 personas vivirán en ciudades. La gestión de servicios en ámbito urbanos será de gran dificultad. La consecuencia directa en el ámbito del transporte y la movilidad es una concentración excesiva de necesidades de movilidad en el tiempo y el espacio entorno a la actividad económica y la geografía urbana, lo que conlleva con el modelo actual de movilidad enfocado en el vehículo privado a numerosos impactos negativos sobre la salud, la calidad de vida y la productividad (emisiones de contaminantes y ruido, uso del espacio público y congestión).

La tendencia tiene, además, un reverso igualmente preocupante: la despoblación de las zonas rurales, algo especialmente crítico en países como España. Según el Banco Mundial, en España el 80% de la población habita en áreas urbanas, pese a que solo representan el 20% del territorio. En contrapartida, la contrapartida de esta concentración de población es igualmente preocupante: la despoblación de las regiones de interior.

Además, en los últimos años el crecimiento urbano se ha producido acompañado de un proceso de dispersión poblacional en las coronas metropolitanas. Por ejemplo, en España en 2018 la población ha disminuido ligeramente en la ciudad central, al tiempo que ha crecido un 10,32% en las zonas periféricas respecto a 2017 (OMM; 2018).

Resulta crucial revisar los modelos de movilidad en los ámbitos urbanos. Políticas de movilidad que prioricen los desplazamientos cortos y que ponen el foco en primer lugar en la reducción del volumen de desplazamientos pueden empezar a tener un papel importante en la planificación de la movilidad en entornos urbanos. Una vez que el desplazamiento está justificado, las administraciones y autoridades estatales, regionales y locales deben priorizar el uso de medios de transporte colectivos y poco contaminantes. La aplicación del principio de Avoid-Shift-Improve (SUTP; 2011) o Evitar-Cambiar-Mejorar en la planificación de la movilidad o el desarrollo de ámbitos urbanos orientados al uso del transporte público (Transit Oriented Development) (ITDP; 2017) son estrategias ampliamente avaladas y empleadas para este fin desde hace décadas. Y en ambos casos, se requiere de una sincronización total de la planificación urbana y la planificación del transporte.

La urgencia ambiental y la creciente tensión a la que está sujetas las ciudades puede acelerar el cambio y/o la consolidación de este tipo de acciones. Muestra de ello es la aprobación reciente de la Agenda Urbana Española del Ministerio de Transportes, Movilidad y Agenda Urbana (AUE; 2021), con medidas destinadas a reducir la movilidad en vehículo privado y a fomentar la movilidad de proximidad, y pilar de la política de movilidad urbana del ministerio.

Por lo general, son estrategias de movilidad y urbanismo que se llevan aplicando en numerosas regiones europeas desde hace décadas. Entre ellas se destacan las experiencias en los Países Bajos con su regulación ABC para la localización de empresas bajo principios de accesibilidad desde 1988 (De Vos; 2015), así como la Ley de Movilidad de Cataluña desde 2003 (y sus Directrices Nacionales de Movilidad de 2006 y decretos que las desarrollan) que establecen la obligatoriedad de que los nuevos planeamientos urbanos incorporen estudios de movilidad generada. Recientemente desde el Ayuntamiento de París se está impulsando la movilidad de proximidad mediante la llamada "Ciudad de los 15 Minutos" (c40knowledgehub; 2021) promovida por la red de ciudades C40. Esta estrategia de fomento de la "movilidad de cuarto de hora", siendo uno de los principales puntos estratégicos de la administración local.

4. RESULTADOS Y CONCLUSIONES

La evolución tecnológica surgida desde finales de la década pasada, el aumento de la concienciación social y el mayor compromiso de las Administraciones públicas por la descarbonización de la economía y la concentración de la población entorno a grandes núcleos urbanos ha motivado un cambio de paradigma en la movilidad, tanto de personas como de mercancías a nivel global.

En este artículo se recogen las principales novedades que el cambio de paradigma en la movilidad ha supuesto en un contexto internacional europeo, destacando las siguientes conclusiones:

- A nivel supranacional, desde la Unión Europea se acompaña este cambio de paradigma mediante diversas acciones normativas y estrategias sectoriales, todas ellas bajo el paraguas del Pacto Verde Europeo y, recientemente, condicionadas al plan de recuperación "Next Generation UE". Destaca especialmente la Estrategia Europea de Movilidad Sostenible e Inteligente de la Comisión Europea, presentada en 2020 y basada en los tres pilares de descarbonización, digitalización y resiliencia.
- De manera general, atendiendo a los principales retos detectados de descarbonización, digitalización y crecimiento urbano, los países analizados comparten objetivos y priorizan los mismos objetivos. En concreto, se han detectado 5 ámbitos de especial interés en las políticas nacionales de movilidad: (i) el uso de datos en la movilidad, (ii) la conducción conectada y autónoma, (iii) los combustibles alternativos, (iv) los sistemas de gestión y financiación de infraestructuras, así como (v) la integración del urbanismo y la movilidad.
- Así, en lo relativo al "uso de datos en la movilidad", la importancia de los datos en la movilidad se ha hecho evidente en las últimas décadas, en especial por la irrupción de la telefonía móvil. La gestión de estos datos no solo ha propiciado la aparición de nuevos modelos de negocio, sino que las técnicas de Big Data permiten obtener de un gran volumen de datos una información valiosa para la planificación y la gestión de la movilidad. La labor de la Administración debe ser la de garantizar el uso y compartición de datos entre todos los agentes, para fomentar la existencia de un ecosistema de empresas y soluciones de movilidad que mejoren la experiencia del usuario. Y todo ello protegiendo los derechos de los ciudadanos.
- En cuanto a "la conducción conectada y autónoma", esta presenta grandes oportunidades para hacer más sostenible la movilidad y tanto la industria del automóvil

como las Administraciones la consideran un elemento clave a largo plazo. Para el desarrollo de la tecnología, sin embargo, se debe de fomentar en el corto plazo la investigación y el desarrollo normativo.

- Relativo al uso de "combustibles alternativos", la urgencia climática y la mayor concienciación ambiental de la población se está traduciendo sobre todo en programas de fomento de la movilidad eléctrica y en la cada vez mayor penetración del vehículo electrificado en los países europeos. Existen también políticas para fomentar combustibles alternativos avanzados de origen no biológico como el hidrógeno verde y los electrocombustibles, con mayor potencial en la descarbonización de la aviación y el transporte marítimo.
- Atendiendo a los "sistemas de gestión y financiación de infraestructuras", las limitaciones presupuestarias de las AAPP y el constante crecimiento de las redes de infraestructuras multimodales en Europa ha supuesto un cambio de paradigma en cuanto a la priorización de las inversiones de estas, bajo criterios de rentabilidad social y análisis expost, así como de una armonización de los modelos de gestión y financiación en el ámbito europeo, vial y ferroviario, a favor de un modelo de pago por uso, a través del cual sean los usuarios de las infraestructuras quienes se hagan cargo, a través de cánones o peajes, del coste de las propias inversiones, así como de su mantenimiento y sostenibilidad durante su vida útil.
- Como parte de la estrategia para descarbonizar el transporte, las políticas de "integración de la planificación movilidad y el urbanismo", aplicadas por ciertas Administraciones desde hace décadas, vuelven a estar presentes en estrategias y leyes globales de movilidad. Solo así, se puede conseguir reducir el número de viajes innecesarios y convertir al transporte público en elemento vertebrador de la movilidad.

Los retos actuales en el sector de la movilidad, la gran mayoría ya detectados previamente a la pandemia de la Covid-19, pero a los que se unen otros derivados de la crisis económica y social derivada de esta, requieren cambios en las políticas de las Administraciones, empezando por el nivel supranacional y la Unión Europea, pasando por los Estados miembros y afectando también a las autoridades regionales y locales.

Los principales ámbitos de actuación detectados y sobre los que en el presente artículo se han recogido las principales líneas de actuación de los estados miembros son solo ejemplos de las muchas medidas y estrategias sectoriales de influencia directa en el sector holístico de la movilidad y que se deben acometer para lograr los objetivos por lo general compartidos por todos los estados de la Unión Europea.

DISPOSICIÓN DE LOS VIAJEROS A ADOPTAR SOLUCIONES MAAS EN ÁREAS METROPOLITANAS EUROPEAS

Iria Lopez-Carreiro
TRANSyT, Universidad Politécnica de Madrid, España
Andrés Monzón
TRANSyT, Universidad Politécnica de Madrid, España

RESUMEN

Se espera que la movilidad como servicio (MaaS) cambie la forma en la que nos movemos.

Sin embargo, todavía no está claro quién adoptará este nuevo modelo de movilidad, ni cómo afectará a los comportamientos de los viajeros. En este estudio, exploramos la disposición de los individuos a adoptar MaaS. Con este objetivo, realizamos una campaña de encuestas online en dos áreas metropolitanas europeas: Madrid (España) y Randstad (Países Bajos). En general, encontramos actitudes positivas hacia las soluciones MaaS.

Tanto las características socioeconómicas y demográficas de los individuos, como sus hábitos de viaje, determinan la probabilidad de que adopten dichas innovaciones tecnológicas. En general, reconocemos dos barreras principales que pueden frustrar la aceptación del MaaS: la baja afinidad tecnológica y la baja apertura a los comportamientos multimodales. Las políticas que se centran en estos dos aspectos pueden fomentar la adopción del MaaS y promover, por tanto, un cambio de comportamiento hacia opciones más sostenibles.

1. INTRODUCCIÓN

El disruptivo avance de las Tecnologías de la Información y la Comunicación (TICs) ha traído consigo nuevas oportunidades para el desarrollo de soluciones innovadoras en el sector del transporte. En los últimos años se han implementado en nuestras ciudades nuevos servicios de movilidad basados en aplicaciones (móviles), como los servicios de uso compartido de coches, bicicletas y patinetes.

A medida que un mayor número de personas adopta estos nuevos servicios, el modelo de movilidad reclama ser reestructurado. En este marco, se propone la noción de *Mobility as a Service* (MaaS), que propone una transición hacia comportamientos de viaje más sostenibles.

El concepto de MaaS fue introducido por primera vez por Heikkilä (2014), quien en su trabajo fin de máster lo describe como "un sistema en el que los operadores de transporte proporcionan una amplia gama de servicios de movilidad a los viajeros". De acuerdo con la autora, un operador de transporte debe entenderse como "una empresa que compra servicios de movilidad a los productores de servicios, los combina como una oferta y los ofrece a los usuarios". Desde ese momento, se han sugerido otras muchas definiciones para la noción de MaaS. Y aunque todavía no existe un consenso claro sobre una única definición (Arias-Molinares y García-Palomares, 2020), los expertos coinciden en que puede concebirse como la combinación de diferentes tipos de movilidad en una única interfaz digital (normalmente, una aplicación móvil o una página web). En base al desarrollo de una revisión exhaustiva de la literatura y de acuerdo con los objetivos de este estudio, decidimos adoptar la definición dada por la *European MaaS Alliance*. Esta institución público-privada describe el concepto de MaaS como "la integración de diversas formas de servicios de transporte en un único servicio de movilidad accesible bajo demanda para satisfacer las expectativas de los viajeros" (MaaS Alliance, 2019).

En los últimos años, el término de MaaS ha ganado gran popularidad gracias a su potencial para reducir las externalidades negativas del sector del transporte, es decir, la congestión del tráfico, la contaminación atmosférica y acústica, el número de accidentes, etc. Sus defensores creen que MaaS permitirá adquirir comportamientos de movilidad más sostenibles y, en particular, disminuir la dependencia del coche privado (Polydoropoulou et al., 2018). Por definición, MaaS representa el paso de un "sistema basado en la propiedad del vehículo privado" a una "perspectiva de movilidad basada en el acceso". En otras palabras, MaaS representa la compra de servicios, y no de los modos de transporte en sí mismos.

Aunque se espera que las oportunidades asociadas a MaaS sean numerosas, un requisito previo para el éxito de este modelo innovador es su "aceptación pública". De acuerdo con Caiati et al. (2020), diferentes innovaciones tecnológicas han fracasado históricamente a la hora de lograr una amplia difusión debido a su incapacidad para responder a las expectativas reales de los usuarios. Especialmente en el caso de MaaS, con su inherente orientación centrada en el usuario, comprender el punto de vista de los individuos es de extrema importancia.

Teniendo en cuenta la (relativa) novedad del concepto, actualmente no se sabe mucho sobre la disposición de los viajeros a adoptar estas nuevas soluciones. Y aunque algunos autores han abordado esta perspectiva (véase la Sección 2), es necesario continuar investigando. Como afirman Danquah y Amankwah-Amoah (2017): "a pesar del creciente cuerpo de investigación sobre el capital humano y la innovación, nuestra comprensión de los efectos y las funciones del capital humano en la mejora de la innovación y la adopción de tecnología en el mundo en desarrollo... sigue siendo limitada".

Además, dado que los resultados científicos tienden a depender del diseño experimental, la especificación del modelo y la selección de variables, cualquier investigación adicional se convierte en una contribución bienvenida a la actual escasez de conocimientos empíricos.

En definitiva, ¿están los viajeros dispuestos a adoptar MaaS? En este estudio, contribuimos a la comprensión de quién está dispuesto a adoptar MaaS, centrándonos en un conjunto de factores socioeconómicos, demográficos y relacionados con los hábitos de movilidad. El estudio se desarrolla en dos áreas metropolitanas europeas con diferentes estructuras urbanas: Madrid (España), con una configuración monocéntrica, y el Randstad (Países Bajos), con una policéntrica.

El documento se organiza como sigue. Tras este capítulo introductorio, la Sección 2 explora los estudios previos centrados en la disposición de los individuos a adoptar MaaS. A continuación, la Sección 3 describe el enfoque metodológico, que se aplica a los casos de Madrid y Randstad en la Sección 4. Por último, la Sección 5 analiza los resultados y la Sección 6 ofrece las conclusiones obtenidas.

2. REVISIÓN DE LA LITERATURA: DISPOSICIÓN DE LOS VIAJEROS A ADOPTAR MAAS

Numerosas ciudades de todo el mundo se sienten atraídas por la noción de MaaS y su potencial para promover comportamientos de viaje más sostenibles. Sin embargo, aunque estas oportunidades sean ciertas, el compromiso de los individuos es un requisito fundamental para lograr una amplia aceptación de estas innovaciones tecnológicas (Strömberg et al., 2018). La Tabla 1 incluye un conjunto de estudios que ya han explorado la disposición a adoptar y utilizar MaaS desde la perspectiva de los viajeros. La literatura considera diferentes tipos de factores explicativos al abordar este tema.

[1] 1: factores socioeconómicos; 2: factores demográficos; 3: factores relacionados con los hábitos de movilidad; 4: actitudes personales.

Tabla 1 – Revisión de la literatura: intención de adoptar MaaS por parte de los viajeros.

Aunque estas investigaciones (Tabla 1) constituyen un primer paso, es necesario seguir investigando para desarrollar un cuerpo de conocimientos completo sobre la aceptación de MaaS. Siguiendo un modelo centrado en el usuario, MaaS proporciona a los viajeros servicios de movilidad personalizados. Por lo tanto, entender las motivaciones, necesidades y preferencias de los individuos es esencial para definir con éxito estas soluciones. En este estudio, exploramos la disposición a adoptar MaaS centrándonos en un conjunto de factores socioeconómicos, demográficos y relacionados con los hábitos de movilidad.

3. METODOLOGÍA

En esta Sección, explicamos la metodología aplicada en el estudio.

3.1 Diseño de la encuesta

En base a estudios previos con un alcance similar (véase la Tabla 1), diseñamos un cuestionario para cumplir nuestros objetivos, que se estructura en las siguientes cinco secciones:

- Sección 1. Introducción. Una sección inicial presenta una descripción conceptual de MaaS y una aplicación ficticia, cuyo diseño se basa en la interfaz de Whim (https://whimapp.com/). Esta sección pretende proporcionar a los participantes un nivel de conocimiento razonable sobre MaaS y sus servicios.
- Sección 2. Características socioeconómicas y demográficas generales, es decir, sexo, edad, nivel de educación (completado), ocupación, estructura del hogar y localización de la residencia.
- Sección 3. Adopción y uso de herramientas tecnológicas. Dado que los viajeros interactúan con MaaS a través de una única interfaz digital, se pide a los individuos que califiquen, en una escala Likert de cinco puntos, su experiencia con las innovaciones tecnológicas. En particular, se les pregunta por el uso de las aplicaciones de planificación de viajes, que se consideran el nivel 1 de las tecnologías MaaS (Schikofsky et al., 2020).
- Sección 4. Hábitos de movilidad y características relacionadas con los viajes. Teniendo en cuenta que los hábitos de movilidad son predictores relevantes de futuros comportamientos, analizamos los patrones de movilidad de los individuos, es decir, la propiedad y disponibilidad de coche, la posesión de permiso de conducir y de abono de transporte público, la frecuencia de los viajes en diferentes medios de transporte y las características del viaje más frecuente (VMF).
- Sección 5. Se pregunta a los participantes sobre su intención de adoptar MaaS, así como su disposición a pagar por utilizar estas innovaciones tecnológicas.

3.2 Análisis de los datos

Los datos se analizaron con el programa estadístico SPSS (versión 25) mediante técnicas de análisis descriptivo, exploratorio y de regresión.

4. APLICACIÓN DE LA METODOLOGÍA A LAS AREAS METROPOLITANAS DE MADRID (ESPAÑA) Y EL RANDSTAD (PAÍSES BAJOS)

4.1 Descripción de los casos de estudio

Como se ha introducido anteriormente, este trabajo explora la disposición de los individuos a adoptar MaaS en dos áreas metropolitanas: Madrid (España) y el Randstad (Países Bajos). Estas regiones presentan similitudes en términos de población, superficie y poder económico. Estudios anteriores (Arias-Molinares y García Palomares, 2020; Caiati et al., 2020; Feneri et al., 2020) han señalado ciertos atributos que hacen de estas áreas potenciales candidatas para la implementación de MaaS: (i) importantes tasas de penetración digital, (ii) un sistema de transporte público integrado y bien estructurado, y (ii) una creciente oferta de servicios de movilidad compartida. La Tabla 2 resume las principales características de cada caso de estudio.

Caso de estudio		Población	Área	Densidad de población	PIB per cápita
AM [1]	Ciudad	*Habitantes*	*Km²*	*Habitantes por Km²*	*Euros*
Madrid	**-**	6.800.000	5.335	1.275	37.621
	Madrid	3.300.000	604	5.464	43.075
Randstad	**-**	6.550.000	5.130	1.277	52.540
	Ámsterdam	872.680	220	3.967	60.855
	Rotterdam	651.450	325	2.004	51.455
	La Haya	544.770	100	5.447	48.010
	Utrecht	358.450	100	3.584	52.900
[1] AM: área metropolitana.					

Tabla 2 – Descripción de los casos de estudio.

4.1.1 El área metropolitana de Madrid (España) y sus patrones de movilidad

El área metropolitana de Madrid es una región monocéntrica localizada en el centro de la península Ibérica, alrededor de la ciudad de Madrid. No está relacionada con ninguna demarcación administrativa y, por tanto, sus límites son ambiguos. En este estudio, adoptamos la definición dada por la Comunidad de Madrid (2002) en el "Atlas de la Comunidad de Madrid en el umbral del siglo XXI". Según este documento, el área metropolitana de Madrid comprende 27 municipios y cubre una superficie de aproximadamente 5.335 kilómetros cuadrados. El área metropolitana de Madrid tiene una población de casi 6,8 millones de habitantes, siendo la tercera más poblada de la Unión Europea (UE), tras París y el Rurh alemán (Ayuntamiento de Madrid, 2020). Siguiendo las tendencias europeas, presenta una densidad de población (relativamente) alta, con un valor medio de 5.464 habitantes por kilómetro cuadrado dentro de su núcleo: la ciudad de Madrid. Madrid es la ciudad más poblada del país, con unos 3,3 millones de habitantes, así como uno de sus centros económicos más relevantes. En las últimas décadas, esta ciudad ha experimentado un rápido crecimiento y un proceso de suburbanización.

De acuerdo con la última Encuesta de Movilidad de Madrid (CRTM, 2019), en el área metropolitana de Madrid se producen (de media) 14,7 desplazamientos en un día laborable.

Estos desplazamientos se reparten entre múltiples modos, con un 39,0% de los viajes realizados en coche/moto, un 34,0% en modos activos (a pie o en bicicleta) y un 24,3% en transporte público. En total, aproximadamente el 33,3% de estos viajes son multimodales.

La movilidad en Madrid se caracteriza por un sistema de transporte público multimodal consolidado, altamente integrado y bien estructurado, que incluye 12 líneas de metro, 209 líneas de autobús urbano, 444 líneas de autobús de cercanías, ocho líneas de ferrocarril de cercanías y cuatro líneas de tranvía/metro ligero (Monzón et al., 2019). Desde 2010, Madrid se ha visto inundada por una amplia oferta de "nuevas movilidades" (es decir, servicios de movilidad compartida y de micro movilidad), que complementan la red de transporte público "tradicional". Según Arias-Molinares y Garacía-Palomares (2020), Madrid concentra actualmente 35 servicios de movilidad compartida gestionados por 29 operadores (públicos y privados) de transporte. Además, en esta área metropolitana existen actualmente varias aplicaciones de planificación de viajes como, por ejemplo, Google Maps, Moovit, City Mapper, Chipi o Mi Transporte. No obstante, ninguna de ellas ofrece la integración del billete electrónico o del pago.

4.1.2 El área metropolitana de Randstad (Países Bajos) y sus patrones de movilidad

El área metropolitana de Randstad es una región policéntrica situada en el centro-oeste de los Países Bajos. Comprende las cuatro mayores ciudades holandesas (Ámsterdam, Rotterdam, La Haya y Utrecht) y una serie de conurbaciones de tamaño medio. La población total del Randstad es de aproximadamente 6,55 millones de habitantes, lo que la convierte en la cuarta región metropolitana más poblada de la UE, tras París, el Rurh alemán y Madrid. El Randstad es de gran importancia social y económica para los Países Bajos, ya que alberga más del 40% de la población nacional y aporta casi el 50% de la renta nacional. La organización administrativa de esta área metropolitana es bastante compleja debido a la estructura urbana desagregada (Spaans et al., 2012). Sin embargo, se cree que el carácter interconectado y complementario de sus ciudades, así como su proximidad, aumenta las ventajas de aglomeración para la región.

En el Randstad, la mayor parte de los viajes y desplazamientos tienen lugar dentro y alrededor de sus cuatro grandes ciudades. Según un informe publicado por el Instituto de Análisis de Políticas de Transporte de los Países Bajos (KiM, 2016), estos viajes se reparten entre múltiples modos, siendo los principales el coche/motocicleta privada (50,0%), la bicicleta (28,0%), los desplazamientos a pie (17,0%) y el transporte público (5,0%). Esta área metropolitana presenta una de las redes de carreteras más densas del mundo, que se utiliza de forma significativa. El Randstad cuenta también con una red de transporte público bien estructurada, compuesta por servicios de ferrocarril, metro (o tren ligero), tranvía y autobús. Además, las bicicletas desempeñan tradicionalmente un papel relevante en la movilidad diaria. En los últimos años, se han implantado diversos servicios de movilidad compartida y de micro movilidad (como servicios de uso compartido de coches, bicicletas o patinetes). Sin embargo, la disponibilidad de estas innovaciones es todavía limitada en comparación con otros países de la Unión Europea. Al igual que en el caso de Madrid, existen varias aplicaciones de planificación de viajes (por ejemplo, Google Maps, HERE Maps, OpenStreetMap, Times Upp, 9292ov y NS Reisplanner), que facilitan el uso de la compleja red de transporte.

4.2 Recogida de datos: cuestionario online

Se consideró que una encuesta online era el método más adecuado para recoger los datos de este estudio, principalmente por las siguientes razones (i) el MaaS está dirigido a un grupo objetivo que tiene acceso a Internet; (ii) los cuestionarios basados en la web permiten contactar fácilmente con usuarios de diferentes medios de transporte; y (iii) los cuestionarios online ya se han aplicado en investigaciones anteriores sobre la disposición a adoptar y pagar por soluciones MaaS (véase la Tabla 1). El cuestionario web se distribuyó entre abril y junio de 2019 en las áreas metropolitanas de Madrid (España) y el Randstad (Países Bajos). Para el reclutamiento de la muestra, nos asociamos con un proveedor de paneles online especializado en cada país. Para garantizar una alta representatividad de las dos poblaciones, se incluyeron cuotas de género, edad y frecuencia de uso del transporte público.

Antes de la encuesta definitiva se realizó un piloto con 300 encuestados en ambas regiones para comprobar la validez del cuestionario y corregir posibles errores. A partir de las respuestas del piloto, el cuestionario se perfeccionó en cuanto a contenido, estructura y diseño gráfico, y se ajustó a los límites de tiempo (unos 20 minutos).

5. RESULTADOS Y DISCUSIÓN

5.1 Análisis descriptivo de la muestra

En total, recibimos 1.000 respuestas completas en Madrid (España) y 418 en el Randstad (Países Bajos). Esta sección resume las características de la muestra de ambos casos de estudio en términos de atributos socioeconómicos y demográficos, y de hábitos de viaje. Algunos de estos datos no pueden considerarse plenamente representativos, lo que parece razonable dado que el método de recogida de datos en la campaña de encuestas requiere que el cuestionario se rellene en línea. Sin embargo, consideramos que la muestra incluye un nivel de heterogeneidad suficiente para nuestros fines científicos.

Las características socioeconómicas y demográficas de los encuestados se recogen en la Tabla 3. En Madrid, la mayoría de los encuestados viven en el centro de la ciudad (83,7%), y sólo un 16,3% en la periferia (o anillo metropolitano). Estas cifras indican que el segmento urbano está sobrerrepresentado. Un primer análisis muestra una proporción de participantes mayores de 65 años inferior a la esperada (7,9%), tal vez debido a la menor afinidad tecnológica que suele mostrar este grupo generacional (Fioreze et al., 2019). También encontramos una alta proporción de individuos con estudios universitarios y trabajadores, y una baja proporción de hogares unipersonales. En el Randstad, una alta proporción de los encuestados viven en las áreas de alta densidad (Niveles 3 y 4). Además, casi el 40% de los encuestados viven en hogares de dos personas.

La Tabla 4 presenta las características relacionadas con los hábitos de viaje de los individuos. La frecuencia de uso de los servicios de transporte público se controló mediante cuotas, ya que estudios anteriores destacan su papel central en las estrategias de MaaS (Alonso-González et al., 2020).

En Madrid, la disponibilidad de un abono de transporte público (personal) es bastante alta entre los encuestados, quizá debido a su atractiva y eficiente red de servicios. Al mismo tiempo, casi el 80% de la muestra dispone de carné de conducir. La encuesta permitió evaluar los hábitos de viaje de los individuos. Se preguntó a los participantes si utilizaban un medio de transporte concreto en sus viajes más frecuentes. El 41,5% de la muestra son viajeros multimodales y el 58,5%, unimodales: el 7,8% de los viajes se realizan en modos activos (a pie y en bicicleta), el 33,6% en transporte público y el 16,6% en coche/moto.

Además, los servicios de movilidad compartida parecen bastante populares. En cuanto a la penetración tecnológica, encontramos valores muy significativos. Más del 60% de los encuestados declararon ser usuarios frecuentes de aplicaciones de planificación de viajes.

En el Randstad, la disponibilidad del carné de conducir entre los encuestados es significativamente mayor que la disponibilidad de un abono de transporte público personal (84,9% frente al 55,3%). A diferencia del caso de Madrid, la proporción de viajeros multimodales parece ser baja (31,8%), mientras que casi el 70% de los individuos son unimodales: con un 16,3% de los viajes realizados en modos activos (a pie y en bicicleta), un 13,0% en transporte público y un 35,6% en coche/moto. Al igual que en el caso de Madrid, la penetración tecnológica parece significativamente alta y casi el 60% de los encuestados utiliza con frecuencia aplicaciones de planificación de viajes.

Tabla 4 – Hábitos de movilidad de los individuos encuestados.

5.2 Intención de los viajeros de adoptar MaaS

En la encuesta, se preguntó a los participantes sobre su disposición a adoptar MaaS. Los resultados muestran actitudes y expectativas positivas hacia estas innovaciones tecnológicas en los dos casos de estudio. En particular, en el área metropolitana de Madrid, casi el 50% de los encuestados declaró un nivel "muy alto" de afinidad con estas soluciones (Figura 1).

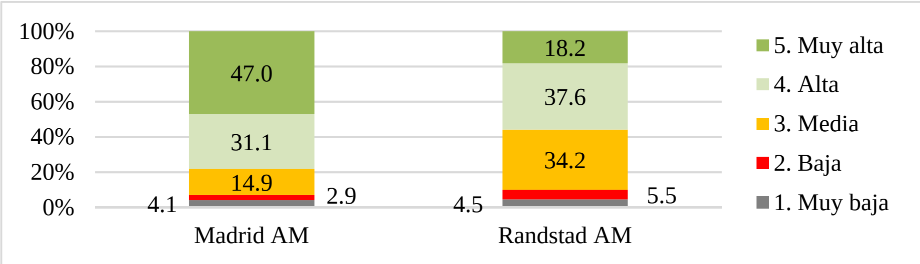

Fig. 1 – Disposición de los individuos a adoptar MaaS:

¿Está dispuesto a adoptar tecnologías MaaS? Nivel de intención: Escala Likert de 1 (mínimo) a 5 (máximo). Sección 5 de la encuesta.

Con el objetivo de comprender en profundidad las motivaciones de los individuos hacia MaaS, exploramos su relación con factores socioeconómicos, demográficos y relacionados con los viajes.

5.2.1 Disposición a adoptar MaaS: características socioeconómicas y demográficas

Como se muestra en la Tabla 5, exploramos la disposición de los individuos a adoptar MaaS en relación con sus características socioeconómicas y demográficas. Las variables consideradas fueron: lugar de residencia, género, edad, nivel de educación completado, ocupación y tamaño del hogar.

En Madrid, la distribución obtenida ilustra que las mujeres muestran una mayor intención a utilizar MaaS que los hombres. Sorprendentemente, la edad no es significativa y la probabilidad de adoptar MaaS parece similar para los diferentes grupos generacionales. No esperábamos este resultado, dado que las personas mayores suelen asociarse negativamente con el uso de las innovaciones tecnológicas (Alonso-González et al., 2020). De acuerdo con nuestros resultados, el lugar de residencia tampoco afecta a la disposición de los individuos a adoptar MaaS, quizás debido a la extensa y bien estructurada red de transporte que sirve al área metropolitana de Madrid. El nivel educativo parece influir en la aceptación del MaaS, así como la ocupación. Por un lado, tener un grado universitario aumenta la afinidad hacia estas soluciones innovadoras. Y, por otro lado, los jubilados muestran una menor afinidad con el MaaS que los estudiantes y los trabajadores. Esto parece razonable dado que (en general) este grupo está compuesto por individuos de mayor edad que tienden a realizar menos viajes (Mulley et al., 2017).

Por último, el tamaño del hogar también resulta significativo. Las personas que viven con dos o más compañeros muestran mayores intenciones de adoptar MaaS.

En el Randstad, los resultados obtenidos revelan que ni el género ni la edad afectan a la disposición a adoptar MaaS. Al contrario que en Madrid, el lugar de residencia parece ser significativo. Los encuestados que viven en las zonas más densas y urbanizadas muestran una mayor afinidad con las soluciones MaaS, quizá motivados por su mayor accesibilidad a los diferentes servicios de movilidad. Al igual que en el caso de Madrid, el nivel educativo y la ocupación parecen influir en la probabilidad de que los individuos adopten MaaS, así como el tamaño del hogar. En esta área metropolitana, los hogares unipersonales resultaron ser los más proclives a las nuevas soluciones tecnológicas.

5.2.2 Disposición a adoptar MaaS: características relacionadas con los hábitos de movilidad

Como se muestra en la Tabla 6, exploramos la disposición de los individuos a adoptar MaaS en relación con sus hábitos de viaje.

En consonancia con investigaciones anteriores (Alonso-González et al., 2020), los viajeros multimodales de Madrid son más proclives a adoptar MaaS que los unimodales. Estas soluciones están también positivamente correlacionadas con el uso de servicios de movilidad compartida, que complementan la oferta "tradicional" de transporte público.

Además, nuestros resultados muestran que el motivo y la duración del viaje más frecuente influyen en la probabilidad de utilizar MaaS. Por un lado, aquellos individuos que se desplazan por cuestiones de trabajo o estudios parecen ser los más inclinados hacia dichas innovaciones tecnológicas. Y, por otro lado, en los viajes cortos (menos de 15 minutos) la disposición a utilizar MaaS disminuye. Por último, la distribución obtenida ilustra que la intención de adoptar MaaS está positivamente asociada a la frecuencia de uso de las aplicaciones de planificación de viajes.

En el Randstad, los comportamientos multimodales y el uso de planificadores de viajes también están positivamente correlacionados con la aceptación de MaaS. Como en el caso de Madrid, el propósito del viaje más frecuente influye en la inclinación de los individuos hacia estas nuevas soluciones. Los individuos que se desplazan por cuestiones de trabajo o estudios parecen ser los más interesados en dichas tecnologías innovadoras. En el área metropolitana de Randstad, la disponibilidad de un pase de transporte público personal resulta estar directamente correlacionada con la intención de adoptar MaaS.

En general, encontramos que tanto las características socioeconómicas y demográficas como las variables relacionadas con los hábitos de viaje determinan la disposición de los individuos a adoptar MaaS.

6. CONCLUSIONES

El documento explora la disposición de los individuos a adoptar MaaS. En general, reconocemos actitudes positivas hacia estas nuevas soluciones en nuestros dos casos de estudios: Madrid (España) y Randstad (Países Bajos). Los resultados confirman que tanto las características socioeconómicas y demográficas como las variables relacionadas con los hábitos de viaje determinan la probabilidad de que los individuos adopten dichas innovaciones tecnológicas.

Por un lado, nuestros resultados muestran que las personas con un alto nivel de estudios y no jubiladas son los segmentos de la población con una mayor probabilidad de adoptar MaaS. Dado que para adoptar estas nuevas tecnologías se requieren ciertos conocimientos tecnológicos (por ejemplo, habilidades para manipular un móvil), esperábamos que las personas de mayor edad estuvieran menos interesadas. Sin embargo, los diferentes grupos generacionales mostraron niveles similares de afinidad con MaaS. Por otro lado, nuestros resultados sugieren que los viajeros multimodales se sienten significativamente más atraídos por MaaS que los unimodales. Esto parece razonable, ya que el MaaS se basa en la integración de varios servicios de movilidad. El propósito del viaje también parece ser clave. Los viajes por trabajo o estudios se reconocen como los más inclinados hacia estas soluciones innovadoras. Por último, la distribución obtenida ilustra que la intención de adoptar MaaS está positivamente asociada a la frecuencia de uso de las aplicaciones de planificación de viajes.

Entender las motivaciones que impulsan a los viajeros a adoptar MaaS es esencial para definir estrategias exitosas orientadas al usuario. Adaptar las soluciones de viaje a las expectativas de los individuos puede conducir a un cambio de comportamiento hacia opciones más satisfactorias y asequibles. La investigación tiene algunas limitaciones que deberían abordarse en futuras contribuciones. Pensamos que es necesario desarrollar pilotos reales con el objetivo de obtener y profundizar en el conocimiento para elaborar nuevas recomendaciones.

RESUMEN

Las ciudades han intensificado la implementación de Zonas de Bajas Emisiones (ZBE) para mejorar la vida urbana a partir de la mejora de la calidad del aire. En este contexto, se ha prestado limitada atención tanto a la aceptabilidad de las medidas adoptadas como al efecto producido sobre los patrones de viaje. Este estudio lleva a cabo un enfoque de modelización para conocer el impacto de cinco grupos de variables (características socioeconómicas y demográficas, actitudes personales, variables relacionadas con el viaje, percepciones y hábitos de movilidad relacionados con la ZBE y elección modal en la ZBE) en la aceptabilidad pública y en el cambio modal hacia modos de transporte más sostenibles. La ciudad de Madrid ha servido como caso de estudio debido a la reciente implementación de Madrid Central. Los datos para realizar los modelos de elección discreta se han obtenido de una encuesta con un total de 799 participantes. Los resultados muestran el poder explicativo de la conciencia ambiental, el modo de transporte más utilizado, el uso de sistemas de movilidad compartida y la frecuencia de viaje a Madrid Central en cuanto a la aceptabilidad pública así como el impacto de la ZBE en la reducción del uso del vehículo privado y la promoción de modos de transporte sostenibles, relacionados principalmente a las características sociodemográficas y a los hábitos de movilidad y las percepciones hacia la ZBE. Estos resultados pueden extrapolarse a otras ciudades en el contexto internacional y servir a los responsables políticos para comprender mejor los factores que influyen en la efectividad de las políticas de transporte.

1. INTRODUCCIÓN

La movilidad sostenible se está convirtiendo en una prioridad en las agendas de planeamiento de muchas ciudades (Banister 2008; Schwanen et al., 2011). Esta situación refleja el creciente interés en el reto que supone mejorar la contaminación atmosférica producida por el transporte a la vez que revela el conflicto entre maximizar los beneficios de la movilidad y reducir su impacto ambiental (Polichetti, 2017; Ramos et al., 2017). Para abordar esta problemática, muchas ciudades (Sao Paulo, Beijing, París, Londres, etc.) han decidido implementar una Zona de Bajas Emisiones (ZBE) para limitar el uso de vehículos de combustión en favor de vehículos eléctricos, movilidad compartida y modos activos (Zainol et al., 2014; Szarata et al., 2017).

La adopción de ZBEs es una de las políticas de transporte más frecuentes para abordar los retos de la calidad del aire en las ciudades (Togel et al, 2014). Las ZBE consisten en un conjunto de políticas específicas que limitan el acceso de los automóviles dentro de un área definida. Dichas restricciones pueden establecerse a través de una variedad de políticas específicas: limitaciones de franjas horarias, cargos a los vehículos de motor, promoción del uso compartido del coche y peatonalización (Cass y Faulconbridge, 2016). La implantación de las ZBEs se produce en lugares con niveles de tráfico muy elevados y con una concentración relevante de actividad económica y social. La naturaleza, la extensión y las características de las ZBEs varían en función, entre otras cosas, de las normas culturales, los sistemas jurídicos y los objetivos de calidad del aire, (Alduán, 2014; Holman et al., 2015).

La implementación de ZBEs en Europa responde principalmente a los requerimientos de la Agenda Urbana de la UE y a su marco legal. La Agencia Europea de Medio Ambiente ha establecido unos límites de emisión para ciertos contaminantes siendo los miembros de la UE los responsables de cumplirlos. En el contexto europeo se han establecido normas específicas sobre las emisiones de contaminantes en las carreteras (por ejemplo, PM y NOx), que desencadenan restricciones al tránsito urbano aplicadas por las autoridades locales en función del tipo de vehículo (de Euro I a Euro VI). Estas restricciones al tráfico de automóviles parecen herramientas adecuadas para lograr ciudades habitables, transitables y saludables, pero su efectividad y viabilidad también está ligada a la alta controversia social que se genera cuando se implementan (Soria-Lara et al., 2019) ya que llevan asociadas cambios significativos en los patrones de movilidad de los ciudadanos (Moser et al, 2007; Graham-rowe et al, 2011; Ahanchian et al, 2019).

La literatura previa referente a ZBE se ha centrado principalmente en la medición directa de sus efectos sobre la calidad del aire y la renovación de la flota (Lutz, 2009; Ellison et al., 2013; Ferreira et al., 2015, Lebrusán & Toutouh, 2020). Para reducir la controversia social generada por estas áreas se considera prioritario estudiar la aceptabilidad social de la ZBE.

Además, se debe analizar su efectividad en cuanto a la reducción del uso del vehículo privado y su impulso al cambio modal hacia modos más sostenibles, para una mejor comprensión de la medida en cuanto a las emisiones producidas por el transporte, tal y como se ha hecho previamente en otras políticas similares (prohibición temporal del uso de vehículos privados, incentivos para los modos sostenibles, suministro de información en tiempo real a los viajeros, la aplicación del sistema de información de estacionamiento telemático, etc.). De esta manera, pueden conocerse repercusiones económicas, ambientales y sociales asociadas a las ZBE que ayuden a los profesionales y a los responsables políticos a nuevos diseños y enfoques de implementación de estas zonas.

Esta investigación tiene como objetivo identificar las variables claves que explican la aceptabilidad de las ZBEs así como el impacto modal de las mismas en contextos urbanos (en especial el cambio modal experimentado por los usuarios de vehículo privado) utilizando un análisis de elección discreta. Para ello, se han utilizado los datos extraídos de una encuesta realizada a 799 ciudadanos de la Comunidad de Madrid. Dicha encuesta está estructurada en cinco bloques: (i) Características socioeconómicas y demográficas; (ii) Actitudes personales; (iii) Variables relacionadas con el tipo de viaje; (iv) Hábitos de movilidad y percepciones relacionadas con la ZBE; y (v) Elección modal de viaje respecto a la ZBE. La ciudad de Madrid ha servido como caso de estudio, por su reciente implementación de Madrid Central (2018).

El artículo se encuentra estructurado de la siguiente manera. El capítulo 2 muestra la literatura previa en este campo. El capítulo 3 presenta el caso de estudio de Madrid. La encuesta realizada y los datos obtenidos se muestran en el capítulo 4. El capítulo 5 describe la metodología utilizada mientras que el capítulo 6 desarrolla los principales resultados obtenidos. Finalmente, el capítulo 7 concluye con las observaciones finales y la propuesta de futuras iniciativas de investigación.

2. REVISIÓN DE LITERATURA: ANÁLISIS DE ZBEs

El análisis previo de las ZBEs y su impacto en la sostenibilidad es un tema de creciente interés en la literatura académica. Para contextualizar la revisión realizada, se han consultado dos grupos de estudios. En primer lugar, aquellos estudios basados en comparar la calidad del aire antes y después de la implementación de una ZBE. En segundo lugar, aquellos estudios que analizan el cambio modal producido por políticas de transporte similares a las ZBEs.

Dentro del primer grupo de estudios revisados, Duque et al. (2016) evalúan un conjunto de estrategias para reducir la contaminación atmosférica en la ZBE de Oporto utilizando una herramienta de modelización numérica. Sus resultados muestran que la ZBE tiene beneficios locales asociados a reducciones del 3% de la concentración de NO_2 mientras que no se observan reducciones en las concentraciones de PM. Del mismo modo, Dias et al. (2012) desarrollaron un enfoque de modelización integrada para evaluar los impactos en la calidad del aire de una ZBE en Coimbra, Portugal. Los autores encontraron una pequeña mejora de la calidad del aire dentro de la ZBE, teniendo dificultades para alcanzar los objetivos de calidad del aire. Además, observaron que las emisiones previstas a nivel de la ciudad podrían aumentar debido a la reconfiguración de los patrones de movilidad. Otro estudio digno de mención fue realizado por Boogaard et al. (2012) en varias ciudades holandesas. Sus conclusiones muestran la escasa capacidad de las ZBE para producir reducciones significativas reducciones significativas de la contaminación de los coches.

Otros autores destacan el impacto de las ZBE en la renovación del parque automovilístico de vehículos en todo el mundo (por ejemplo, en Berlín, Londres y Lisboa), provocando avances tecnológicos que reducen las emisiones por vehículo y mejoran la calidad del aire (Lutz, 2009; Ellison et al., 2013; Ferreira et al., 2015). Por último, el estudio realizado por Holman et al. (2015) en diferentes ciudades europeas, señala las dificultades para distinguir entre los efectos causados por una ZBE en la calidad del aire y los efectos provocados por otras medidas políticas. como la renovación de la flota. En el mismo sentido, York y Rouleau (2017) señalaron la escasa evidencia entre la aplicación de la ZBE y la mejora de la calidad del aire, dado el escaso número de evaluaciones ex-post, la influencia de los efectos de rebote no controlados y el desarrollo de la tecnología de los vehículos.

El segundo grupo de estudios se centra en el análisis de la elección modal impulsada por diferentes políticas de transporte similares a las ZBE, con especial interés en la reducción del tráfico de automóviles. Como indican Graham-Rowe et al. (2011), cabe destacar que no hay muchos estudios de alta calidad metodológica para evaluar la reducción del uso del vehículo privado. Sus autores señalan la escasa evaluación de las políticas de transporte con datos de movilidad ex-ante y ex-post como uno de los puntos más débiles de los estudios de investigación anteriores. A pesar de los problemas mencionados, cabe mencionar las siguientes aportaciones sobre el impacto de las políticas de movilidad en el cambio modal. Tertoolen et al. (1997) detallan cómo varias razones psicológicas (independencia, dinamismo de la persona, ingresos, etc.) pueden determinar el uso (o no) del vehículo privado. Los autores realizan una investigación basada en el suministro de información sobre el coste económico y medioambiental del uso del coche de 350 usuarios de la ciudad de Gouda (Países Bajos). Los resultados indican un aumento de la conciencia económica y medioambiental de los conductores, que no se refleja en un cambio de sus hábitos de elección modal. Eriksson et al. (2008) realizaron un experimento en dos ciudades suecas que consistía en interrumpir las pautas habituales de uso del coche. Se reclutó a un total de 71 usuarios de automóviles para el experimento. Los resultados muestran una relación directa entre la voluntad de reducir el uso del vehículo privado y el cambio modal. Croci (2016) realizó una evaluación comparativa de tres experiencias de tarificación vial en Europa para evaluar su eficacia en la reducción de las externalidades generadas por el tráfico rodado: Londres, en funcionamiento desde 2003; Estocolmo, en funcionamiento desde 2007; y Milán, en funcionamiento desde 2012. En todos los casos, se evidenciaron reducciones los niveles de tráfico y un cambio en los patrones de movilidad. La principal tendencia fue un cambio de los conductores de automóviles al transporte público superior al 10% en las tres ciudades europeas.

Más recientemente, Ahanchian et al. (2019) desarrollaron un modelo basado en agentes para simular patrones emergentes derivados de las acciones individuales para analizar las oportunidades de cambio modal en Dinamarca. Establecieron cuatro escenarios alternativos para probar el efecto sobre el cambio modal, con un enfoque especial en el cambio modal desde el vehículo privado: incentivos para los modos sostenibles, expansión de la infraestructura pública, desincentivos para los coches privados y combinación de estas medidas. Los resultados muestran, para el horizonte de 2050, una reducción general del uso del vehículo privado en todos los escenarios y el consiguiente aumento del transporte no motorizado y del uso del transporte público. Otros estudios destacan diferentes efectos que pueden cambiar los hábitos de movilidad y reducir el uso del vehículo privado, como un cambio de residencia (Bamberg, 2006), o una reubicación laboral para reducir el tiempo de desplazamiento (Mullins y Mullins, 1995).

Esta investigación añade a la literatura una evaluación ex post de la aceptabilidad pública hacia la implementación de una ZBE y la exploración de los efectos de las ZBE en el cambio modal.

3. LA IMPLEMENTACIÓN DE LA ZBE DE MADRID CENTRAL

La ciudad de Madrid (España) tiene una superficie de 605 km^2 y una población de más de 3 millones de habitantes (5300 habitantes/km^2), por lo que se trata de una ciudad compacta con una alta densidad de población. Desde la década de 1990, Madrid ha experimentado un rápido proceso de suburbanización, expandiéndose por su área metropolitana (8.022 km^2 y 6,5 millones de habitantes). Sin embargo, la ciudad de Madrid sigue ofreciendo la mayor oferta de empleo, comercio y ocio entre los municipios situados en su área metropolitana, generando una fuerte interdependencia con sus municipios circundantes. Como dato, sólo la ciudad de Madrid concentra el 60% del PIB regional.

Los índices de movilidad han aumentado significativamente en la región en los últimos años. Según la última encuesta de movilidad, se producen 15,8 millones de desplazamientos en día laborable en Madrid (Monzón, 2019). El número de desplazamientos dentro del área metropolitana ha aumentado un 30,4% desde 1996 hasta 2017, siguiendo un ritmo similar al del crecimiento de la población (32,7%). Sin embargo, se observan notables diferencias en función del modo de transporte. Por ejemplo, el número de viajes en transporte público ha aumentado un 10%, mientras que el crecimiento del uso del vehículo privado es mucho mayor (+60%). Esta tendencia es el resultado del proceso de suburbanización comentado anteriormente.

El reparto modal muestra un uso predominante del vehículo privado, incluyendo coches y motos (57,8%), entre las áreas metropolitanas, mientras que el uso del transporte público cubre el 36,9% de esos viajes, y los modos de transporte no motorizados (bicicleta y caminar) alcanzan el 3,8%. Se observa un reparto modal diferente dentro de la ciudad de

Madrid, donde la relevancia de los sistemas de transporte colectivo y de los modos no motorizados asciende al 37,8% y 36,8%, respectivamente. Por el contrario, el uso del vehículo privado es del 24,7%.

El área metropolitana de Madrid cuenta con una amplia red de transporte por carretera, que incluye diez autopistas. En particular, hay cuatro autopistas alrededor de la ciudad de Madrid (M-30, M-40. M-45 y M-50) que conectan diferentes municipios de su área metropolitana. La red de transporte público existente se basa en un sistema integrado, compuesto por autobuses, ferrocarril y servicios de metro. Para la fijación de las tarifas del transporte público, tanto la ciudad de Madrid como su área metropolitana se dividen en ocho zonas de transporte. Para cada una de estas zonas, el consorcio de transporte ofrece tres tipos de billetes: billete sencillo, billete de diez viajes y abono de transporte público, que permite el uso ilimitado del transporte colectivo durante un mes o un año. Dicho abono de transporte colectivo es muy utilizado entre los viajeros habituales, llegando a los 3,6 millones de usuarios. Además, existen precios reducidos en el abono de transporte colectivo para usuarios jóvenes (<26 años), mayores (>65 años), familias numerosas y personas discapacitadas. Además, para incrementar las oportunidades de elección modal en la ciudad, el gobierno local ha implantado un sistema público de bicicletas compartidas (BiciMAD). Otros servicios recientes de movilidad compartida son ofrecidos por operadores privados, como patinetes, motocicletas y coches eléctricos. La oferta de estos sistemas de movilidad compartida se concentra en el centro de la ciudad.

El elevado crecimiento de los desplazamientos motorizados dentro del área metropolitana de Madrid ha aumentado las emisiones de gases de efecto invernadero (GEI) y de contaminantes (por ejemplo, NOX y PM). El mayor problema se produce en la ciudad de Madrid, donde el tráfico rodado genera el 74,4% de las emisiones locales, según los datos del Ayuntamiento de Madrid (2017). Desde 2011, los límites de calidad del aire establecidos por la UE se han superado durante varios episodios, sobre todo para el NOx y el O3. Las condiciones meteorológicas desfavorables de la ciudad de Madrid (inversión térmica) dificultan la eliminación de dichos contaminantes de la atmósfera de la ciudad, especialmente durante el otoño y el invierno. Para abordar este problema, el gobierno local de Madrid desarrolló un plan de calidad del aire llamado "Plan A" (2017), siendo la implantación de una Zona de Bajas Emisiones uno de los más destacados esquemas políticos del Plan. Dicha ZBE fue implementada con el nombre de Madrid Central.

Madrid Central fue implementado el 30 de noviembre de 2018, abarcando una superficie de 5 km^2 en el centro de la ciudad de Madrid. Cuenta con múltiples modos de transporte para acceder a dicho área, con un total de 70 líneas de autobús, 4 líneas de metro, 57 estaciones de bicis compartidas 27 paradas de taxi y 5946 plazas de aparcamiento subterráneo. Su objetivo es mejorar la calidad del aire y promover un centro de la ciudad más amigable para peatones, ciclistas, vecinos y visitantes.

Las restricciones de tráfico para los vehículos privados dependen de un sistema de etiquetado según el tipo de motor (Cero, Eco, C, B o A; de menor a mayor nivel de contaminación). Las características del parque automovilístico de Madrid y su área metropolitana se muestran en la Tabla 1.

Población		Etiqueta ambiental				
		A	B	C	Eco	Zero
No residentes	Coche	No	Excepto parking/garajes	Excepto parking/garajes	Sí	Sí
	Motocicleta	No	Horario restringido (7 a 22h)	Horario restringido (7 a 22h)	Sí	Sí
	Distribución de mercancías	No	Horario restringido	Horario restringido	Sí	Sí
Invitados (máx.20/mes)		Sí (hasta 2020)	Sí	Sí	Sí	Sí
Residentes		Sí (hasta 2025)	Sí	Sí	Sí	Sí

Tabla 1 – Características de la flota de vehículos en Madrid y su área metropolitana.

Con el objetivo de reducir el uso de vehículos privados, se han impuesto restricciones de tráfico a los coches y motos privados para entrar en "Madrid Central" en función de cinco etiquetas medioambientales: Cero (nivel de contaminación más bajo), Eco, C, B o A (nivel de contaminación más alto) (Tabla 2). Estas categorías medioambientales están armonizadas a nivel nacional, en función del tipo de motor, la antigüedad y el tipo de vehículo. Hay que destacar que las restricciones para motocicletas son menores que para los coches. Asimismo, existen excepciones de acceso para residentes, discapacitados y vehículos de seguridad y emergencia. Además, los residentes disponen de un máximo de 20 invitaciones al mes para acceder a Madrid Central en vehículo privado.

Flota de vehículos	Etiqueta ambiental (%)				
	A	B	C	Eco	Zero
Motocicleta particular	25.4	17.1	56.6	0.9	0.0
Coche particular	25.5	34.1	37.4	2.7	0.3

Tabla 2 – Características de la flota de vehículos en Madrid y su área metropolitana.

Madrid Central fue una de las medidas políticas emblemáticas aplicadas por el antiguo gobierno de la ciudad, que contaba con el apoyo de una coalición de partidos de izquierda.

La aplicación de la medida suscitó una gran controversia en el debate político y en la opinión pública, tanto antes como después de su aplicación. Las disputas fueron sobre todo sobre la eficacia de la medida para reducir la contaminación, y su impacto en los viajeros y los servicios minoristas de la zona. La coalición de derechas que gobierna la ciudad desde mayo de 2019 ha establecido un nuevo plan de movilidad, con el nombre de Madrid 360, que mantiene la ZBE con algunos pequeños cambios en su funcionamiento y operación.

4. BASE DE DATOS: ENCUESTAS A LA POBLACIÓN

Se utiliza un enfoque basado en la modelización para abordar el objetivo principal de esta investigación, a saber, identificar las variables clave que explican la aceptabilidad pública y el cambio modal de Madrid Central. La principal fuente de datos fue una encuesta individual online que recogía diferentes tipos de variables: socioeconómicas y demográficas, actitudes personales, variables relacionadas con el viaje, percepciones y hábitos de movilidad vinculados a Madrid Central, y elección modal respecto a Madrid Central. Se realizó una encuesta piloto con un pequeño grupo de personas. Sus respuestas proporcionaron al equipo de investigación información para perfeccionar el diseño de la encuesta (por ejemplo, la legibilidad), añadiendo nuevas preguntas cuando fue necesario.

La encuesta definitiva se difundió entre los ciudadanos de Madrid y su área metropolitana de enero a junio de 2019. El plan de difusión incluyó redes sociales, páginas web especializadas y la difusión en la calle de folletos indicando el objetivo de la investigación.

Con esto último se pretendía incluir una adecuada heterogeneidad en la muestra en cuanto a las características sociodemográficas de la misma, dadas las limitaciones de difusión online para captar a todos los segmentos de población. Un total de 1300 personas rellenaron el cuestionario. Al final se obtuvieron 799 respuestas válidas. La encuesta constaba de los siguientes cinco bloques principales (Tabla 3):

(i) Características socioeconómicas y demográficas de los individuos: género, edad, nivel de educación, ingresos mensuales y código postal de residencia.
(ii) Actitudes personales, recogiendo información sobre las creencias y la ideología de los individuos, incluida la conciencia económica, social y medioambiental.
(iii) Variables relacionadas con los viajes que afectan a los desplazamientos diarios: posesión individual de un permiso de conducir o un abono de transporte, la disponibilidad de un vehículo privado y la frecuencia de uso de los distintos modos de transporte (transporte colectivo y servicios de movilidad compartida).
(iv) Percepciones individuales y hábitos de movilidad vinculados a la implementación de Madrid Central: frecuencia de viajes para acceder a Madrid Central, principales actividades realizadas dentro de esta zona, modos de transporte elegidos para acceder/salir de Madrid Central antes y después de la implantación de la ZBE, percepción de Madrid Central como peatón; y nivel individual de aceptabilidad de Madrid Central, incluyendo una pregunta abierta sobre posibles acciones para mejorar la aceptabilidad de la ZBE.
(v) Elección modal en Madrid Central: cambio modal tras la implantación de Madrid Central, modos de transporte frecuentes para acceder a Madrid Central (máx. 2) antes y después de la implantación de la ZBE, factores que determinan la elección modal.

Bloque	Variables	Descripción	Tipo de pregunta
Características socioeconómicas y demográficas	Edad	Edad del encuestado (varias categorías)	Pregunta multirespuesta
	Género	Hombre/Mujer	
	Nivel de estudios alcanzado	Universitario / No universitario	
	Estado de empleo	Estudiante; trabajador; estudiante y trabajador; otro (amo de casa, desempleado, jubilado)

		compras, tiempo de ocio, zona de paso)	
Elección modal en Madrid Central	Cambio en la elección modal tras la implementación de Madrid Central	Si el encuestado ha cambiado (o no) su modo de transporte para acceder a Madrid Central tras la implementación de la ZBE	Pregunta multirespuesta
	Modos de transporte habituales (máx.2) para acceder a Madrid Central antes de implementar la ZBE	Selección de los principales modos de transporte para acceder a Madrid Central antes de implementar la ZBE (solo los 2 modos de transporte más habituales)	
	Modos de transporte habituales (máx.2) para acceder a Madrid Central después de implementar la ZBE	Selección de los principales modos de transporte para acceder a Madrid Central después de implementar la ZBE (solo los 2 modos de transporte más habituales)	
	Factores que determinan su elección modal	Coste; tiempo; comodidad; flexibilidad horaria; posibilidad de carga; otros	

Tabla 3 – Estructura de la encuesta y variables incluidas.

Como se observa en la Tabla 4, la muestra presenta una mayor proporción de hombres (59,1%) y una menor presencia de personas mayores de 65 años (2,4%). Según su situación laboral, el 56,9% de los encuestados son asalariados, destacando la presencia de estudiantes (16,8%) y de asalariados a tiempo parcial que estudian al mismo tiempo (18,8%). Cabe mencionar que el 75,3% de los encuestados tiene estudios universitarios. En cuanto a la estructura del hogar, el 38,3% de los encuestados comparte hogar (compañeros de piso y parejas), el 30,8% son familias con hijos y el 28,4% vive con sus padres. El nivel de ingresos se distribuye uniformemente en la muestra, con un porcentaje representativo de encuestados en todos los subgrupos de ingresos incluidos en el cuestionario. El código postal se ha diseñado como una variable adicional en seis categorías: (i) Dentro de Madrid Central; (ii) Entre Madrid Central y la M-30; (iii) Entre la M-30 y la M-40; (iv) Entre la M-40 y la M-50; y (vi) Sin respuesta. Cabe destacar que todas las categorías incluidas en cada variable están adecuadamente representadas en la muestra.

El segundo bloque de la encuesta se centra en las actitudes personales (Tabla 4). Hay una mayor presencia de la ideología de izquierdas (36,9%) en comparación con otras opciones. Los encuestados también declararon niveles muy altos de concienciación en temas sociales (38,4%), económicos (40,3%) y medioambientales (53,4%).

Tabla 4 – Información socioeconómica y demográfica y actitudes personales

La Tabla 5 muestra también la información recogida sobre las variables relacionadas con los viajes. La mayoría de los encuestados tiene carnet de conducir (91,9%) y dispone de al menos un coche en su domicilio (79,2%). Sólo el 13,9% tiene un ciclomotor o una motocicleta en casa. La mayoría de los participantes (73,3%) tiene abono de transporte público, y la frecuencia de uso del transporte colectivo se distribuye uniformemente entre todas las categorías incluidas en la encuesta. Por último, los encuestados declaran un uso muy bajo de las formas de movilidad compartida existentes (el 72,2% de los encuestados rara vez utiliza estos servicios), lo que se alinea con los resultados obtenidos por la última Encuesta de Movilidad de Madrid (Monzón et al., 2019).

	N	%		N	%
Variables relacionadas con el tipo de viaje					
Carnet de conducir			***Disponibilidad de vehículo***

Alto	108	13.5	Muy alto	19	2.4
Muy alto	255	31.9			

Tabla 5 – Variables relacionadas con el tipo de viaje.

El cuarto grupo de variables contiene las percepciones individuales y los hábitos de movilidad vinculados a Madrid Central (Tabla 6). Más de una cuarta parte de los encuestados (27,3%) mostró que la implantación de Madrid Central ha tenido un impacto muy negativo o negativo en sus desplazamientos habituales, mientras que un total del 23% señaló un impacto positivo o muy positivo. Sólo una pequeña parte de los participantes indicaron una valoración negativa (6,3%) o muy negativa (4,4%) como peatones al caminar dentro de Madrid Central. Además, el 24,7% de los encuestados han aumentado su tiempo de caminar en la ZBE después de la implementación de Madrid Central, pero la mayoría de ellos (71,5%) mantuvo sus hábitos previos. La variación de tiempo dedicado a las actividades de comercio y ocio de los individuos tras la implementación de Madrid Central muestra porcentajes similares entre los encuestados que afirman que han disminuidos dichas actividades (38,2%), las han aumentado (34,9%) o han mantenido constantes sus hábitos (26,9%) en comparación con la situación anterior a la ZBE. La frecuencia y el día habitual de los viajes se distribuyen adecuadamente en la muestra, con un número notable de encuestados para cada categoría. Las actividades realizadas en "Madrid Central" son ocio (32,0%), trabajo (27,9%) y compras (21,8%).

Por último, mostramos las tendencias resultantes en cuanto a la aceptabilidad de los individuos de Madrid Central. El grado de aceptabilidad se divide en cinco categorías utilizando una escala de Likert de cinco puntos (1-muy negativo, 5-muy positivo). Un 36,2% de los encuestados mostró una opinión muy positiva de "Madrid Central", mientras que el 31,7% manifestó una opinión positiva. Por el contrario, sólo el 9,5% de los encuestados señaló una opinión muy negativa hacia "Madrid Central", mientras que un 14,6% señaló una opinión negativa. El 8,3% restante ofreció una evaluación neutra. En general, se observa que Madrid Central parece contar con bastante apoyo por parte de la población.

Percepciones y hábitos de movilidad relacionados con Madrid Central

Impacto de Madrid Central en los viajes habituales			***Evaluación como peatón de Madrid Central***		
Muy negativo	94	11.8	Muy negativo	35	4.4

Negativa	75	9.4	Muy positiva	290	36.3
Neutra	66	8.2			

Tabla 6 – Percepciones y hábitos de movilidad en relación a Madrid Central.

Además, se animó a todos los encuestados a señalar posibles acciones para mejorar la satisfacción con Madrid Central. Los participantes con una aceptación positiva o muy positiva de Madrid Central indicaron principalmente las siguientes acciones: aumentar los servicios actuales de transporte público (80,6%); una mejor promoción del coche compartido (44,7%); apoyo financiero para renovar la flota de vehículos privados (44,1%); y ampliar Madrid Central (31,9%). Los participantes con una aceptación negativa o muy negativa de Madrid Central señalaron: la necesidad de una mayor oferta de servicios de transporte colectivo (49,7%) y de apoyo financiero para renovar la flota de vehículos privados (46,1%). Otras medidas mostradas por este grupo de encuestados fueron permitir que los vehículos de combustión lleguen a Madrid Central durante algunas franjas horarias (34,6%); implantar una tasa para acceder a Madrid Central en vehículo privado (22,8%); y reducir la extensión actual de Madrid Central (22,0%).

El último bloque aborda la elección modal de los individuos antes y después de la implementación de Madrid Central (Tabla 7). La mitad de los encuestados (49,9%) indicaron un cambio modal provocado por la ZBE. Los encuestados también indicaron sus dos modos de transporte más frecuentes para acceder a Madrid Central antes y después de su implantación. El coche privado (solo o con acompañante) y el metro (53,3%) eran la opción más frecuente para viajar a la ZBE antes de la implantación de Madrid Central (50,6%). A estos modos de transporte les seguían el autobús (21,1%), el tren de cercanías (12,5%) y caminar (12,6%). Tras la puesta en marcha de Madrid Central, el metro sigue siendo el modo de transporte más utilizado para acceder a Madrid Central, seguido del autobús (27,4%), el coche privado (solo o con acompañante) (21%), caminar (18,4%) y el tren de cercanías (16,4%). Además, los encuestados indicaron los factores más determinantes para explicar su elección modal. En este sentido, destacaron los siguientes factores: comodidad (55,3%) y tiempo de viaje (53,4%), seguidos del coste (42,9%).

5. METODOLOGÍA: MODELOS DE ELECCIÓN DISCRETA

El enfoque de la investigación se centra en el uso de un marco de elección discreta basado en especificaciones logit. La formulación original de los modelos logit, derivada de la teoría de la maximización de la utilidad y el comportamiento, supone que los responsables de la toma de decisiones son maximizadores de la utilidad. Es decir, los individuos elegirán la opción con la mayor utilidad para ellos. La investigación sobre el transporte ha utilizado previamente los modelos logit (Thrane, 2015; Hammadou y Papaix, 2015; Arbués et al. 2016). En el estudio se realizan tres modelos logit (un logit binario y dos logit ordenados).

El primer modelo explora la aceptabilidad de la población respecto a Madrid Central utilizando un modelo logit ordenado. La variable dependiente es la aceptabilidad individual de Madrid Central, medida mediante una escala Likert de cinco puntos. La aceptabilidad de la ZBE Madrid Central se ha recogido como una variable discreta ordenada (1 = Muy negativa; 2 = Negativa; 3 = Neutral; 4 = Positiva; 5 = Muy positiva).

El segundo modelo analiza los cambios en la elección modal para llegar a Madrid Central, asumiendo dichos cambios desde una lógica binaria (0 = la elección modal no cambia tras implantar Madrid Central; 1 = la elección modal cambia tras implantar Madrid Central). La naturaleza discreta de la variable dependiente ha llevado a la adopción de una especificación logit binaria para este modelo.

El tercer modelo obtiene información sobre los cambios de elección modal entre los individuos que utilizaban el vehículo privado antes de la implantación de Madrid Central.

La variable dependiente se basa en una variable discreta ordenada que capta una graduación de las opciones de cambio modal tras la implantación de Madrid Central. A partir de la información reportada sobre los modos de transporte utilizados antes y después de la implantación de la ZBE, se construyó una variable dependiente con la siguiente codificación: (1) aumento del uso del vehículo privado en comparación con la situación anterior a la ZBE (este grupo de individuos renunció a utilizar otros modos de transporte y sólo utilizó su vehículo privado para llegar a Madrid Central); (2) mantenimiento del hábito de uso del vehículo privado después de "Madrid Central"; (3) reducción del uso del vehículo privado favor del taxi/VTC; (4) reducción del uso del vehículo privado en favor del transporte público o modos activos; (5) abandono del uso del vehículo privado para llegar a Madrid Central. Estas cinco categorías establecen una graduación de la sostenibilidad derivada del cambio modal de los conductores de vehículo privado tras la implementación de Madrid Central.

6. RESULTADOS

Esta sección presenta los principales resultados del análisis realizado en esta investigación.

En primer lugar, la sección 6.1 muestra los resultados obtenidos del modelo logit sobre la aceptabilidad de la ZBE. La sección 6.2 presenta los resultados descriptivos sobre el cambio modal tras la aplicación de Madrid Central, que llevaron al desarrollo del modelo logit binario sobre el cambio modal y al modelo logit ordinario sobre el cambio modal de los antiguos usuarios de vehículo privado, principal grupo afectado por la medida, de los cuales se analizarán sus principales resultados.

6.1 Análisis de la aceptabilidad de Madrid Central

Dado que las variables explicativas utilizadas en el modelo eran en su mayoría categóricas, la interpretación de los resultados de la modelización requería la selección de un caso base. Esto nos permitió determinar si, para cada variable explicativa, las respuestas de los individuos eran estadísticamente significativas entre categorías en comparación con el caso base. Las categorías base elegidas pueden consultarse en la Tabla 8.

Los resultados del modelo logit ordenado que explora la aceptabilidad hacia Madrid Central se muestran en la Tabla 8. El modelo identifica las variables explicativas que desde un punto de vista estadístico (p valor < 0,05) influencian el nivel de aceptabilidad de Madrid. Un signo positivo indica una mayor aceptabilidad hacia Madrid Central en comparación con el caso base. La mayoría de las variables explicativas que resultaron no estadísticamente significativas fueron finalmente eliminadas de la última versión del modelo.

Tabla 8 – Nivel de aceptabilidad de Madrid Central: resultados del modelo logit ordenado.

De acuerdo a los resultados del modelo, un pequeño número de variables sociodemográficas han resultado estadísticamente significativas en la explicación de la aceptabilidad pública de Madrid Central (ver Tabla 8). Los individuos que trabajan y estudian simultáneamente presentan una actitud más positiva hacia la ZBE. Los participantes que comparten vivienda también presentan una mayor aceptabilidad. Estos resultados están relacionados con el hecho de que las personas que forman parte de estos dos grupos son jóvenes (el 83,3% de los individuos que simultáneamente trabajan y estudian y el 90,8% de las personas que comparten piso son menores de 26 años), de bajos ingresos (el 70% de los individuos que trabajan y estudian simultáneamente y el 72,4% de los participantes que comparten un hogar tienen unos ingresos mensuales inferiores a 1300 €/mes), y menos dependientes del coche (el 68,6% de las personas que trabajan y estudian y el 86,2% de los individuos que comparten un hogar no utilizan un vehículo privado para acceder a Madrid Central) según los resultados de la encuesta. Por lo tanto, los modos de transporte colectivo son una buena opción para ellos, dadas las características de la red de transporte público de Madrid y el reducido precio de su abono transporte. Estos segmentos de población no parecen tener necesidad de un vehículo privado en casa, lo que supondría además un sobrecoste.

La ideología política y la conciencia medioambiental resultan cruciales para entender la aceptabilidad de Madrid Central por parte de los ciudadanos. La ideología política parece ser un factor muy importante para la aceptación de Madrid Central, siendo todas las categorías de esta variable estadísticamente significativas (valor p = 0,000). Los encuestados con una ideología política de izquierdas muestran una aceptabilidad mucho mayor en comparación con otras ideologías políticas, especialmente los partidarios de los grupos políticos de derechas. En particular, para los individuos que apoyan a los partidos de izquierda, la probabilidad de valorar muy positivamente Madrid Central es cuatro veces mayor en comparación con los individuos que apoyan otras ideologías políticas. Este resultado está alineado con estudios anteriores que correlacionan las políticas restrictivas de transporte implementadas por los gobiernos locales (Christiansen, 2018).

Cabe destacar que la implementación de Madrid Central fue una de las medidas más importantes adoptadas por un gobierno local formado por una coalición de partidos de izquierdas. La medida ha sido objeto de numerosos debates entre partidos políticos de diferentes ideologías sobre su eficacia e influencia en cuestiones económicas y sociales. Nuestros resultados muestran claramente que los participantes con ideología de izquierdas estaban muy a favor de estas medidas, mostrándose en línea con la coalición de izquierdas en el gobierno. No obstante, cabe mencionar que Madrid Central parece ser una medida bastante apoyada por los madrileños, ya que más del 65% de los encuestados declaran tener una opinión positiva o muy positiva hacia la ZBE.

De acuerdo con el objetivo de las ZBE, la conciencia medioambiental de los individuos se relaciona fuertemente con la aceptabilidad. Es lógico que las personas más preocupadas por los problemas medioambientales sean propensas a apoyar iniciativas como Madrid Central" Los encuestados con una conciencia medioambiental alta y muy alta apoyan la implementación de "Madrid Central" (p-valor = 0,008), a pesar de que la eficacia de esta medida en la mejora de la calidad del aire aún no se ha demostrado de forma sólida. Además, cabe destacar que la conciencia social y económica de los individuos no se encontró estadísticamente significativa en la determinación de la aceptabilidad hacia la ZBE, a pesar de los impactos que pueda generar Madrid Central en la sociedad y la economía.

Los atributos relacionados con el viaje también influyen en el nivel de aceptabilidad de la población. La posesión de abono de transporte público o la posesión de una motocicleta privada están relacionadas con una mayor aceptabilidad de Madrid Central (p-valores = 0,023 y 0,003, respectivamente). Los propietarios del abono de transporte público de la muestra son usuarios que realizan una media de más de cuatro viajes al día. No es de esperar que se vean muy afectados por las restricciones del coche para acceder a Madrid Central, donde la accesibilidad y la oferta de transporte público son muy elevadas.

Como se ha demostrado anteriormente, las motocicletas han sufrido menos restricciones que los coches para entrar en Madrid Central, por lo que pueden verse favorecidas en el nuevo escenario de circulación. Esta razón probablemente lleva a tener una actitud más favorable hacia las políticas de movilidad basadas en las restricciones a los coches.

Sorprendentemente, los usuarios frecuentes de los servicios de movilidad compartida muestran un menor grado de aceptabilidad (p-valor = 0,009) en comparación con los usuarios ocasionales de estos servicios. Los usuarios frecuentes pueden temer que Madrid Central aumente el uso general de los servicios de movilidad compartida (por ejemplo, atrayendo a nuevos usuarios), reduciendo así su disponibilidad en el futuro.

Las variables de este grupo tienen un papel importante en la explicación de la aceptabilidad pública hacia Madrid Central. En primer lugar, el nivel de aceptabilidad está directamente relacionado con el impacto positivo o negativo de esta política en los desplazamientos realizados por los encuestados. Razonablemente, los participantes que han mantenido o mejorado su experiencia de viaje muestran una mayor aceptabilidad (valor p = 0,000) que aquellos que la han empeorado. Estos resultados son similares a los de otras políticas de transporte restrictivas, que han recibido valoraciones más bajas por parte de los usuarios perjudicados (Gaunt, 2007). Además, los ciudadanos que han aumentado sus rutinas diarias de caminar dentro de la ZBE también muestran una mayor aceptabilidad hacia "Madrid Central" (p-valor = 0,000). Este efecto se debe probablemente a que las políticas de restricción del uso del coche implican el desarrollo de ciudades más amables y transitables.

Los encuestados que aumentaron o mantuvieron sus actividades comerciales y de ocio en la zona tras la implementación de Madrid Central son más favorables a la ZBE, en comparación con los que redujeron sus niveles de actividad. En cuanto a los patrones de movilidad, los ciudadanos que viajan ocasionalmente a Madrid Central (como máximo dos veces a la semana o durante los fines de semana) muestran un mayor nivel de aceptabilidad. Sin embargo, los individuos cuya actividad principal dentro de la ZBE es ir de compras presentan una menor aceptabilidad, tal vez como consecuencia del impacto negativo que pueden tener las restricciones a los vehículos privados para cargar bolsas pesadas.

Los participantes que cambiaron su modo de transporte tras la implementación de Madrid Central presentan una aceptabilidad más negativa que aquellos que no lo hicieron. Por último, en cuanto al modo de transporte más utilizado antes y después de la implantación de Madrid Central, los ciudadanos que utilizaban su vehículo privado antes y después de la implementación de la ZBE muestran una menor aceptabilidad, mientras que los ciudadanos que se desplazan en bicicleta después de la adopción de Madrid Central tienen actitudes más favorables. Este resultado demuestra que Madrid Central ha sido eficaz para crear un mejor entorno para el uso de los modos activos.

6.2 Resultados descriptivos sobre el cambio modal tras la implementación de Madrid Central

Se observa un cambio relevante hacia patrones de movilidad sostenible tras la implementación de Madrid Central (Figura 1). La mitad de los encuestados (49,9%) ha declarado haber cambiado su modo de transporte habitual para acceder a Madrid Central tras la adopción de la medida.

En cuanto a la elección modal, hay que recordar que los encuestados podían seleccionar sus dos modos de transporte más frecuentes para llegar a Madrid Central. Así, los datos obtenidos indican la cuota modal captada por cada uno de los modos de transporte en relación con el número total de viajeros. Los resultados descriptivos indican un notable descenso en el uso del vehículo privado (-28,5% del total de encuestados), lo que significa que el 60% de los antiguos usuarios del coche han cambiado su modo de transporte habitual. Estos viajeros han cambiado principalmente a modos de transporte alternativos.

En particular, el transporte público y los modos activos son los modos de transporte más beneficiados por la implantación de Madrid Central. El transporte público aumentó su cuota modal del 66,7% al 75,6%. Del mismo modo, los modos activos (viajar a pie y/o en bicicleta) aumentaron del 16,8% al 25,0%. Los modos de transporte minoritarios, como los servicios de movilidad compartida, han duplicado sus usuarios la ZBE. Los servicios de taxi y VTC han aumentado su cuota del 4,0% al 8,3%, mientras que el uso de las opciones de movilidad compartida (carsharing, scooter sharing, etc.) creció del 3,8% al 8,4%.

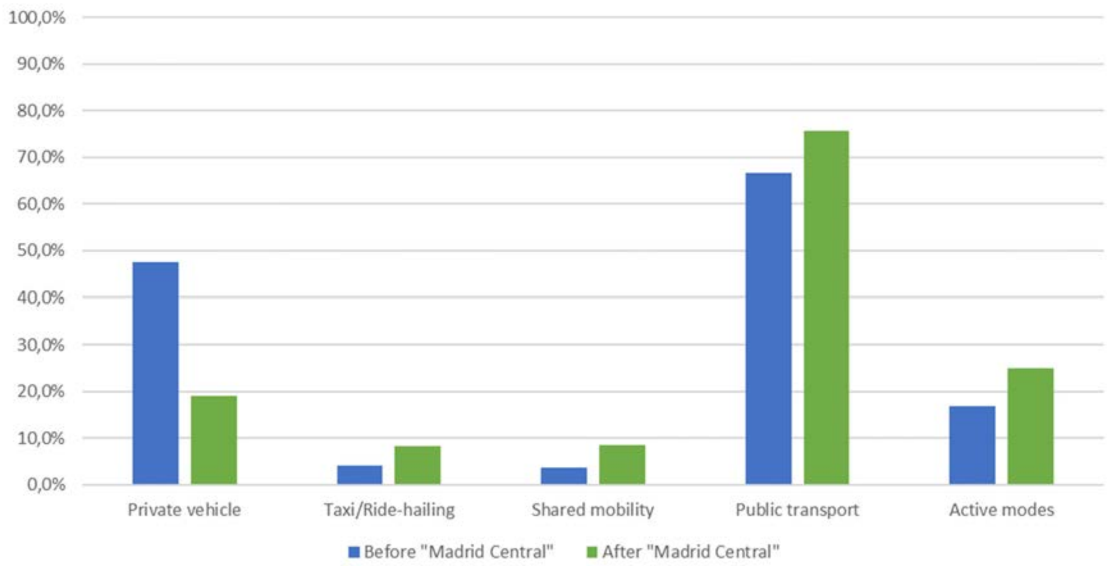

Fig. 1 – Elección modal antes y después de Madrid Central

6.3 Análisis del cambio modal en Madrid Central

Esta sección presenta los resultados del modelo dedicado a la exploración del cambio (o no) de elección modal para acceder a Madrid Central después de aplicar la ZBE. Para ello, se ha desarrollado un modelo logit binario (Tabla 9) que indica, desde un punto de vista estadístico (p-valor < 0,05), las variables que influencian dicha elección. Un signo positivo indica una mayor probabilidad de haber experimentado un cambio modal, mientras que un signo negativo indica una mayor probabilidad de haber mantenido su patrón de viaje.

Tabla 9 – Cambio modal ocasionado por Madrid Central: resultados del modelo logit binario.

El sector de empleo parece ser la única variable sociodemográfica que influye en el cambio modal tras la implantación de Madrid Central. Hay dos sectores que muestran una influencia significativa (p-valor < 0,05): comercio y hostelería, y transporte y logística. Los individuos que trabajan en estos sectores tienen una menor probabilidad de cambiar su modo de transporte habitual para circular en Madrid Central. Una de las razones sería el uso del vehículo privado o de empresa como herramienta de trabajo con disponibilidad de garaje. En este sentido, cabe destacar que Madrid Central permite la entrada de vehículos siempre que aparquen en garajes privados.

En cuanto a las actitudes personales, la concienciación de los individuos sobre la sostenibilidad, recogida a través de una escala Likert de cinco puntos, es la única variable con un efecto estadísticamente significativo sobre el cambio modal.

Sorprendentemente, la conciencia medioambiental no es estadísticamente significativa para explicar el cambio modal.

En lo que respecta a las variables relacionadas con los viajes habituales, la disponibilidad de coches privados resulta crucial para explicar los cambios en la elección modal tras la implantación de Madrid Central. El principal cambio en la movilidad observado después de Madrid Central ha sido una disminución significativa del uso del coche. Otras variables relacionadas con el transporte, como la posesión de un abono de transporte público o el uso de modos de movilidad compartida, no resultan estadísticamente significativas en este modelo.

Por el contrario, los hábitos de movilidad de los individuos y las percepciones vinculadas a Madrid Central tienen un papel importante a la hora de explicar el cambio modal tras la adopción de la ZBE. En primer lugar, se observa que el impacto de Madrid Central en la movilidad diaria (viajes frecuentes) está inversamente relacionado con el cambio modal.

Razonablemente, las personas que no se han visto afectadas por las restricciones de Madrid Central o que incluso han visto mejoradas sus condiciones de acceso no han cambiado su modo de transporte, en comparación con aquellas personas cuyas opciones de movilidad se han visto limitadas. Además, la situación como peatón en Madrid Central presenta dos conclusiones diferentes. Por un lado, los encuestados que valoran positivamente la peatonalización de Madrid Central no han cambiado su modo de transporte, lo que puede deberse a que ya utilizaban modos de transporte sostenibles. Por otro lado, cabe destacar que los ciudadanos que han experimentado un cambio modal han aumentado su tiempo de paseo en Madrid Central.

Los individuos que viajan ocasionalmente a Madrid Central (más de 1 viaje/mes y menos de 2 viajes/semana) son más propensos a cambiar su modo de transporte habitual para llegar a la ZBE. Estos encuestados probablemente utilizaban el vehículo privado en estos desplazamientos antes de la implementación de Madrid Central, ya que no les resultaba familiar utilizar servicios como el transporte público o la movilidad compartida.

Los resultados del modelo también muestran que los encuestados cuya actividad principal en la zona es ir de compras son significativamente menos propensos a cambiar su modo de transporte. Esto puede estar relacionado con el uso del vehículo privado para facilitar la carga de bolsas.

Por último, es interesante analizar la influencia del modo de transporte utilizado antes de la implementación de Madrid Central en el cambio modal. Como se observa, los individuos que eran usuarios del vehículo privado antes de la ZBE son más propensos a cambiar su modo de transporte (valor $p = 0{,}000$).

En línea con lo comentado anteriormente, podemos concluir que, al menos en el caso de Madrid, el vehículo privado ha sido la opción de transporte más afectada por la implantación de la ZBE, provocando así tendencias positivas de movilidad más sostenible.

Por último, se observa que los individuos que utilizan modos de movilidad compartida tras la implantación de Madrid Central (por ejemplo, carsharing, ciclomotor compartido, etc.) son más propensos a haber cambiado su modo de transporte para desplazarse a Madrid Central. Este resultado puede indicar que los usuarios actuales de estos servicios proceden en su mayoría de otros modos de transporte debido a las restricciones establecidas por la ZBE.

6.4 Análisis del nivel de cambio modal experimentado por los usuarios de vehículo privado

Esta sección muestra los resultados del modelo logit ordenado que explora nivel de cambio modal de los conductores de vehículos privados tras la implantación de Madrid Central. Este modelo se centra exclusivamente en la submuestra de participantes que utilizaban su vehículo privado para acceder a la zona de Madrid Central antes de la implantación de la ZBE (380 encuestados). La tabla 10 resume cómo se codificó la variable dependiente y el número de participantes para cada categoría.

	N	%
Nivel de cambio modal de los antiguos usuarios de vehículo privado (comparados con la situación previa a Madrid Central)		
Incremento del uso de vehículo privado	7	1.8
Uso similar del vehículo privado	112	29.5
Reducción de uso del vehículo privado en favor del uso del taxi o VTC	32	8.4
Reducción de uso del vehículo privado en favor del uso de transporte público o modos activos	33	8.7
Abandono total del uso del vehículo privado	196	51.6

Tabla 10 – Caracterización de los antiguos usuarios de vehículo privado.

Dado que las variables explicativas utilizadas en el modelo eran en su mayoría categóricas, la interpretación de los resultados de la modelización requería la selección de un caso base. Esto nos permitió determinar si, para cada variable explicativa, las respuestas de los individuos eran estadísticamente significativas entre categorías en comparación con el caso base. Las categorías base elegidas pueden consultarse en la Tabla 11.

Un signo positivo en los resultados del modelo indica una mayor probabilidad de reducir el uso del vehículo privado en favor de otro modo de transporte para llegar a Madrid Central. Por el contrario, un signo negativo indica una probabilidad hacia el mantenimiento o el aumento del uso del vehículo privado para acceder a la zona de Madrid Central.

El modelo concluye que, desde un punto de vista estadístico (valor $p < 0,05$), el cambio modal de los antiguos usuarios del vehículo privado (personas que utilizaban el coche antes de la implantación de Madrid Central) está notablemente influenciado por una amplia gama de variables explicativas incluidas en la encuesta.

Tabla 11 – Nivel de cambio modal de los antiguos usuarios de vehículo privado: resultados del modelo logit ordenado.

El modelo muestra que las características sociodemográficas juegan un papel importante para entender el cambio modal de los usuarios de vehículo privado. En primer lugar, se observa cómo la edad está cerca de ser estadísticamente significativa (p-valor = 0,068), lo que indica que los menores de 26 años son más persistentes en el uso del vehículo privado tras la implementación de Madrid Central. Tanto el género como el nivel de estudios son estadísticamente significativos a la hora de explicar el abandono del vehículo privado. Los hombres muestran una mayor tendencia que las mujeres (p-valor = 0,063) a reducir y dejar el vehículo privado para ir a Madrid Central. Además, los encuestados con estudios universitarios son más propensos a seguir utilizando el coche para llegar a la ZBE (p-valor = 0,032).

La composición del hogar es otra variable crucial que determina el cambio modal de los antiguos usuarios de vehículos privados. Las familias con personas dependientes (por ejemplo, niños menores de 10 años, personas mayores y discapacitadas, etc.) son más propensas a seguir utilizando sus vehículos privados para acceder a Madrid Central que las familias con niños mayores de 10 años. Esta situación puede asociarse a la necesidad de este tipo de familias de realizar desplazamientos puerta a puerta.

Los resultados del modelo también indican que el nivel de ingresos desempeña un papel importante para explicar el cambio modal de los usuarios de coche. Los individuos con ingresos mensuales inferiores a 1.300 euros son más propensos a reducir el uso del coche privado (p-valor = 0,017) en comparación con la categoría de referencia base (individuos con ingresos superiores a 2.000 euros/mes). Así pues, la población con niveles de ingresos elevados se muestra más reticente a dejar y sustituir sus coches para llegar a Madrid Central, ya que pueden permitirse tarifas de aparcamiento privado dentro de la ZBE y/o comprar un vehículo menos contaminante.

En cuanto a las actitudes personales, la ideología política parece ser estadísticamente significativa para explicar el cambio modal de los usuarios de vehículos privados tras la implantación de "Madrid Centra. Sorprendentemente, los modelos muestran que las personas de derechas y las personas que no revelaron su ideología política son más propensos a reducir y dejar de usar los coches para llegar a Madrid Central en comparación con las personas de centro, mientras que el resultado para las personas con ideología de izquierdas no es estadísticamente significativo.

Este hallazgo, similar al obtenido anteriormente por Tertoolen et al. (1997), parece contradictorio con las ideologías tradicionalmente asociadas a una mayor conciencia medioambiental y social (por ejemplo, la de izquierdas). Esto refuerza el argumento de que las razones personales tienen mucha más relevancia que la ideología para promover el cambio modal.

Asimismo, la posesión del abono de transporte público y hacer un uso intensivo de los sistemas de transporte público son variables estadísticamente significativas para explicar el abandono y la disminución del uso del vehículo privado. Este resultado está fuertemente alineado con el objetivo de las ZBE. El uso del transporte público en general facilita el abandono del coche. Otras variables relativas a los hábitos de movilidad y las percepciones relacionadas con Madrid Central resultaron estadísticamente significativas en el modelo.

En primer lugar, el impacto general de Madrid Central en los viajes regulares de los individuos tiene un efecto significativo en la elección modal actual de los usuarios del coche. Como se esperaba, las personas que perciben que Madrid Central les afectó negativamente tienen más probabilidades de haber reducido el uso del coche. Del mismo modo, los individuos que aumentan el tiempo dedicado a caminar dentro de Madrid Central después de su implantación tienen más probabilidades de haber abandonado y reducido el uso del vehículo privado para llegar a la ZBE.

El tipo de día en que los individuos viajan a Madrid Central también es estadísticamente significativo. Los individuos que acceden a la ZBE en días no laborales son más propensos (p-valor = 0,000) a abandonar o reducir el uso del vehículo privado. Esto puede explicarse por el hecho de que esas personas encuentran una mayor flexibilidad en la organización de sus viajes que las personas que llegan a Madrid Central en días laborales. Esta conclusión subraya la conveniencia para algunos ciudadanos de utilizar el vehículo privado para ahorrar tiempo en la vida cotidiana. Las iniciativas en materia de política de transportes deberían esforzarse por encontrar opciones sustitutivas del coche en términos de ahorro de tiempo en los desplazamientos. La actividad principal realizada en Madrid Central también está fuertemente relacionada con la elección de los individuos de utilizar (o no) vehículos privados tras la implantación de la ZBE. Los encuestados que declararon que su actividad principal era ir de compras presentan una mayor tendencia (p-valor = 0,004) a seguir utilizando sus vehículos privados. Esto está probablemente relacionado con el hecho de que el uso de vehículos privados facilita la carga de bolsas, como se ha comentado con anterioridad.

Por último, se estudia la influencia de los factores clave de los individuos (como el coste, el tiempo, la comodidad, etc.) para seleccionar su modo de transporte habitual. Como parece razonable, las personas con alta sensibilidad al coste del viaje son más propensas a reducir o abandonar el uso de su coche privado para llegar a Madrid Central.

Esto puede deberse a que llegar a Madrid Central en coche implica pagar un garaje privado, que es muy caro en la zona, mientras que el transporte público es asequible. Por otro lado, las personas sensibles al ahorro de tiempo, a la comodidad y muy preocupadas por la posibilidad de cargar peso son tienden a persistir en el uso de sus vehículos privados para llegar a Madrid Central. Estos tres factores están muy asociados a los atributos que suelen destacarse en os vehículos privados.

7. CONCLUSIONES

Este artículo aborda el necesario estudio sobre la aceptabilidad y el impacto en la elección modal del transporte consecuencia de la implementación de una ZBE. Tomando datos de una ZBE recientemente implementada en Madrid (llamada Madrid Central), se ha realizado un análisis de elección discreta para: i) determina los factores clave para explicar la aceptabilidad pública, ii) identificar los factores clave que explican el cambio modal después de implementar la medida, y iii) explorar los cambios en la elección modal entre los conductores de vehículos privados, lo cual es particularmente interesante dado que la reducción de vehículos privados es uno de los principales objetivos de las ZBE. Los resultados obtenidos pueden ser una plataforma interesante para que los responsables políticos consigan una mejor comprensión de las características de las personas que se sienten perjudicadas por las ZBE y determinar las variables clave para comprender mejor la elección modal y su efecto múltiple tras la aplicación de una ZBE. De esta manera, se pueden reorientar los impactos negativos y maximizar los beneficios sociales de las políticas de restricción de vehículos. Además, los resultados obtenidos podrían alimentar los procesos de planificación participativa, en los que se pueden seleccionar y comprometer diferentes perfiles de ciudadanos con respecto a la aceptabilidad de las ZBE (May e Isson, 2008; Whitmarsh et al., 2009; Soria-Lara et al., 2019)

Un hallazgo interesante es que la aceptabilidad de las ZBE en áreas urbanas, al menos en el caso de Madrid Central, está débilmente relacionada con aspectos socioeconómicos como el género, la edad, la educación o el nivel de ingresos. Por el contrario, la aceptabilidad se explica mucho mejor por la ideología política, la conciencia medioambiental y el impacto de las restricciones al uso del coche en los hábitos de movilidad individuales. En general, la aceptabilidad de Madrid Central es bastante positiva entre los madrileños, dada su alta conciencia medioambiental (77,1% de la muestra). Estos resultados están en consonancia con los obtenidos por Oltra et al. (2021) en el contexto de Barcelona, donde las personas con una alta conciencia medioambiental mostraron un mayor nivel de aceptación de las políticas de restricción del uso del coche. La fuerte relación entre ideología política y aceptabilidad es razonable, ya que la implementación de Madrid Central ha estado en el punto caliente del debate político en la región durante 2018, generando confrontación entre los partidos políticos.

En este sentido, aunque no se puede evitar cierta influencia política, las autoridades públicas deberían trabajar para ofrecer una mejor información a la comunidad basada en estudios de investigación cuantitativos que demuestren su impacto en aspectos como la contaminación atmosférica, el cambio modal y los impactos económicos y sociales. Eso contribuirá a que la gente obtenga un juicio objetivo, en lugar de pensamientos basados en la alineación ideológica con los partidos políticos.

Un resultado relevante es que la aceptabilidad de Madrid Central se asocia en gran medida con el impacto que esta política tiene en los hábitos de los individuos, especialmente en lo que se refiere al comportamiento de los viajes en movilidad. Los ciudadanos que han mejorado la calidad de sus viajes muestran una mayor aceptabilidad hacia Madrid Central. Los usuarios frecuentes del transporte público, los motociclistas y los usuarios ocasionales de servicios de movilidad compartida están a favor de Madrid Central, probablemente porque la medida les beneficia o al menos no les perjudica. Además, Madrid Central es más apoyado por aquellas personas que aprovecharon la medida para desarrollar una actividad comercial y de ocio más intensa, para disfrutar de los paseos a pie, o para empezar a ir en bicicleta hacia o dentro de la ZBE.

Sin embargo, Madrid Central es menos apoyado por las personas influenciadas negativamente por la ZBE. Los encuestados que se vieron obligados a cambiar su modo habitual para llegar a Madrid Central, especialmente las personas que utilizaban el vehículo privado, se oponen a las restricciones de automóviles. Este es un tema controvertido en la planificación del transporte, donde estudios anteriores (Szarata et al., (2017)) subrayan el rechazo inicial de los usuarios de automóviles y de los grupos locales a políticas similares que restringen el acceso en coche. Madrid Central tampoco es apoyado por las personas que van a comprar, probablemente porque el coche es la forma más cómoda para ellos de llevar bolsas pesadas. Finalmente, los usuarios frecuentes de servicios de movilidad compartida no están muy a favor de Madrid Central, probablemente porque pueden acabar experimentando una mayor competencia para alquilar estos servicios en la zona.

Para mejorar la aceptabilidad sin comprometer los estándares de sostenibilidad, las autoridades locales deberían centrarse en promover esquemas políticos que minimicen los impactos negativos sobre aquellos que se sienten perjudicados por las ZBE. En la encuesta, los autores del trabajo dejaron un texto libre a los encuestados para que sugirieran acciones que pudieran mejorar o complementar las políticas de restricción de coches dentro de Madrid Central. Una gran parte de los encuestados sugirió aumentar la frecuencia de los servicios de transporte público en la zona, proporcionar apoyo financiero a la renovación del parque de vehículos y promover enfoques de movilidad compartida. Ofrecer soluciones dentro de un marco sostenible puede contribuir, sin duda, a mejorar la aceptación de ciertos grupos de población.

En cuanto a la influencia sobre los patrones de movilidad, parece evidente el notable poder de Madrid Central para provocar cambios en la elección modal hacia medios más sostenibles. Según las respuestas de la encuesta, se produjo una reducción importante del uso del coche (-28,5% del total de encuestados), así como un aumento del uso del transporte público (+8,9%) y de los modos activos (+8,2%). Adicionalmente, cabe destacar el notable crecimiento observado en los servicios de transporte colectivo (+4,3%) y en las opciones de movilidad compartida (+4,6%) para desplazarse a Madrid Central.

Para ello será necesario aumentar la frecuencia y disponibilidad de los servicios de transporte público, así como la cantidad de puntos de recarga eléctrica.

Otro conjunto de conclusiones relevantes se refiere al cambio modal después de la ZBE, que se asocia en gran medida con las percepciones de los individuos y los hábitos de movilidad relacionados con Madrid Central. Por ejemplo, la frecuencia de los viajes y el tipo de actividad que suelen realizar los encuestados dentro de Madrid Central influyen enormemente en el cambio modal. Las personas que viajan a Madrid Central menos de dos veces por semana y más de una vez al mes son más propensas a cambiar de modo para acceder a la ZBE, mientras que los individuos cuya actividad principal realizada en Madrid Central es ir de compras son significativamente menos propensos a cambiar su modo de transporte. Esto revela un punto interesante para la elaboración de políticas: los viajeros no frecuentes son más propensos a cambiar su modo de transporte. Sin embargo, la zona tiene muchos viajes regulares ya que Madrid Central tiene una importante concentración de puestos de trabajo que obliga a muchas personas a desplazarse diariamente. Un problema similar se observa en los viajes de compras, ya que el comercio minorista es una de las principales actividades económicas dentro de Madrid Central. Las políticas futuras deberían explorar medios para contribuir a mejorar la accesibilidad de esas personas a Madrid Central en modos sostenibles sin comprometer el potencial comercial y laboral de la zona.

Un último nivel de conclusiones se centra en el impacto de Madrid Central en el cambio modal entre los usuarios de automóviles. Los encuestados con ingresos mensuales bajos (<1.300€/mes) tienden a dejar o reducir el uso de su vehículo privado más que las personas con ingresos altos.

Sin embargo, las familias con familiares dependientes (niños, ancianos y discapacitados) siguen utilizando su vehículo privado, dadas sus limitaciones de movilidad. Esta situación podría comprometer el carácter inclusivo y los efectos sociales de Madrid Central, ya que los ciudadanos con altos ingresos que se desplazan en su vehículo privado pueden permitirse aparcar en garajes y es más posible que puedan comprarse vehículos de menores emisiones.

Además, los factores clave para las opciones de movilidad de los individuos (como el coste, el tiempo, la comodidad, etc.) resultan ser cruciales para explicar el cambio modal. Es particularmente notable cómo las personas que se desplazan para hacer compras tienden a seguir eligiendo sus vehículos privados a pesar de la aplicación de la ZBE. En este sentido, el documento muestra que las razones personales parecen ser más importantes para la elección modal que la ideología o la concienciación. Este resultado se ve corroborado por el primer modelo, en el que variables como la conciencia medioambiental no tienen una influencia significativa.

Los resultados son especialmente útiles para el diseño de futuras estrategias políticas para la aplicación y el funcionamiento de las ZBE, de acuerdo con los objetivos ambientales, económicos y sociales. Se pueden señalar algunos aspectos para una mayor investigación.

Las futuras contribuciones deberían profundizar en múltiples aspectos derivados de la implantación de una ZBE: la optimización de los sistemas de transporte público para que se conviertan en una alternativa real a los vehículos privados en la zona afectada, las desigualdades sociales generadas por las ZBE, los efectos de dichas ZBE sobre el comercio minorista y otras actividades relevantes situadas en el centro de la ciudad, etc.

AGRADECIMIENTOS

Esta investigación se ha desarrollado dentro del proyecto Co-Mov [Y2018/EMT-4818], cofinanciado por la Comunidad de Madrid (España), el Fondo Social Europeo y el Fondo Europeo de Desarrollo Regional.

ABSTRACT

The objective of this paper is to study the relationship between personal mobility and attitudes towards the environment related to travel behavior considering sociodemographic characteristics.

The dataset used for this study was collected through a web-based survey carried out in Valencia (Spain) during 2017 and 1684 valid responses were obtained. In this research a subpart of the survey is used, including 5 items which measure attitudes towards the environment related to travel and 5 items to measure personal mobility. The items were measured using a 5 points Likert Scale. Additionally, individual and household demographic characteristics are considered.

The methodology of this research consist on descriptive analysis and frequency distributions. Factor Analysis (Exploratory and Confirmatory) is used to construct the latent variables which measure attitudes and Mann-Whitney U is test are assessed to find significant differences among the variables of the study.

Preliminary results show that environmental concerns are taken into account by women as a factor to decrease their car use, while men do not consider this factor that relevant. Next, young people and men carry our more activities while traveling in public transport, for instance: reading, listening to music or checking social networks. The results of this research are useful for the development of transport policies to promote sustainable transport.

1. INTRODUCTION

This research is part of a wider project, called MINERVA, which is funded by the I+D+i National Program of Society Challenges of the Spanish Ministry of Economy and Finance of Spain). The aim of MINERVA is to study the influence of personal values, attitudes and perceptions and social interactions on travel behavior.

This paper aims to study attitudes towards personal mobility and attitudes towards the environment related to travel considering sociodemographic characteristics.

1.1. Explicative factors of travel behavior

The prediction of individual's travel behavior is an essential component of transportation planning and policy analysis. The ultimate mission of travel demand forecasting research is to develop the capability to predict how individuals respond to changes in their travel environment (Kitamura, 1988). Such predictions are based on a set of factors that influence travel behavior. For this reason it is relevant to identify and characterize such factors.

Among the factors that influence travel behavior, one of the main objectives of the Minerva Project is to collect information regarding attitudes towards the environment and attitudes towards personal mobility.

The displacement of people towards their usual places generates a demand for modes of transport, which are largely related to certain factors that make the individual decide one or another type of transport. In this line, people's attitudes are strongly influenced for beliefs as well as individual travel behaviors. A person's intention is a function of two basic determinants; one personal in nature and the other reflecting social influence (Ajzen, 1991).

Travel behavior research has long recognized the role of attitudes and preferences in influencing mobility. Even though attitudes are often included as control variables for self-selection, many studies have concluded that they play a significant role in influencing travel behavior (Hunecke et al., 2010; Bopp et al., 2011; Spears et al., 2013; Runing Ye et al, 2017). The measurement of attitudes is carried out using scales that involve the application of standardized questionnaires to enable individuals to be placed on a dimension indicating degree of favorability towards the object in question.

This research contributes to gain more knowledge about these factors taking into account also demographic and socioeconomic characteristics.

2. OBJETIVE AND RESEARCH QUESTIONS

2.1 Objective

The aim of this paper is to study the relationship between personal mobility and attitudes towards the environment related to travel behavior considering sociodemographic characteristics.

2.2 Research questions

Main research questions are presented below:

- To what extent personal mobility and attitudes towards the environment can contribute to travel behavior analyses and how to measure these variables.
- How demographic factors and socio economic characteristics might influence personal mobility.
- How demographic factors and socio economic characteristics might influence attitudes towards the environment.

3. DATA COLLECTION

3.1 Instrument design and recruitment

The dataset used for this research is part of the data collection developed for MINERVA research. For this project, a web based survey was developed ad-hoc to gather information regarding attitudes and perceptions, personal values, social interactions and travel behavior. In this study, a subpart of this survey is used (Arroyo et al, 2017).

The web-based survey was distributed mainly online and several organizations, public administration and companies contributed with the dissemination of the survey. Data collection took place between May and October 2017, excluding August in order to avoid non-recurrent mobility and long-distance trips executed during summer holidays. The main area of the study was Valencia (Spain) and its metropolitan area, although different residential locations were also accepted.

The survey is composed by 5 parts. Firstly, a brief questionnaire gathers information about demographics and socio-economic characteristics (both at personal and household level), as well as transport accessibility and built environment attributes of the residence area. Secondly, a two-day activity-travel diary collects all the activities and trips performed during a week day and a week-end day, including characteristics of the companions of each episode. Next section collects information regarding social interactions, for this purpose the list of the companions already defined is displayed and a brief questionnaire of each person should be complimented, including: gender, age, type of relationship, closeness degree, approximate residential location distance from the respondent, frequency of face to face meetings, frequency of communication and degree of influence of the companion in the respondent’s mobility. The fourth part is the Values survey, based on Schwartz theory of human values (Schwartz, 1994).

The last step consists on a survey regarding cognitive, affective and behavioral attitudes towards transport modes, attitudes towards innovative travel modes, use of ICTs and personal mobility and perceptions of the built environment. Additionally, the on-line questionnaire collects intentions to use travel modes; semantic differential towards travel modes, which measures mental representations of travel modes through certain adjectives.

Further details of the questionnaires analyzed in this paper are provided later, including individual items and constructs to measure attitudes towards the environment and personal mobility.

3.2 Sample characteristics

After data cleaning and validation, the sample is composed by 1684 individuals (Table 1). The distribution according to gender reasonably balanced. However, considering age, those over 50 years old are under-represented in the sample. Participants are mainly employed individuals, followed by students and other occupations are including in "other", for instance retired and unemployed people.

	Respondents	Percentage
GENDER		
Male	774	46 %
Female	910	54 %
AGE		
16-25	471	28 %
26-35	385	23 %
36-50	522	31 %
>50	306	18 %
OCCUPATION		
Student	398	23 %
Employed	1022	61 %
Other	264	16 %

Table 1 – Sample characteristics

4. METHODOLOGY AND ANALYSIS

4.1 Variables: description and measurement

- Demographic and socio-economic characteristics

Several demographic and socio-economic characteristics were considered both at individual and house hold level (Table 2).

- Attitudes towards the environment and personal mobility

Three latent constructs were developed in order to measure attitudes towards the environment and personal mobility. Details and validation are described in the next section.

DEMOGRAPHICS		
Gender	0 = male; 1 = female	Categorical
Age	Age of the respondent	Continuous
Transport Pass	1 = respondent has an integrated public transport pass; 0 = otherwise	Categorical
Car	Bike availability (0 = low to 5 = high)	Continuous
Bike	Car availability (0 = low to 5 = high)	Continuous
Motorbike	Motorbike availability (0 = low to 5 = high)	Continuous
Bikes in HH	Number of bikes available in the household	Continuous
Cars in HH	Number of cars available in the household	Continuous
Marital status	1 = single; 2 = married; 3 = civil partner; 4 = couple; 5 = widow; 6 = divorced; 7 = others	Categorical
Education level	1 = no studies; 2 = primary level; 3 = vocational training ; 4 = secondary level; 5-6 = higher education; 7 = university degree or higher	Categorical
Occupation	1 = student; 2 = employed; 3 = self-employed; 4 = student and employed; 5 = unemployed; 6 = retired; 7 = housekeeper; 8 = others	Categorical
Income (net monthly)	1 = any income; 2 = less thant 500€; 3 = 500-1000€; 4 = 1000-1500€; 5 = 1500-2000€; 6 = 2000-2500€; 7 = 2500 - 3000; 8 = more than 3000	Categorical

Table 2 – Definition of variables

4.2 Scale reliability and validity of constructs

Attitudes towards environment and self-mobility were measured using 10 item (5 items for each type of attitude):

<u>Attitudes towards the environment</u>

- Item 130. I try to use less the car to improve air quality.
- Item 131. If I had to buy a car, or replace the current one, I would choose a more energy efficient one, even if it was smaller or more expensive.
- Item 132. We should increase the price of fuel to invest in improving public transport.
- Item 133. I support restricting the use of the car in the city to reduce congestion.
- Item 134. In my city, air quality is a major problem.

<u>Attitudes towards personal mobility</u>

- Item 135. I usually make arrangements online or by phone to avoid trips.
- Item 136. When I need to buy something, I prefer to go to the nearest shop as possible.
- Item 137. When I travel, I usually do other activities (reading, listening to music, checking social networks online, etc.)
- Item 138. I try to walk or cycle as much as possible and only use a motor vehicle for long distances.

- Item 140. I plan my trips and choose the mode of transport considering my daily schedule of activities.

Firstly, descriptive analysis were carried out and basic statistics and measures of normality, symmetry and kurtosis were obtained. Some of the items presented slightly signs of asymmetry and non-normality, which lead us to select robust estimators for Confirmatory Factor Analysis.

Cronbach’s alpha was used to measure internal consistency which indicates how closely related a set of items are as a group. It was observed that item 130 did not show a strong correlation with the construct and it was deleted. The obtained measures (attitudes towards the environment = 0.751; attitudes towards personal mobility = 0.713) point out an adequate value for Cronbach’s alpha for both latent constructs, thus, the scale reliability can be assumed.

The Kaiser-Meyer-Olkin Measure of Sampling Adequacy (KMO) is used to determine the proportion of variance in the variables that might be caused by underlying factors. High values are obtained (>0.9) which indicate that factor analysis technique may be appropriate with the data. Bartlett's Test of Sphericity tests the hypothesis that the correlation matrix is an identity matrix, which would indicate that variables are unrelated and therefore unsuitable for structure detection. Null value is obtained, which also supports the use of factor analysis with the data.

Pearson correlation matrix shows strong correlation among the items belonging to each construct, as it was expected.

4.3 Exploratory Factor Analysis (EFA)

In order to evaluate the scales and validate the latent variables generated, Exploratory Factor Analysis (EFA) was conducted based on the proposed theoretical constructs: attitudes towards the environment and attitudes towards personal mobility.

The results of EFA, using Varimax rotation and a factor loading of 0.40 as the threshold to maintain items in a factor, led to two independent factors as shown in Table 3.

Variable	Mean	SD	Median	Mode	EFA (Factor loading)
Attitudes towards the environment					
a131	3.72	1.280	4.00	5.00	0.553
a132	2.51	1.427	2.00	1.00	0.735
a133	3.02	1.303	3.00	3.00	0.629
a134	3.56	1.369	4.00	5.00	0.730
Attitudes towards personal mobility					
a135	3.79	1.334	4.00	5.00	0.712
a136	3.69	1.245	4.00	4.00	0.657
a137	3.76	1.297	4.00	5.00	0.629
a138	3.74	1.332	4.00	5.00	0.478
a140	3.90	1.274	4.00	5.00	0.688

Table 3 – Exploratory factor analysis

4.4 Confirmatory Factor Analysis (CFA)

Next, Confirmatory Factor Analysis (CFA) was conducted. Unlike EFA, in this method the posited relationships of the observed indicators to the latent variables are specified previously. The following goodness of fit indices were obtained: Chi square/df = 2701.721 (36), Comparative Fit Index (CFI) = 0.958, Tucker Lewis Index (TLI) = 0.935, Standarized Root Mean Square Residual (SRMR) = 0.035 and Root Mean Square Error Of Approximation (REMSEA) = 0.031. These statistics support the validity of the constructed scales. As shown in Table 4, all coefficients exceed 0.4, and most of them are higher than 0.5. It is confirmed that all statements are strongly correlated with the latent variables defined.

Variable	STDYX Standarized Loadings (S.E.)
Attitudes towards the environment	
a131	0.650 (0.023)
a132	0.673 (0.027)
a133	0.515 (0.023)
a134	0.500 (0.031)
Attitudes towards personal mobility	
a135	0.697 (0.020)
a136	0.408 (0.042)
a137	0.489 (0.038)
a138	0.479 (0.039)
a140	0.607 (0.029)

Table 4 – Confirmatory factor analysis

Results of Exploratory and Confirmatory Factor Analyses confirm the validity of the construct and reliability of the scales employed to measure the variables of the study.

This, it can be assumed that attitudes that the items developed to measure attitudes towards the environment and attitudes towards personal mobility can be used for this purpose after this validation process.

5. RESULTS

5.1 Frequency distributions

Firstly, frequency distributions are obtained for each item individually (Figure 1) in order to explore how participants perceive each factor in general, considering the entire sample of the study.

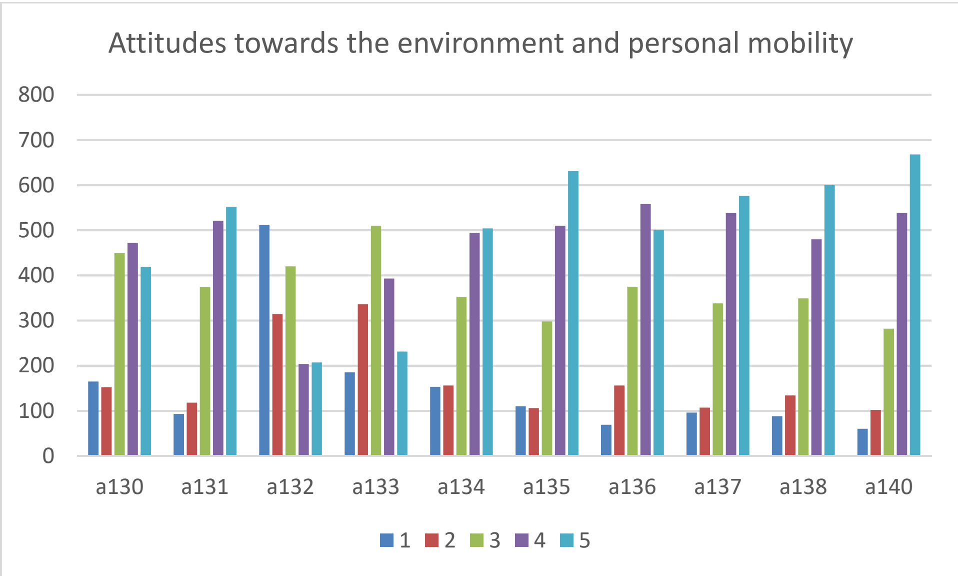

Figure 1. Attitudes towards the environment and personal mobility. Frequency Distribution.

In general, items which represent environmental concern issues related to travel (a130-a134) present lower scores that those regarding personal mobility. For instance an extended rejection to price increase of fuel is observed (item a132). The restriction of the use of private vehicle in order to reduce congestion seems controversial, with a relevant number of participant who support and who reject this measure simultaneously (a133). A higher amount of respondents reported their intention to choose a more energy efficient (a131) and a smaller part of the participants agreed with the intention to use less their cars to improve air quality.

Higher scores are observed for the items regarding personal mobility. In general, participants reported their willingness to avoid unnecessary trips which can be easily replaced with ITCs (a135), a high multitasking while traveling (a137), elevated preference for active transport for short distances (a138) and a high level of planning of their daily schedule when choosing their transport mode (a140). The item 136 was scored slightly lower, which represents the preference of buying as closest to home as possible.

5.2 Mann-Whitney test

The Mann-Whitney U test is a nonparametric test that allows two groups or conditions or treatments to be compared without making the assumption that values are normally distributed. The two independent samples are combined and ordered together, to notice if they mix randomly in the rank order or if they are grouped in opposite ends. In the first case it would indicate that the two samples are not different, while in the second it would indicate a difference between them.

In this research, Mann-Whitney U test is used to explore differences between attitudes towards the environment and attitudes towards personal mobility and sociodemographic characteristics.

The p-value chosen as a threshold to reject the null hypothesis that imply that both samples are equal in the population of the study was 0.005. Hence, p-value minor to 0.05 are taken into account. Two items related to attitudes towards the environment (a130 and a132) provided significant differences when gender is considered. Similar results were obtained for attitudes towards personal mobility, where other two items were found significant for gender (a137 and a140) (Table 5).

	Gender			
	U Mann-Whitney	W Wilcoxon	Z	p
a130	327447	625053	-2.313	0.021*
a131	347124	644730	-0.266	0.791
a132	327475.5	739253.5	-2.304	0.021*
a133	346235	758013	-0.354	0.723
a134	344477	756255	-0.540	0.589
a135	346559.5	644165.5	-0.327	0.744
a136	330770.5	628376.5	-1.984	0.047
a137	308381	605987	-4.352	0.000*
a138	338749.5	636355.5	-1.148	0.251
a140	315024	612630	-3.690	0.000*

Table 5 – Mann-Whitney U test. Gender

The items aforementioned which provided significant differences are considered now. Table 6 shows the percentage of frequency distribution of responses for each factor and score (1 to 5) considering gender. As it can be seen, women score higher than men in most of the responses (a130, a137 and a140). This means that women try to use less the car to improve air quality, usually do other activities while travelling (reading, listening to music, checking social media, etc.) and try to use active transportation as much as possible. It should be taken into account that women use more public transport and active modes than men in general in the area of the study. Contrary to that, men seem slightly less reactive than women to the increase of carburant prices to invest it on public transport improvements. However, in this case the general reaction to this measure is negative.

	1		2		3		4		5	
	Men	Women	Men	Women	Men	Women	Men	Women	Men	Women
a130	11%	9%	9%	9%	28%	26%	27%	29%	23%	27%
a132	30%	32%	17%	20%	25%	26%	12%	12%	16%	10%
a137	6%	5%	7%	6%	23%	18%	34%	31%	29%	40%
a140	4%	3%	8%	5%	19%	16%	33%	33%	36%	44%

Table 6 – Distribution of responses. Significant variables. Gender

In order to study how age is related to the variables of the study, percentiles of the sample were obtained. None of the items related to attitudes towards the environment provided significant differences among participants under 25 years and those over 47. Thus, no conclusions can be obtained according to age. On the other hand, three of the five factors which measure attitudes towards personal mobility (a135, a136 and a137) resulted significant when both age groups are taken into account (Table 7).

Age				
	U Mann-Whitney	W Wilcoxon	Z	p
a130	99487	212537	-0.875	0.382
a131	99967.5	193928.5	-0.758	0.449
a132	99398	193359	-0.896	0.370
a133	96518	190479	-1.643	0.100
a134	102667.5	215717.5	-0.044	0.965
a135	91427	204477	-3.002	0.003*
a136	94020	207070	-2.325	0.020*
a137	69718	163679	-8.755	0.000*
a138	102320	215370	-0.137	0.891
a140	99951	193912	-0.774	0.439

Table 7 – Mann-Whitney U test. Age

Following the same methodology as in the previous case, the next step consists in the analysis of responses distribution of the variables that provided significant differences. As it is shown in Table 8, respondents over 47 seem more inclined to make arrangements online/ by phone in order to avoid unnecessary trips (a135) and prefer to do the shopping as close to their home as possible. In this case the differences observed are smaller. On the other hand, a relevant contrast if found for item a137. Younger individuals of the sample (those under 25) seem more inclined to multitask during their trips. This could be related to a higher use of ICTs of those under 25 who use their phones for multiple purposes while traveling.

	1		2		3		4		5	
	AgeQ1	Age Q3	Age Q1	Age Q3	Age Q1	Age Q3	Age Q1	Age Q3	Age Q1	Age Q3

a136	4%	3%	11%	9%	22%	20%	34%	35%	29%	34%
a137	2%	11%	4%	10%	14%	25%	31%	30%	49%	24%

Table 8 – Distribution of responses. Significant variables. Age

Similar results are obtained for different occupation status (Table 9). In this case, the differences between the variables of the study are assessed considering students and employed individuals. Although attitudes towards the environment did not provided significant differences, much more interesting results are obtained for attitudes towards personal mobility, with four significant factors: a135, a137, a138 and a140.

Table 9 – Mann-Whitney U test. Occupation

Next, the significant factors for occupation are explored (Table 10). Participants with employment reported a highest inclination to make arrangements online in order to avoid trips (a135). This could be explained by a better time management of those who work.

Next, students tend to multitask more that employees during their trips (a137) which is in line with previous results related to age. Last, students seem to plan their trips considering their daily schedule slightly more than employees. However, it should be taken into account that high scores are observed in the whole sample for this factor.

	Students	Employees	Students	Employees	Students	Employees	Students	Employees	Students	Employees
a135	11%	5%	10%	6%	19%	16%	26%	33%	34%	40%
a137	2%	6%	5%	7%	12%	23%	30%	36%	51%	29%
a138	5%	6%	9%	8%	16%	24%	30%	30%	41%	32%
a140	4%	3%	6%	6%	13%	19%	29%	36%	48%	36%

Table 10 – Distribution of responses. Significant variables. Occupation

6. CONCLUSIONS AND FUTURE RESEARCH

This research aims to study attitudes towards personal mobility and attitudes towards the environment. The latent variables constructed to evaluate these attitudes have been validated and the scale reliability is confirmed in this research. Thus, it can be assumed that the instrument developed to measure these factors is adequate and could be used in future research.

Results of this study reveal interesting conclusions which could be useful for policy making in order to promote sustainable travel modes. For instance, the increase of fuel price and restriction of private vehicle use are perceived as controversial measures by the participants of this research with divided opinions. On the other hand, respondents are inclined to avoid unnecessary trips which can be easily replaced with ITCs. Multitasking (reading, listening to music, checking social media, etc.) while traveling was also evaluated positively.

Considering gender, it was found that women try to use less the car to improve air quality, usually do other activities while travelling and try to use active transportation as much as possible. Taking into account that women use more public transport and active modes than men in general in the area of the study, more gender perspective studies are encouraged to better plan and design public transport systems as well as pedestrian and cyclist infrastructures.

Older respondents were more inclined to make arrangements online/ by phone in order to avoid unnecessary trips and prefer to do the shopping as close to their home as possible.

On the other hand, younger individuals prefer multitasking during their trips. The different use of ICTs for traveling should be considered for the promotion of sustainable travel.

Specific campaigns should be addressed to each cohort of the population. Additionally, special attention should be paid to design of public transport systems so as to facilitate multitasking, i.e. charging station for devices, wifi connection, comfortable spaces, etc.

Participants with employment reported a highest inclination to make arrangements online in order to avoid trips. Further cooperation among public administrations is still needed to enhance online services.

These results suggest interesting relationships between attitudes towards personal mobility and attitudes towards the environment. In order to confirm how this variables can explain travel behavior further analyses will be conducted based on Structural Equation Modelling.

Additionally, similar analyses will be assessed for the subsample of the survey which includes information about the activity and travel diary to include observed mobility.

Limitations of this study include sample size and underrepresentation of the older population cohort, which is a common limitation in web-based surveys. Additional attention should be paid in the future in order to enlarge participation of older respondents.

AKNOWLEDGEMENTS

This study has been developed within the framework of Minerva Project, founded by the I+D+i National Program of Society Challenges of the Spanish Ministry of Economy and Finance (TRA2015-71184-C2-1-R).

RESUMEN

El presente artículo muestra los resultados de los estudios realizados en las estaciones de Cercanías situadas en los municipios de Jerez de la Frontera, Reus, Benalmádena y Dos Hermanas. En estos estudios se calcularon matrices de movilidad en las áreas de influencia de las estaciones, a partir de datos georreferenciados de telefonía móvil y se realizaron encuestas de preferencias declaradas y reveladas y aforos vehiculares que permitieron caracterizar la movilidad en la situación actual y estimar la demanda futura.

El presente artículo tiene como objetivo revisar el concepto de la intermodalidad dentro del modelo “movilidad como servicio” y analizar los factores que influyen, en este aspecto, en la demanda de estaciones de Cercanías.

Uno de los factores principales que afectan a la demanda de las estaciones es el tiempo de acceso y dispersión de éstas desde/hasta el origen o destino final del viaje. Cómo se resuelve esta etapa de viaje de “última milla”, tanto desde el punto de vista de la oferta como de la gestión público-privado son claves para aumentar la demanda de las estaciones en un contexto de liberalización de los servicios de cercanías sujetos a Obligaciones de Servicio Público (OSP) en 2027.

1. INTRODUCCIÓN

En el contexto actual, los servicios de cercanías de los núcleos están sujetos al Contrato entre la Administración General del Estado y la sociedad mercantil estatal Renfe Viajeros SME, S.A. para la prestación de los servicios públicos de transporte de viajeros por ferrocarril de cercanías, media distancia convencional, alta velocidad media distancia

(AVANT) y ancho métrico competencia de la Administración General del Estado, sujetos a Obligaciones de Servicio Público (OSP) en el periodo 2018-2027.

El contrato firmado entre la A.G.E y Renfe Viajeros determina el régimen de derechos y obligaciones al que queda sujeta Renfe como operadora de los servicios ferroviarios de los núcleos de cercanías de Asturias, Bilbao, Cádiz, Madrid, Málaga, Murcia, San Sebastián, Santander, Sevilla, Valencia y Zaragoza.

La trasposición al ordenamiento jurídico español del llamado “cuarto paquete ferroviario” de la Unión Europea, dibuja un escenario futuro que liberalizará los servicios de cercanías sujetos a OSP en 2027.

Este artículo revisa la movilidad de los servicios ferroviarios de cercanías de cuatro corredores y reflexiona sobre el papel de las estaciones de cercanías en el futuro próximo, alineado con la Estrategia de Movilidad Segura, Sostenible y Conectada (EMSSC) del MITMA. La visión de dicha Estrategia es la de “hacer de la movilidad un derecho, un elemento de cohesión social y de crecimiento económico”, en base a tres principios básicos, seguridad, sostenibilidad y conectividad.

2. SERVICIOS DE CERCANÍAS

El presente artículo muestra el análisis de la accesibilidad y movilidad global de las estaciones actuales de cercanías de Reus, Jerez de la Frontera, Dos Hermanas y Torremuelle (Benalmádena) pertenecientes a los núcleos de servicios ferroviarios de Tarragona, Cádiz, Sevilla y Málaga respectivamente. Los datos utilizados para el análisis de movilidad de las estaciones han sido obtenidos a partir de encuestas de preferencias reveladas (EPR) y encuestas de preferencias declaradas (EPD) a usuarios de las estaciones.

Por otro lado, el análisis de la movilidad global muestra las matrices calculadas en las áreas de influencia de las estaciones de los corredores estudiados; obtenidas mediante datos de telefonía móvil, encuestas y aforos realizados durante el año 2018.

En la siguiente tabla se muestran las estaciones en la que se ha estudiado la movilidad global, así como el núcleo y la línea de cercanías a la que pertenecen.

Estación de Cercanías	Reus	Jerez de la Frontera	Dos Hermanas	Torremuelle
Núcleo de Cercanías	Rodalies de Tarragona Rodalies de Catalunya	Cádiz	Sevilla	Málaga
Línea de Cercanías / Servicios de Media Distancia	RT-1 Tarragona-Reus R-14 Barcelona Estació de França-Lleida R- 5 Barcelona Estació de França-Reus-Riba-roja d´Ebre	C-1 Cádiz-Jerez de la Frontera-Aeropuerto de Jerez	C-1 Lebrija - Utrera - Santa Justa - Lora del Río	C -1 Málaga Centro - Fuengirola

Tabla 1 – Características de las estaciones estudiadas. Fuente: Renfe

2.1 Demanda de las estaciones y ordenación del territorio

Las estaciones analizadas presentan una demanda entre 500 y 5.000 viajeros diarios (subidos+ bajados) para valores de 2018 (según los datos de los aforos realizados por RENFE en día medio laborable de otoño). Las líneas a las que pertenecen las estaciones presentan una demanda entre 20 y 25 mil viajeros diarios para el caso de Dos Hermanas y Torremuelle, en torno a 10 mil para Reus y cerca de 7 mil viajeros diarios para Jerez de la Frontera.

	Demanda de viajeros diarios 2018 (subidos + bajados) (1)			
	Reus	Jerez de la Frontera	Dos Hermanas	Torremuelle
Estación de Cercanías	2.644	3.266	4.630	763
Núcleo de Cercanías	Rodalies Tarragona: 811 Rodalies Catalunya: 34.906 Total: 35.717	6.901	27.919	26.985
Línea de Cercanías	RT1: 301 R14: 2.252 R15: 7.938 Total: 10.491	C-1: 6.678	C-1: 23.242	C-1: 25.040
Servicios hora punta AM	5	5	5	5

(1) Los datos del núcleo y de las líneas corresponden a viajeros subidos

Tabla 2 – Demanda diaria de las estaciones objeto de estudio (2018). Fuente: Renfe

Atendiendo a la ordenación del territorio, las estaciones de Dos Hermanas y Jerez de la Frontera se encuentran situadas en el centro urbano con una población atendida superior a los 35 mil habitantes en un radio de captación de 1.000m, mientras que Reus y Torremuelle se encuentran en áreas perimetrales al núcleo urbano y por lo tanto la población atendida de la estación se reduce a 18,3 mil y 4,7 mil habitantes respectivamente.

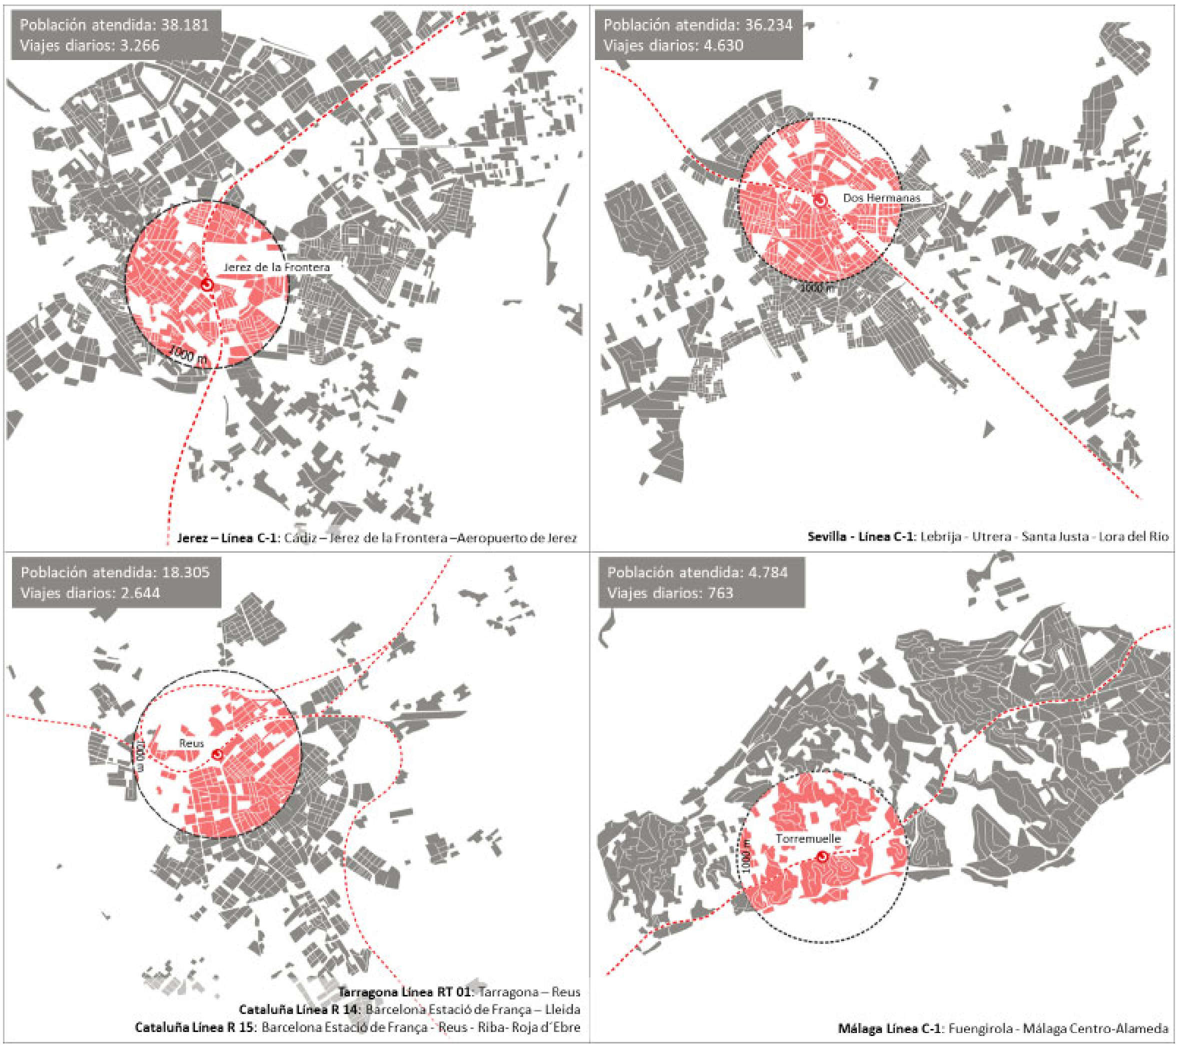

Fig. 1– Población atendida en el ámbito de influencia (1.000m) de las estaciones. Fuente: Elaboración propia.

2.2 Accesibilidad a las estaciones

En lo referente a la accesibilidad, los resultados de las encuestas de preferencias reveladas realizadas a los viajeros actuales de las estaciones de Reus, Jerez de la Frontera, Torremuelle y Dos Hermanas reflejan los siguientes resultados:

-Motivo de viaje: Tal como se muestra en la siguiente figura, estudios y trabajo es el principal motivo de viaje para los viajeros de los servicios ferroviarios de cercanías. Torremuelle al situarse en un entorno turístico con mezcla de usos muestra un mayor porcentaje de viajes asociados al ocio o al turismo.

En el caso de la estación de Jerez de la Frontera el más del 50% de los viajeros presentan como motivo de viaje estudios.

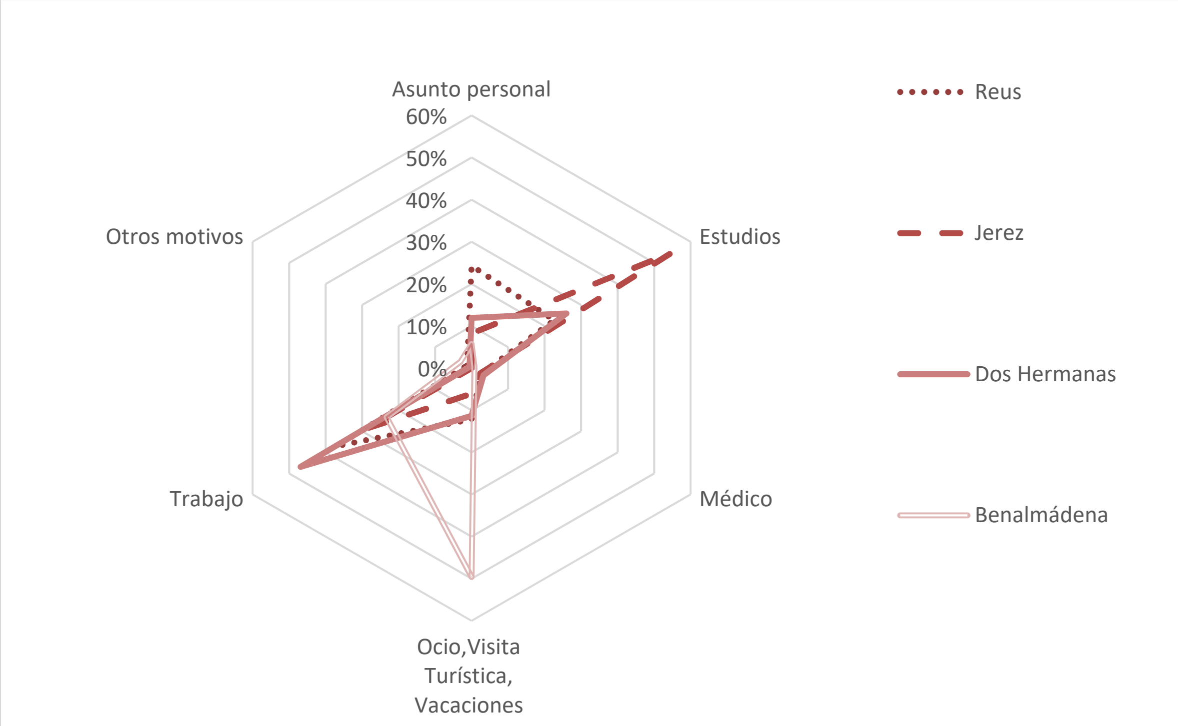

Fig. 2– Motivo de viaje de los viajeros de las estaciones de Reus, Jerez, Dos Hermanas y Torremuelle. Fuente: Campaña de encuestas de preferencia revelada, Ineco 2019.

-Modo de acceso: Más del 50% de los viajeros que acceden a las estaciones de Cercanías de Reus, Dos Hermanas, Jerez de la Frontera y Torremuelle lo hacen a pie (ver Figura 3). El segundo modo de acceso más frecuente es como acompañante en vehículo privado. En Dos Hermanas el porcentaje de viajeros que acceden en bicicleta y los que acceden como acompañantes en vehículo privado es similar, un 12 y un 16% respectivamente. En Jerez de la Frontera destaca la accesibilidad en autobús con un porcentaje significativo del 11%.

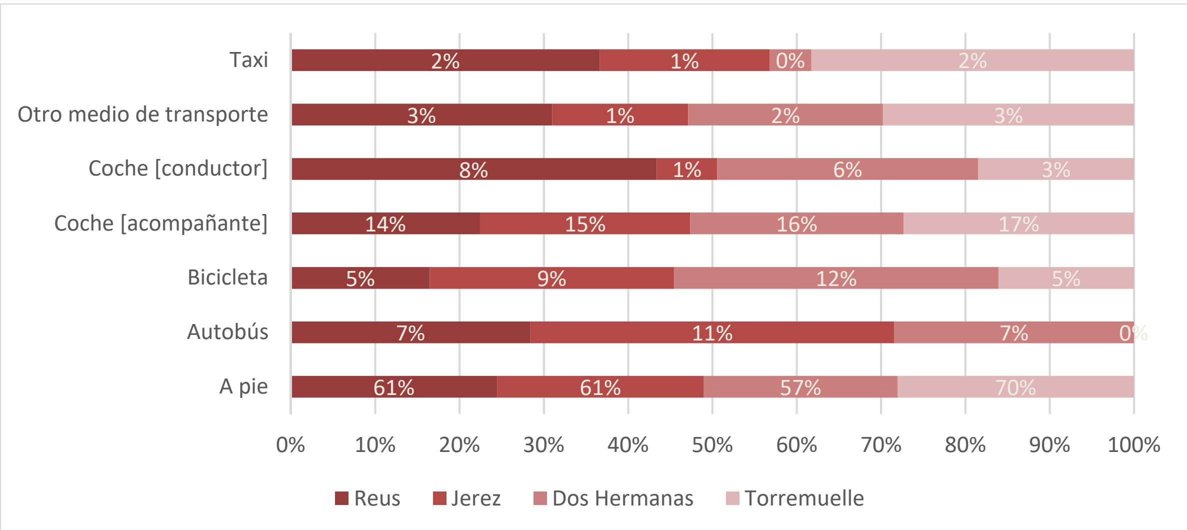

Fig. 3– Modo de acceso las estaciones de Reus, Jerez, Dos Hermanas y Torremuelle. Fuente: Campaña de encuestas de preferencia revelada, Ineco 2019.

-Frecuencia: Respecto a la frecuencia de acceso a la estación, en el caso de Jerez de la Frontera y Dos Hermanas, el mayor porcentaje de viajes se realiza con una frecuencia de cinco o más días, representando este segmento el 48% en el caso de Jerez y el 61% en el caso de Sevilla. En Reus, el 47% se reparte entre una frecuencia de 1-2 veces por semana y una de 5 días a la semana, mientras que en Torremuelle la frecuencia de viaje está muy repartida, destacando con un 26% la frecuencia de viaje ocasional seguida de una frecuencia de más de 5 días a la semana (22%).

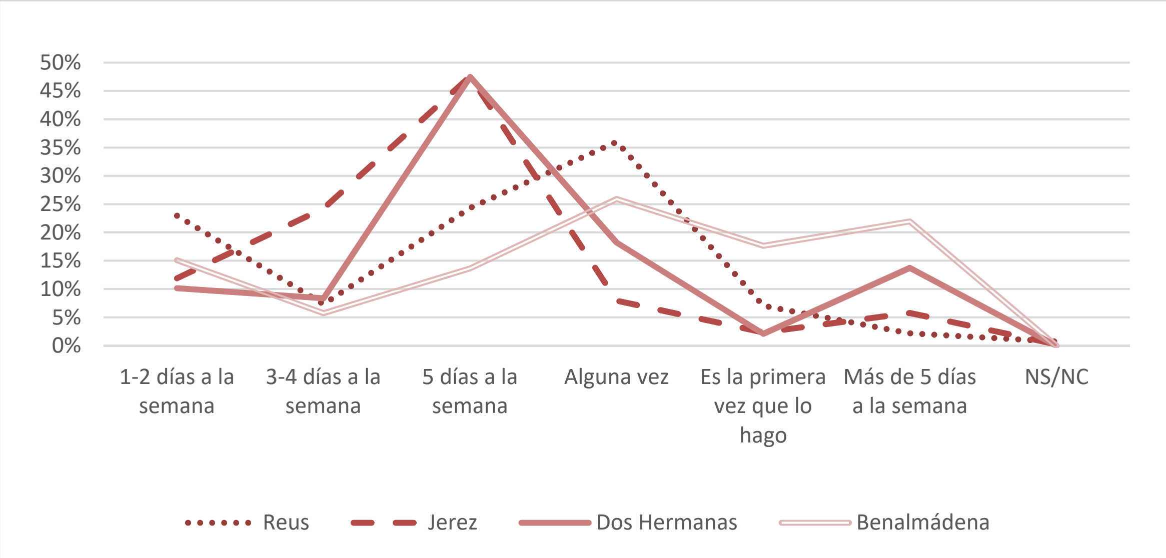

Fig. 4– Frecuencia de viaje de las estaciones de Reus, Jerez, Dos Hermanas y Torremuelle. Fuente: Campaña de encuestas de preferencia revelada, Ineco 2019.

Considerando que el principal modo de acceso a las estaciones es “a pie”, resulta interesante pone el foco en la distribución territorial. En el siguiente gráfico se puede observar la población atendida en las estaciones de Cercanías en un área de captación de 1.000 m y la demanda correspondiente en términos de viajeros diarios (subidos + bajados).
Jerez de la Frontera y Dos Hermanas se localizan en áreas urbanas consolidadas con una captación de población elevada, aunque en términos de viajes/habitantes destaca sobre el resto Jerez de la Frontera con mayor ratio de captación.

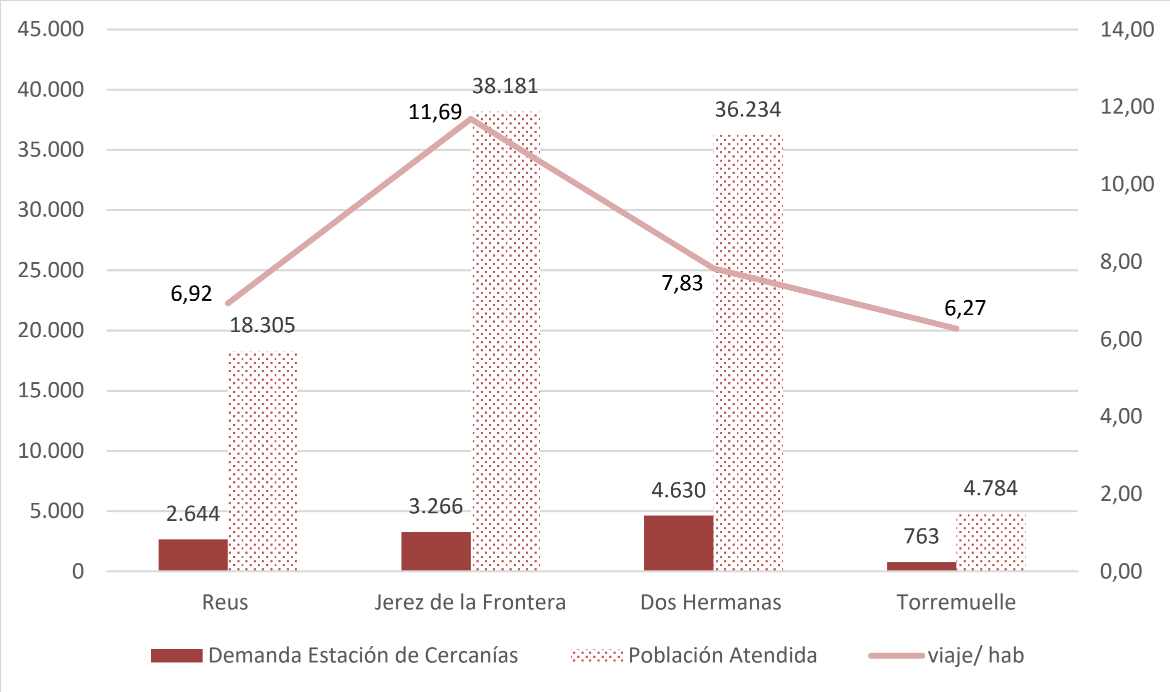

Fig. 5– Frecuencia de viaje de las estaciones de Reus, Jerez, Dos Hermanas y Torremuelle. Fuente: Elaboración propia, Ineco 2019.

2.3 Principales orígenes/destinos

En las siguientes figuras se muestran los principales orígenes y destinos obtenidos a partir de las encuestas de preferencias reveladas (ERP) realizadas en las estaciones objeto de estudio.

Los viajeros encuestados en Dos Hermanas presentaron como principales orígenes/destinos las estaciones de Sevilla San Bernardo, Sevilla Santa Justa y Virgen del Rocío con un 29%, un 19% y un 14% respectivamente, resultando también significativa la atracción y generación de viajes con la estación de Utrera (15%).

En el caso de Jerez de la Frontera, los principales orígenes y destinos se agrupan en las estaciones de Cádiz (25%), San Fernando (16%), El Puerto de Santa María (13%) y Universidad (11%).

La estación de Reus muestra una atracción más polarizada que el resto de las estaciones analizadas. Los resultados de las EPR muestran una atracción y generación viajes centrada en Barcelona Sants (28%) y Tarragona (24%). Del mismo modo, los viajeros de la estación de Torremuelle presentan como principales orígenes y destinos las estaciones de Málaga María Zambrano y Málaga Centro Alameda con porcentajes del 18% y la estación de Benalmádena-Arroyo de la Miel con un 15%.

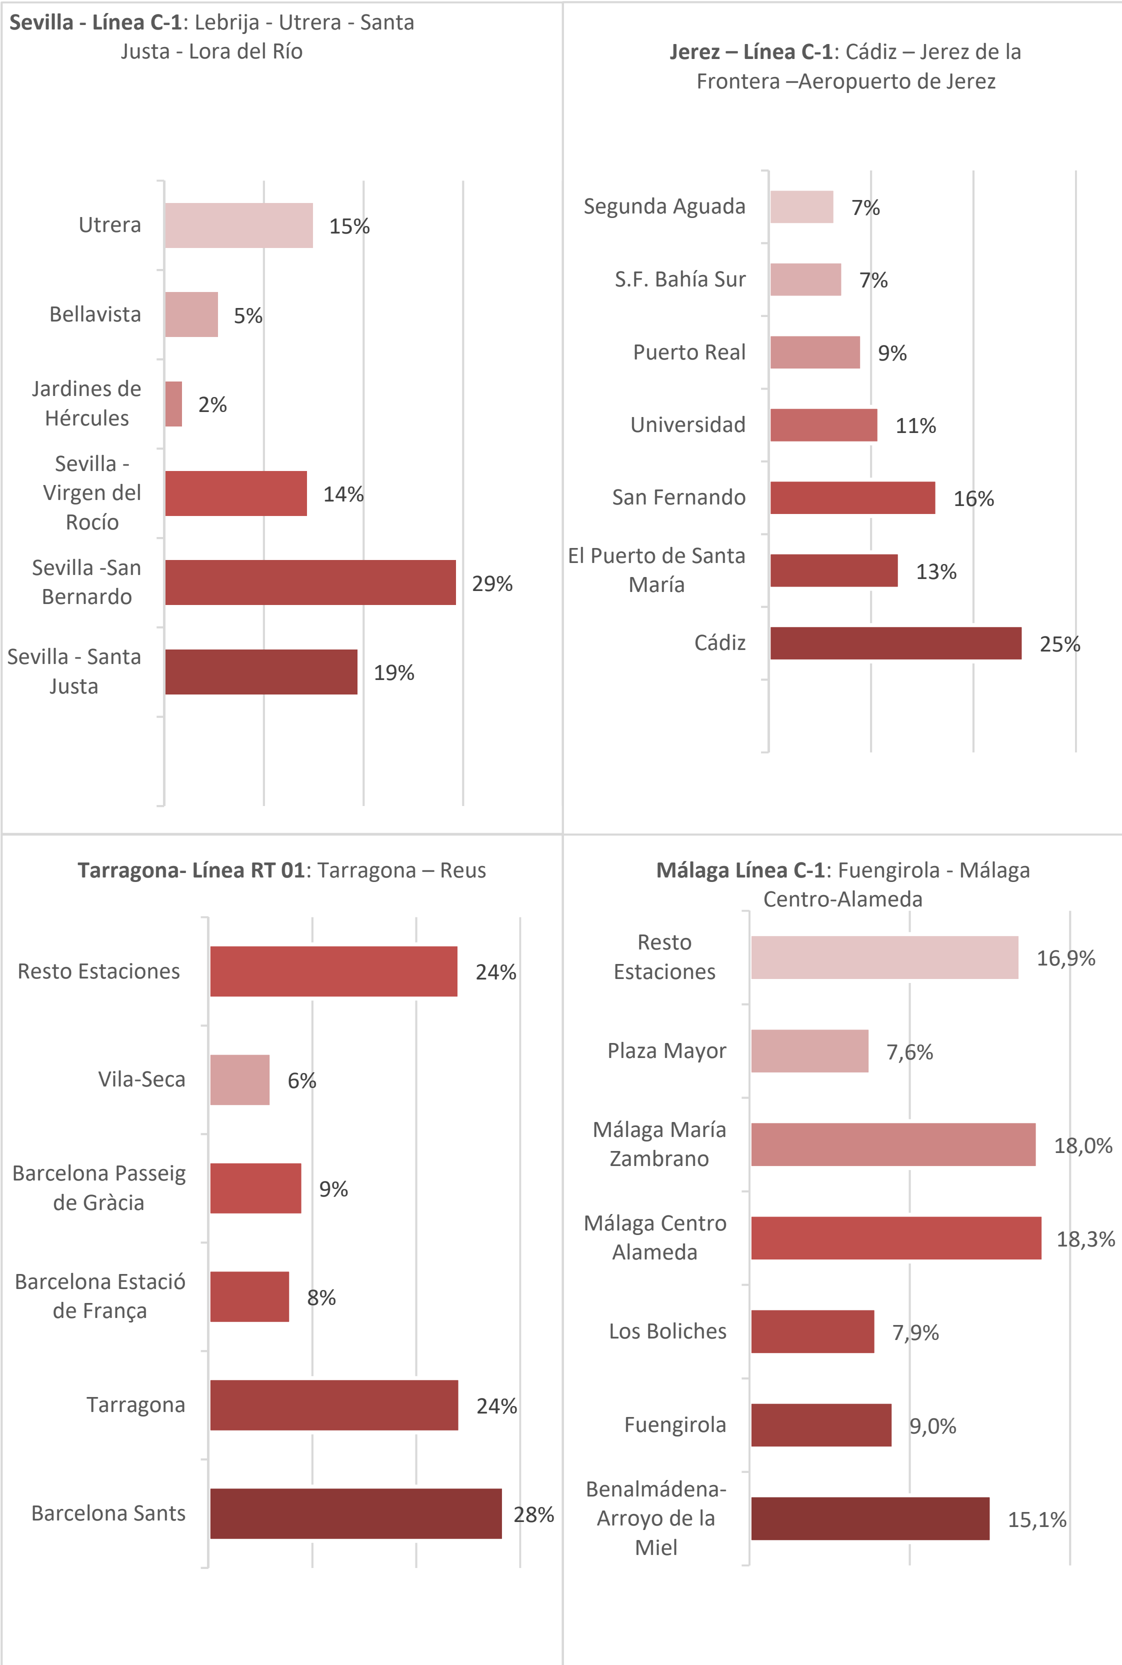

Fig. 5– Principales destinos de las estaciones de Reus, Jerez, Dos Hermanas y Torremuelle. Fuente: Elaboración propia, Ineco 2019.

2.4 Potenciales de demanda de las estaciones

La estimación de los potenciales de demanda de las estaciones ferroviarias de Cercanías en los corredores de los núcleos de estudio (Tarragona, Cádiz, Sevilla y Málaga), se ha obtenido a partir de un modelo general de movilidad.

Para la aplicación del modelo se han calculado matrices de viajes (origen/destino) por modo de transporte a partir de datos de telefonía móvil, aforos automáticos de vehículos, aforos manuales de viajeros de tren y autobús y datos de origen destino de encuestas de preferencias declaradas.

La caracterización de la movilidad en la situación en el escenario base (datos de movilidad de 2018) permite analizar los potenciales de demanda global (viajes diarios en carretera+ferrocarril) de los principales orígenes y destinos de las estaciones analizadas.

2.4.1 Potenciales de demanda estación Dos Hermanas (Sevilla)

En el siguiente gráfico se muestran los potenciales de demanda del área de influencia de la estación de Dos Hermanas (Zona 1) con las áreas de influencia de las estaciones con las que hay mayor relación de movilidad. Es decir, el área de influencia de las estaciones de Sevilla-Santa Justa-San Bernardo-Virgen del Rocío (Zona 5), estación de Bellavista (Zona 4) y estación de Utrera (Zona 6).

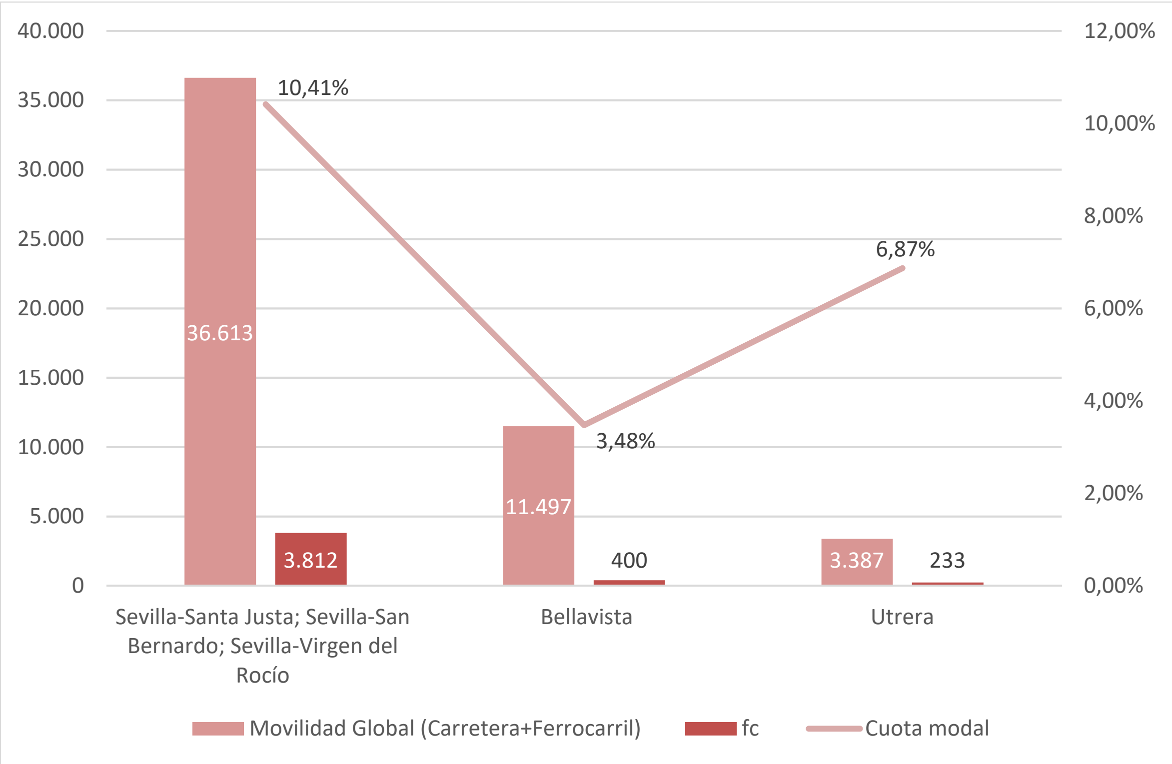

Fig. 6– Potenciales de demanda diaria desde/hacia la zona de influencia de Dos Hermanas (Zona1) hacia/desde las zonas de Sevilla (Zona 5), Bellavista (Zona4) y Utrera (Zona 6). Fuente: Elaboración propia, Ineco 2019.

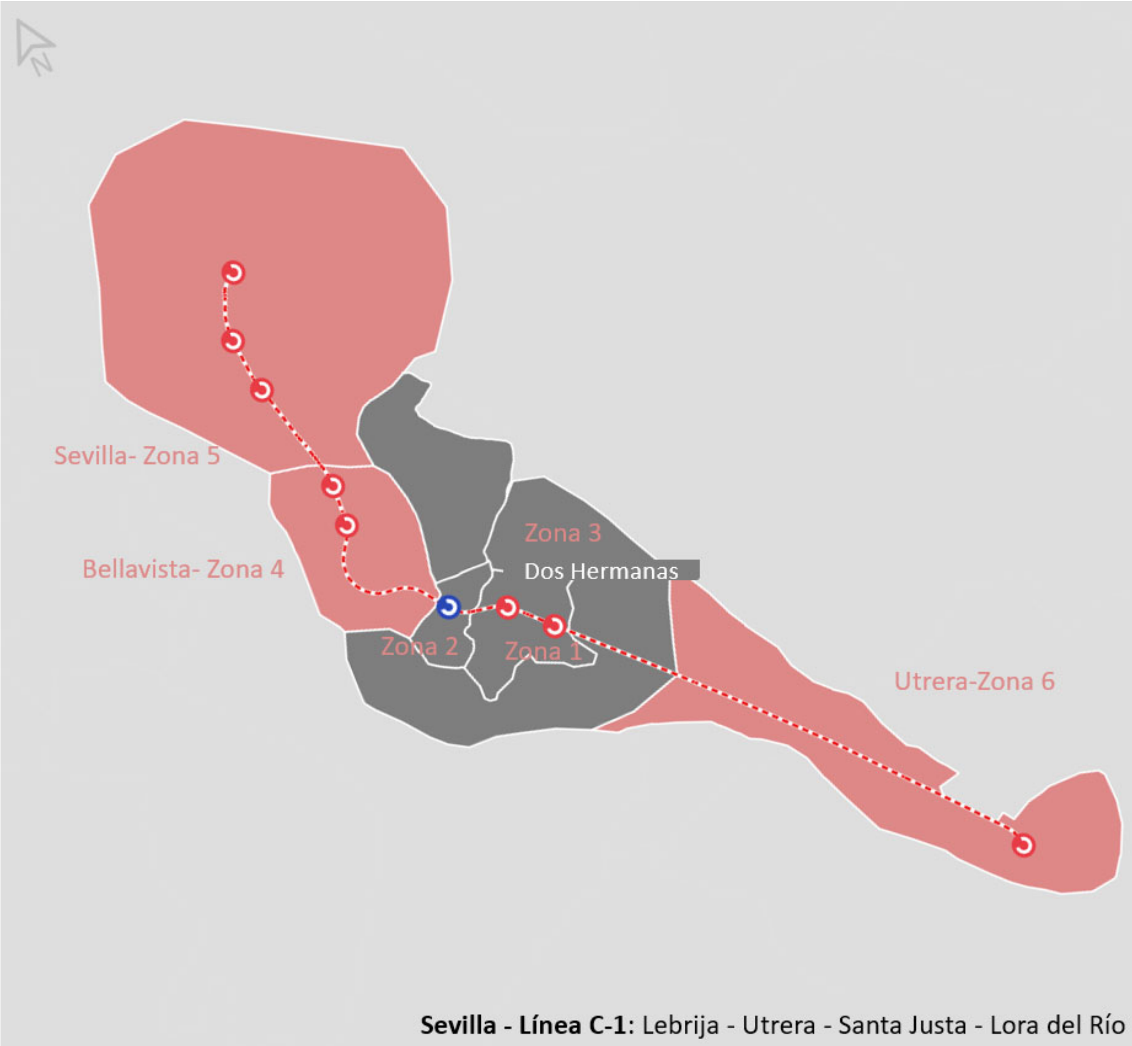

Fig. 7– Zonificación ámbito de estudio del corredor de la Línea C-1: Lebrija-Utrera-Santa Justa-Lora del Río. Fuente: Elaboración propia, Ineco 2019.

El potencial de demanda de la zona de influencia de la estación la estación de Dos Hermanas (Zona 1) hacia/desde las zonas de influencia de las principales relaciones (Zonas 4-5-6) muestran un total de 51,5 mil viajes diarios en términos de movilidad global (carretera y ferrocarril).

Sin embargo, este potencial de demanda aumenta un 50,19% si se amplía el área de influencia a las áreas adyacentes al área de influencia de Dos Hermanas (Zona 2 y Zona 3).

Zonas	Potenciales de demanda (viajes diarios)	Incremento
Movilidad Global Áreas Adyacentes (Zona 1, Zona 2 y Zona 3)	77.343	50%
Movilidad Global Dos Hermanas (Zona 1)	51.497	

Tabla 3 –Potenciales de demanda de las áreas de influencia de la estación de Dos Hermanas. Fuente: Elaboración propia, Ineco 2019

2.4.2 Potenciales de demanda estación Jerez de la Frontera (Cádiz)

A continuación, al igual que en el caso anterior, se expone el potencial de demanda del área de influencia de la estación de Jerez de la Frontera (Zona 3) con las áreas de influencia de las estaciones reflejadas en las encuestas de preferencias reveladas como principales nodos de atracción y generación de viajes.

En el siguiente gráfico se muestra que la relación de movilidad global desde/hacia Jerez de la Frontera con el área de influencia de las estaciones de Cádiz; S.F. Bahía Sur; Segunda Aguada; Puerto Real; Universidad; San Fernando (Zona 6) es de más de 19 mil viajes diarios (carretera + ferrocarril) mientras el potencial de demanda del Puerto de Santa María (Zona 4) es de unos 7,5 mil viajes diarios (carretera + ferrocarril).

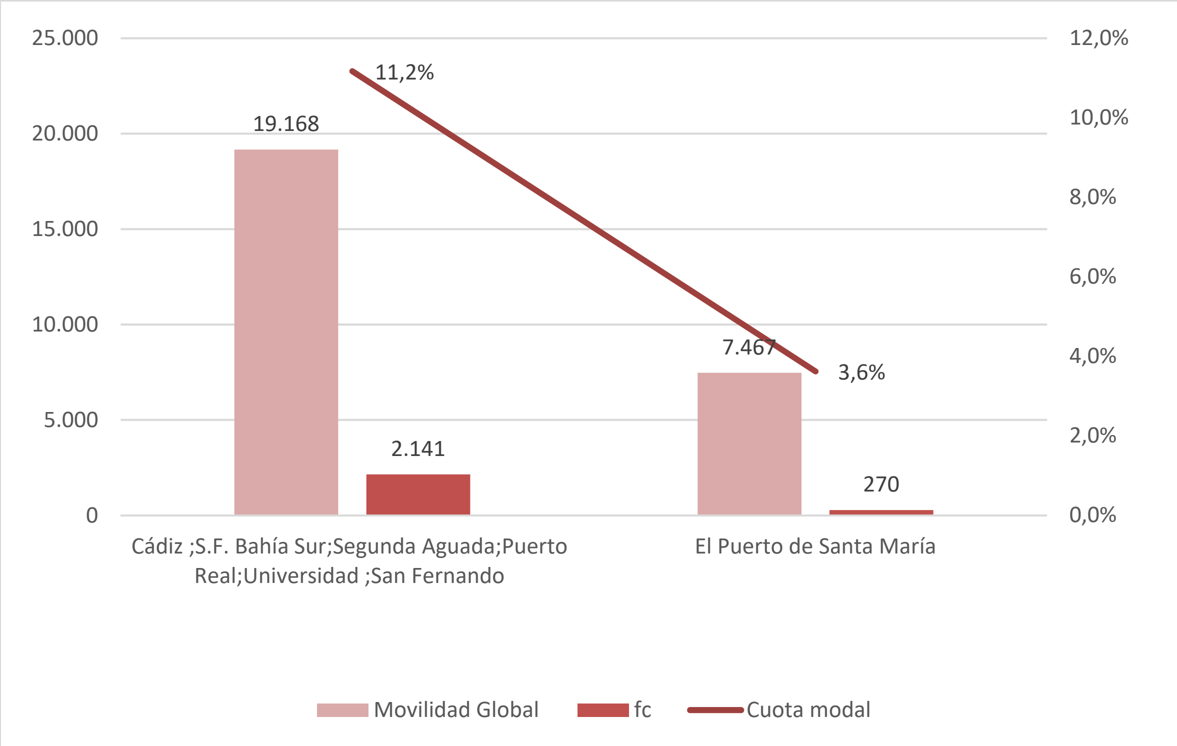

Fig. 8– Potenciales de demanda diaria desde/hacia la zona de influencia de Jerez de la Frontera (Zona 3) hacia/desde las zonas de Puerto de Santa María (Zona 4) y Cádiz-San Fernando (Zona 6). Fuente: Elaboración propia, Ineco 2019.

Las matrices de movilidad muestran la demanda de viajes en carretera y ferrocarril para cada una de las zonas en las que se ha dividido el corredor de la Línea C-1: Cádiz – Jerez de la Frontera –Aeropuerto de Jerez.

Este cálculo permite comparar el potencial de demanda de la estación de Jerez de la Frontera (Zona 3) con las zonas de mayor demanda ferroviaria (Zona 4 y Zona 6), este potencial de demanda es de 26.635 viajes diarios en ambos sentidos.

Ampliando la cobertura a las áreas adyacentes a la estación de Jerez de la Frontera (Zona 2, Zona 3 y Zona 7), tal y como se observa en la siguiente tabla, se produce un incremento del 33%.

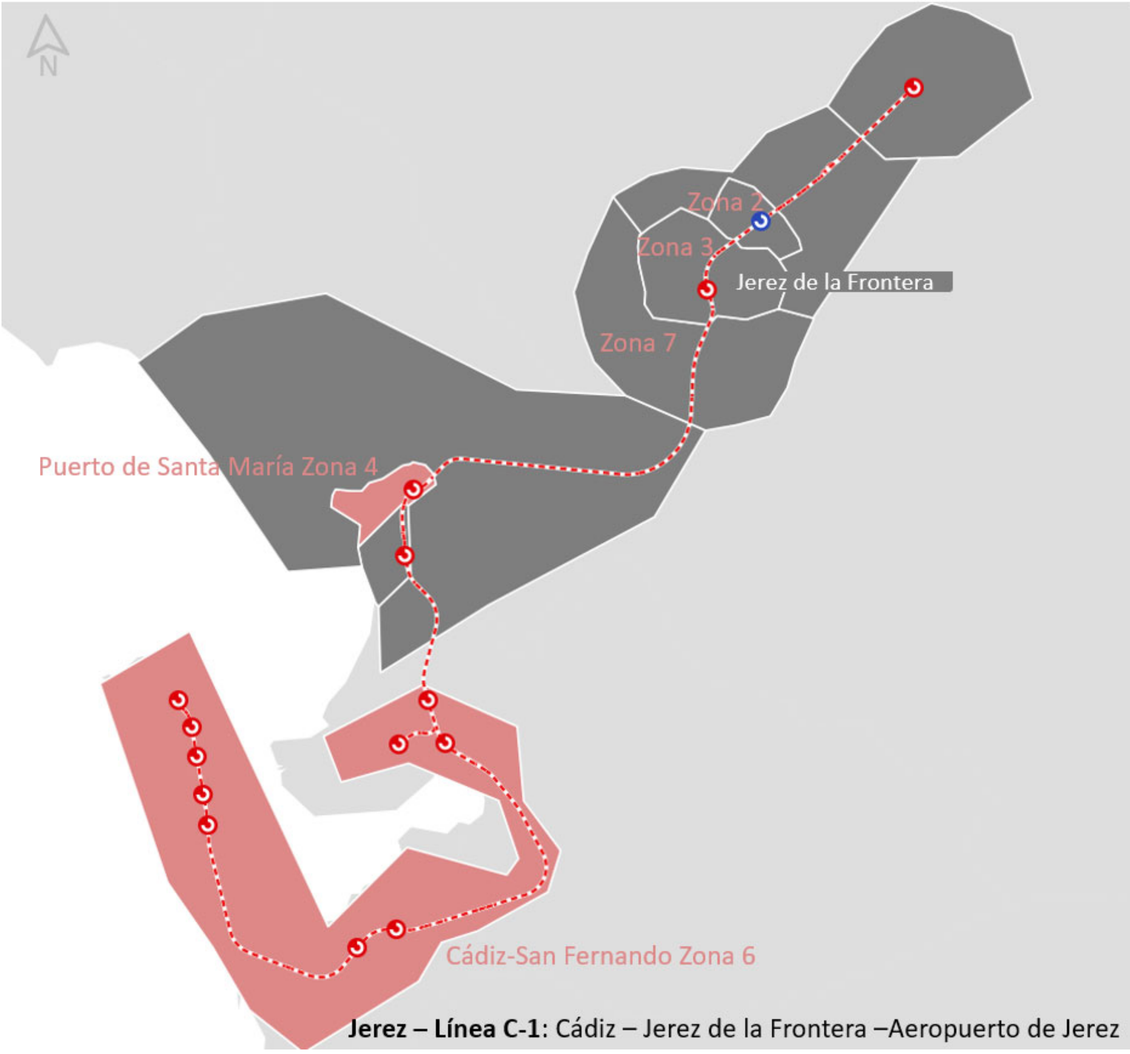

Fig. 9– Zonificación ámbito de estudio del corredor de la Línea C-1: Cádiz-Jerez de la Frontera-Aeropuerto de Jerez. Fuente: Elaboración propia, Ineco 2019.

Zonas	Potenciales de demanda (viajes diarios)	Incremento
Movilidad Global Áreas Adyacentes (Zona 2, Zona 3, Zona 7).	35.423	33%
Movilidad Global Jerez de la Frontera (Zona 3)	26.635	

Tabla 4 –Potenciales de demanda de las áreas de influencia de la estación de Jerez de la Frontera. Elaboración propia, Ineco 2019

2.4.3 Potenciales de demanda estación Reus (Tarragona)

El potencial de demanda de movilidad global (ferrocarril+carretera) del área de influencia de la estación de Reus (Zona 2) con las áreas de influencias de las principales estaciones reflejadas en las encuestas de preferencias reveladas, es de 12 mil viajes diarios con el área de influencia de la estación de Tarragona (Zona 6), 1,79 mil viajes diarios con el área de influencia de las estaciones que pertenecen Barcelona (Zona 10) y cerca de 3 mil con el área de influencia de la estación de Vila-Seca (Zona 5).

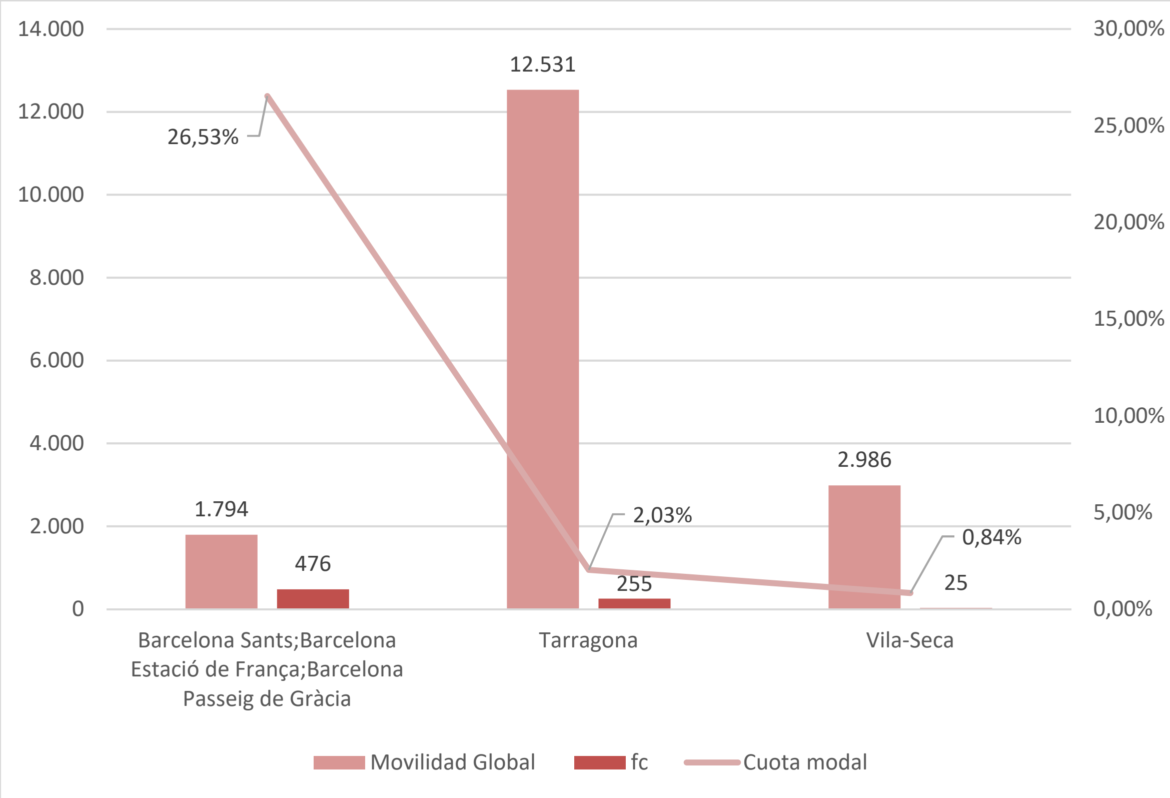

Fig. 10– Potenciales de demanda diaria desde/hacia la zona de influencia de Reus (Zona 2) desde/hacia Barcelona (Zona 10), Tarragona (Zona 6) y Vila-Seca (Zona 5) Fuente: Elaboración propia, Ineco 2019.

El potencial de demanda global diaria desde/hacia el área de influencia de la estación de Reus (Zona 2) con las zonas de influencia de las estaciones de Vila-Seca (Zona 5), Tarragona (Zona 6) y Barcelona (Zona 10) asciende de 17,3 mil viajes.

Sin embargo, si se amplía el ámbito de influencia a las zonas adyacentes a la estación de Reus (Zonas 1-2-3-4) el potencial de demanda asciende a 63,4 mil viajes diarios hacía/desde las zonas de mayor demanda del corredor (Zonas 5-6-10).

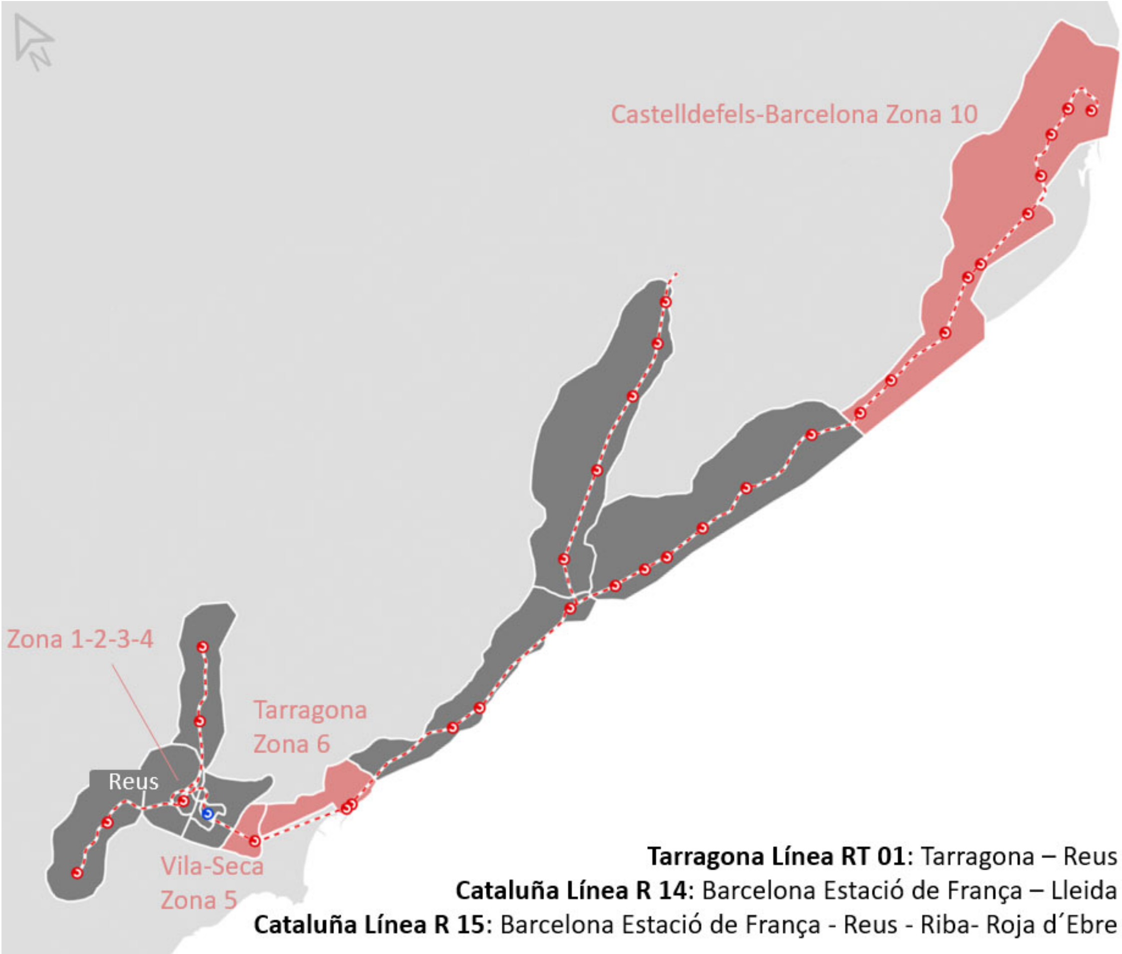

Fig. 9– Zonificación ámbito de estudio del corredor de las líneas RT 01, R 14 y R 15. Fuente: Elaboración propia, Ineco 2019.

Zonas	Potenciales de demanda (viajes diarios)	Incremento
Movilidad Global Áreas Adyacentes (Zonas 1-2-3-4)	63.456	266%
Movilidad Global Área Reus (Zona 2)	17.330	

Tabla 5 –Potenciales de demanda de las áreas de influencia de la estación de Reus. Elaboración propia, Ineco 2019

2.4.4 Potenciales de demanda estación Torremuelle (Benalmádena)

La estación de Torremuelle no presenta una relación de movilidad polarizada como en los casos anteriores, estas relaciones principales se reparten entre las áreas de influencia de Benalmádena-Arroyo de la Miel (Zona 8), Málaga (Zona 7), Fuengirola (Zona 5) y Plaza Mayor (Zona 12).

La principal relación potencial de demandada (3,6 mil viajes diarios) se produce con el área de influencia del núcleo urbano de Benalmádena.

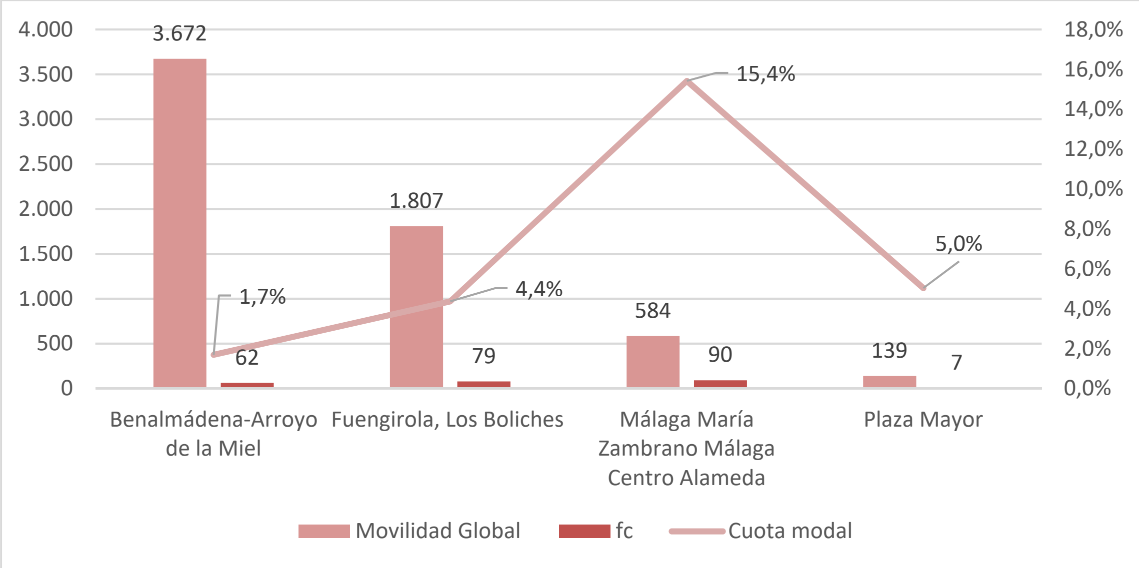

Fig. 10– Potenciales de demanda diaria de la zona de influencia de Torremuelle (Zona 2) con Benalmádena-Arroyo de la Miel (zona 8), Fuengirola (Zona 5), Málaga (Zona 7) y Plaza Mayor (Zona 12). Fuente: Elaboración propia, Ineco 2019.

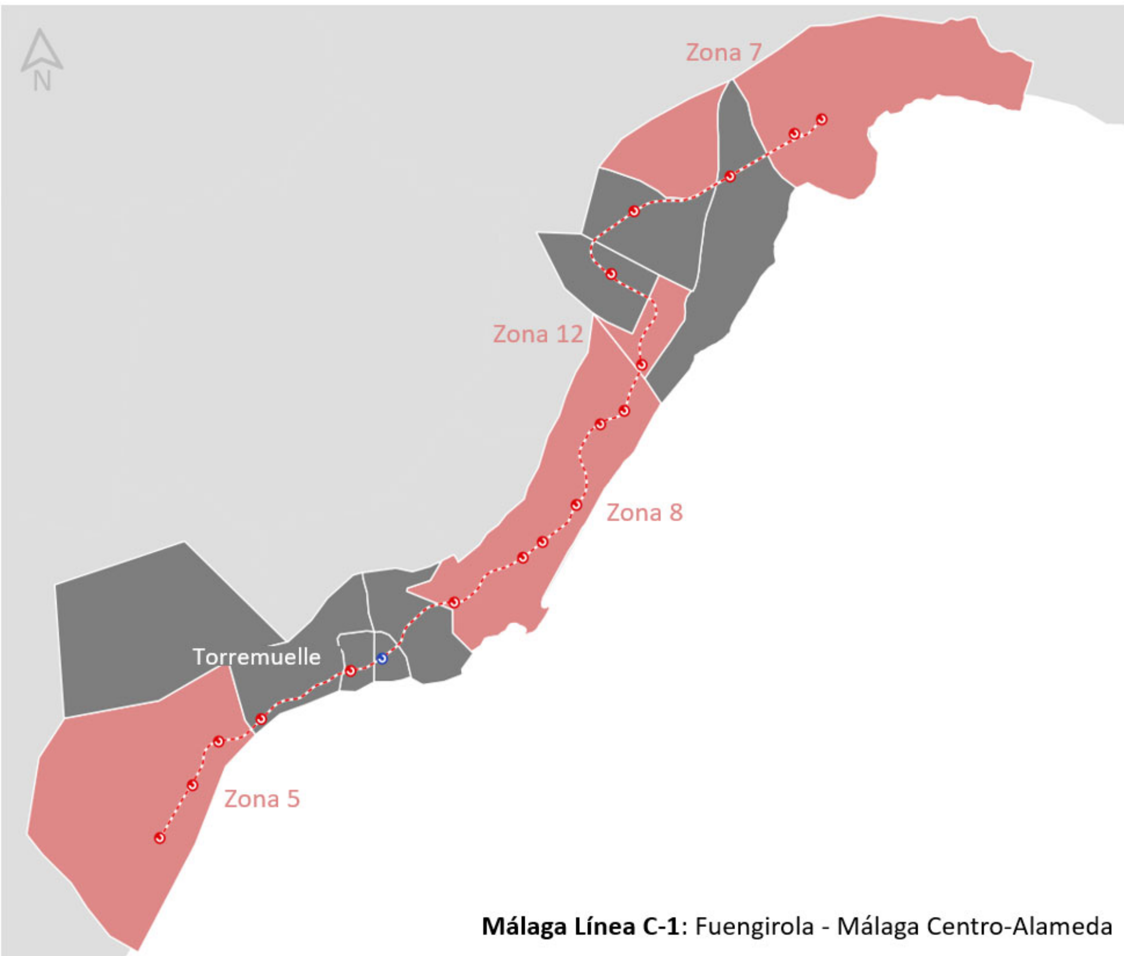

Fig. 11– Zonificación ámbito de estudio del corredor de la Línea C-1: Fuengirola-Málaga Centro-Alameda. Fuente: Elaboración propia, Ineco 2019.

Zonas	Potenciales de demanda (viajes diarios)	Incremento
Movilidad Global Áreas Adyacentes (Zonas 1-2).	13.256	114%
Movilidad Global Área Torremuelle (Zona 1)	6.202	

Tabla 5 –Potenciales de demanda de las áreas de influencia de la estación de Torremuelle. Elaboración propia, Ineco 2019

El potencial de demanda la zona de la estación de Torremuelle (Zona 1) con las zonas de influencia de las estaciones las áreas de Benalmádena - Arroyo de la Miel (Zona 8), Málaga (Zona 7), Fuengirola (Zona 5) y Plaza Mayor (Zona 12) asciende a 6,2 mil viajeros diarios (movilidad global). Ampliando la zona de cobertura de Torremuelle a la zona adyacente (Zona 2) el potencial de demanda se incrementa de 6,2 mil a 13,2 mil viajeros diarios (ferrocarril + carretera).

3.RESULTADOS

Los resultados del análisis realizado exponen un perfil de usuario de Cercanías de las estaciones de Reus, Jerez de la Frontera, Dos Hermanas y Torremuelle. El principal motivo de viaje es estudios o trabajo con valores entre el 60 y 83% de los viajeros en Reus, Jerez de la Frontera y Dos Hermanas, mientras que esta cifra en los viajeros de Torremuelle, situada en un entorno turístico y residencial de vacaciones, desciende hasta el 25%.

Respecto a la frecuencia de viaje, cerca del 50% los viajeros de las estaciones de Jerez de la Frontera y Dos Hermanas acceden a la estación 5 días a la semana, mientras que en el caso de Reus se reduce al 24% y en Torremuelle desciende esta cifra al 14%.

	Demanda de viajeros diarios 2018 (subidos + bajados)			
	Reus (Tarragona)	Jerez de la Frontera (Cádiz)	Dos Hermanas (Sevilla)	Torremuelle (Málaga)
Estación de Cercanías	2.644	3.266	4.630	763

Tabla 6 –Demanda de viajeros diarios (subidos y bajados) en 2018. Renfe

Por lo tanto, se observa que las estaciones de mayor demanda responden principalmente a un perfil de viajeros de movilidad obligada y uso frecuente en días laborales, por lo que son determinantes las características del servicio en las horas punta donde el valor subjetivo del tiempo es mayor.

Las variables que determinan la elección modal de los servicios de cercanías serán aquellas asociadas con las características particulares del viaje en ferrocarril (fiabilidad, regularidad y puntualidad del servicio, así como confort de este) y coste del viaje.

Además, es determinante para la elección modal del viajero, en el ámbito de influencia de los corredores de los núcleos de Cercanías, dónde las congestiones por carretera son menores que en un ámbito urbano y los tiempos de viaje son relativamente ajustados; que el acceso y dispersión a las estaciones esté integrado con otros modos de transporte.

La movilidad global desde/hacia las estaciones de estudio presenta siempre un máximo de demanda con un principal polo de atracción y generación de viajes, en el caso de Reus con Tarragona, Jerez de la Frontera con Cádiz, Torremuelle con Benalmádena y Dos Hermanas con Sevilla; observándose que los potenciales de demanda aumentan significativamente al ampliar las conexiones entre las zonas de influencia del área adyacente de la estación.

Para resolver las conexiones en los corredores ferroviarios de Cercanías se puede optar por nuevas estaciones cuando las distancias entre dichas áreas son suficientes y los planes generales de ordenación urbana contemplan desarrollos urbanísticos con mezclas de usos en el entorno de las potenciales estaciones que garanticen la demanda. Es el caso de las potenciales estaciones en estudio en Jerez de la Frontera, Dos Hermanas y Reus, donde además su puesta en servicio no perjudique a la funcionalidad de la línea ni al resto de usuarios de las líneas de Cercanías donde se ubican.

En otras ocasiones, sin embargo, implantar nuevas estaciones de Cercanías atienden a menor población y pueden restar funcionalidad a la línea actual.

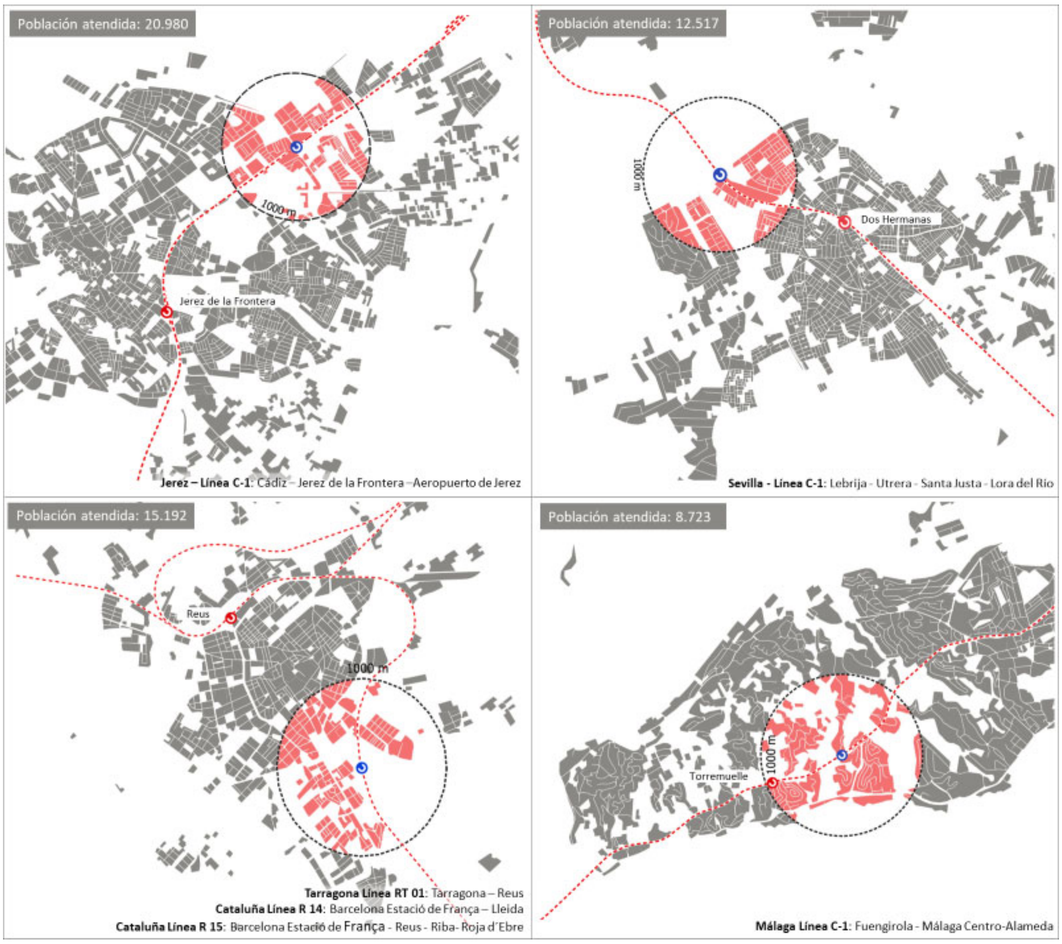

Fig. 11– Población atendida de nuevas estaciones en estudio en el ámbito de influencia de las estaciones de Jerez, Sevilla, Reus y Torremuelle. Fuente: Elaboración propia, Ineco 2019.

4. CONCLUSIONES

La reducida demanda de viajeros de las estaciones de los servicios de cercanías sujetos a OSP analizados (Jerez de la Frontera, Dos Hermanas, Reus y Torremuelle) en comparación con los potenciales de demanda de movilidad global sugieren nuevas medidas que aumenten la demanda de viajeros en estas estaciones y mejoren la calidad y la percepción del servicio por parte de los usuarios potenciales.

Para ello, es necesario actuar en todas las etapas del viaje en Cercanías. Claramente, las mejoras previstas en las inversiones en infraestructura, material rodante y personal repercutirán en mejoras de tiempo de viaje, confort, fiabilidad y regularidad del servicio, y aumentarán las demandas actuales. Sin embargo, las etapas de acceso y dispersión pueden ser tan determinantes para la elección modal como el propio tiempo de viaje en ferrocarril.

Por lo tanto, es necesario redefinir el papel de las estaciones de Cercanías en la red ferroviaria con acciones que aporten a estos servicios de una herramienta de conexión eficiente y vertebración del territorio.

Se proponen a continuación algunas acciones y requisitos de las estaciones de Cercanías del futuro:

- Mejora de la intermodalidad: Adaptación de los servicios de transporte público a la red ferroviaria, potenciando la complementariedad e intermodalidad entre modos, aprovechando la mayor capacidad de transporte del sistema ferroviario.
- Movilidad como servicio: Método de pago integrado con las redes de transporte locales, coordinación entre modos y digitalización de los sistemas de información al viajero en tiempo real. Se reducirán así los tiempos de espera y, en consecuencia, supondrá un ahorro del tiempo de viaje del usuario, disminuyendo también su percepción del tiempo.
- La estación como destino de viaje: optimización de la infraestructura de la estación mediante la generación espacios destinados a co-workings, salas de reuniones, unidades sanitarias bibliotecas, puntos de recogida de paquetería de última milla.
- Desarrollos orientados al transporte de Cercanías: implementar en los P.G.O.U la ubicación de las estaciones vinculados a desarrollos urbanos con mayor densidad y con mezclas de usos que garanticen una distribución mayor del perfil del viajero y una mayor potencialidad de su uso.

LOS PLANES DE ACCIÓN PARA LA MOVILIDAD DE GRANDES EVENTOS DEPORTIVOS

Rodrigo Pérez Senderos
Experto Senior en G.A. Economía y Política del Transporte de INECO
Sonia Mateos Manzaneque
Técnico en G.A. Economía y Política del Transporte de INECO

RESUMEN

Los grandes eventos deportivos, como los Juegos Olímpicos o los Mundiales de Fútbol, se enfrentan a importantes retos organizativos: desde garantizar unas infraestructuras deportivas adecuadas, hasta asegurar una oferta hotelera suficiente u ofrecer una oferta cultural y de ocio alternativa o complementaria.

Entre estos retos, sin duda, cabe señalar el objetivo de garantizar una oferta de movilidad eficiente y atractiva para todos.

Este reto se soporta en varios objetivos, entre los que cabe destacar:

1. Minimizar el impacto de la movilidad generada por los eventos deportivos en la movilidad diaria de las ciudades que acogen dichos eventos.
2. Garantizar un adecuado funcionamiento de la movilidad asociada a las distintas actividades de los eventos deportivos en cuestión, siempre desde un enfoque que prime la sostenibilidad del sistema.
3. Aprovechar el legado de las inversiones realizadas en el sistema de transporte para el desarrollo de la movilidad diaria una vez finalizado el evento deportivo.

Dentro del segundo punto, en la organización de la movilidad asociada al evento, hay que tener en cuenta las necesidades y condicionantes de un amplio abanico de usuarios: deportistas y equipo técnico, autoridades, medios de comunicación, cuerpos de seguridad y, por supuesto, los espectadores.

También cobran especial interés otros aspectos como la información a los usuarios, la seguridad vial o la seguridad personal en el transporte.

Por último, cabe señalar las distintas necesidades de eventos como los Juegos Olímpicos, que se desarrollan en su mayoría en una sola ciudad o área metropolitana, o los Mundiales de Fútbol, que distribuyen su actividad en varias ciudades.

Una excepción a este hecho puede ser el futuro Mundial de Catar que, debido a los condicionantes territoriales del país, se desarrollará prácticamente en su totalidad en el área metropolitana de Doha.

1. OBJETIVOS Y RESPONSABILIDADES

Un evento deportivo como los Juegos Olímpicos, el Mundial de Fútbol, o una final de competiciones europeas son eventos que se caracterizan por la concentración de un gran volumen de personas en un limitado espacio de tiempo y con una gran repercusión social.

Esta concentración de participantes y visitantes se superpone a la actividad habitual de las ciudades que acogen estos eventos.

Como criterio general, para gestionar las condiciones especiales de movilidad derivadas de estas situaciones, se debe potenciar el transporte público, y una de las medidas es limitar el acceso en vehículo privado en las inmediaciones. Por ello el sistema de transporte ha de ayudar a que el evento se celebre sin ningún contratiempo.

En consecuencia, los objetivos del sistema de transporte para un evento deportivo son:

- Proporcionar transporte seguro, inclusivo, rápido y confiable para todos los asistentes y grupos de clientes.
- Proporcionar una oferta de transporte suficiente, accesible, respetuosa con el medio ambiente y sencilla para espectadores y visitantes, tanto de las ciudades donde se celebran las competiciones, como de otras regiones.
- Respetar la actividad diaria de las ciudades organizadoras, sin producir grandes cambios ni restricciones en el servicio ofertado.
- Dejar un legado positivo, así como facilitar la integración y el uso del transporte público durante y después del evento.
- Lograr el mayor aprovechamiento de los recursos asignados a transporte.

2. ÁMBITO TERRITORIAL Y CALENDARIO DEPORTIVO

La concentración de actividades derivadas de un gran evento deportivo en una misma ciudad o país es un reto para el transporte y para el éxito de asistencia a la competición. En competiciones donde los eventos tienen lugar en una misma ciudad o ciudades cercanas entre sí se suelen vender entradas por días, o por competencias deportivas, como es el caso de los Juegos Olímpicos.

Las fases finales de los Mundiales de Fútbol o las Eurocopas suelen repartir los partidos entre distintos estadios de diversas ciudades, diluyendo parcialmente los efectos sobre la movilidad si se compara con unos Juegos Olímpicos, que concentran la mayor parte de la actividad en una sola ciudad o área metropolitana. Pero cuando estas fases finales de Mundiales o Eurocopas se celebran en países pequeños, el problema es más complejo.

Una práctica habitual es que las entradas a los diferentes eventos deportivos vayan asociados a un título de transporte que permita el acceso ilimitado al mismo durante los días que dura la competición, o para los días en los que es válida la entrada adquirida.

Por ejemplo, en Londres se vendieron las entradas por días, junto con un título de transporte válidos para los días de entrada. En competiciones de Champion que se han celebrado en Europa en los últimos años, la venta de entradas ha llevado asociado un título de transporte válido desde que el visitante llega al lugar de la competición, que suele ser un día antes de la misma

3. STAKEHOLDERS Y MODELO DE GOBERNANZA.

En la organización del sistema de transporte suelen estar involucrados los siguientes organismos y autoridades:

- Comité Organizador del evento deportivo
- Ministerio de Transportes
- Autoridades de transporte metropolitano
- Autoridades locales
- Operadores
- Vigilancia y policía
- Voluntarios

El proceso habitual para organizar la movilidad durante estos eventos es que Comité organizador exponga las necesidades de transporte de los grupos de interés, así como la afluencia de participantes y de visitantes esperados en cada una de las sedes de competencia y entrenamiento, y dimensione, de forma conjunta con el Ministerio de Transportes y las autoridades locales, el sistema de transporte necesario, teniendo siempre como punto de partida la oferta y características del sistema existente. Las autoridades de vigilancia y los voluntarios se encargan de que el sistema sea seguro y confiable para todos los asistentes, y contribuya al éxito de la celebración de la competición.

4. NECESIDADES DE TRANSPORTE POR TIPO DE USUARIO

A continuación, se incluyen los tipos de usuarios habituales de las grandes competiciones deportivas, el tipo de transporte más habitual en cada caso y el tiempo con el que cada tipo de usuario debe estar previo y después de las competiciones. Mención especial tienen las ceremonias de apertura y clausura de la competición.

USUARIO	TIPO DE TRANSPORTE	TIEMPO PREVIO A LA COMPETICIÓN
Deportistas y equipo técnico	Autobús discrecional	2h
Staff Estadios	Transporte público	3-4h
Prensa	Autobús discrecional	3h
Retransmisión del evento	Autobús discrecional	3h
Autoridades	Vehículo privado	30 min
Espectadores	Transporte público	2,5h

Tabla 1 – Tipo de transporte por tipo de usuario y tiempo de estancia previo a las competiciones

USUARIO	TIPO DE TRANSPORTE	TIEMPO DESPUÉS DE LA COMPETICIÓN
Deportistas y equipo técnico	Autobús discrecional	1h
Staff Estadios	Transporte público	2h
Prensa	Autobús discrecional	2h
Difusión del evento	Autobús discrecional	2h
Autoridades	Vehículo privado	30 min
Espectadores	Transporte público	Desde que finaliza el evento hasta 1,5h

Tabla 2 – Tipo de transporte por tipo de usuario y tiempo de estancia después de las competiciones

4.1 Jugadores y cuerpos técnicos

Se requiere diseñar rutas a los estadios y hacer una correcta planificación de itinerarios y horarios.

4.2 Espectadores

Los espectadores se desplazarán preferentemente en transporte público. Para lograrlo, es necesario un plan de comunicación específico. La movilidad será diferente para los estadios que tengan estación de Metro/Cercanías, o no. Si es necesario crear un servicio especial, se hará mediante autobuses lanzadera que conecten con los centros neurálgicos de las ciudades.

4.3 Autoridades

Se requiere diseñar rutas a los estadios donde la seguridad es un criterio fundamental.

Suelen requerir escolta policial y prioridad de paso en todo el recorrido. Es necesaria una adecuada planificación y gestión de los itinerarios en los últimos metros de aproximación a los estadios, donde las aglomeraciones de espectadores pueden comprometer la agilidad (y la seguridad) de los trayectos.

5. CALENDARIO DEL EVENTO. FECHAS CLAVE y ESTIMACIONES DE VISITANTES

5.1 Inauguración y clausura

El calendario de competición es diferente en función del tipo de evento deportivo.

En los Juegos Olímpicos, tras el pico de asistencia a la jornada de inauguración, la demanda es más estable, y sufre un descenso progresivo hasta la clausura de los mismos. En el caso de los Mundiales de Fútbol, son las semanas de la fase de grupos, donde hay un elevado número de partidos diarios, y llevan asociado un elevado volumen de público. Las semanas previas a la final son más variables en función de los países que lleguen a la final, y la proximidad al lugar de competición de estas regiones.

Como ocurre con los Juegos Olímpicos, las ceremonias de apertura y clausura o final son eventos clave de la competición y generalmente tienen una afluencia de asistentes importantes. En los Mundiales de Fútbol se estima que la afluencia a los estadios en estos eventos es en torno a un 20% mayor que en otros partidos en sedes de dimensiones similares. Por ello, deben tener un sistema de transportes reforzado estos días.

5.2 Tipología del evento.

Aunque la accesibilidad universal del transporte ha de garantizarse siempre, es importante tener en cuenta los clientes de la competición. En el caso de los Juegos Olímpicos, se celebran a continuación los Juegos Paraolímpicos, de menor repercusión en cuanto a número de visitantes, pero más exigente en cuanto a los criterios de accesibilidad universal. Por ello, deberá ponerse más hincapié en que el sistema de transporte sea accesible para todos los asistentes.

5.3 Sedes de competencia y entrenamiento

Por último, en los eventos deportivos como Juegos Olímpicos, o Mundiales de Fútbol, son igual de importantes las sedes de competencia como las sedes de entrenamiento. Estas sedes más pequeñas generan también demandas de movilidad, aunque más reducidas, por parte de deportistas, prensa, aficionados, etc. Es posible que estas sedes de entrenamiento no dispongan de una oferta adecuada de transporte público con el sistema de transporte habitual de la ciudad, por lo que será importante dotarlos de autobuses lanzadera desde puntos estratégicos de las diferentes ciudades, con unos horarios suficientes para que los asistentes tengan flexibilidad suficiente para acceder a dichas sedes.

6. ESTRATEGIAS DE TRANSPORTE

6.1 La gestión de la movilidad

En el diseño y gestión de la estrategia de movilidad es necesaria la coordinación efectiva de todos los organismos y agentes implicados. El reparto de competencias entre distintas Administraciones suele hacer recomendable la creación de un comité específico para la gestión de la movilidad durante el evento. Entre las funciones de este comité pueden plantearse:

- La planificación, regulación, mejora y gestión de todas las formas de transporte durante la duración del evento.
- La planificación de la infraestructura para el transporte público realizadas con ocasión del evento.
- Planificación y coordinación de las medidas de gestión de circulación asociadas.
- La gestión de los contratos de transporte público de pasajeros y sus modificaciones temporales vinculadas al evento.
- El diseño, aprobación y gestión de la política tarifaria asociada al evento, así como la puesta en funcionamiento de la billética especial.
- Información a los usuarios.
- Seguimiento de la calidad de los servicios.

6.2 Acciones en los diferentes modos de transporte

6.2.1 Metro y Cercanías

El Metro y las Cercanías deben ser los modos de transporte prioritarios en este tipo de eventos. Se trata de modos de transporte de alta capacidad, rápidos, confiables y seguros en los casos en los que las sedes tienen acceso al mismo en las inmediaciones. En los casos en los que no sea así, será necesario complementar estos modos de transporte con un sistema de autobuses que alimente a la red de Metro o la red de Cercanías desde las ciudades.

6.2.2 Autobuses

Se intentarán respetar los horarios de los servicios habituales para interferir lo menos posible en la rutina de la población que residen en la ciudad o ciudades donde se están celebrando las competencias.

La flexibilidad que otorga el autobús, en cuanto a número de vehículos y creación de rutas nuevas debe aprovecharse para la implantación de un sistema de lanzaderas en los casos en los que la red de Metro no llegue a todas las sedes de competencia, y autobuses alimentadores a la red de transporte de Metro.

6.2.3 Bicicletas

En el caso de las bicicletas, su uso va a depender de muchos factores.

El factor principal será la existencia de una infraestructura ciclista amplia y segura junto con una cultura del usos de la bicicleta. También pueden tener incidencia las fechas de celebración de la competición y la climatología asociada a las mismas. Aunque la mayoría de las veces suelen celebrarse en época estival, esto no siempre es así. También pueden influir la orografía de la ciudad donde tenga lugar la competición, la existencia de un servicio de bicicleta pública o la existencia de empresas de alquiler de bicicletas. En cualquier caso, se deberán reservar espacios en las zonas próximas a las sedes para aparcar las mismas, y carriles reservados para bicicletas en el viario urbano.

6.2.4 Vehículo privado y carriles reservados

El vehículo privado debe reservarse para los tipos de usuarios en los que este tipo de transporte es necesario. Se asume que las autoridades accederán , en la mayoría de los casos, en vehículos oficiales con fuertes medidas de seguridad. Por ello, es necesario que el aparcamiento en las sedes de competencia y entrenamiento este fuertemente limitado, incluso prohibido, para el público general y los trabajadores.

Además, resulta especialmente importante no colapsar la ciudad por un aumento de tráfico en las inmediaciones ya que esta congestión compromete la llegada y circulación de los autobuses que llevan a los deportistas, personal técnico, y a todo el personal de trabajo necesario para el desarrollo de la competición.

Se puede plantear la reserva provisional de carriles específicos para transporte público, para el acceso de deportistas o para vehículos de autoridades.

6.2.5. Accesos peatonales y última milla

En el diseño de las sedes de competencia, se deben recoger un determinado número de espacios para los asistentes previstos considerando el aforo de cada una dichas sedes. Así cada una de las sedes debe contemplar zonas de:

- Drop on-drop off: zonas de embarque y desembarque de autobuses y taxis
- Bolsa de taxis: que permitan asegurar una oferta adecuada de este servicio cuando finalice la competición.
- Front of house: zonas libres en el entorno del estadio para la libre circulación de personas. En ella se suele instalar las fans zone, food trucks o zonas con espacios publicitarios con sponsors de la competición.
- Back of house: zonas en la parte trasera del estadio para prensa, broadcasting, salas VIP, otros.

Además, se deben diseñar itinerarios peatonales desde las estaciones próximas y zonas de drop on-drop off hasta el recinto de la sede de competencia. Estos itinerarios deben ser seguros para el peatón y con la señalética especifica de la competición.

Desde el punto de vista de la seguridad, también es importante guiar a los asistentes hasta el perímetro y zona de front of house.

Se deben crear mapas de última milla, que pueden ser descargados y consultados por los espectadores. En las áreas de drop off y drop on conviene que haya voluntarios repartiendo estos mapas que faciliten el conocimiento del entorno, o desde las estaciones de Metro y Cercanías más próximas.

6.2.6 Sistemas Park&Ride

En la medida de lo posible, y con la finalidad de limitar el uso del vehículo privado en las inmediaciones de las sedes de competencia y entrenamiento, otra de las medidas a implantar es la implantación de sistemas Park&Ride en puntos estratégicos de la ciudad o en las proximidades de las estaciones de la red de Metro.

6.2.7 Sistema de tarifas. Billete único

Como se ha comentado anteriormente, en este tipo de eventos es habitual que el billete de transporte público se facilite con la entrada al evento y que tenga validez variable, normalmente cubriendo desde un día antes del evento hasta el mismo día en el que se tenga entrada. Esto favorece que los asistentes, desde el momento en el que llegan a la ciudad a las estaciones de tren o aeropuerto, usen el transporte público.

6.3 Información al usuario

Es necesario crear un plan de comunicación sobre la movilidad para dar a conocer las posibilidades del sistema a los visitantes y que dar a conocer a los residentes las modificaciones implantadas con motivo de la celebración del evento deportivo.

El plan debe incluir una página web que centralice toda la información señalada anteriormente.

También puede contemplarse el despliegue de voluntarios en puntos clave (aeropuerto, estaciones, proximidades del estadio) con dispositivos móviles para que puedan dar respuesta a las consultas de transporte realizadas por los usuarios.

El plan de comunicación debe tratar de informar a los usuarios de la importancia de iniciar el viaje con tiempo, para poder disfrutar de las actividades que se ofrecerán en los alrededores del estadio (música, deportes, actividades culturales, etc.). Esto permitirá una mejor gestión de la demanda en momentos clave antes del inicio de los partidos, evitando el colapso del sistema de transporte.

6.3.1 Llegadas y salidas al país

Los grandes eventos deportivos atraen participantes, periodistas y espectadores de todo el planeta. Un aspecto a analizar es la capacidad de los infraestructuras de transporte de entrada al país anfitrión, en especial los aeropuertos y su conexión con las ciudades.

En grandes ciudades con aeropuerto internacionales importantes o en países con una fuerte oferta turística, como España, Italia o Francia, la capacidad de acogida de los aeropuertos no suele ser un problema. Además, en Europa, la proximidad entre países permite diversificar los modos de entrada al posible país anfitrión.

En otros casos puede ser necesario analizar la capacidad de estas infraestructuras y, sobre todo, reforzar la oferta de transporte entre las terminales aéreas y las ciudades destino de los visitantes.

7. LEGADO Y BUENAS PRÁCTICAS

7.1 Legado

A la hora de elegir una ciudad anfitriona para un gran evento deportivo, una de los condicionantes es, entre otras, el legado que le puede traer la celebración de la competición a la ciudad. En algunos casos, la utilización posterior de la infraestructura deportiva es importante, pero resulta igual de importante dotar a la ciudad de una buena experiencia en el sistema de transporte y aprovechar el desarrollo de la competición para implementar medidas que hagan que una vez la competición finalice, siga siendo el modo elegido por la población residente, en caso de que no lo sea antes de la competición.

Por ello, es importante dotar al sistema de transporte de un aporte presupuestario suficiente que permita el desarrollo de la competición de forma segura y exitosa como hemos mencionado anteriormente, y que permita desarrollar medidas que, si bien son necesarias para la ciudad, la celebración de la competición en la misma las acelera.

7.2 Medidas temporales limitadas

Por el contrario, deberá limitarse el número de medidas que sean necesarias para el desarrollo de la competición, pero no encajen con la configuración de ciudad y no sean necesarias una vez finalizada la misma, con el objetivo de lo incurrir en un coste que posteriormente no tendrá un legado definido.

EXPLORING THE SPATIO-TEMPORAL DYNAMICS OF MOPED-STYLE SCOOTER SHARING SERVICES IN URBAN AREAS.

RESUMEN

Spain is one of the countries with the highest shared mobility fleet in the world. The shared use of motorcycles, also known as moped-style scooter sharing, has spread far and wide throughout the country at a dramatic pace in recent years. Despite its increasing popularity and impact on urban mobility, efforts devoted to the study of its spatio-temporal travel patterns are still scant.

Based on the analysis of GPS records of an operator present in seven Spanish cities, this study aims to contribute to this research gap by analysing mopeds' location patterns over time and assessing how different dynamics influence its usage level and self-balance potential. Our study is replicable to different cities and different shared modes, since we propose a methodology to identify the most important origins and destinations over time and analyse the system's self-balance capacity based on spatial autocorrelation tools. These insights are useful for operators to adjust and optimise vehicle distribution routes and maintenance/recharge tasks, decreasing congestion and increasing efficiency. The results may also be helpful for policy makers when planning and offering effective policies and infrastructure to encourage shared mobility.

1. INTRODUCTION

In recent years, shared mobility has grown in many cities around the world. It has been defined as the short-term access to shared vehicles (cars, bicycles, moped-style scooters, and scooters), according to the user's needs and convenience, instead of requiring vehicle ownership (Shaheen et al., 2016). More specifically, the term micromobility was coined to refer to low-speed shared vehicles like bicycles and scooters (moped and kick-style) that have recently drawn more attention (Shaheen & Cohen, 2019). Micromobility offers a flexible transport option capable of avoiding road congestion, reducing the required parking space, lowering noise/air pollution, since all vehicles are hybrid-electric/electric, and last but not least, encouraging intermodality with mass transit. Additionally, mopeds particularly provide faster speeds than bicycles, and this is a very attractive mode for non-flat cities (Aguilera-García et al., 2020).

Studies regarding micromobility essentially focus on docked and dockless bike-sharing systems (for example, Gu et al., 2019; Ji et al., 2020; Lazarus et al., 2020), comparing bike-sharing to scooter-sharing services (McKenzie, 2019) or analysing scooter-sharing travel patterns (Feng et al., 2020; McKenzie, 2020), but there is almost nothing to be found related to moped-style scooter sharing particularly. Most contributions regarding mopeds are related to accidents and safety issues (Aare & von Holst, 2003; R. A. Blackman & Haworth, 2013; Haworth, 2012; Huang & Wong, 2015) or riders' attributes, but they only consider those *who own* a motorcycle (R. Blackman & Haworth, 2010; Jamson & Chorlton, 2009; Rose & Delbosc, 2016; Yannis et al., 2007). As a clean alternative to the car and as a growing shared mobility sector, we consider this effort to be worthwhile. The few studies that exist on shared mopeds focus on user characteristics and preferences (Degele et al.,2018; Aguilera-García et al., 2020).

Our study will focus not on users, but rather of their trips. Our objective is to analyse and visualise mopeds' urban footprint and compare its spatio-temporal dynamics in different cities. The research aims to fill a knowledge gap related to the spatio-temporal patterns of shared mopeds. It proposes an original methodology that uses spatial autocorrelation tools to analyse travel patterns and visualise spatio-temporal behaviour over time, identifying the spots where most trips begin or attend, and assessing to which extent the system is self-balanced, obtaining insights from different dynamics. We based our analysis on a dataset provided by an operator present all throughout Spain called Muving.

These kinds of data-sharing initiatives have grown increasingly popular in recent times and will continue to do so, especially with the institutional support that they are attracting; an example of this is the recent proposal to build the European Common Mobility Data Space (European Commission, 2020) as a strategy to enable data availability, access, and exchange between different stakeholders.

Our findings are useful for authorities to understand the mobility patterns of this important sector, plan and offer strategies or public policy, design infrastructure to promote their use, and regulate accordingly.

They are also important for shared mobility operators, adding value to raw datasets and using insights to improve everyday operational tasks (maintenance, recharging, and distribution of vehicles). The rest of the article is divided into four sections. Following the introduction, Section 2 summarises the related literature. Section 3 describes the study context, data, and methods used for the research. Results are presented in Section 4, and lastly, the main conclusions are outlined in Section 5.

2. RELATED LITERATURE

Urban mobility technologies have undergone substantial and increasingly rapid change over the past two decades, especially in relation to shared mobility services (Pangbourne et al., 2020; Shaheen & Cohen, 2018). The rapid development of social media, Information and Communication Technologies (ICT), and new business models based on the sharing economy have enabled these new services to appear in many cities, changing the transport supply and causing an important impact on travel behaviour. The European Commission has highlighted the importance of multimodality and new shared mobility solutions that take advantages from each mode and are proving crucial to improve the transport system's resilience (especially during the COVID-19 pandemic) (European Commission, 2020).

Some even consider shared mobility development as one of the three revolutions in urban transportation, along with vehicle electrification and automation (Fulton, 2018).

Shared mobility and micromobility are still relatively recent topics because the technology that allowed them to arise in many cities only occurred about a decade ago. Nevertheless, many studies related to bike-sharing (Eren & Uz, 2019; Ricci, 2015) have been published.

This was not the case for the scooter sharing sector (kick or moped-style), which is understandable, since it mostly started running operations only a few years back (in the case of Spanish cities, around 2017). Given the recent nature of their worldwide expansion, to our knowledge, only two studies have been found regarding moped-style scooter sharing. With the data provided by a German operator, Degele et al.,(2018) developed a cluster analysis to segment users according to their age, time between rides, distance driven, and revenue per customer.

They identified four types of moped users (power users, generation-X casual users, generation-Y casual users, and one-time users), analysed which type provided the most revenue, and proposed strategies to retain and promote their usage.

On the other hand, (Aguilera-García et al., 2020) conducted a generalised ordered logit model to identify the key drivers determining the adoption and frequency of use of mopeds in Spanish urban areas. They found that both personal socioeconomic characteristics and trip-related attributes played a major role in explaining the adoption of scooter-sharing services. Young and highly-educated people proved to be the segment of the population with the highest probability of using mopeds, but they also found a considerable amount of people in middle-aged groups.

None of the previously mentioned studies examined the spatial distribution patterns of moped trips. However, bikeshare-related studies can offer some lessons on travel behaviour associated with these systems. Temporal usage patterns show a morning and an evening peak, especially for commuting (Wang et al., 2018). Spatial analyses show that bikes are commonly taken from residential areas to travel to commercial zones, central business districts (CBDs), employment centres, and train stations in the morning, and back to residential areas during evenings (Caspi et al., 2020). In addition, it has been found that the temporal and spatial concentrations of dockless bikes are mainly influenced by the built environment, particularly density and street connectivity (Xu et al., 2019), and that most riders cycle short distances in urban centres (Li et al., 2018). Bicycle travel times are especially competitive compared to other transport modes for short trips in the city centre during peak periods (Romanillos & Gutiérrez, 2019). Most of these papers used GPS datasets collected by operators.

Studies regarding micromobility and the analysis of spatial patterns using spatial autocorrelation tools are particularly scarce. An exception is the study on shared e-scooters by Jiao & Bai (2020) which uses univariate LISA to identify areas of high demand (hot spots) as a preliminary step before applying regression models. We elaborate on this research line and use the most common spatial autocorrelation tools to explore micromobility trips, making use of univariate and bivariate Global Moran's I and LISA statistics and including the temporal component (time bands) in order to capture the dynamics of the system. Univariate analysis allows us to answer the questions of when and where demand is more clustered, and bivariate analysis allows us to answer the question of when and where demand is more self-balanced. Both issues (demand concentration and self-balance potential) are key elements for good management and planning of micromobility services.

3. STUDY CONTEXT, DATA, AND METHODOLOGY

3.1 Study context

Spanish city centres are generally characterised by old historic urban structures, with narrow streets and recurrent congestion problems, which could positively influence the use of shared mopeds. Whatever the reason, the country is one of the hubs with the highest shared moped fleet in Europe, resulting in approximately 9,000 motorcycles (Aguilera-

García et al., 2020; Howe, 2018). This research was conducted with a dataset provided by one of the most important operators present in seven Spanish cities in 2019: Madrid, Valencia, Seville, Saragossa, Malaga, Cordova, and Cadiz. Table 1 summarises some of their relevant characteristics for the study. As can be seen, Madrid and Valencia are the most important cities in terms of population; however Saragossa, Seville, and Cadiz also show high density (Inh/km^2) which is an important factor influencing the adoption of shared services (Munkácsy, 2017; Velázquez Romera, 2019).

Three of them are coastal cities, which usually have higher tourist activities promoting the use of mopeds. Warmer cities are mostly within the Andalusia Region in the south of Spain (Seville, Malaga, and Cadiz). Annual precipitation level is low in the seven cities analysed, which is also important to consider, as rainfall may reduce the use of micromobility in general.

Attribute		Madrid	Valencia	Seville	Saragossa	Malaga	Cordova	Cadiz
Population (municipality)		3,174,000	791,413	688,711	666,880	571,026	325,701	116,027
Average annual temperature (ºC)		15.0	18.3	19.2	15.5	18.5	18.2	18.6
Average annual precipitation (mm)		421	475	539	322	534	605	523
Coastal city		No	Yes	No	No	Yes	No	Yes
Modal split (%)	Public transport	24	21.8	26.2	24	13.2	12.04	7
	Car	39	21.5	35	28	37	44.15	48
	Active**	37	56.7	38.8	48	49.8	43.81	45
Moped-style scooter-sharing operators	Number of operators	4	3	2	2	1	1	1
	Name of companies	Acciona, Movo, Ecooltra, Muving	Acciona, Ecooltra, Muving	Acciona, Muving	Acciona, Muving	Muving	Muving	Muving
Topography		Hilly	Flat	Flat	Flat	Flat	Flat	Flat

Table 1 -Summarised characteristics of the seven cities analysed. Source: the authors with data from Greenpeace, (2019). *updated with results from the last Mobility Survey in 2018 (Comunidad de Madrid, 2018). ** Active = walk + bicycle + other low-speed mode. Data for Cordova and Cadiz was extracted from official reports (ETRALUX, 2011; Junta de Andalucía, 2018).

Only Valencia and Madrid have three or more moped-style scooter sharing operators. In the case of Madrid alone, some studies point to its role as one of the most important shared mobility labs in Europe, with an estimated fleet of more than 20 thousand vehicles (Arias-Molinares & García-Palomares, 2020a; Granda & Sobrino, 2019). These operators usually manage and maintain a fleet offered through an application where individuals access and subscribe to their service. Users pay a fee every time they use a vehicle, while operators are in charge of energy consumption and maintenance. In Spain, electric vehicles do not have parking restrictions in city centres and generally benefit from free on-street parking, providing an attractive alternative for inner districts (for example, in the case of Madrid, within the M-30 highway) (Aguilera-García et al., 2020).

3.2 Data

The dataset for the study contains data collected by the GPS devices installed on mopeds owned by Muving. The data was provided in CVS format, including all trips made between 13 February 2019 and 31 December 2019, and the following information:

- *Id_vehicle:* an identification number for each motorcycle.
- *Id_customer:* an identification number for each user.
- *Start_time:* trip starting timestamp (format: yy-mm-dd hh:mm:ss).
- *Start_latitude and longitude:* xy coordinates where the motorcycle was picked up.
- *End_time:* trip ending timestamp (format: yy-mm-dd hh:mm:ss)
- *End_latitude and longitude:* xy coordinates where the motorcycle was left.
- *Trip time:* trip duration in minutes.
- *Travelled distance:* travelled distance in km of the real trajectory by the street network.

3.3 Methodology

The data workflow covered entering, cleaning, transforming, describing, analysing, and visualising data. Given the size of the dataset (almost two million entries), we processed it using Python (vs 3.8) programming language. A script performing all steps was created: to load the CSV files, extract the day and hour of the trip in the timestamp information, and obtain a new output table. This output table was then imported to a GIS environment (ArcGIS Pro vs. 2.5.2) to display coordinates, geolocate points, and create a new column with the city name. An outlier cleaning process followed, using travelled distances, which in some cases went unrealistically higher than average. In order to discard these outliers, boxplots were made for each city and the final valid dataset included 1,797,2228 trips (see Table 2).

City	Trips with outliers	Distance (km) from which outliers were identified (boxplot)	Trips without outliers
Madrid	307,876	9.3	298,031
Valencia	437,795	8.1	425,683
Seville	477,424	8.4	463,825
Saragossa	201,294	8.6	195,942
Malaga	135,626	9.8	131,940
Cordova	126,061	6.4	121,034
Cadiz	163,616	6.7	160,773
Total	**1,849,692**		**1,797,228**

Table 2 -Dataset without outliers. Source: the authors.

Since time and distance travelled were provided, we calculated average speed, as well as some other indicators, like average usage (trips/customers) and average vehicle rotation per day (trips/vehicles/365days per year). Consequently, a model builder was created in ArcGIS to split the dataset by city, day of the week, and time band. We decided to aggregate the days of the week into two groups: working days (from Monday through Thursday) and weekends (Saturday and Sunday).

We excluded Friday from working days because in Spain, as described by Romanillos (2018), it is common to finish work earlier on Fridays, with particular travel patterns that could influence the normal working-day dynamic.

Regarding time bands, we selected four different hour periods: from 07 to 10 to evaluate the morning peak, especially for obligatory trips (commuting to work/study), 13 to 16 to analyse midday behaviour (lunchtime or midday activities), then 19 to 22 for after-work activities and/or return-to-home trips, and finally, from 23 to 02 hours to evaluate nightlife patterns. After splitting the dataset by time bands, the different layers according to each scenario (city, day of the week, and time band) were spatially aggregated into a hexagonal grid, obtaining the number of starting/ending trips by hexagon. Studies focusing specifically on walking distances to pick up shared mopeds were not found, but (Aguilera-García et al., 2020) found that users were willing to walk up to 500m. Hence, we determined 200 meter-sided hexagons with a surface area of 10,3923048 Has as the optimal size to aggregate our data, since 200m appears to be an acceptable walking distance to pick up a motorcycle.

Lastly, the hexagonal grids were used to perform location patterns analysis using ESDA tools. To this end, we used GeoDa software (vs 1.16.0.16) to calculate two different Global Moran's Indices (Anselin, 1995). The first one was univariate Global Moran's I statistics for origins and destinations separately. This helped us to study the level of concentration or dispersion of the origins and destinations of moped trips, and their variation over the course of the day. This insight could be of interest to inform operators as to the most optimal time and location to carry out operational tasks, like vehicle redistribution, recharging, and maintenance, and to know when/where demand is coming from. In addition, bivariate Global Moran's

I was calculated to measure the spatial association between the destinations and origins of trips. Insights from this statistic served to analyse whether the system is self-balanced throughout the day by answering the question: "*are users ending their trips near where others are starting theirs?*" If the system is balancing itself, then the locations where users are arriving at a certain time are also the locations where other users are starting their trips, allowing for higher vehicle rotation. Both univariate and bivariate Global Moran's I statistics were calculated using a contiguity weight matrix of 1st order. The resulting univariate and bivariate Global Moran Indices and their z-score were graphed, and symbology was applied to the hexagonal grids, generating maps by time bands.

Figure 1 illustrates the conceptual framework of the different Global Moran's Indices calculated, in relation to expected origin-destination location patterns. Our hypothesis predicts that origins are more dispersed than destinations in the early morning band (predominance of trips from residential areas to the city centre), while the opposite should occur in the last bands of the day (predominance of return-to-home trips).

It also expected that the system will tend to balance itself during the middle bands, since, at those hours, the population tends to be concentrated in the city centre, which produces a greater proximity between origins and destinations.

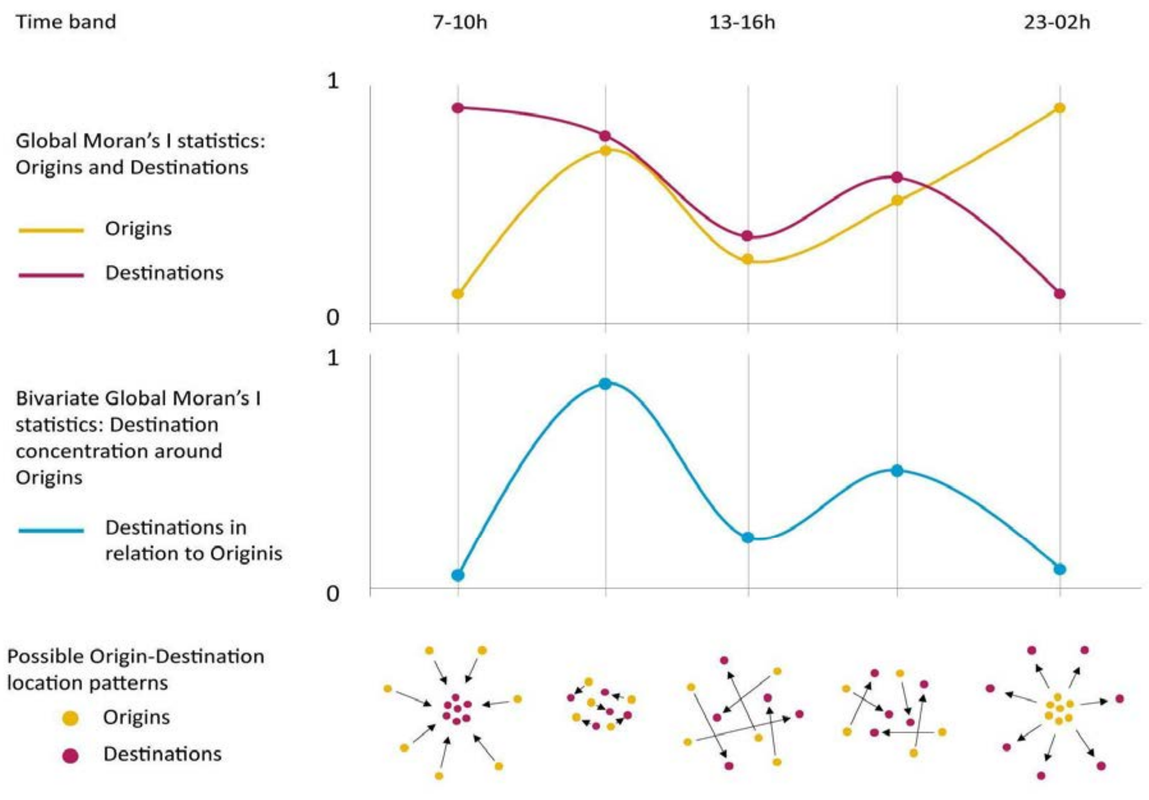

Fig 1- Conceptual framework of the different Global Moran's Indices calculated. Source: the authors.

In addition, univariate Anselin Local Moran's I (LISA statistic) was used in order to identify and map local tendencies (clusters and outliers) related to the location of origins and destinations by time bands. With LISA statistics, it is possible to distinguish High-High clusters (a high value surrounded primarily by high values), Low-Low clusters (a low value surrounded primarily by low values), and spatial outliers, either High-Low (high values surrounded primarily by low values) or Low-High (low values surrounded primarily by high values) (Anselin, 1995). Lastly, bivariate LISA cluster maps for origins and destinations, by time bands, and on working days, were graphed in order to identify areas with a high concentration of both origins and destinations (HH clusters) in which the system self-balances, or other areas with imbalances between origins and destinations (HL and LH outliers).

4. RESULTS

4.1 Service characteristics and performance

Table 3 shows the descriptive characteristics of the dataset analysed. Seville and Valencia generated the greatest number of trips during 2019, with 463,825 and 425,683 trips respectively, while Madrid, the most populated city, generated 298,031.

In relation to this fact, it is important to consider that large metropolitan areas usually have more operators, so competition is a crucial factor that determines their market share. In addition, Madrid is one of the cities with the highest shared mobility fleet, not only of mopeds, but also of other modes like bicycles, cars, kick-scooters, etc.

This context could also explain why, although Madrid has more deployed vehicles, Valencia and Seville show a higher number of trips and more trips per customer throughout the year, with 13.87 and 12.92 respectively, in comparison with Madrid, with 9.33 trips per customer. The average vehicle rotation per day results in 2.04. Cities above this average, like Cadiz, Saragossa, Seville, and Valencia, are more attractive for companies (as the system is more profitable) than, for instance, Madrid, which bears the minimum value with just 1.08 vehicle rotations per day.

City	Trips	Vehicles	Customers	**Usage** (trips by customers)	**Veh. rotation/day** (trips/vehicles/365 days)	**Average trip time** (min)	**Average trip distance** (km)	**Average Speed** (km/hr)
Madrid	298,031	755	31,934	9.33	1.08	11.48	3.49	18.24
Valencia	425,683	578	30,692	13.87	2.02	10.28	3.18	18.56
Seville	463,825	591	35,902	12.92	2.15	10.40	3.23	18.63
Saragossa	195,942	240	15,313	12.80	2.24	10.53	3.42	19.49
Malaga	131,940	196	12,613	10.46	1.84	10.86	3.68	20.33
Cordova	121,034	184	9,715	12.46	1.80	9.06	2.67	17.68
Cadiz	160,773	186	10,755	14.95	2.37	9.05	2.73	18.1
Total	**1,797,228**	**2,414** (316 vehicles duplicated in different cities)	**129,384** (17,540 users duplicated in different cities)	**13.89**	**2.04**	**10.24**	**3.20**	**18.72**

Table 3 -Descriptive characteristics of the dataset analysed. Source: the authors.

Average trip time, distance, and speed prove relatively homogenous across the different cities, with a trip time of around 10 minutes, a 3 km distance, and an 18km/hr speed. The city with the highest trip time is Madrid (11.48 minutes), which could be expected since it is the capital of Spain and is a more congested urban area.

However, this 12-minute ride is still relatively fast compared to other services, such as bike-sharing, which displays trip times of 15 minutes or more (Romanillos, 2018). In any case, travel time and distance may be highly influenced by the size of the company’s service area. Certainly, future expansions of these areas could allow users to travel longer distances. Regarding distances travelled, mopeds are mostly used for short urban trips between 1 and 3 km (see Figure 2). Madrid, Valencia and Seville, which are large metropolitan areas, display a considerable number of trips with longer distances.

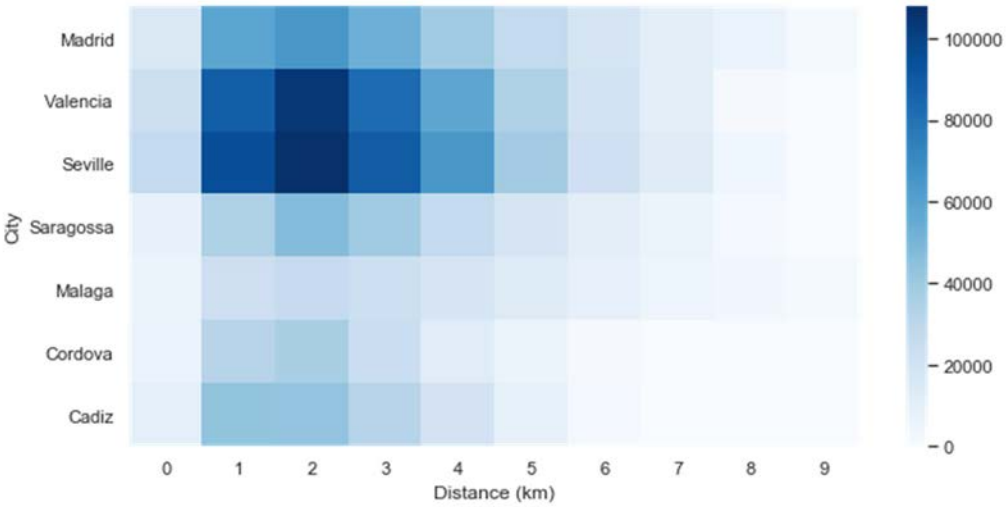

Fig 2 - Number of trips by distance travelled and city. Source: the authors.

In addition to this comparative analysis between cities, when it comes to general fleet and customers, we found that 2,414 mopeds were operating in Spain during 2019 and almost 130,000 clients used one (of which 17,540 made trips in more than one city). The fact that some customers use the app in different cities could demonstrate their intention to use this kind of platform when travelling to different areas, which is an important insight, especially with the introduction of new concepts like Mobility as a Service (MaaS) (Arias-Molinares & García-Palomares, 2020b; Jittrapirom et al., 2017).

4.2 Temporal patterns

When analysing average daily trips by month, we identify a general trend for Spanish cities, with high peaks in March, May and October, and valleys in April and August (see Figure 3). Peaks are related to the beginning of spring season, when the temperatures rise and shared mobility becomes more attractive. High trip counts in September and October correspond to the return from summer holidays when users begin their daily routines again.

The valley seasons (April and August) concentrate most holidays (especially the summer season), when most Spaniards travel for holiday; this is very notorious in the case of Madrid, where the trip count drops considerably. Cities that follow a different trend are, for example Seville, which shows a high peak in April. This is probably due to the increase in tourist and local activity during the Holy Week and Seville’s Fair.

Other cities that follow different patterns are Malaga and Cadiz, which display high number in August, possibly related to the fact that these cities are summer tourist destinations. In these latter cities, trip counts are homogenous throughout the year, increasing notoriously only during the summer season, from which we might infer that many of the moped users during those months are tourists.

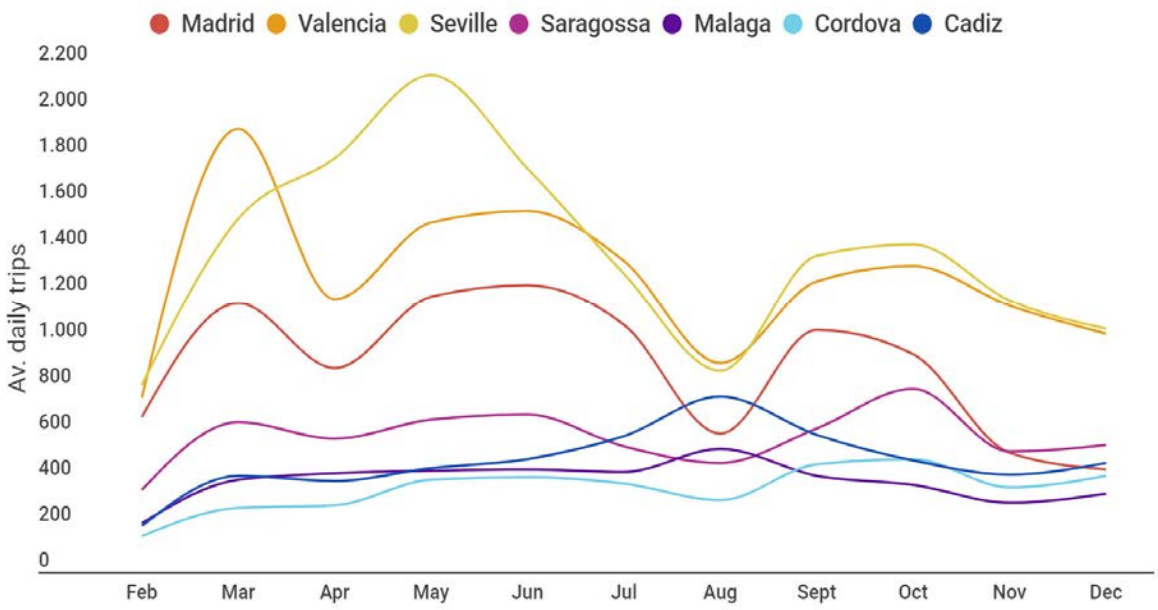

Fig 3 - Average daily trips by month (2019). Source: the authors.

When aggregating data by day of the week, Table 4 shows that in general, 72% of the trips are made on working days and 28% over weekends. These results lead us to infer that mopeds are not only used for recreational trips, but also for other purposes, like commuting or running errands. Figure 4 shows that the distribution of trips is quite homogeneous throughout the week in greater detail.

City	Working days (M-T)	Friday	Weekends (S +D)	Total
Madrid	169,425	45,773	82,833	298,031
Valencia	240,681	62,587	122,415	425,683
Seville	262,801	71,843	129,181	463,825
Saragossa	107,846	29,684	58,412	195,942
Malaga	73,771	20,030	38,139	131,940
Cordova	67,629	18,869	34,536	121,034
Cadiz	90,363	24,037	46,373	160,773
Total	**1,012,516**	**272,823**	**511,889**	**1,797,228**

Table 4 -Trips by day of the week. Source: the authors.

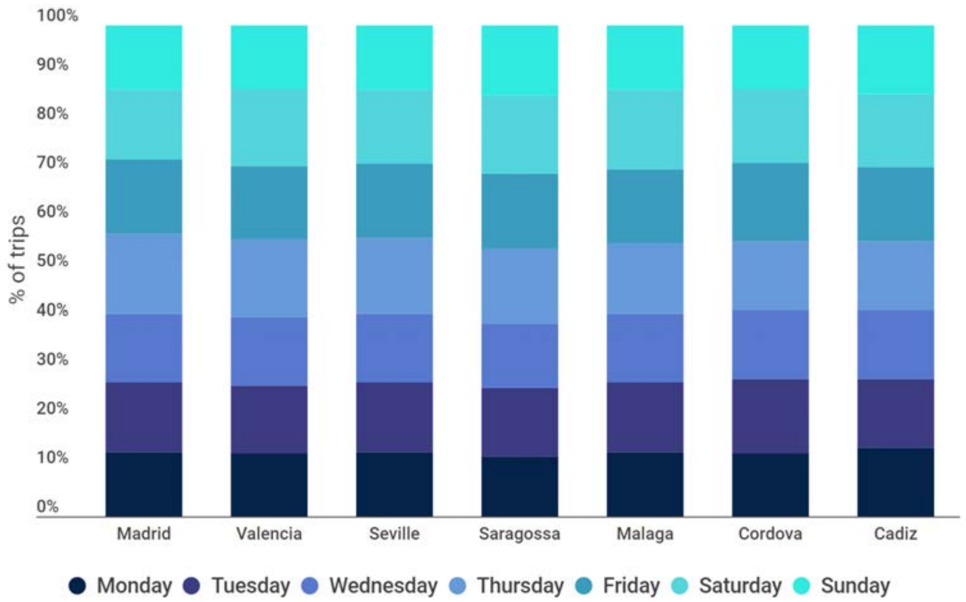

Fig 4 -Percentage of trips by day of the week. Source: the authors.

When exploring hourly patterns, Figure 5 shows the average daily trips on working days and weekends. Relatively homogeneous temporal behaviour is revealed with trips increasing toward the afternoon. We noticed three different peaks: the smallest one from 8 to 9 for commuting, a medium one from 13 to 14 related to midday activities (i.e., lunchtime), and the greatest one from 18 to 20 related to after-work activities and/or returning home. On the other hand, over weekends, the early morning rush hour disappears, and the midday peak (13-14 hrs) becomes as great as the night-time period (19-20 hrs), since many people start doing their activities from late morning onward. And lastly, over weekends, a significant percentage of trips is observed in the early hours (dawn), when customers use mopeds to return home from their night-life activities, given that the subways or public transport options are more limited. Given the lower usage over the weekend and the greater diversity in purpose, the spatial analysis was performed only for working days.

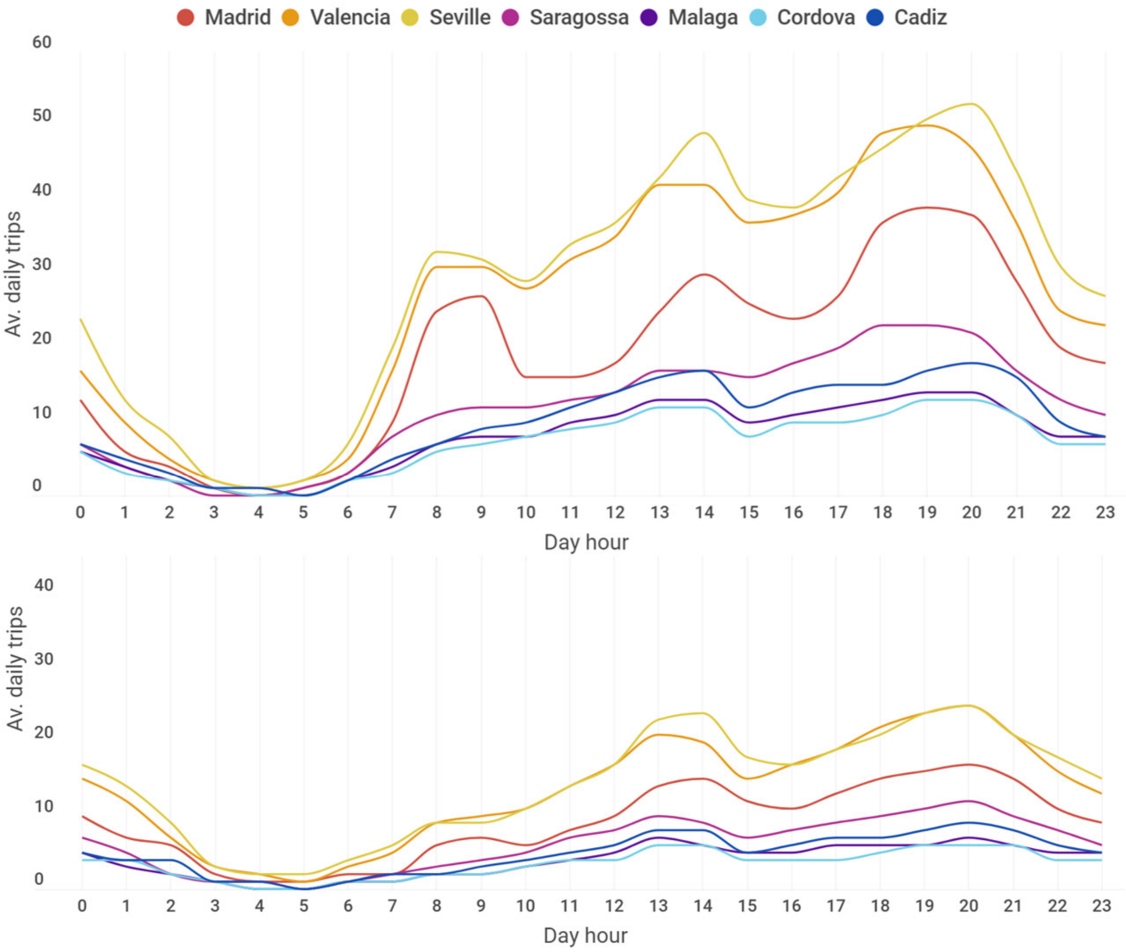

Fig 5- Average daily trips by hour of the day (top: working days, bottom: weekends). Source: the authors.

4.3 Mapping origins and destinations of trips over time

Visualisation of the spatial distribution of trip origins and destinations over the course of a working day is shown in Figure 6. In general terms, it reveals that, in the first band (07-10), origins are more dispersed than destinations, while in the last time band (23-02), the opposite occurs. This pattern follows the hypothesis outlined in the initial conceptual framework, as morning users usually come from different residential zones and commute to (mostly) specific clustered workplaces. In the late hours, users do the opposite, coming from clustered after-work locations and returning to those dispersed residences. In some cases, these residential areas may match, meaning that late-night users are leaving mopeds at the same or near the same areas where morning users will take them, which will make the system self-balanced. However, in most cases, the ending spots do not match the starting ones, which requires vehicle redistribution by the operator to cover demand areas in mornings.

On the other hand, band 2 (13-16) and 3 (19-22) have more similar dynamics since origins and destinations are homogeneously distributed, with a slight difference in band 3 when destinations appear to be a bit more concentrated. In these two bands, trips are coming and arriving at similar areas, enabling a higher vehicle rotation. This time period of the day responds to midday-activities, like having lunch, running errands, and doing after-work activities, which usually take place at public facilities, restaurants, bars, gyms, and entertainment locations that are very spread throughout the city. This contributes to a less marked difference between origins and destinations. Hence, this is the period of time when the system's self-balance potential is most realized, in comparison with bands 1 and 4.

These results illustrate that the different spatio-temporal dynamics for shared mopeds in cities are closely related to their land-use distribution. For each city, we can identify the most important origins and destinations by time of the day, which informs operators where to allocate their resources at each time to cover a greater demand, and also for public authorities to know where to allocate infrastructure like parking facilities. The results obtained in the particular case of Cadiz, for this analysis and subsequent analyses, must be carefully interpreted, considering its particular location and shape: the city of Cadiz is located on a narrow slice of land surrounded by the sea. All results and maps are affected by this spatial singularity.

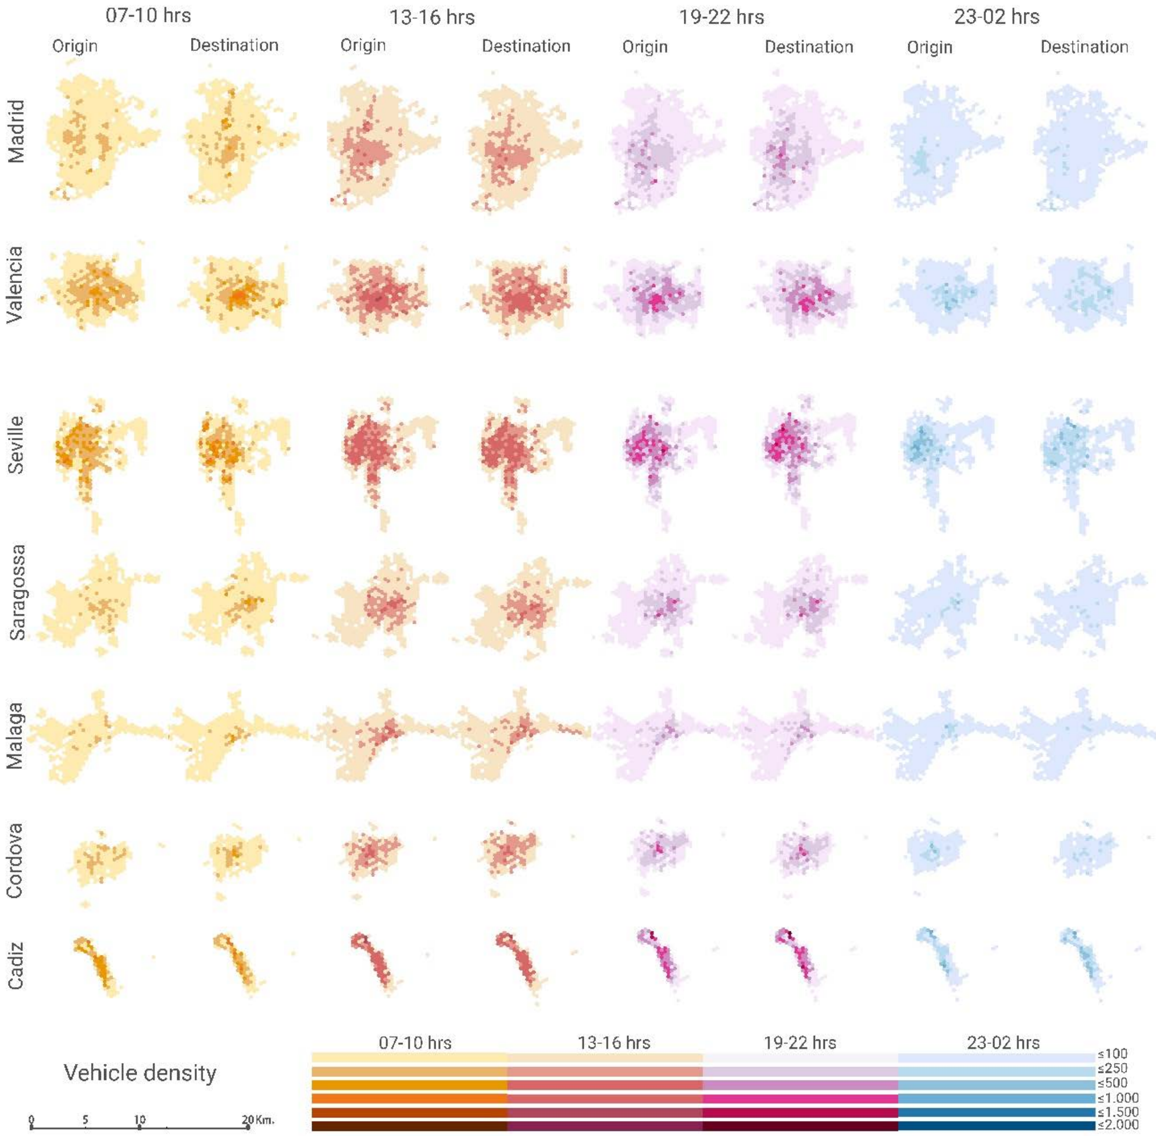

Fig 6- Spatio-temporal dynamics of mopeds during working days. Source: the authors.

4.4 Spatial autocorrelation analysis: local trends

As described in the methods section, in addition to map visualisations, we performed a series of spatial statistical analyses in order to further explore and quantify the trends previously identified. Firstly, Anselin Local Moran's I statistic was calculated in order to map the presence of origin and destination clusters at local level. The maps illustrated in Figure 7 show the marked differences between High-High clusters in bands 1 and 4, due to the location of residential zones and workplaces, especially in Valencia and Madrid, whereas HH clusters in bands 2 and 3 are located quite similarly. In all cases, there is a clear concentration of HH clusters in the city centre and LL on the periphery. Interestingly, the HH cluster maps of destinations in each time band are very similar to the HH cluster maps of origins in the following time band, which proves that the availability of vehicles near the users' location clearly influences increased usage.

Moreover, interesting results are obtained from observing spatial outliers, especially in the first band, which is mostly for commuting trips. In Madrid, for example, an HL spatial outlier for origins is located at Ciudad Universitaria, which is Madrid's main higher-education hub, meaning that from 07 to 10 AM, many trips begin on these university campuses.

Fig 7- Univariate LISA cluster maps for origins and destinations by time bands and working days. Source: the authors.

When considering Madrid as an example case to zoom closer, we differentiate certain dynamics throughout the day, especially during band 1 (see Figure 8). In the morning hours, demand mostly comes from districts that concentrate residential zones with a medium-high income population (Chamberi, Salamanca, and the east area of Tetuan) and mostly arrives at workplaces and offices located over the north-south axis of Paseo de la Castellana. The geolocation of demand is consistent with results obtained by Aguilera-García et al. (2020), which revealed that most moped users had relatively high incomes.

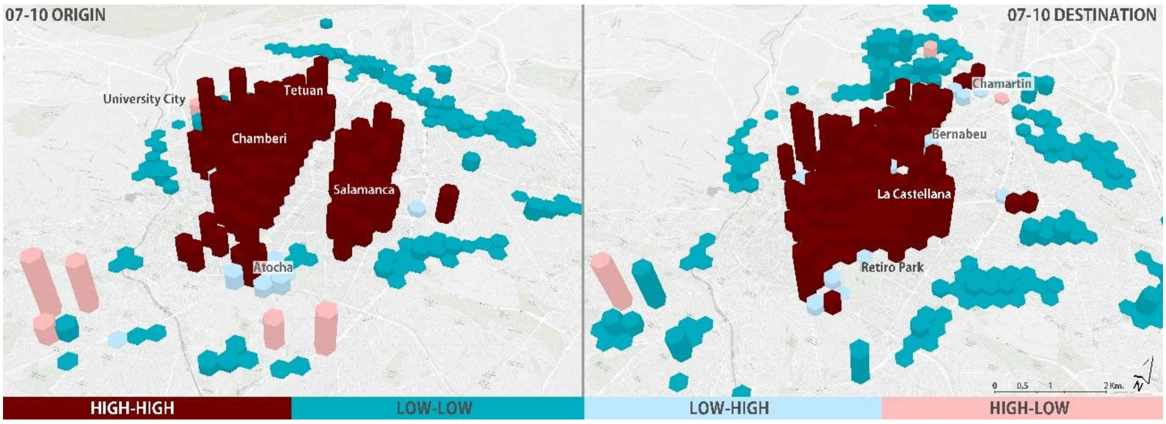

Fig 8-visualisation of Madrid's spatial clusters on band 1 during working days. Source: the authors.

Moreover, Bivariate Anselin Local Moran's I statistics for destinations around origins were calculated for every city and time band on working days. The results illustrated in Figure 9 show the same centre-periphery pattern for all case studies, with the exception of Cadiz, which seems to rather have a north-south pattern with HH clusters in the north area and LL clusters in the south. We observe that in time bands 2 and 3, HH clusters are more compacted around the city centres in comparison with bands 1 and 4.

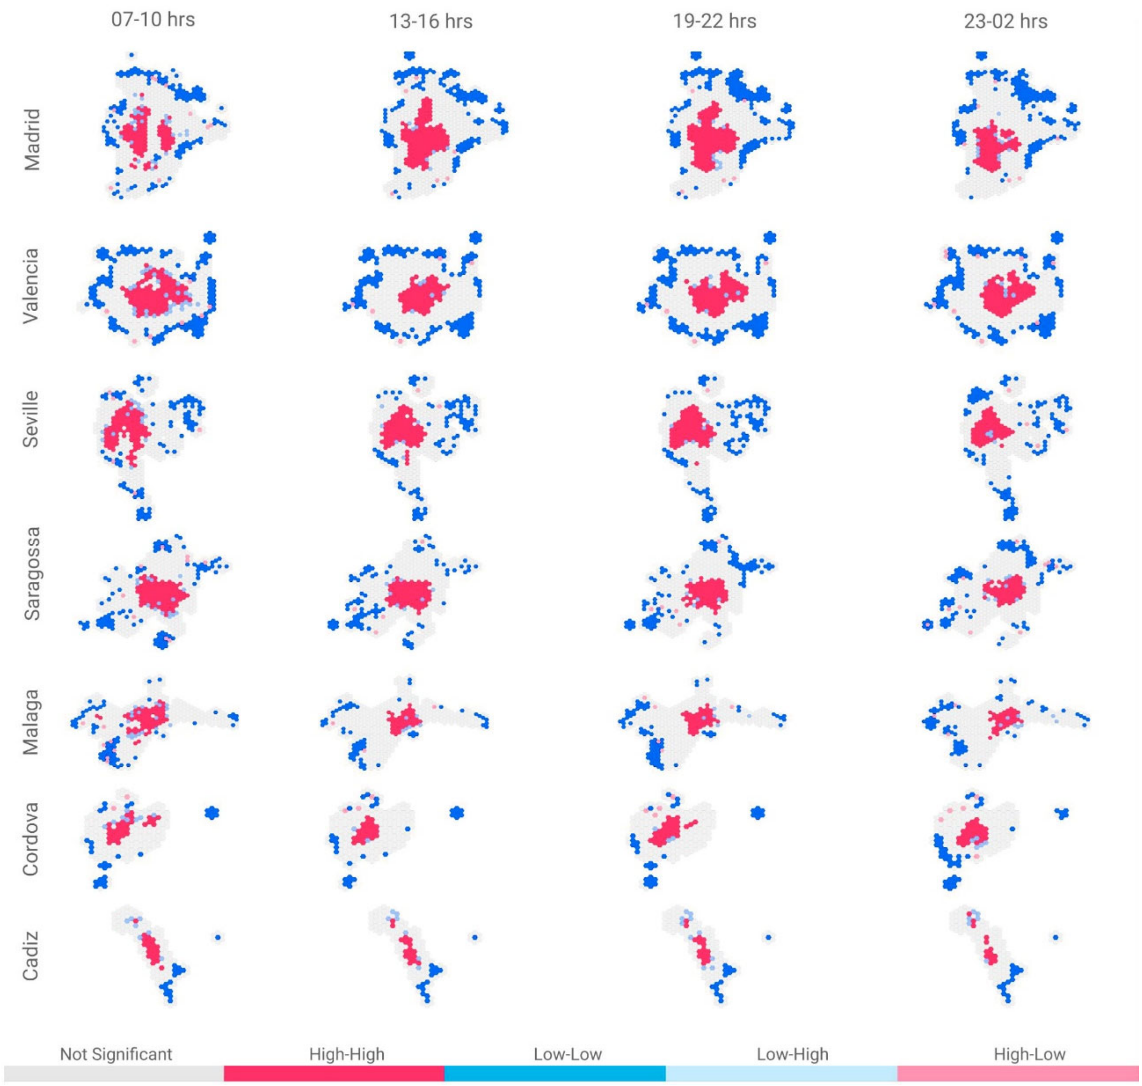

Fig 9- Bivariate LISA cluster maps for origins around destinations by time bands for working days. Source: the authors.

4.5 Spatial autocorrelation analysis: global trends

In order to better understand the system's spatio-temporal trends and assess its potential to be self-balanced, we graphed the calculated Global univariate and bivariate Moran's indices for each time band as seen in Figure 10. Most of the cities fall under the expected conceptual framework and their clustering degree is very similar in the central time bands (2 and 3), whereas origins are more clustered than destinations in late hours (band 4), and the opposite tends to occur in early hours (band 1). More interestingly, when observing the result from bivariate Global Moran's I statistics, the seven cities display the same dynamic: low values in early and late hours (07-10 and 23-02), since people are arriving at places where no trips are starting, and high values in midday and afternoon hours (13-16 and 19-22), since they are arriving at the same places where others are starting their trips. This dynamic makes the system less self-balanced during the first and last time bands, requiring moped redistribution, while band 2 and 3 are the hours when the system balances itself because mopeds are arriving where other users are starting their trips.

An exception, as we mentioned before, is Cadiz, which in general behaves as an outlier, most likely influenced by its particular urban structure, since its urban centre is located on a narrow peninsula, detached from peripheral residential areas.

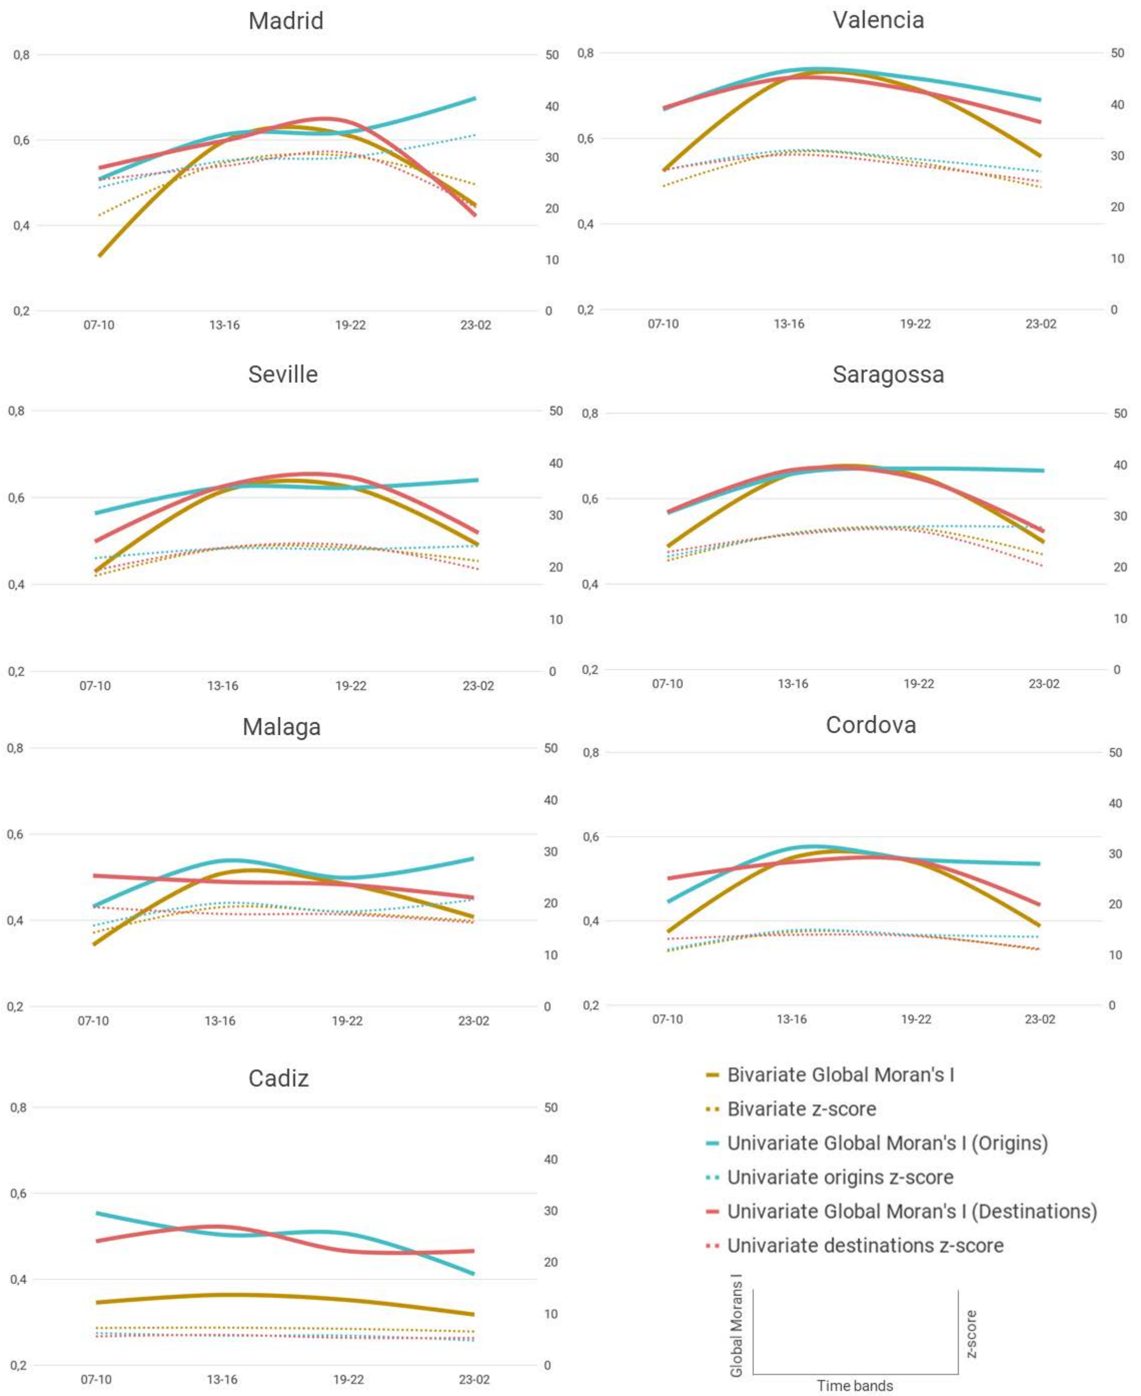

Fig 10- Global univariate and bivariate Moran Indices calculated for working days. Source: the authors.

The bivariate LISA results for working days also show how destinations in one time band are similar to origins in the following time band. When considering the results from the bivariate local Moran's I statistic between destinations and origins in all time bands, the highest numbers are found in the relationships of destinations with origins in the next time band (see Table 5).

	Origin (07-10 h)	Origin (13-16 h)	Origin (19-22 h)	Origin (23-02 h)
Madrid				
Destination (07-10 h)	0.327 (18.6)	0.529 (26.9)	0.486 (26.3)	0.393 (23.7)

Table 5 - Bivariate Moran's I (z-score) between destinations and origins for all time bands on working days. Source: the authors.

4.6 Relationship between spatial patterns and number of vehicles used

To explore the possible relationship between potential vehicle rotation and the number of vehicles used, we graphed the bivariate Global Moran's I results with the percentage of vehicles used by time band on working days (see Figure 11). A clear relationship was revealed, as the resulting curves tend to follow a similar pattern throughout the day for all the cities. Nevertheless, all the cities show a peak in the percentage of vehicles used around band 3 (19-22 hrs), while the peak for the bivariate results is in band 2 (13-16 hrs).

Consequently, potential vehicle rotation could support and stimulate a higher number of trips, but not determine it. The number of trips would be the result of a high demand and high moped availability and proximity, increased when origins and destinations are closed to each other. Therefore, operators should foster this dynamic, especially in band 2 and 3.

These differences between time bands are important when operators need to know how many vehicles to deploy according to the day of the week. Hence, operators could adjust their logistics to respond to the different dynamics, which could reduce and optimise their distribution tasks.

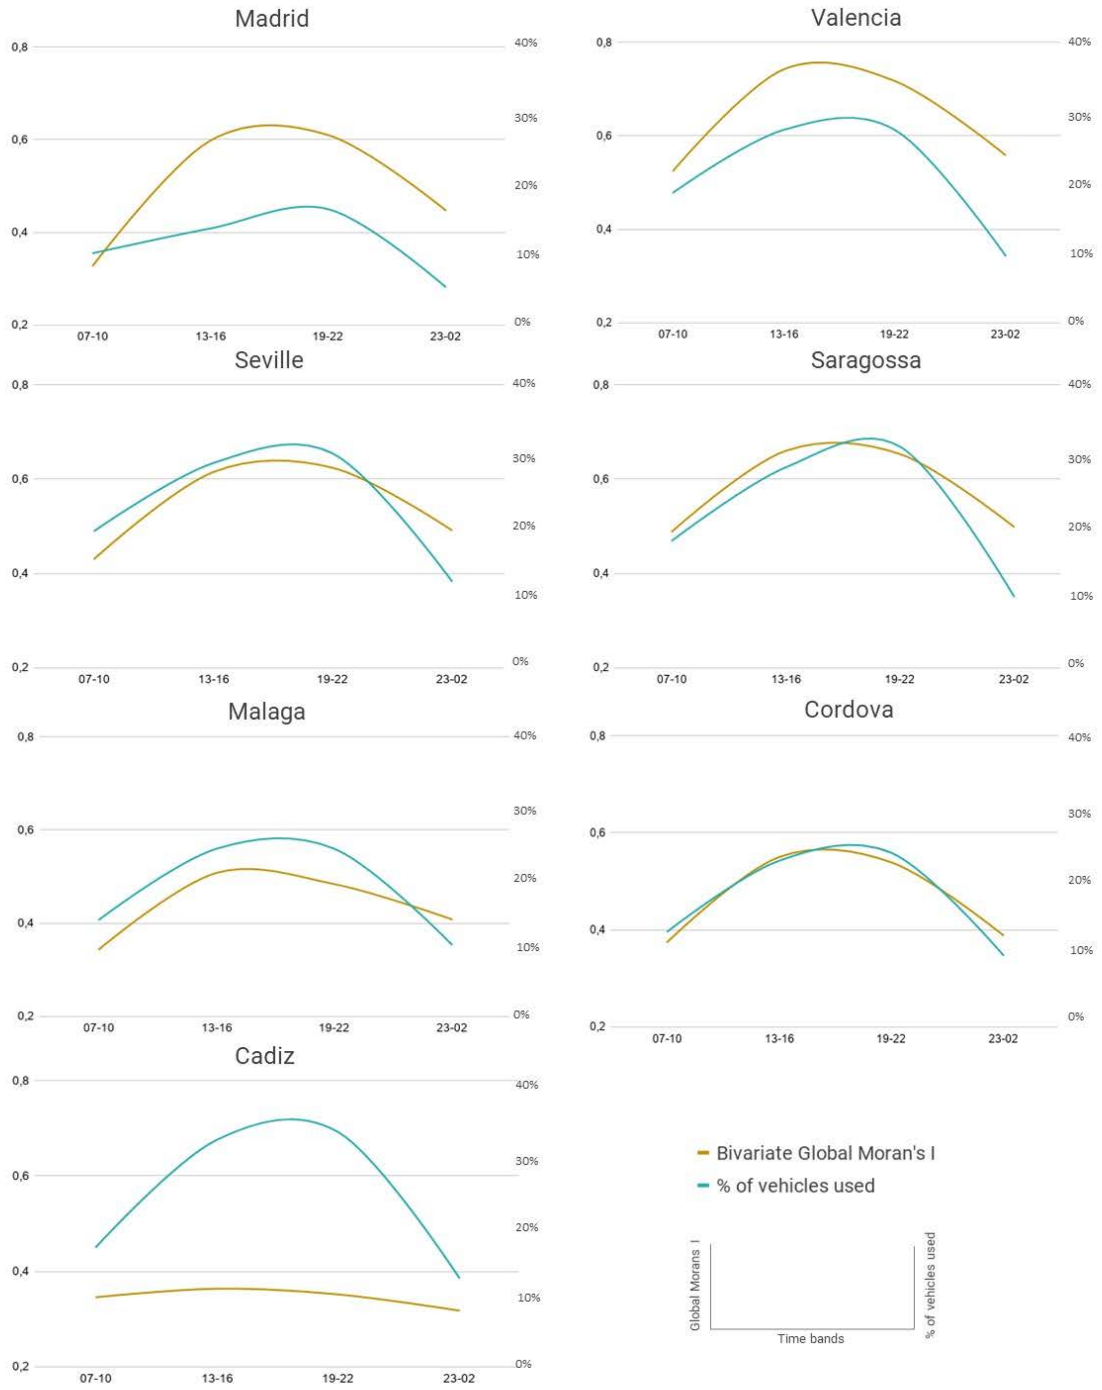

Fig 11- Bivariate Moran vs. percentage of vehicles used (working days). Source: the authors.

5. CONCLUSIONS

Based on GPS data collected, this paper explored the different dynamics of a moped-style scooter sharing service in urban areas over the course of a day. The research provides valuable information regarding the temporal and spatial patterns of this scarcely-studied micromobility service.

More importantly, it proposes a useful methodology based on the use of ESDA tools to understand travel patterns, increasing our knowledge of where demand comes from, when the service's peaks and valleys take place, popular destinations, the extent to which the system is potentially self-balanced, and how this is related to the percentage of vehicles being used. All these are insights that contribute to making better decisions in the shared mobility sector.

A considerable number of users have subscribed to moped services and use this shared mode even across different cities, which is an interesting fact related to the introduction of new concepts like mobility as a service beyond the city scale.

They ride mopeds mostly during warmer months in spring (May-June) and October when daily routines start. The dynamics revealed respond to certain patterns and variations that could be closely related to the existing land-use distribution in each city. In general, the spatio-temporal patterns identified correspond to what could be expected according to the conceptual framework initially outlined. We have learned that similarly to bicycles, mopeds are generally used for short urban trips (around 3.5 km). However, average speed is significantly higher for mopeds in comparison with cycling (14.3 kph in the case of bikeshare and 18.2 kph in the case of mopeds) (Romanillos & Gutiérrez, 2019). This fact makes this mode an attractive alternative, especially for cities like Madrid, which are not completely flat.

We have also demonstrated that time band 2 and 3 (13-16 and 19-22) are the most profitable hours for shared mopeds, as vehicle rotation (trip start and end locations are nearer) and the number of vehicles used are higher.

Our methodology also allowed us to identify when demand is more clustered (HH clusters in the univariate analysis) and more self-balanced (HH clusters in the bivariate analysis), pointing to the most profitable areas within the cities, and other areas where demand is particularly low (LL clusters) or not self-balanced (HL outliers). The assessment of both, the location of demand hubs, and the extent to which the system can balance itself, are important aspects to consider when planning and managing these micromobility services.

Our exploration results are useful for operators and authorities to make better decisions related to shared mobility services, especially in the post-pandemic era, when most of them are experiencing a worldwide boom (Ardila-Gomez, 2020; Harrabin, 2020).

As a clean alternative to cars, knowing where moped trips mostly start and end could have an impact on the infrastructure offered to improve the service and promote intermodality with mass transit.

Our study also demonstrated the importance of analysing and representing the dynamics of mopeds over time and illustrating activity during working days and weekends, which provides relevant knowledge when promoting policies or measures for specific periods of time. The fact that our methodology was tried in different cities allowed for comparisons and demonstrated that our methods are replicable.

Since our study was based on the dataset provided by one of the many moped-style scooter-sharing operators, it is important to consider that, while the sample is absolutely representative in small- and medium-sized cities where no other companies besides

Muving operate (we have all records), this is not the case for Madrid, Valencia, Seville, and Saragossa, which have more than one moped operator. In these cities, results must be carefully interpreted, as we are not covering the entire available moped fleet. When considering Madrid, Muving represented 14% of the available moped fleet during 2019, thus the presence of other companies would vary the vehicle density in some areas, which could have an impact that we are not yet able to identify. Nevertheless, the dataset allowed us to glean more meaningful insights into a sharing sector that has not been exhaustively studied.

Future studies could complement our study by analysing the all moped-sharing services in cities with more than one operator, and even by considering other shared services, in order to holistically comprehend what basically conforms the interconnected

Mobility as a Service network. Future research lines could also focus on monitoring travel behaviour in the coming months and even years, monitoring and visualising the impact of the COVID-19 pandemic on the use of this and other shared modes.

ABSTRACT

Medium-size cities around the world are experiencing rapid changes in their urban centers regarding sustainable mobility, pedestrianization of streets, and vehicle-access control to their city center. This situation is particularly important in the last-mile urban distribution in city centers due to the fact that private cars, public transportation, and freight transportation fiery compete for the same space. This article contextualizes this phenomenon in two European medium-size cities: Angers (France) and Pamplona (Spain).

The paper also draws the current situation regarding their mobility and freight-delivery systems in their city centers. Thus, an apposite survey has been deployed in both cities in order to collect social perceptions and mobility patterns data. Additionally, we have included a conjoint analysis study for examining the characteristic determinants for aerial (drone) distribution. Likewise, meaningful conclusions can be extracted from the analysis of the results generated by the current analysis.

Firstly, we have realized the immediate effects of a recent sustainable urban-mobility plan at Pamplona, which contrasts with the Angers case, where no similar plan has been deployed yet. Secondly, we have focused our attention on the socio-economic factors that determine the mobility in both cities. Thirdly, we have observed, in both cities, a clear preference for electric vehicles and cargo-bikes for driving inside the city center. Finally, there is a rejection to use drones for merchandise delivery.

1. INTRODUCTION

Urban distribution in medium-size cities is facing a major challenge. On the one hand, the growth in e-commerce and the development of commercial and leisure streets in the inner areas of cities are demanding for better freight and passenger transportation systems. On the other hand, medium cities do not have the required infrastructures for absorbing such a demand due to scarce public transportation and weak transportation network, among other factors. As a result, private cars, public transportation, and freight transportation fiery compete for the same space. Additionally, medium size cities are also encouraging sustainable transportation such as walking, biking, and a greater utilization of public transport (Boisjoly and Yengoh, 2017). That leads to pedestrianization of streets, creation of biking lanes, and higher frequency for bus lanes, respectively. Consequently, freight transportation companies have to comply with this new urban environment (Gedik and Yildis, 2016; Atakara and Akyay, 2017; Slovic and Ribeiro, 2018). Accordingly, this work draws the current urban freight distribution situation in two European medium size cities, i.e.: Pamplona, in Spain, and Angers, in France. Both cities have around 200,000 inhabitants in their metropolitan areas. In the study, we conduct a survey for collecting social perceptions and mobility patterns data to understand how urban freight distribution could be improved in medium size cities. Moreover, the survey pays a special focus on drone freight (Frachtenberg, 2019), medical distribution (Rabta et al., 2008), and the use of other environmental-friendly vehicles (Juan et al., 2016).

1.1 Angers and Pamplona: A tale of two cities

Angers is located in Western France, at the intersection of three major motorways: the A11 between Paris and Nantes, the A87 bound to La Roche-sur-Yon, and the A85 bound to Tours and Lyon. Due to its location, Angers is one of the most important logistic centers in the region. Furthermore, the city has several trains (including a high-speed connection to Paris) and central bus stations with direct connection to big cities. Hence, it is a transportation hub for travelers and freights from Western France to Paris. The transportation network is completed with a tramway system that runs through the Eastern part of the city. Moreover, there are more than 30 bus lines and a self-service cycling system.

Likewise, Pamplona is located in Northern Spain, about 45 km away from the French border. The city is crossed by one major motorway, the AP15 bound to Madrid, Zaragoza, and San Sebastian. It is also near another two motorways, the A12 and A21 to Logroño and Huesca, respectively. There are also train and bus central stations, but without high-speed connections. Finally, buses, including one electrified line, are the core of its public transportation. As a final point, Table 1 contains socioeconomic information regarding the two cities, remarking the homogeneity among them.

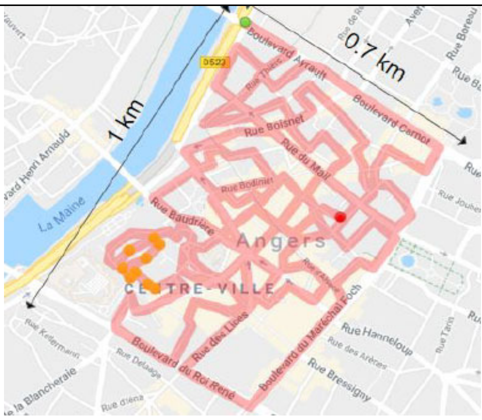
With respect to urban freight transportation, both city centers are characterized by the irregular morphology of their narrow streets, which makes it difficult for vehicles and pedestrians to share these spaces. Moreover, the areas are very dynamic, with shops, government offices, bars, and restaurants. Table 2 shows the characteristics of the city centers of Angers and Pamplona.

	Angers	Pamplona
Population (number of people)*	152,960	199,066
Area (km^2)	42.70	23.55
Density (people per km^2)	3,582	8,500
Per capita GDP (EUR €)**	28,619	28,520

* Data from 2018 ** Data from 2015 at regional level (Maine et Loire for Angers and Navarre for Pamplona).

Table 1 – Socioeconomic data from Angers and Pamplona.

Additionally, the sustainable urban mobility plan (SUMP) of Pamplona, which was recently adopted (Alvarez et al. 2018), led to many changes in the freight transportation in the city center. In particular, the SUMP establishes time windows for freight distribution, while deliveries are only allowed from 8am to 11am and between 2pm to 16:30pm. This policy is not running in Angers.

	Angers city center	Pamplona city center
		


Area	0,7 km^2	0.48 km^2
Road length	14 km	10 km
# bars*	40	20
# stores*	20	20
# hotels*	19	17

* Data from 2019

Table 2 – City center characteristics of Angers and Pamplona.

2. METHODOLOGY

Data collection consisted in the development of some online surveys carried out between April and June 2019 in the cities of Angers and Pamplona.

The questionnaire dissemination was based on mailing distribution lists at the Public University of Navarre and at the Polytechnic University of Angers, as well as its promotion from local authorities and retailers in the area. As a general approximation, we obtained 178 valid observations, 71 from Angers and 107 from Pamplona.

The questionnaire contained 38 closed questions and one open question organized in four different sections, as can be seen in Table 3. The average duration for completing one of the questionnaires was about 14 minutes.

Section	Time	Topic
I	2’	Introduction and classification data
II	4’	Mobility habits and city center weaknesses
III	3’	Freight transportation
IV	5’	Aerial distribution

Table 3 – Questionnaire structure.

Concerning the survey structure in general, and its inner description of its questionnaire, we can make the following description. Firstly, there is an introductory section in which the respondent is asked for sociodemographic information, including age, gender, and economic status, among others. Secondly, the respondent comes across a number of questions regarding the mobility habits in the city. These include how often he / she uses public transportation and the frequency in which he / she visits the city center. Moreover, this section also includes questions with the aim of identifying weaknesses in the city center, e.g.: too much traffic, lack of public transportation, lack of cycling lanes, etc.

Thirdly, there is a specific section for the freight transportation that includes different issues the respondent may suffer from. Thus, this group of questions is particularly important, since the social perception is clearly revealed in the areas of air and noise pollution, urban space invasion, or visual impact. Additionally, the restriction of entering / delivering in the city center is also investigated.

To this respect, we differentiate between traditional internal combustion engine vehicles, electric vehicles based on vans or small trucks, and cargo bikes / trikes deliveries. Finally, the survey contains a section devoted to aerial distribution. Similarly, we include in that section the following characteristics: firstly, general information related to drone-delivery concerns and, secondly, a conjoint analysis (Green et al., 2011) with the attributes and levels shown in Table 4.

In the conjoint analysis subsection, two options are made up by randomly blending their attributes levels. Then, the respondent is asked to choose one of those.

Finally, this is repeated 5 times per respondent with the different options randomly generated.

Attribute	Level
Height/ noise	20 meters off the ground
	120 meters off the ground
Frequency	Few times per day
	Many times per day
Product type	Medical deliveries
	Parcel deliveries
Proximity	Drones do not fly around my house
	Drones may fly around my house

Table 4 – Drone distribution attributes and levels for the conjoint analysis.

3. RESULTS

A comparative descriptive analysis is provided simultaneously in Table 5 and Figure 1. Gender and age distribution is generally balanced in both Angers and Pamplona samples.
Nevertheless, they are slightly biased with respect to their populations. In particular, our samples contain a higher proportion of young participants and a lower proportion of elderly population. This is mainly explained by the data sources as we used the mailing lists of the local universities in Angers and Pamplona. Gender proportion are consistent as 55% and 45% are male or female in the samples and populations, respectively. Regarding the educational level, both samples show similar proportions in elementary, secondary, and undergraduate levels whereas graduates show a higher proportion in the Angers sample and Master / PhD holders show a higher proportion in Pamplona sample.

		Angers	Pamplona	Total
Men	>64	1	0	1
	55-64	1	8	9
	45-54	8	10	18
	35-44	7	10	17
	25-34	4	5	9
	<24	18	22	40
	Total Men	39	55	94
Women	>64	0	2	2
	55-64	2	6	8
	45-54	5	13	18
	35-44	6	5	11
	25-34	4	10	14
	<24	15	16	31
	Total Women	32	52	84
Total		71	107	178

Table 5 – Gender/age sample distribution in Angers and Pamplona.

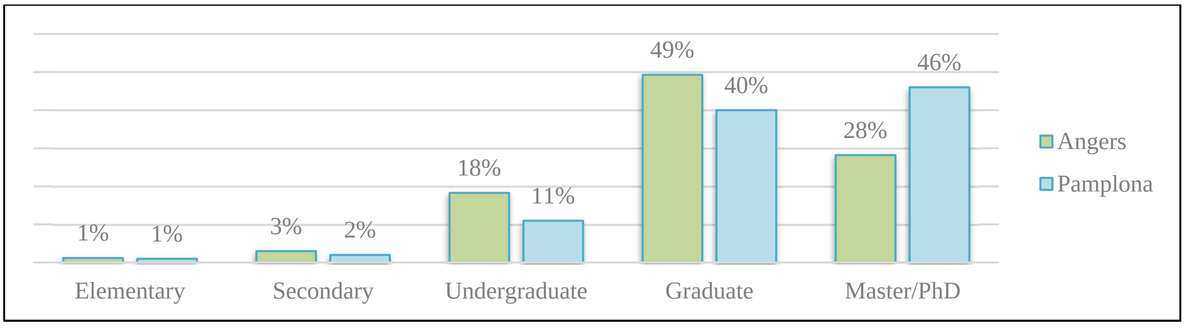


Figure 1 –Level of education in Angers and Pamplona.

The mobility habits are described in Figure 2. Most of the respondents walk regularly to move around the city. Nevertheless, a significantly higher proportion of Angers citizens habitually walk to reach their destinations. Similarly, biking and public transportation are more frequent in the city of Angers. The explanations of these figures are based on two characteristics. Firstly, the public cycling service that is currently running in Angers, which is not in Pamplona. Secondly, the stronger public transportation system in Angers which counts with more bus lines and the tramway system. Consequently, the use of private cars is significantly higher in the city of Pamplona than in Angers.

As the focus of our research is on the freight distribution in the city centers, we also asked for the patterns of going to the city center. These results are shown in Table 6. There are higher proportions of Angers citizens going to the city center more often than citizens from Pamplona. In particular, 69% of Angers respondents go frequently to the city center (at least once a week) whereas that number drops to 42% in the case of Pamplona.

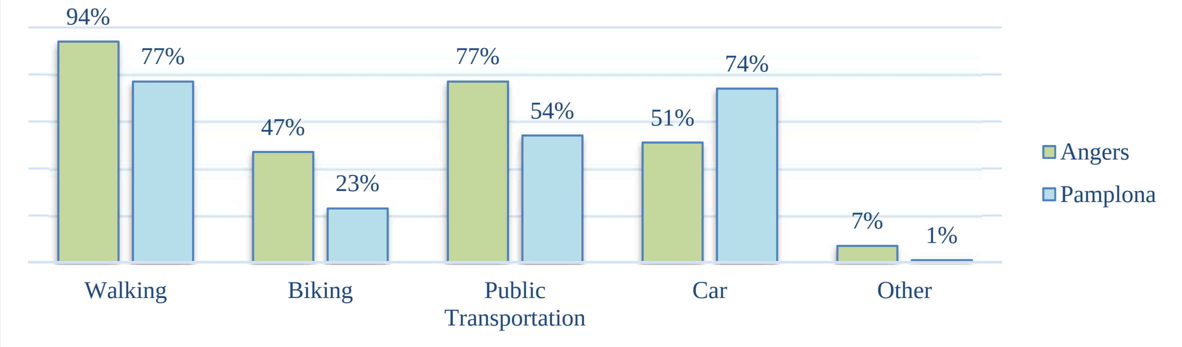

Figure 2 – Mobility habits in Angers and Pamplona.

	Angers	Pamplona
Everyday	28%	10%
At least once a week	41%	32%
Several times a month	4%	48%
Once a month	10%	6%
Almost never/ never	7%	4%

Table 6 – Frequency of going to the city center in Angers and Pamplona.

Table 7 refers to results associated with the restrictions of entering the city center depending on the type of the vehicle (combustion or electric characteristics), and the purpose (freight delivery, including parcels, taxi / bus / ambulance / police services, private nonresident, and private resident). It is particularly interesting how the percentage of participants significantly drops when denying the access to electric vehicles. For example, in Angers 62% would deny entry in the city center to combustion private nonresident vehicles, whereas that figure falls to 23% in the electric case. Similarly, respondents from Pamplona have a higher propensity to allow the entrance of combustion vehicles.

Finally, the respondents identified the city center weaknesses shown in Figure 3. To this respect, pollution, noise, and the lack of cycling lanes are the weakest points in Angers, whereas the noise, excessive freight traffic, and pollution are the ones in Pamplona.

Additionally, levels of importance are always greater in Pamplona than in Angers. That is particularly clear in the case of public transportation and the excessive freight traffic perceptions.

	Angers		Pamplona	
	Combustion	Electric	Combustion	Electric
Deliveries	23%	13%	22%	7%
Services	22%	18%	13%	4%
Private nonresident	62%	23%	50%	39%
Private resident	7%	5%	7%	4%

Table 7 – Denying vehicles entry in the city center of Angers and Pamplona.

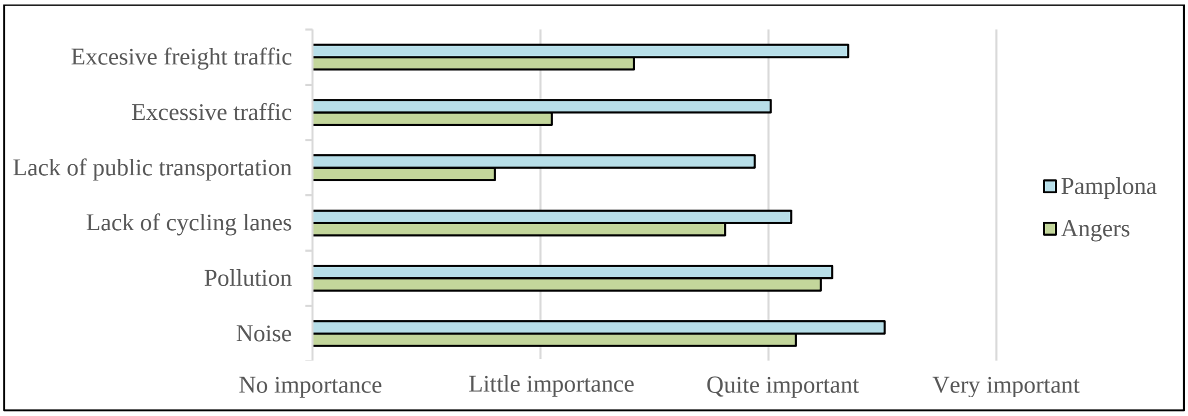

Figure 3 – Transportation issues importance in the city center.

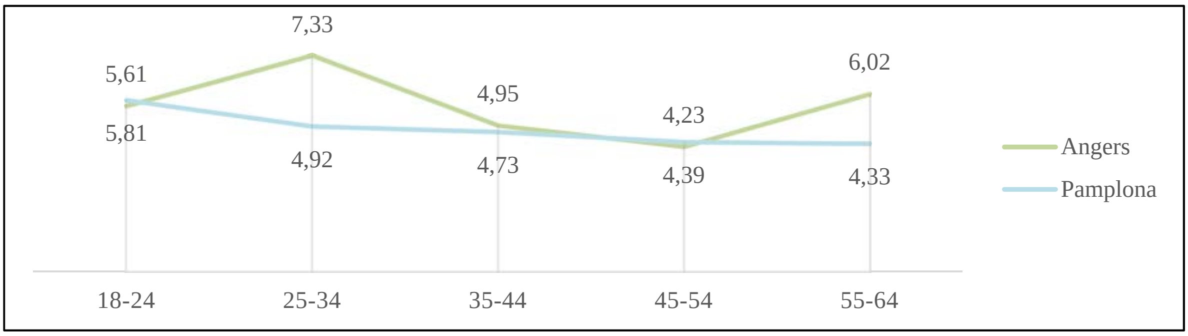

Figure 4 – Sustainability of freight delivery by age group (0: least sustainable; 10: most sustainable).

Concerning the freight transportation particularities, Figure 4 shows the results corresponding to the sustainability perception of the urban deliveries by age group, while Figure 5 shows the freight distribution issues identified. On the one hand, young participants found freight deliveries to be more sustainable than older responders. This is particularly strong in the case of Pamplona, in which there is a clear downward tendency.

On the other hand, Pamplona city center is clearly more annoyed by the freight distribution than Angers one as urban space invasion, excessive speed, and the visual impact are much more important for the former than for the later. However, there are still important issues in the city center of Angers, especially the case of accidents.

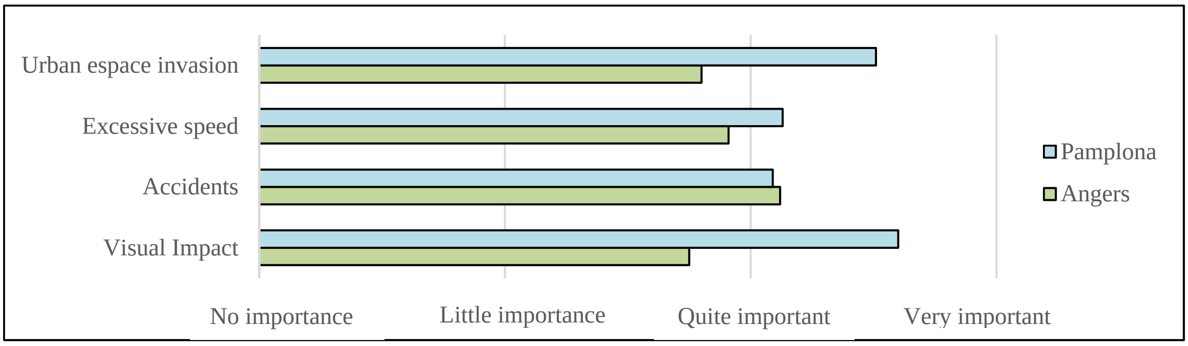

Figure 5– Freight transportation issues importance in the city center.

Finally, future perspectives of urban deliveries are investigated, with a special focus on aerial distribution (drones). To this respect, Table 8 shows the outcomes regarding using the same distribution policy (vans and small trucks), changing to electric vans, changing to a cargo bikes and trikes distribution, and changing to an aerial distribution. Most of the respondents declared that they would like to change the current approach (81.7% and 76.0% in Angers and Pamplona, respectively) to a more sustainable distribution mode. Thus, most of the population agrees on the use of electric vans or cargo bikes / trikes for urban deliveries. The aerial distribution is still scarcely preferred in Pamplona, as only 39.5% of the respondents approved it. This mode is supported in Angers by 69.0% of the respondents.

Following with the drone distribution, Figure 6 shows a preliminary exploration of the conjoint analysis we have developed in these two scenarios. It summarizes the attribute relative importance of choosing an option as a consequence of mixing the attribute levels described in Table 4. As can be seen in the charts from Angers and Pamplona (Figure 6), the 'product type' attribute (i.e., whether the drone is used for delivering parcels or medical deliveries) results in the most determinant with a 38% and 30%, respectively. It means that the use of aerial distribution for medical commodities or parcels significantly affects its approval. Secondly, the flying proximity also strongly determines the drone characteristics.

Here, it is interesting to observe the small distance between the 'product type' and 'proximity' attribute distance in Pamplona city (around 1%), whereas that distance grows up to 11% in Angers. Thirdly, the flying height, which is related to the noise a drone produces, weighs around 25% in both cities. Finally, the least important attribute is related to the flying frequency, as only accounts for about 15%. All in all, the most preferred product consisted in a drone carrying medical supplies that flies high, a few times, and far from home.

	Maintaining		Electric vans		Bikes and trikes		Drone	
	A	P	A	P	A	P	A	P
I'd very much	0.0%	1.9%	33.8%	40.4%	40.8%	30.8%	35.2%	13.5%
I'd like	18.3%	22.1%	52.1%	50.0%	52.1%	45.2%	33.8%	26.0%
Yes	18.3%	24.0%	85.9%	90.4%	92.9%	86.0%	69.0%	39.5%
I'd like a little	57.8%	52.9%	12.7%	8.7%	1.4%	14.4%	21.1%	25.0%
I'd not like	23.9%	23.1%	1.4%	0.9%	5.6%	9.6%	9.9%	35.6%
No	81.7%	76.0%	14.1%	9.6%	7.0%	24.0%	31.0%	60.6%

Table 8 –Opinion about changing (maintaining) to new distribution approaches.

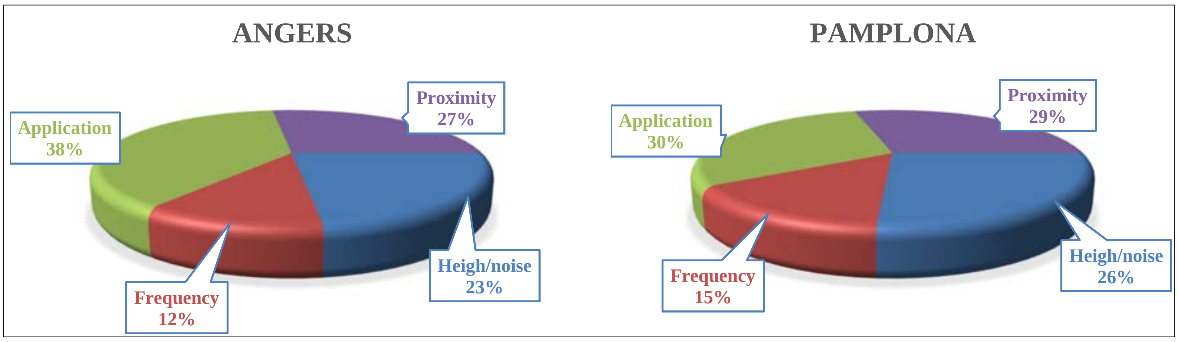

Figure 6– Attribute relative importance resulting from the conjoint analysis.

4. CONCLUSIONS

Medium-size cities are experiencing many changes related to sustainable mobility, which significantly affects the traditional last-mile urban distribution. In this paper, we have deployed a survey in the cities of Angers (France) and Pamplona (Spain) in order to investigate the current status of their mobility policies, with a special focus on the comparison of their mobility patterns and city center freight transportation. That is particularly interesting as the city of Pamplona has recently unfolded a sustainable urban mobility plan whilst Angers has not.

The analysis of the results allows us to describe a number of conclusions:

1) The current situation of transport and mobility in both cities are similar in terms of city-center dimension and services, i.e.: administrative-related paperwork, monuments, and bars or restaurants. However, Angers transport and mobility infrastructure seems to be stronger as the presence of public transportation is higher. While the mobility in each city includes buses routes, in Angers, cycling is an important transportation mode, with a self-service bike service. The tramway also brings variety to the French city.

2) As regards to freight delivery, both cities are at the same point, finding solutions like cargo bikes or tricycles and other electric vehicles to replace traditional combustion vans and small trucks. However, mobility patterns are significantly different, being Angers much more sustainable in the way of higher use of public transportation and lower use of private cars. However, the frequency and the affluence of people in the city center is greater in Angers than in Pamplona. Clearly, the transportation systems and mobility policies are ruling better in the French city, while the SUMP in Pamplona is not offering comparable results in terms of the public transportation share.
3) Both cities face similar weaknesses in their city centers. Nevertheless, in Pamplona these weaknesses are considerably more serious. In fact, noise and air pollution are major problems in both city centers, and some other problems have been identified affecting specially to Pamplona -e.g., the excessive freight traffic or the lack of biking lanes.
4) It is of high interest the propensity to allow electric vehicles to enter in the city centers. This policy involves the detriment of the traditional combustion vehicles, especially if they are private cars. Actually, there is a clear tendency to change the current freight distribution systems, which are generally supported by the population. This behavior is particularly evident when moving towards electric distribution. Furthermore, freight transportation is clearly worse organized in Pamplona, resulting in higher levels of urban space invasion, excessive speed, and visual impacts concerns.
5) Aerial distribution at city centers are somehow conflictive. On the one hand, around half of the sample are prone to allow drone distribution, a much lower ratio than the use of electric distribution using vans or bikes / trikes, which accounts for approximately 90% of respondents. On the other hand, there is a clear difference between the approval of the two cities. Just 39% of Pamplona participants support drone distribution, whilst this figure grows up to 69% in the city of Angers. Thus, we have observed clear culture-related issues to tune when dealing with a real and effective drone distribution deploy. Finally, we have identified what are the most important characteristics of this kind of distribution, being dominated by the product type transported (medical / parcel) and height the drone flies. Hence, a clear rejection for using drones for parcel distribution has been observed in our survey.

ACKNOWLEDGEMENTS

Ineco, España

RESUMEN

Con la entrada de la telefonía móvil en el análisis de la movilidad se ha cambiado la forma tradicional de obtención de las matrices origen-destino de viajes. Las ventajas de utilizar estos datos georreferenciados se traducen especialmente en los grandes tamaños de muestra, lo que conlleva la detección de viajes en gran parte de los pares O-D, la reducción de plazos y costes y la posibilidad de analizar periodos de tiempo pasados. Sin embargo, la caracterización del viaje (modo, motivo) y del viajero (nivel socioeconómico, motivo de elección) quedan en cierta medida algo desdibujados en este nuevo escenario.

La experiencia acumulada en el desarrollo de estudios con este tipo de soluciones ha permitido detectar la importancia de llevar a cabo un proceso de enriquecimiento y alimentación de las matrices de telefonía móvil para aunar las ventajas del método tradicional y de las nuevas tecnologías e incrementar la calidad de los resultados a obtener. Para ello se describen las fuentes de datos disponibles y los trabajos de campo complementarios que se pueden llevar a cabo en función del tipo de resultados que se deseen obtener.

Las matrices enriquecidas con este proceso deben ser convenientemente validadas, para lo cual es necesario analizar posibles inconsistencias en los resultados y, en ocasiones, realizar una tarea de ajuste final con ayuda del modelo de transportes.

1. INTRODUCCIÓN

La irrupción de la información espacio-temporal de los teléfonos móviles en los análisis de movilidad cuenta ya con varios años de utilización para este tipo de estudios. Para el Censo de población de 2021 el INE ha confiado en esta solución para la obtención de la información sobre movilidad, sustituyendo al cuestionario tradicional.

En Ineco se comenzó a trabajar con esta fuente de datos en el año 2017 y se ha utilizado hasta el momento en una veintena de proyectos de diversas características, aunque todos ellos con un denominador común: la necesidad de obtener matrices de viajes con más detalle que la matriz de movilidad general.

Dentro del contexto de la Movilidad Segura, Sostenible y Conectada 2030 y su predecesora nuestros proyectos se orientan a nuevas infraestructuras, servicios o eficiencia del transporte público. Por ello, resulta de especial importancia la segmentación de las matrices de demanda por modo y motivo de viaje, pudiendo caracterizar los usuarios susceptibles de ser captados por las actuaciones analizadas.

Con base en nuestra experiencia y en las lecciones aprendidas, se ha elaborado una relación de fuentes de datos y trabajos complementarios como herramientas para mejorar la precisión de las matrices obtenidas de la telefonía móvil (matrices primarias) en las matrices modales más idóneas para cada tipo de estudio (matrices segregadas).

2. MATRICES PRIMARIAS, FORTALEZAS Y ÁREAS DE MEJORA

A continuación, se exponen fortalezas y áreas de mejora detectadas en el trabajo realizado con matrices primarias obtenidas a partir de registros de telefonía móvil.

2.1 Fortalezas de las matrices primarias

Actualmente la telefonía móvil es empleada frecuentemente para la detección de desplazamientos en forma de matrices primarias, dadas las numerosas ventajas que presenta esta solución. Entre las principales fortalezas se encuentran:

Datos de movilidad de usuarios recogidos de forma pasiva: los usuarios, objeto de investigación, no forman parte activa del proceso de recolección de datos, al no tener que realizar ninguna tarea específica para que estos datos queden registrados.

Monitorización o seguimiento continuo de datos: en caso de ser necesario, los datos de movilidad pueden recogerse de forma continua durante un periodo de tiempo determinado, que puede prolongarse en el tiempo. Esto facilita el análisis de la evolución continua de la movilidad en algunos ámbitos.

Análisis de eventos históricos: pueden recogerse y analizarse datos históricos de eventos para examinar patrones o situaciones que, de otra forma, no podrían analizarse, de no planificarse antes de suceder.

Muestras de gran tamaño: en general, esto depende de la cuota del operador de telefonía móvil en el ámbito de estudio, aunque habitualmente es factible contar con un alto porcentaje de muestra entre la población investigada, ante la generalización que existe actualmente en el uso del teléfono móvil. Esta alta cantidad de muestra puede además estar repartida en diferentes momentos temporales a lo largo de un periodo, permitiendo aumentar la representatividad de esta.

Grado de penetración: el uso de datos de telefonía móvil permite investigar generalmente la movilidad en todo tipo de zonas y a todo tipo de usuarios, aunque ello depende también de la composición de usuarios que forma la cuota del operador. Además, al ser un proceso de registro pasivo, pueden evitarse sesgos asociados con la selección de individuos que realiza el investigador o entrevistador, en el caso de encuestas.

Plazo y coste de ejecución: el proceso de registro y tratamiento de estos datos de telefonía para la obtención de matrices de viajes suele llevar un menor tiempo de ejecución de tareas y con ello, además, un menor coste en la producción de estos resultados.

2.2 Áreas de mejora de las matrices primarias

Sin embargo, en la obtención de matrices de viajes a partir de datos de telefonía móvil existen también áreas de mejora, entre las que se encuentran:

Caracterización del viaje y del usuario: la información disponible para caracterizar en detalle a los viajeros y sus desplazamientos mediante telefonía móvil es reducida, en comparación con la metodología de encuestas. Actualmente, las variables de análisis que pueden determinarse mediante la telefonía móvil no son muy numerosas, quedando con escaso detalle características como el motivo o la frecuencia del desplazamiento.

Identificación de viajes en determinados modos de transporte: frecuentemente se presentan dificultades en el momento de segmentar los viajes de la matriz según modos de transporte, especialmente en el caso de desplazamientos entre distintos medios asociados a la carretera (autobús, vehículo particular, camiones, furgonetas, etc.) o en el caso de distintos modos terrestres (ferrocarril y carretera), si estos discurren por una infraestructura paralela, con escasa separación y velocidades medias similares.

Desplazamientos asociados al transporte de mercancías: como se menciona en el punto anterior, la dificultad para segmentar a los distintos tipos de usuarios de la carretera entre tipos de vehículos hace que no puedan detectarse con claridad todos los desplazamientos asociados al transporte de mercancías, que son realizados por conductores profesionales utilizando camiones o furgonetas.

Esto resulta un inconveniente en el caso de estudios de movilidad donde únicamente se desee identificar viajeros potenciales de modos de transporte públicos y se acentúa especialmente si este análisis desea efectuarse sobre el ámbito de un polígono industrial con gran volumen de transporte de mercancías.

Muestras insuficientes en ámbitos espaciales muy pequeños: cuando el análisis de la movilidad desea efectuarse sobre espacios reducidos como, por ejemplo, un polígono industrial o zona residencial pequeña y poco urbanizada, la muestra de usuarios a investigar puede ser muy limitada, en función de la cuota y penetración del operador de telefonía móvil.

Investigación de movilidad internacional: habitualmente la posibilidad de obtener registros de telefonía móvil en territorio extranjero es limitada y depende de los convenios existentes con las distintas operadoras de telefonía móvil en cada país.

3. ELEMENTOS PARA EL ENRIQUECIMIENTO DE LA MATRIZ PRIMARIA

Las matrices primarias pueden enriquecerse integrando datos procedentes de otras fuentes o de trabajos de campo específicos para realizar segmentaciones más precisas.

3.1 Fuentes de datos complementarias

Las fuentes de datos complementarias aportan información adicional en el proceso de obtención de las matrices de viajes por modo, ayudando a paliar determinados aspectos del proceso sobre los que hay una mayor incertidumbre. Estas fuentes de datos externas pueden englobarse en:

Datos de usuarios de modos de transporte público: esta información, generalmente aportada por operadores o administradores de transporte, puede contener detalles sobre los viajeros que utilizan el servicio indicando sus paradas de subida y bajada, o bien, sobre el conjunto de viajeros que se suben y se bajan en las distintas paradas, sin indicar la relación entre las paradas de subida y bajada.

Estos datos suelen tener su origen en el registro del uso o compra de los billetes o títulos de transporte de los usuarios del modo de transporte público o, en algunos casos, en aforos realizados específicamente por los operadores dentro de su labor de gestión, control y regulación de la explotación del servicio.

Estos datos facilitan la identificación, en la matriz global de viajes, de usuarios que utilizan modos de transporte público. Por otro lado, cuando la infraestructura de estos discurre de forma paralela y con escasa separación a lo largo de un corredor, también puede ayudar a desagregar la demanda entre modos de transporte terrestre.

Entre las limitaciones que presentan este tipo de datos se encuentra, frecuentemente, la ausencia del registro del resto de etapas del viaje entre origen y destino, la relación entre parada de subida y bajada si existe transbordo o si solo se cuenta con datos agregados de subidos o bajados por parada, sin relación entre paradas.

Aforos de vehículos en carretera: los mapas de tráfico que se generan habitualmente a nivel regional o estatal proporcionan la intensidad de vehículos ligeros y pesados en numerosos puntos de la red de carreteras del Estado.

Estos datos facilitan la detección de vehículos pesados, que en su mayor parte están asociados al transporte de mercancías, aportando además información sobre los vehículos ligeros, en su mayoría vehículos particulares. Esta información resulta de interés cuando no es posible segmentar los viajes realizados en carretera, entre el autobús y el vehículo privado.

No obstante, estos datos de intensidades ofrecen información puntual de vehículos, sin detallar relación entre origen y destino y sin identificar el número de ocupantes de dichos vehículos, de forma que pudieran transformarse los datos de vehículos en viajes.

Adicionalmente, este tipo de datos no presentan una identificación desagregada en detalle entre vehículos asociados al transporte de mercancías y vehículos asociados al transporte de viajeros o vehículos particulares. Este hecho sucede dado que, generalmente, dentro de la categoría de vehículos ligeros se incluyen, no solo turismos y motocicletas o ciclomotores, sino también furgonetas o furgones dedicados al reparto y distribución de mercancías.

Igualmente, dentro de la categoría de vehículos pesados, en ocasiones se encuentran agrupados camiones o vehículos dedicados al transporte de mercancías y autobuses o vehículos dedicados al transporte de viajeros, dificultando así la identificación directa de vehículos asociados al transporte de mercancías y de viajeros.

Estadísticas públicas de movilidad general: son varias las estadísticas generales públicas disponibles que pueden encontrarse y utilizarse para enriquecer las matrices de viajes, aunque una parte de ellas no ofrecen detalles de viajes completos, sino de etapas. Entre estas estadísticas se encuentran las de distintos organismos públicos en España, como:

- El Instituto Nacional de Estadística (INE): proporciona información mensual sobre el número de viajeros transportados en su Estadística de transporte de viajeros. Esta información se encuentra además segmentada según medio de transporte, distancia o ámbito. El INE publica también la Estadística de movimientos turísticos en frontera, que proporciona estimaciones mensuales y anuales del número de visitantes no residentes en España que llegan al país.
- El Observatorio del Transporte y la Logística en España (OTLE): proporciona datos, gráficos, mapas e indicadores generales de movilidad agregada y en los distintos modos de transporte (carretera, ferrocarril, aéreo y marítimo).

- AENA: en la página web de Aena pueden consultarse datos de pasajeros en los aeropuertos españoles, indicando la relación entre aeropuerto de salida y aeropuerto de llegada de los pasajeros.
- El Observatorio del Ferrocarril en España (OFE): facilita anualmente un registro de estadísticas de viajeros en ferrocarril, indicando los viajeros en las principales estaciones ferroviarias y una segmentación de estos según los distintos tipos de servicios ferroviarios, entre otros indicadores generales de movilidad.
- La Encuesta Permanente de Transporte de Mercancías por Carretera (EPTMC): registra anualmente el tráfico de mercancías por carretera en España, indicando además del tipo de vehículo, el origen y destino de los vehículos entre las distintas Comunidades Autónomas, entre otras variables.
- Memorias anuales de operadores de transporte: las empresas públicas operadoras de transporte de viajeros publican habitualmente de forma anual las estadísticas y cifras generales de viajeros transportados en su ámbito de operación, encontrándose desagregada esta información en ocasiones, según líneas o paradas, entre otras características.
- Anuario estadístico del Ministerio de Transportes, Movilidad y Agenda Urbana (MITMA): proporciona información estadística anual sobre los viajeros transportados en ferrocarril, avión, barco y autobús urbano o internacional, además de estadísticas de tráfico por carretera.
- Anuario estadístico de Puertos del Estado: en este anuario se encuentra información sobre los pasajeros que utilizan los servicios de transporte marítimo en las distintas Autoridades Portuarias de España.

Estas son solo algunas de las estadísticas públicas que pueden ayudar a enriquecer la obtención de las matrices de viajes de un estudio de movilidad, aportando información por modos de transporte, datos sobre viajeros internacionales no residentes en España, viajes encaminados a determinados nodos de transporte como puertos y aeropuertos o detectando movilidad asociada a transportistas de mercancías.

Al igual que otras fuentes de datos, las principales limitaciones que presentan estas estadísticas están asociadas a la ausencia de la relación entre origen y destino o, en caso de que esta información exista, no se encontrará recogida la información de todas las etapas del viaje, entre otros aspectos.

Otros estudios específicos: además de las fuentes de datos anteriormente mencionadas, es recomendable la recopilación y consulta de antecedentes de estudios en el ámbito de análisis que puedan contener datos de movilidad. Entre estas fuentes de datos, pueden existir Encuestas Domiciliarias de Movilidad (EDM) recientes o Planes de Movilidad Urbana o Regional en las zonas de estudio.

Como ejemplo, entre las EDM que han sido publicadas recientemente se encuentra la de la Comunidad de Madrid (2018), donde se ofrecen los resultados de viajes en un día laborable en la Comunidad, según origen y destino, modos de transporte, títulos de viaje, etc. La zonificación recogida en esta EDM cuenta con una extensa división de más de mil zonas.

Como puede observarse, existen diferentes fuentes de datos que pueden utilizarse como herramientas que ayuden a enriquecer la obtención de matrices de viajes en un estudio de movilidad. Sin embargo, al realizar este proceso es necesario tener presente las limitaciones o carencias de cada una de estas fuentes de datos complementarias.

3.2 Trabajos de campo *ad hoc*

Los trabajos de campo pueden planificarse específicamente para aportar un mayor grado de detalle al proceso de segmentación por modos de las matrices de viajes, tras conocer en detalle el ámbito de estudio, la zonificación empleada y los medios de transporte que serán analizados entre otros aspectos.

De esta forma, la realización de encuestas de preferencias reveladas (PR) y/o de aforos pueden enriquecer el proceso de obtención de resultados aportando de la siguiente forma:

Mayor detalle de las características del viaje y del viajero: La encuesta de preferencias reveladas permite obtener un mayor detalle acerca del motivo y frecuencia del viaje, la utilización de modos de acceso y dispersión, la situación laboral del usuario o su ocupación profesional, etc.

Desagregación de los viajes realizados en carretera: La realización de encuestas PR a usuarios de autobús ayuda a conocer un subconjunto de los viajes que se realizan por carretera y que son difícilmente detectables mediante telefonía móvil. Puede plantearse también la realización de estas encuestas a los usuarios del vehículo privado, sin embargo, es posible que exista un mayor sesgo en la selección de usuarios, además de las dificultades para interceptar a estos durante la realización de su viaje. En función de la disponibilidad de datos de viajeros, puede ser necesario contar también con la realización de un aforo de viajeros de este medio público.

Desagregación de viajes terrestres (ferrocarril y carretera): En el caso de que la situación geográfica dificulte la segregación de demanda entre ferrocarril y carretera, puede plantearse la realización de encuestas de preferencias reveladas a usuarios del ferrocarril para caracterizar los desplazamientos de este subconjunto de viajes y permitir diferenciar entre ambos modos terrestres. La necesidad de realizar conjuntamente aforos de viajeros en ferrocarril, para la expansión de esta muestra de viajes, será variable en función de la disponibilidad de otros datos, por ejemplo, registros de demanda proporcionados por el operador.

Identificación de viajes realizados por transporte de mercancías: En determinados ámbitos de estudio, el volumen de este tipo de desplazamientos puede adquirir un peso significativo en la movilidad global, lo que puede requerir un conocimiento detallado de estos viajes para poder caracterizarlos adecuadamente. La realización de aforos para identificar este tipo de vehículos puede ser de gran ayuda para cuantificar estos flujos en las principales relaciones de análisis.

Cabe recordar que este tipo de tareas específicas también conllevan determinadas limitaciones, dado que pueden ser trabajos que involucren un mayor coste o introducir algunos sesgos.

Como ejemplo de aplicación simultánea de tareas de investigación de campo y utilización de datos de telefonía móvil, cabe destacar la realización de la última encuesta de movilidad de la Comunidad de Madrid (EdM2018), donde se utilizaron, en este caso, la encuesta domiciliaria para investigar la movilidad de los residentes en la Comunidad, empleando los datos de telefonía móvil para estudiar la movilidad de los no residentes.

4. AJUSTES FINALES Y VALIDACIÓN

Tras obtener las matrices de viajes segregadas es relevante validar los resultados obtenidos mediante la generación de estadísticas e indicadores de movilidad vinculados a la demografía y al territorio o comparando nuevamente con fuentes de datos complementarias.

Algunos de los indicadores que pueden extraerse a partir de los datos de desplazamientos de la matriz son:

Generación de viajes por habitante (viajes/habitante): Esta relación puede obtenerse para la matriz global de viajes, según relaciones origen-destino, y analizar la dispersión de estos valores conjuntamente con las características del territorio, o comparar las tendencias observadas con otros estudios.

Índice de etapas (etapas/viaje): Este índice revela la composición de etapas de los distintos viajes, permitiendo analizar en determinadas relaciones origen-destino y modos de transporte, la coherencia de los viajes y sus cadenas de etapas.

Atracción de viajes laborales (viajes/empleado): Si se disponen de datos estadísticos sobre el número de empleados en las zonas de concentración empresarial, analizando esta ratio puede observarse el comportamiento de los viajes en estas zonas, en función de las características de dichas empresas. Esta relación dependerá del tipo de empresa y del número de visitantes asociados a la misma.

Comparativa con datos de usuarios de operadores de transporte: Estos datos, además de tenerse en consideración en el proceso de obtención de la matriz de viajes como fuente externa, puede utilizarse igualmente como fuente de datos de validación del proceso seguido. En este caso es posible, por ejemplo, comparar las etapas entre zonas, ya que los datos de viajeros de operadores de transporte contienen habitualmente etapas en el modo entre paradas, en vez de viajes completos entre origen y destino.

Analizando los valores de estas ratios a nivel global y en las distintas relaciones origen-destino, pueden observarse tendencias sobre valores medios y su dispersión, que pueden conducir a detectar anomalías en la caracterización de viajes de la matriz.

Adicionalmente, en la mayoría de los estudios de demanda se construye un modelo de transportes como herramienta para la simulación de escenarios y estimación de previsiones a futuro. El modelo está formado por tres componentes principales: zonificación, modelo de oferta y modelo de demanda.

Este modelo ha de estar debidamente calibrado y validado en el año base con la información de referencia previamente recopilada, a fin de que sea capaz de reproducir adecuadamente la realidad observada, respondiendo además de forma adecuada frente a cambios tanto a nivel socioeconómico como de la oferta de transporte.

Es habitual que, durante el proceso iterativo de calibración del modelo en el año base, este sirva además como herramienta de apoyo en el análisis de los datos geolocalizados de telefonía móvil y la validación de las matrices origen destino segregadas, las cuales constituyen uno de los pilares de la modelización.

En este análisis que se lleva a cabo con el objetivo de validar los resultados, se detectan en ocasiones inconsistencias en los datos, que pueden ser resueltas mediante ajustes concretos con ayuda del modelo de transportes. A continuación, se describen algunos ejemplos de ajustes realizados mediante la utilización del modelo de transportes construido de forma específica para el estudio de demanda en cada caso.

Hay que tener presente que la fiabilidad en las matrices de movilidad obtenidas mediante estos métodos alternativos de ajuste es siempre inferior a la que se puede alcanzar si directamente la información es obtenida con el detalle necesario desde un primer momento.

Zonificación: En general, resulta más indicado que las zonas origen destino que se definan como referencia espacial en la obtención de los datos para elaborar la matriz de viajes sean consistentes con la zonificación empleada en el modelo de transportes, con una desagregación igual o de mayor detalle. No obstante, en el caso de que el nivel de desagregación en que se obtengan las matrices origen destino no sea suficiente, es posible utilizar submodelos de generación y distribución para estimar los viajes con el grado de detalle requerido de forma sintética. Para ello, se procede según los pasos que se indican a continuación.

En primer lugar, es preciso definir el submodelo de generación de viajes, el cual permite reproducir la mecánica de producción y atracción de viajes en cada una de las zonas del modelo. Así, para cada uno de los segmentos de demanda y motivos de viaje se estiman ratios de producción de viajes, que representan el número de viajes de un motivo realizados a nivel individual. Para el cálculo de las atracciones zonales se emplea la información relativa a los usos del suelo y a variables relacionadas con la actividad económica.

Una vez se tienen las ratios de producción por grupo de demanda y motivo de viaje, estas se aplican sobre las variables socioeconómicas con el nivel de desagregación inferior, obteniendo así los vectores de generación (producciones y atracciones) relativos a la zonificación del modelo de transporte.

A continuación, se define el submodelo de distribución espacial de viajes cuyo objetivo es estimar el número de viajes que se realizan entre dos zonas origen destino a partir del total de viajes producidos por la zona origen y el total de viajes atraídos por la zona destino. Si se trata de un modelo de tipo gravitatorio, la distribución se hace depender también de la impedancia al transporte existente entre ambas zonas.

Para la calibración del submodelo de distribución espacial de viajes por cada segmento de demanda y motivo de viaje, se ajustan los parámetros de la función de impedancia de manera que se minimicen las diferencias entre la matriz origen destino de partida para la segregación y la ajustada por el modelo. Para poder realizar la comparación entre ambas matrices, éstas deben tener la misma zonificación, para lo cual es necesario agregar los viajes estimados por el modelo hasta que su referencia espacial coincida con la de la matriz de partida.

Finalmente, una vez concluido el proceso de calibración del submodelo de distribución, la nueva matriz origen destino segregada será la estimada por aquél.

Detección de inconsistencias: En ocasiones, en el proceso de cálculo de los modelos de generación se observan ratios de producción inferiores o superiores a lo esperado según experiencias previas en estudios similares. Este hecho puede hacer detectar inconsistencias en el registro de datos.

Entre las distintas experiencias analizadas en los últimos años, cabe destacar la detección de ratios de generación más elevadas en determinadas zonas fronterizas de España.

Además, en la calibración del submodelo de reparto modal, se detectó que las cuotas de vehículo privado eran muy superiores al resto de los modos.

Tras analizar este caso concreto, fue necesario optar por ajustar las matrices de partida, tomando como referencia ratios de generación (para la matriz de movilidad general) y cuotas de reparto modal (para la segregación por modos) procedentes del propio estudio en otras zonas no afectadas.

5. NUESTRA EXPERIENCIA

Desde el año 2017 se han desarrollado en Ineco los siguientes proyectos con base en matrices de telefonía móvil.

- Estudios de demanda para la implantación de cinco nuevos apeaderos en polígonos industriales sobre la red de Cercanías existente de Madrid.
- Estudios de demanda para la implantación de cinco nuevas estaciones sobre la red de Cercanías existente. Varios núcleos.
- Estudio de demanda de cinco núcleos de Cercanías.
- Estudio de demanda de viajeros para la rehabilitación de la línea ferroviaria transfronteriza Zaragoza-Pau.
- Estudio de demanda de viajeros en el Corredor Sur de la isla de Gran Canaria para la implantación de un ferrocarril.
- Estudio de demanda de viajeros del Corredor Mediterráneo.
- Modelo Nacional de transporte de viajeros.

TWITTER Y MOVILIDAD ESPACIO-TEMPORAL: VISUALIZACIÓN 3D DE FLUJOS DE MOVILIDAD

Joaquín Osorio Arjona
Investigador predoctoral, Universidad Complutense Madrid, España

RESUMEN

La movilidad individual de un individuo está estructurada en la necesidad de conducir diferentes actividades que requieren estar en unas determinadas coordenadas espaciales y temporales. La Geografía del Tiempo es una aproximación que reconoce que la localización en el espacio no puede estar separada del momento en el tiempo. Los progresos recientes en los SIG y computación y la riqueza de los datos espacio-temporales obtenidos a partir de nuevas fuentes basadas en las Tecnologías de la Información y Comunicación han contribuido a la evolución de la Geografía del Tiempo. Actualmente es posible visualizar y representar los movimientos de la gente en su doble dimensión espacio-temporal. En este trabajo, usamos datos geolocalizados de la red social Twitter para mostrar el valor de las nuevas fuentes de datos para la Geografía del Tiempo. La metodología consiste en visualizar prismas espacio-temporales tanto en 3D como en 2D en cuatro zonas de estudio de la ciudad de Madrid, cada una con diferentes perfiles de uso del suelo (residencial, trabajo, estudios, y ocio). Para ello se han empleado como datos tweets recopilados durante un periodo de dos años que se han combinado con información de usos del suelo del Catastro. Aprovechando las ventajas de la visualización 3D y 2D es posible analizar la movilidad individual tanto en el tiempo como en el espacio. Los resultados muestran los diferentes comportamientos de movilidad de los individuos en cada zona de estudio durante el día, con datos complementarios para mostrar la actividad principal de la población en diferentes horarios.

1. INTRODUCCIÓN

La movilidad diaria de un individuo se estructura por la necesidad de realizar diferentes actividades que requieren estar en determinadas localizaciones durante tiempos concretos (Miller, 2005). El espacio no está completamente separado del tiempo, sino que ambos se combinan, por lo que la localización en el espacio no puede ser separada del momento temporal (Hägerstraand, 1970). La Geografía del Tiempo es una aproximación orientada a entender las actividades en esa doble componente espaciotemporal, reconociendo que la gente puede estar físicamente solo en un lugar y un tiempo en concreto (Miller, 2017).

Los datos diarios de las actividades realizadas por muestras de individuos en un determinado periodo de tiempo han servido como fuente de datos en muchos estudios de actividades humanas espaciotemporales. La ciencia de la información geográfica y las

Tecnologías de la Información y la Comunicación (TIC) están convergiendo para recrear una revolución temporal en la que las ciencias urbanas y del transporte pasan de ser ciencias basadas en el lugar a ciencias basadas en las personas (Miller, 2005). Con los avances en la computación y los Sistemas de Información Geográfica (SIG), es actualmente posible cartografiar los procesos que ocurren en el espacio en diferentes momentos temporales. Juntos, la geografía del tiempo y los SIG pueden dar un ambiente analítico útil para visualizar y explorar datos de actividad a nivel individual en un contexto espacio-temporal (J. Chen et al., 2011; Q. Huang & Wong, 2015).

Desde la perspectiva de la visualización en los SIG, es posible representar los datos espaciales tanto en vistas 2D cómo 3D dependiendo de la información suministrada. Las representaciones 2D son mejores para ilustrar relaciones espaciales precisas. Sin embargo, con esta visualización no se puede observar información basada en el tiempo (Keskin et al., 2014). Mientras, los métodos 3D en los cuales el tiempo es integrado ortogonalmente a un plano geográfico llevan de forma cualitativa a un pensamiento visual claro sobre los comportamientos humanos, la accesibilidad, y los patrones geoespaciales (Neutens, Van de Weghe, Witlox, & De Maeyer, 2008). Sin embargo, hay varias dificultades técnicas y de usabilidad: la orientación del usuario en una escena visualizada (la gente puede encontrar difícil percibir la información en 3D con ángulos cambiantes), la complejidad de los datos visualizados, y la falta de diseño cartográfico (Keskin, Dogru, Çelik, Doğru, & Pakdil, 2014). Por ello, en esta comunicación se propone diseñar una visualización 3D de cada área de estudio, apoyada en una visualización 2D, para poder complementar las ventajas de cada visualización.

Para la visualización en 3D, la herramienta propuesta es el camino espaciotemporal. Esta herramienta de representación mide el movimiento de un individuo en el espacio tridimensional, situándose el espacio en una llanura horizontal y el tiempo en una dirección perpendicular, a partir de una lista de puntos de control estrictamente ordenados en el tiempo (Miller, 1991, 2005). En el espacio-tiempo el individuo describe un camino en el que el lugar donde está ahora está críticamente atado al “lugar de ahora” de un tiempo anterior. Un camino puede ser enseñado gráficamente fácilmente si se colapsa el espacio tridimensional en una llanura bidimensional y se usa una dirección perpendicular para representar el tiempo. El individuo no puede pasar un punto en el espacio-tiempo más de una vez, pero tiene que estar siempre en un punto (Hägerstraand, 1970). La región espacio-temporal de un camino está representada con una triada ortogonal de ejes, dos ejes x e y definiendo el espacio bidimensional plano, y un eje z representando el tiempo. Un objeto localizado en (x, y, z) muestra las coordenadas de localización del objeto en un espacio bidimensional en el tiempo z (Miller, 1991).

Dentro de las TIC, los datos de Twitter contienen información espacial y temporal precisa en forma de coordenadas donde ocurre un evento específico, permitiendo el análisis a diferentes escalas (García-Palomares et al., 2018). Los datos de fuentes como Twitter no generan caminos espaciotemporales directamente, sino que generan una secuencia temporal de localizaciones espaciales que son usadas para construir el camino. Con estos puntos, los investigadores pueden representar caminos espacio-temporales para individuos, y usar estas trayectorias para desarrollar la localización y el tiempo de actividades (L. Yin, Shaw Shih-Lung, & Yu, 2011). Los datos georreferenciados suelen ser generados por usuarios de forma voluntaria y hay que tener en cuenta que no tienen como objetivo analizar patrones de actividades.

Sin embargo, aunque hay que tratar de forma cuidadosa la calidad de los datos, estos capturan algunos aspectos de las trayectorias espaciotemporales de los usuarios. Aunque los datos de Twitter pueden no reflejar la trayectoria detallada de un usuario en el día, ofrecen localizaciones seleccionadas del individuo sobre periodos más largos de tiempos.

Además, estos datos normalmente incluyen un gran número de usuarios para periodos relativamente largos, a coste mínimo (Q. Huang & Wong, 2015). El análisis espaciotemporal de esos datos puede revelar numerosa información oculta sobre comportamientos humanos en el espacio y tiempo, e interrelaciones con otras variables que afectan la movilidad (Keskin et al., 2014). Agrupando la información de la localización por múltiples días, los marcos de muestra temporales más largos pueden compensar la escasez espacial de la muestra en cada día, permitiendo el diseño de caminos espacio-temporales precisos (Q. Huang & Wong, 2015).

En esta comunicación, se busca indagar en el comportamiento temporal de la movilidad metropolitana y la naturaleza de las diferentes actividades desarrolladas a lo largo del día. Para este fin se propone como metodología la visualización de caminos espacio-temporales construidos a partir de datos de Twitter, el uso de datos de usos del suelo para predecir la actividad realizada por los usuarios en unas coordenadas espaciotemporales específicas, y la combinación de visualización en 2D y 3D para obtener la máxima información posible.

Mientras ha habido trabajos previos que han creado caminos espaciotemporales o han usado Twitter como fuente de datos para analizar la movilidad, solo se ha encontrado un estudio que ha empleado Twitter para la construcción de caminos espaciotemporales (Q. Huang & Wong, 2015). Este trabajo ha querido combinar estas dos vertientes. Sin embargo, los datos de Twitter capturan tiempo y localización, pero no recogen información más detallada como la naturaleza de los eventos o actividades realizadas. Por ello, una mejora metodológica que realiza este trabajo para paliar esta desventaja es la combinación del mapeado de caminos espacio-temporales creados a partir de datos de Twitter con datos estadísticos de usos del suelo. Unir los datos de usos del suelo con la actividad recopilada por los usuarios de Twitter tiene el potencial de informar de forma profunda el modo en el que los usuarios de Twitter interactúan con el espacio.

2. ÁREA DE ESTUDIO

Esta comunicación usa como área de estudio el Área Metropolitana de Madrid durante días laborables. Dentro de la ciudad de Madrid se han escogido cuatro zonas con actividades y usos del suelo dominantes o específicos. El objetivo a la hora de escoger dichas zonas es recoger la actividad y usos del suelo de los usuarios de Twitter en días laborables a cada hora, y usar estos resultados como proxy para estudiar los usos del suelo del Área Metropolitana de Madrid a lo largo del día (Figura 1).

1. Distrito de Puente de Vallecas. – Este distrito es un espacio netamente residencial y una de las zonas más densamente pobladas de la ciudad de Madrid. Para recoger usuarios de Twitter asociados a este espacio residencial, se han seleccionado los usuarios que han tuiteado habitualmente en este distrito en horario de noche (8 PM a 9 AM), de manera que podemos pensar son usuarios residentes en dicho espacio.

2. Complejo Nuevos Ministerios-AZCA. – Situado en el eje de la Castellana (una de las arterias principales de la ciudad que conecta el centro con el sector norte), es una de las principales zonas empresariales y financieras de Madrid, con un importante número de empleos. En este caso, se han seleccionado usuarios de Twitter que han tuiteado habitualmente en esta zona en horario de mañana (8 AM a 3 PM), considerando por tanto que se trata de usuarios cuyo empleo está en esta zona.

3. Ciudad Universitaria. - Es el principal campus universitario de la ciudad, donde se concentran las principales facultades de la Universidad Complutense de Madrid, pero también de la Universidad Autónoma de Madrid y otras universidades de ámbito privado. Nuevamente la selección de usuarios de Twitter se ha realizado a partir de aquellos usuarios que han tuiteado en este espacio en horario de mañana (8 AM a 3 PM).

4. Parque del Retiro. – Uno de los principales atractivos turísticos del centro de la ciudad, además de ser una de las zonas de ocio más utilizadas y uno de los pulmones más importantes de Madrid. En este caso, los usuarios de Twitter asociados al parque son aquellos que han tuiteado habitualmente en horario de tarde y tarde-noche (4 PM a 9 PM).

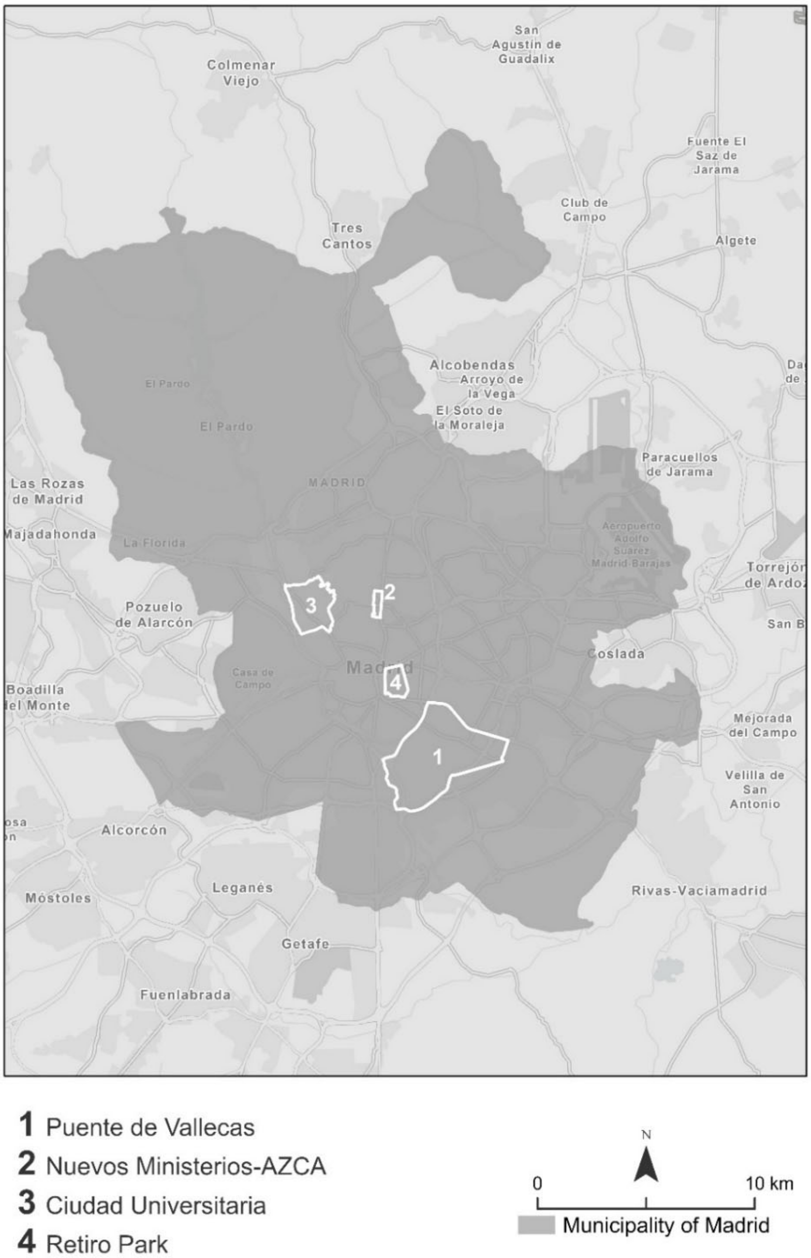

Fig. 1 – Zonas de estudio a analizar dentro del municipio de Madrid.

3. DATOS Y METODOLOGÍA

La base de datos de Twitter empleada para para esta comunicación tiene un total de 2.229.253 tweets, todos ellos georreferenciados y producidos por 171.631 usuarios localizados dentro del área metropolitana de Madrid. Estos tweets fueron recogidos en un periodo de dos años (desde el 1 de junio de 2016 hasta el 31 de mayo de 2018). Cada tweet cuenta con información relativa al identificador de usuario, el nombre de usuario, coordenadas espaciales de latitud y longitud, estampa temporal de fecha y hora, idioma y los hashtags que incluye el tweet.

Una vez incorporados los datos en un SIG, se procedió a una selección general de filtros para seleccionar usuarios útiles para la investigación y eliminar lo máximo posible el sesgo y ruido de los datos: Primero se eliminaron de la base de datos tweets cuyo identificador de usuario perteneciese a cuentas bot (cuentas con más de 1000 tweets publicados y con las mismas coordenadas en todos sus tweets, o cuentas con más de 10 tweets publicados con el mismo contenido semántico en el campo de texto de los tweets). Después, se eliminaron usuarios con muy baja actividad en Twitter, borrando los tweets de usuarios que hayan publicado menos de 20 tweets en total. A continuación, se eliminaron los mensajes de aquellos usuarios con poca movilidad espacial (una distancia media menor a 50 metros en la localización de todos sus tweets), y poca movilidad temporal (usuarios que tienen todos sus mensajes concentrados en un periodo temporal de dos semanas seguidas). De esta forma, se filtran posibles visitantes o turistas, y se asegura trabajar con población residente.

Además, se añadió un filtro consistente en eliminar usuarios con un rango horario igual o menor a ocho horas, con el fin de obtener solamente usuarios que hayan estado activos en la mayor parte del día.

A continuación, se amplió la muestra de datos a partir de la descarga de los últimos mensajes publicados por cada usuario con el objetivo de aumentar la precisión espacial y temporal de los movimientos individuales. Esta ampliación permite conseguir los últimos 3.200 tweets de cada usuario. Tras este segundo proceso de descarga, se filtraron los tweets no geolocalizados y que no se hallasen en el área de estudio o durante el periodo temporal de la muestra original. De esta forma se obtuvo una base de datos final con 18923 tweets de 2706 usuarios. Para mejorar la resolución temporal de los datos de Twitter, se trabajó agregando los tweets de múltiples días laborables, con el fin de obtener localizaciones concretas suficientes en una secuencia de 24 horas y diseñar así los caminos espacio-temporales diarios de cada usuario (Q. Huang & Wong, 2015). Estos tweets ya están previamente enriquecidos con datos del uso del suelo del Catastro. Al trabajar con tweets en días laborables se pueden hallar comportamientos regulares de movilidad, mientras que la movilidad urbana en los fines de semana es más errática. A partir de las fechas de cada tweet, y trabajando con un total de 516 días laborables, se calculó el número de días que cada usuario ha twitteado en un lugar y hora determinada.

Por cada usuario, se agregó el número de hora y el identificador de la zona de transporte de cada uno de sus tweets, con el objetivo de extraer en que zonas ha publicado cada usuario un mayor número de tweets en un número determinado de hora. Sin embargo, un individuo puede tener más de una localización visitada regularmente o múltiples trayectorias de viaje. Los puntos que están relativamente lejos de otros puntos tanto espacialmente como temporalmente pueden ser resultados de actividades aleatorias. En cambio, puntos cercanos espaciotemporalmente reflejan actividades regulares (Q. Huang & Wong, 2015). En casos en los que un usuario ha tuiteado desde más de una zona en una misma franja horaria, se seleccionó la zona de transporte donde se tuiteo un mayor número de días en dicha hora.

Si la frecuencia máxima de días en una hora dada coincide en más de una zona de transporte, se seleccionó la zona teniendo como referencia las zonas en las que se había escrito con mayor frecuencia en la hora anterior y posterior a la tratada.

Esta metodología de trabajar con los datos agrupados para el conjunto de días permite conocer patrones de actividad regular de los usuarios, pero pueden incluir actividades irregulares, introduciendo ruido o incertidumbre (Q. Huang & Wong, 2015). Para calcular caminos espaciotemporales de recorrido recurrente, se han definido estancias en cada una de las franjas horarias para las localizaciones de zonas de transporte donde el usuario ha tuiteado durante un mínimo de 3 días laborables. De esta forma se descartan puntos con potencial actividad aleatoria. Entonces, se simplificó la base de datos para que solo hubiese un punto registrado por usuario, lugar, y zona de transporte. Como resultado, se han obtenido 18923 puntos con los que se puede simular el camino espacio-temporal de 2706 usuarios en el Área Metropolitana de Madrid.

A continuación, se seleccionaron las cuatro áreas de estudio con una orientación fuerte a un uso de suelo concreto en las horas más propicias para el desarrollo de determinadas actividades. El siguiente paso fue seleccionar de la base de datos los usuarios que tengan un punto dentro de cada franja temporal definida en cada zona de estudio. La Tabla 1 presenta el número de usuarios válidos para los que se han obtenido caminos espaciotemporales en las distintas zonas de estudio. Finalmente, para la representación de los recorridos espaciotemporales en 3D, se ha otorgado a cada punto un valor de altura igual al número de hora, multiplicado por un factor de exageración de 200. Con estos valores, se han construido capas de líneas para representar los caminos espaciotemporales.

Zona	Horario	Tipo	Número usuarios validos
Puente de Vallecas	Noche (8 PM a 9 AM)	Residencial	27
Nuevos Ministerios-AZCA	Mañana (8 AM a 3 PM)	Trabajo	19
Ciudad Universitaria	Mañana (8 AM a 3 PM)	Estudios	30
Parque del Retiro	Tarde (4 PM a 9 PM)	Ocio	39

Tabla 1 – Número de usuarios en cada zona de estudio.

3. RESULTADOS

Los resultados obtenidos muestran el comportamiento de los usuarios en distintos momentos del día acorde con las actividades principales en cada una de las zonas de estudio seleccionadas para la elaboración de este capítulo (a partir de las muestras de usuarios detalladas en la Tabla 1). La zona residencial de Puente de Vallecas muestra una disminución gradual del porcentaje de usuarios durante la mañana, y un aumento del porcentaje a lo largo de la tarde, hasta llegar al horario de noche donde se concentran los mayores porcentajes de usuarios. Esta es una pauta característica del carácter residencial de la zona. En el área de oficinas de Nuevos Ministerios-AZCA se aprecia una mayor concentración de usuarios a lo largo de la mañana (con un pico determinado en las 2PM, fin del horario laboral por la mañana) y un fuerte descenso de usuarios por la tarde. El caso de Ciudad Universitaria es relativamente similar, aunque el porcentaje de usuarios aumenta de forma más brusca a primeras horas de la mañana y desciende más lentamente por la tarde. En el Parque del Retiro, el porcentaje de usuarios va en aumento a lo largo del día, con predominancia de usuarios en el horario de tarde. Cuando llega la noche, este porcentaje de usuarios empieza a disminuir prolongadamente (Figura 2).

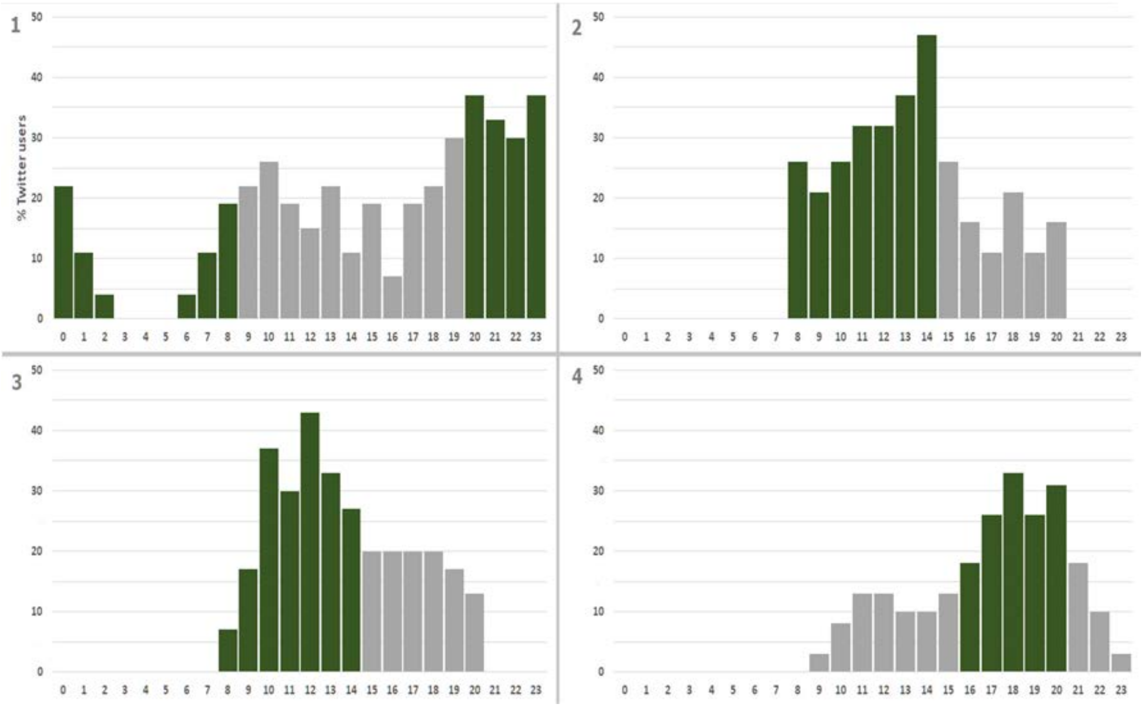

Fig. 2 – Distribución de usuarios por hora en Puente de Vallecas (1), Nuevos Ministerios-AZCA (2), Ciudad Universitaria (3), y Parque del Retiro (4).

La distribución temporal de usuarios basada en los usos del suelo, corrobora la situación observada en las zonas de estudio. En la zona de Puente de Vallecas, el principal uso del suelo, el residencial, consta de un continuo aumento a lo largo del día a partir de primera hora de la tarde hasta llegar a su máximo por la noche. Se puede observar en menor grado un constante uso comercial a lo largo del día, y un uso de hostelería en las horas de almuerzo y cena. Nuevos Ministerios-AZCA presenta un uso del suelo principal de oficinas en horario de mañana y que va descendiendo por la tarde, cuando a su vez, el uso comercial pasa a ser la principal actividad de los usuarios de la zona. También se pueden apreciar dos picos de hostelería a la hora del desayuno y almuerzo. El uso cultural es predominante en Ciudad Universitaria durante todo el día, especialmente durante la mañana y las primeras horas de la tarde. Se puede apreciar usos del suelo de oficinas e industrial por la mañana, y uso de los espacios deportivos a últimas horas de la mañana y durante la tarde. Finalmente, el Parque del Retiro presenta sus mayores porcentajes de usos del suelo en horario de tarde, a la vez que paralelamente se da uso del suelo de hostelería (Figura 3).

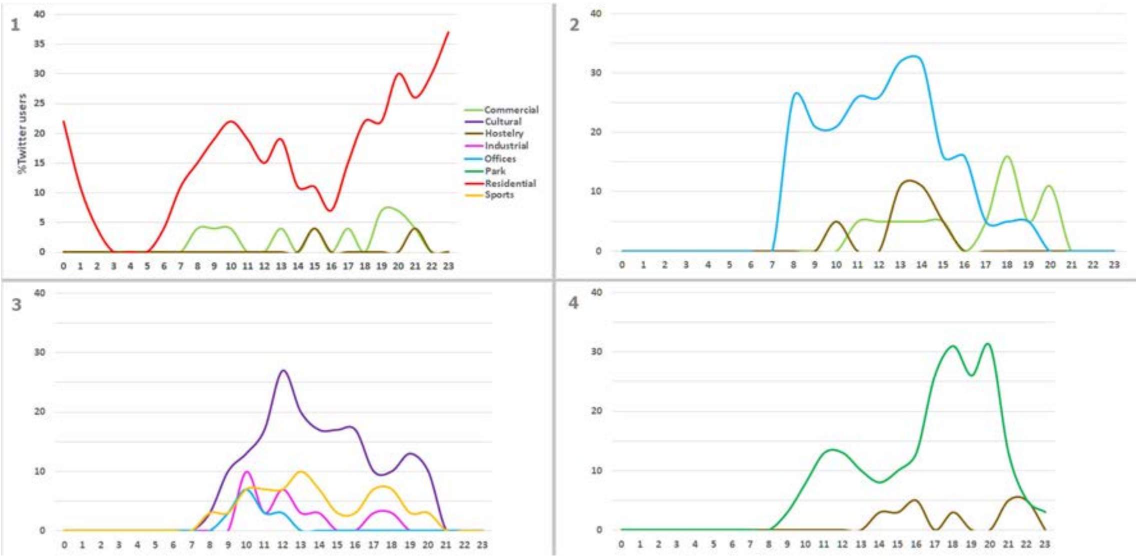

Fig. 3 – Distribución de usuarios por usos de suelo y hora en Puente de Vallecas (1), Nuevos Ministerios-AZCA (2), Ciudad Universitaria (3), y Parque del Retiro (4).

La visualización de los caminos espaciotemporales en 2D muestra los destinos de los desplazamientos para los residentes en el espacio residencial de Puente de Vallecas y los orígenes de los trabajadores en la zona de oficinas de AZCA, los estudiantes de Ciudad Universitaria o los usuarios del parque del Retiro (Figura 4). Mientras, la visualización en 3D permite contemplar los movimientos de estos usuarios a lo largo del día y su distribución temporal en las zonas de estudio (Figura 5).

En la visualización 3D se puede apreciar que los residentes detectados en Puente de Vallecas salen del barrio preferentemente a primera hora de la mañana y se desplazan principalmente a la cercana estación de trenes de Atocha, desde donde se mueven a otros puntos de la ciudad (principalmente el centro o zonas del norte de la ciudad que concentran la oferta de trabajo). También se aprecia algunos movimientos de regreso y salida entre las 2PM y las 4PM, usuarios que vuelven a la residencia a almorzar y vuelven al trabajo, y un regreso al barrio a partir de las 8PM. Paralelamente se puede apreciar un movimiento interno de usuarios que se desplazan a lo largo del día por la zona, mostrando el carácter dinámico de un distrito de población obrera que también cuenta con actividad de trabajo y ocio internos.

Mientras, la zona de oficinas de Nuevos Ministerios-AZCA recibe usuarios en horario de mañana, que provienen principalmente de las estaciones de tren de la ciudad (usuarios del área metropolitana que viajan a la zona en tren) y también del este de la ciudad o de los municipios colindantes del norte o del oeste (caracterizados por una población empresarial con niveles altos de renta). Igualmente, se aprecia una amplia diversificación de los caminos al resto de la ciudad a lo largo del día, principalmente por la tarde (usuarios que retornan a su residencia).

Una situación similar aparece en la Ciudad Universitaria, donde destaca un número importante de caminos a partir de las estaciones de tren, que van a la universidad en horario de mañana y salen de la universidad constantemente durante la tarde. En este caso se aprecia un flujo de caminos importante que proviene principalmente de las zonas residenciales del oeste y del sur del área metropolitana, pero que cuenta con un área de influencia mayor que la zona de oficinas. Además, las horas del día en la que los estudiantes llegan a Ciudad Universitaria están más concentradas, principalmente por la mañana y a primera hora de la tarde.

En el Parque del Retiro se pueden apreciar movimientos en la zona durante todo el día provenientes principalmente de espacios próximos en norte y el este de la ciudad y con mayor frecuencia en horario de tarde. La visualización en 2D muestra un área de influencia de sus visitantes mucho más pequeña en comparación con las dos zonas anteriores de trabajo y estudios, e indica un desplazamiento de ciudadanos principalmente del propio municipio de Madrid debido a su carácter temático y recreacional.

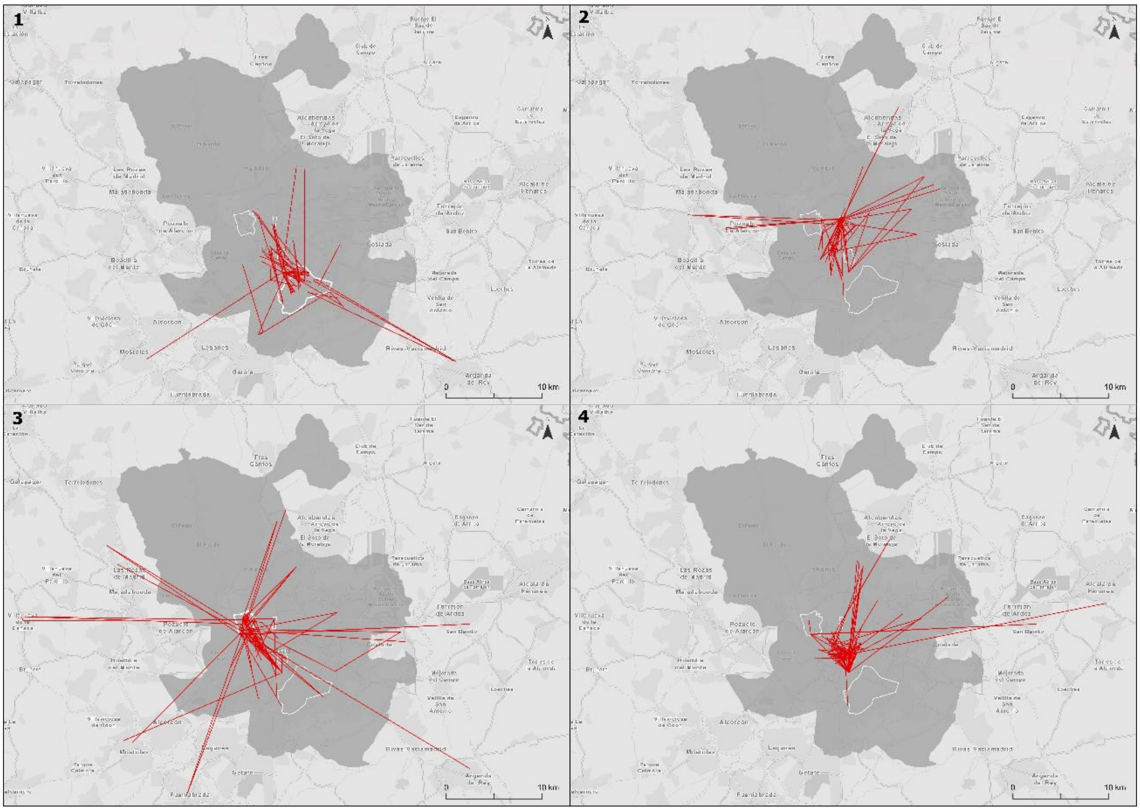

Fig. 4 – Caminos espaciotemporales a lo largo del día (2D) en Puente de Vallecas (1), Nuevos Ministerios-AZCA (2), Ciudad Universitaria (3), y Parque del Retiro (4).

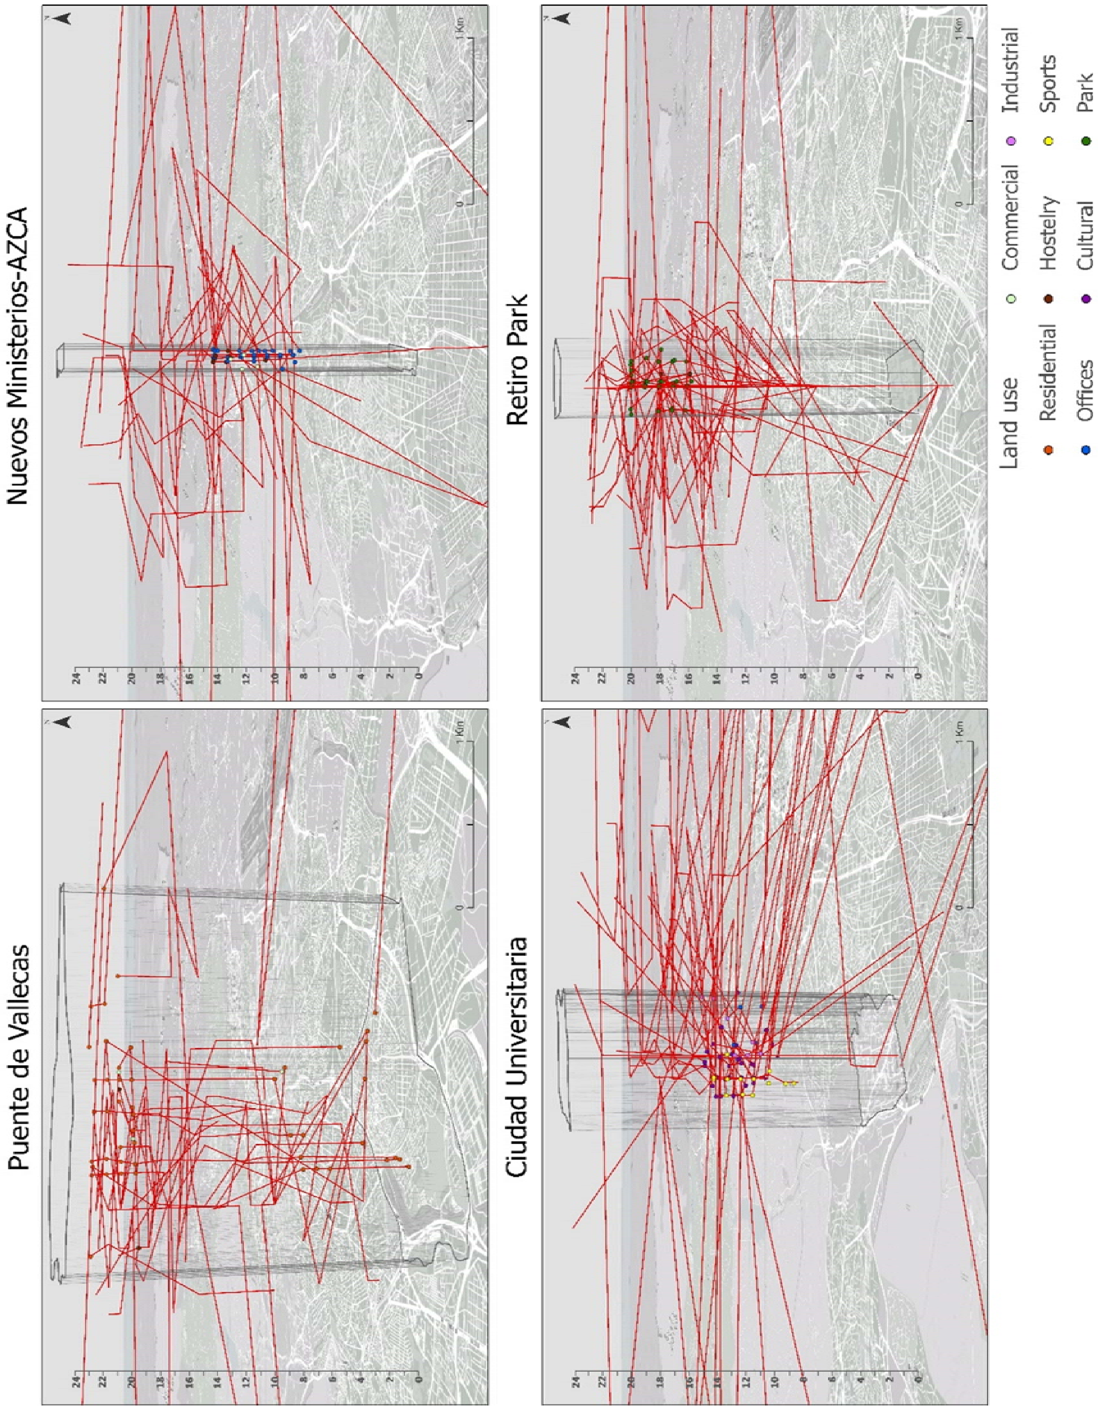

Fig. 5 – Caminos espaciotemporales a lo largo del día (3D).

4. CONCLUSIONES

La evolución en los últimos años de los SIG para el análisis y computación de datos, aunada con la aparición de nuevas fuentes de datos basadas en las TIC, han propiciado una nueva etapa en la Geografía del Tiempo. Una de las herramientas más empleadas en este campo es el camino espacio-temporal diseñado por Hägerstraand. Este tipo de análisis estaba limitado tradicionalmente por la disponibilidad de datos. Sin embargo, los datos procedentes de telefonía móvil o de redes sociales geolocalizadas, permiten hoy el procesado de caminos espaciotemporales con una alta resolución espacial y temporal.

En esta tesis se ha buscado indagar en las oportunidades de los datos de Twitter y las herramientas y visualizaciones necesarias para conocer la movilidad temporal de usuarios de distintos tipos de espacios urbanos.

De forma general se ha podido apreciar que los ciudadanos se desplazan a las áreas especializadas en trabajo por la mañana y regresan a sus residencias a lo largo de la tarde.

La distribución de los usos del suelo por hora concuerda con la visualización de la distribución de los usuarios de Twitter en el área de estudio, pudiéndose apreciar usuarios principalmente en usos de suelo relacionados con oficinas y estaciones de transporte por la mañana, y un número en aumento en parcelas residenciales a lo largo de la tarde.

Algunas limitaciones tradicionales de la geografía del tiempo consisten en que habitualmente, las vidas diarias presentan varias rutas o actividades, que, aunque ocurren en ciertas localizaciones primarias, pueden ocasionalmente ser conducidas en localizaciones alternativas. Igualmente, un individuo puede no realizar las mismas actividades en los mismos tiempos todos los días, o puede ir a un mismo sitio siguiendo una ruta alternativa (Q. Huang & Wong, 2015). El uso de filtros en datos de Twitter en función al número de días en los que un usuario ha estado en unas coordenadas espaciales y temporales puede ayudar a paliar estas limitaciones eliminando puntos aleatorios, y mostrando los puntos adecuados para realizar un camino espacio-temporal preciso y concurrente.

La cartografía tanto en 2D como en 3D realizada permite mostrar la utilidad del uso de Twitter como alternativa para la construcción de caminos espaciotemporales. Los datos de Twitter tienen la ventaja de una alta resolución espacial, en forma de coordenadas (x, y) a diferencia de los datos de telefonía, y la posibilidad de obtener datos a un coste bajo. Además, estos datos pueden enriquecerse con datos complementarios, como los usos de suelo del Catastro para poder estudiar la actividad principal de los usuarios en las distintas zonas de estudio a determinadas horas.

Sin embargo, este trabajo ha tenido algunos retos y limitaciones a tener en cuenta. El principal problema encontrado ha sido la baja muestra de usuarios en cada zona de estudio.

Este problema se debe principalmente al sesgo de la red social y a la poca cantidad de usuarios de Twitter que activan la opción de geolocalizar sus tweets. Otro desafío consiste en que habitualmente, las actividades diarias de la población se realizan en unas pocas localizaciones habituales (casa, trabajo, etc.), pero ocasionalmente pueden realizarse en localizaciones alternativas. Igualmente, un individuo puede no realizar una misma actividad en distintos tiempos según los días, o puede ir a un mismo sitio siguiendo una ruta alternativa (Q. Huang & Wong, 2015).

El uso de filtros en datos en función del número de días en los que un usuario ha estado en unas coordenadas espaciales y temporales puede ayudar a paliar estas limitaciones eliminando puntos aleatorios.

Un aumento del periodo temporal de la muestra permitiría recopilar más usuarios o caminos espaciotemporales más precisos, al disponer de mayor cantidad de localizaciones. Sin embargo, el aumento de la muestra también conlleva un mayor riesgo de obtener puntos aleatorios. Precisamente, otra mejora puede ser aumentar el número de días máximos en los que un usuario haya twitteado en un lugar a una hora para disminuir la probabilidad de tener puntos aleatorios, permitiendo el aumento de la muestra incrementar el filtro.

AGRADECIMIENTOS

Los autores agradecen la financiación del Minsiterio de Educación, Cultura y Deporte (Programa FPUAP2015- 0147), y del Ministerio de Ciencia, Innovación y Universidades y el Fondo Europeo de Desarrollo Regional (FEDER) (Proyecto DynMobility, RTI2018-098402-B-I00).

ABSTRACT

The World Health Organization (WHO) declared COVID-19 a pandemic on March 11, 2020. Three days later, the Spanish Government declared a state of alarm, which lasted until June 20. This state consisted of a two-month lockdown with mobility restrictions and a two-month phased easing of lockdown.

This paper analyses the evolution of mobility patterns in the Region of Madrid through statistical information to study the impact of the COVID-19 crisis based on data from the Spanish National Statistics Institute (INE).

The results obtained in this paper show that, during the lockdown, trips made in the Region of Madrid fell by 70% compared to the usual scenario. However, the variations in mobility were very different in each area of the territory. For example, trips to San Sebastián de los Reyes were reduced by more than 90%, while trips from San Fernando de Henares decreased by only 30%.

Once the easing of lockdown phases began, there was an increase in trips in the Region of Madrid of more than 60% compared to trips made during the lockdown. This growth was also very irregular. For example, travels from Arganda del Rey increased by more than 260%, while trips to the same municipality only increased by 13%.

The mobility study is complemented with the analysis of socioeconomic variables, land use, and transport network to clarify the evolution of the different areas in the Region of Madrid during the COVID-19 crisis

1. INTRODUCTION

This document analyzes the evolution of mobility in the Region of Madrid during the state of alarm declared by Royal Decree 463/2020, of March 14, to manage the health crisis caused by the COVID-19, extended until June 21, 2020.

As a data source, the information provided by the Spanish National Statistics Institute (INE) is used, whose collection and preparation methodology is analyzed and discussed in the first section of this document.

With these data, the intra-areal and inter-areal movements in the Region of Madrid during the different phases of the state of alarm will be studied. Finally, a study of socioeconomic variables, land use, and transport network will be carried out to characterize how the state of alarm has affected the mobility of each territory of the region.

2. METHODOLOGY

2.1 Geographical and temporal scope

INE divides the national territory into 3,200 mobility areas. This unit comprises between 5,000 and 50,000 inhabitants, being much more homogeneous than the municipalities. Thus, in sparsely populated areas, an area of mobility will be the union of several municipalities, and in large cities, these areas will be districts or neighborhoods. The data are added from mobility areas, obtaining results at provincial, regional, and national levels.

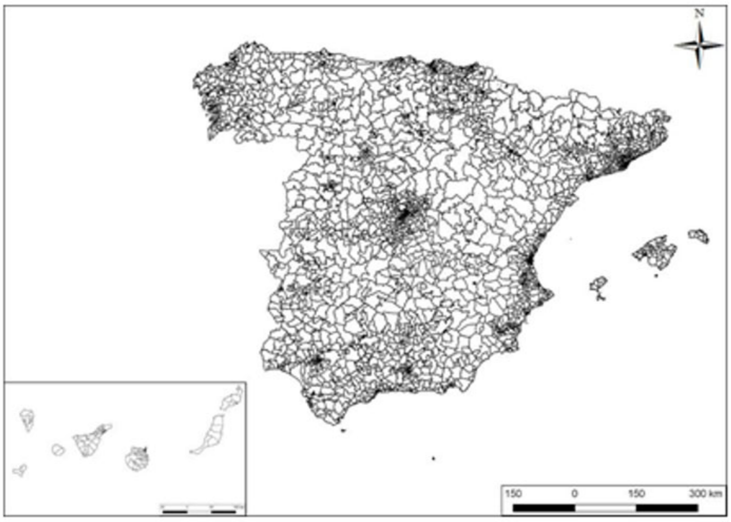

Fig. 1 – Mobility areas. Source: Own elaboration from INE

Because the data is based on the positioning of mobile devices, it is worth mentioning the precision of this method to analyze the data. According to sources, the accuracy will be tens or hundreds of meters in urban areas and kilometers in rural areas.

The temporal scope dealt with exclusively comprises the state of alarm, offering data from March 16 to June 20, 2020. On the other hand, the reference week to contrast the mobility data used is the week from Monday 18 to Thursday 21, November 2019, taking the average of this week's data as the mobility of a “normal” day.

2.2 Data sources, preparation, and supply of information

The primary data source for this study is anonymized mobile phone records, working with more than 80% of mobile phones throughout Spain in collaboration with the three leading mobile phone operators (Orange, Telefónica, and Vodafone). Regarding demographic data, these are obtained from the Municipal Register of Inhabitants on January 1, 2019.

In the technical project of the study, it is specified that the areas of residence are identified as the areas in which the telephone spends most of the time between 12 a.m. and 6 a.m. Destination areas are calculated as the most frequent area where the phone is between 10 a.m. and 4 p.m. as long as the device has been in that area for more than two hours.

Operators offer movements between areas as long as there are more than 10 or 15 movements, depending on the operator, to protect their users' privacy. For its part, the INE aggregates this information and offers the flows as long as it exceeds 100 movements.

This information allows knowing which part of the population remains in their area of residence most of the time, taking into account that movements within the area of residence are not counted.

The INE offers the population and its movement by mobility areas, provinces, regions, and the national total and data and origin-destination flows between mobility areas.

3. MOBILITY STUDY

3.1 Geographical and temporal scope

INE divides the Region of Madrid into 293 mobility areas. In this way, the most populated municipalities, such as Madrid or Móstoles, are divided into smaller areas. Similarly, the less populated municipalities are united in the same larger mobility area.

This study will work with the most significant territorial unit in each case. In the case of Madrid, for example, the 141 areas proposed by INE will be joined. In contrast, in the less populated areas, the INE mobility area will be used. In this way, the Region of Madrid will be divided into 102 study areas.

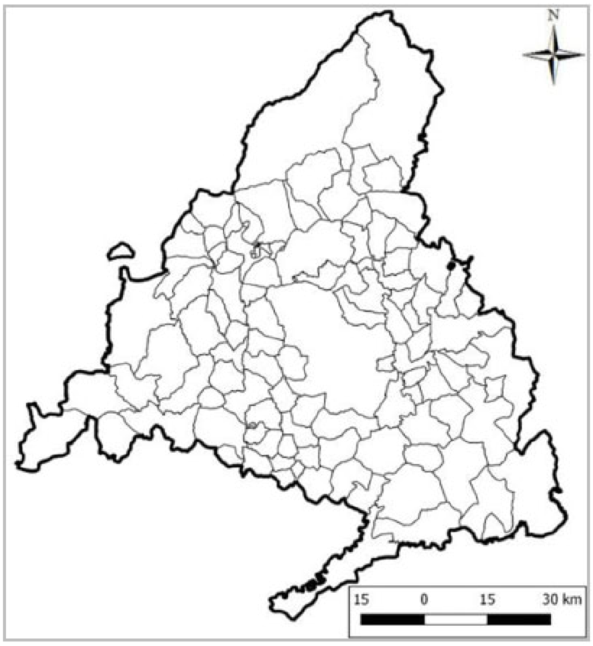

Fig. 2 – Study areas. Source: Own elaboration from INE

Before starting with the mobility data analysis, the different phases that the Region of Madrid went through during the state of alarm should be clarified:

- Lockdown: from March 15 to May 10, 2020.
- Phase 0: from May 11 to 24, 2020.
- Phase I: from May 25 to June 7, 2020.
- Phase II: from June 8 to 21, 2020.

To carry out an analysis throughout the different phases of the state of alarm, six dates have been selected for which an analysis of the origin-destination flows is made:

- Normality: average of data from November 18 to 21, 2019.
- Lockdown: average of data from March 26 and April 30, 2020.
- Phase 0: data from May 21, 2020.
- Phase I: data from May 28, 2020.
- Phase II: data from June 18, 2020.

3.2 General mobility

First, the number of total trips made with origin in the Region of Madrid will be analyzed.

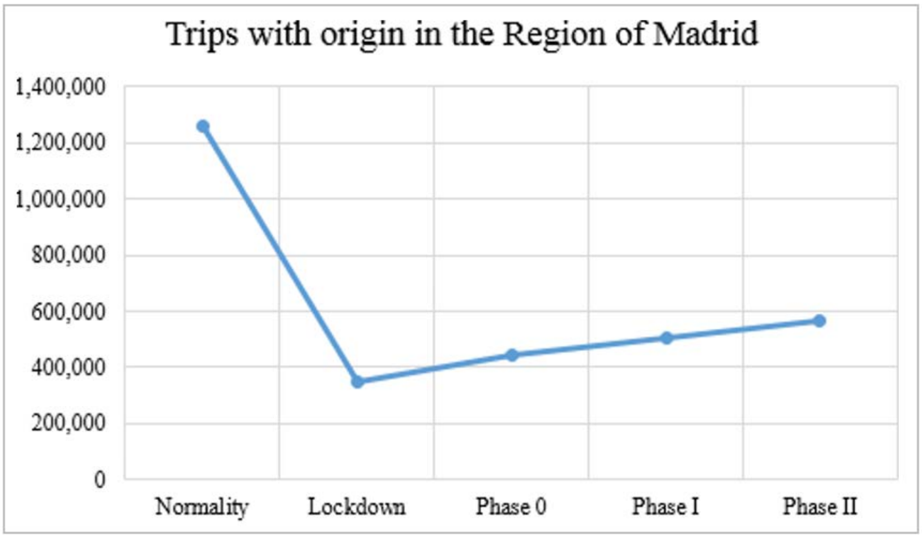

Fig. 3 – Evolution of trips with origin in the Region of Madrid during the state of alarm. Source: Own elaboration from INE

As shown in the previous figure, the data analysis allows us to see that the number of trips made in the Region of Madrid during a normal period is more significant than 1,250,000 trips. During the lockdown, this amount fell by more than 70%, with just over 350,000 trips. With the easing of lockdown, trips increased progressively but did not reach 50% of the trips made during a normal period

3.3 Intra-areal mobility

The analysis of intra-areal mobility consists of the study of movements within the same study area. For this reason, this analysis is only carried out in areas that are divided into several mobility areas, these being the most populated areas of the Region of Madrid.

Before entering into the data analysis, the particular case of Alcalá de Henares and Los Santos de la Humosa should be discussed. The municipality of Alcalá de Henares is divided into five mobility areas, the last of which is linked to Los Santos de la Humosa, so these two municipalities will be analyzed together as Alcalá de Henares.

STUDY AREA	MOBILITY AREAS	POPULATION (2019)
Alcalá de Henares	5	198,239
Alcobendas	3	117,040
Alcorcón	4	170,514
Aranjuez	4	59,607
Coslada	3	81,661
Fuenlabrada	9	193,700
Getafe	4	183,861
Leganés	7	189,861
Madrid	141	3,266,126
Majadahonda	2	71,826
Móstoles	6	209,184
Parla	3	130,124
Pinto	2	52,526
Pozuelo de Alarcón	2	86,422
Rivas-Vaciamadrid	3	88,150
Las Rozas de Madrid	3	95,814
San Sebastián de los Reyes	3	89,276
Torrejón de Ardoz	4	131,376
Valdemoro	2	75,983

Table 1 – Study areas in the intra-areal mobility analysis. Source: Own elaboration from INE

Intra-areal movements of the study areas correspond to approximately 70% of the trips made in the Region of Madrid. That is, 70% of the people do not leave their area of residence.

These intra-areal movements decreased by 68% during the lockdown, and during the easing of lockdown, they gradually increased until reaching 47% of the mobility of the normal period.

Analyzing the evolution of mobility in the different areas, the effect of mobility restrictions has not been uniform in all areas. Thus, the most affected areas have been Alcalá de Henares, Aranjuez and Madrid and the least affected Leganés, Móstoles and Torrejón de Ardoz.

LEVEL	DECREASES INTRA-AREAL	STUDY AREAS
Very high	> 70%	3
High	60-70%	5
Moderate	50-60%	8
Low	< 50%	3

Table 2 – Decreases in intra-areal mobility during the lockdown. Source: Own elaboration from INE

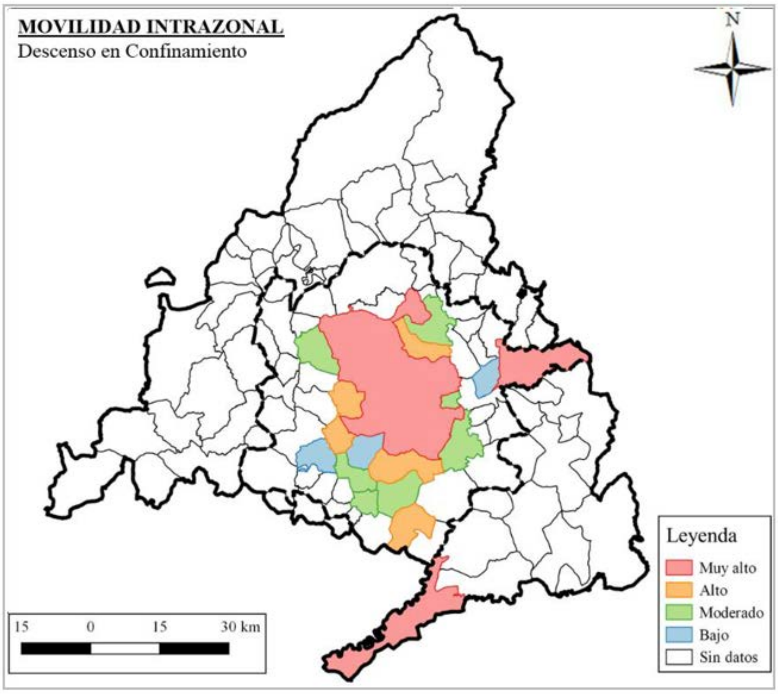

Fig. 4 – Decreases in intra-areal mobility during the lockdown.
Source: Own elaboration from INE

In the same way, the increase in mobility that occurred in the different phases of the easing of lockdown was not the same in the areas, with recoveries of between 4% and 30%, being the most pronounced in Alcalá de Henares and San Sebastián de los Reyes.

LEVEL	INCREASES INTRA-AREAL	STUDY AREAS
Very high	> 25%	2
High	20-25%	6
Moderate	15-20%	5
Low	< 15%	6

Table 3 – Increases in intra-areal mobility during the easing of lockdown. Source: Own elaboration from INE

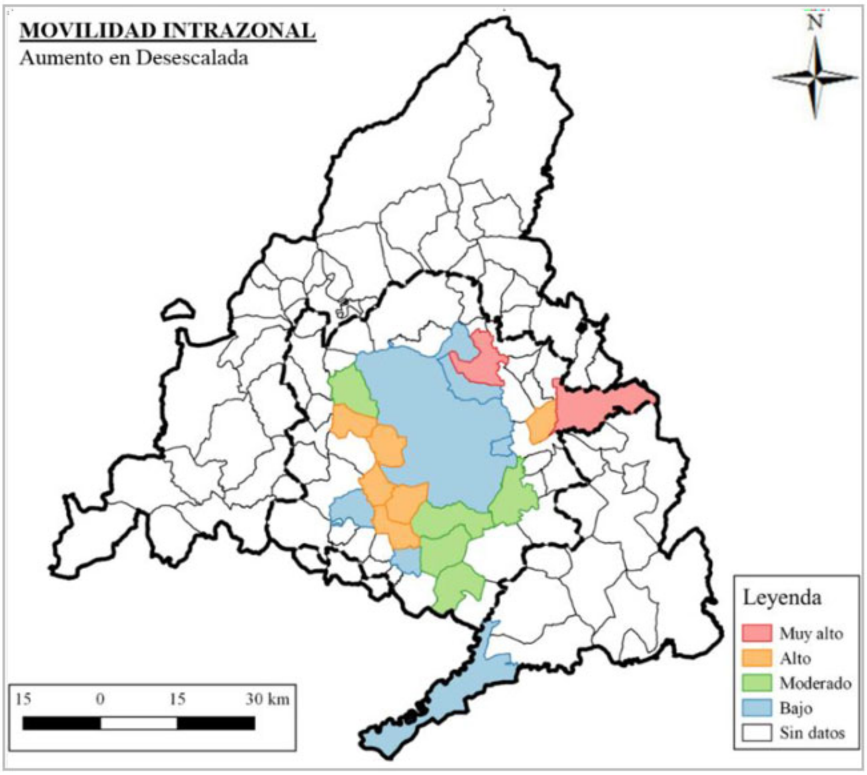

Fig. 5 – Increases in intra-areal mobility during the easing of lockdown.
Source: Own elaboration from INE

3.4 Inter-areal mobility

The analysis of inter-areal mobility consists of the study of the incoming and outgoing movements of each area. In this case, all study areas of the Region of Madrid are taken into account, and different areas of the Region of Castilla-La Mancha, which receive trips from Madrid.

The inter-areal movements of the study areas correspond to approximately 30% of the trips made in the Region of Madrid. That is, 30% of the people leave their area of residence.

These inter-areal movements decreased by 80% during the lockdown, and during the easing of lockdown, they gradually increased until reaching 42% of the mobility of the normal period.

3.4.1 Flows

To understand the evolution of the relationships of the study areas during the state of alarm, six flow maps have been made.

The first of them corresponds to the period of normality, in which it can be seen that the trips are concentrated in the capital and the north, west, and south sectors and, to a lesser extent, in the Henares Corridor. Most of the trips are located within the metropolitan area, with more superficial relationships in the provincial area, from which trips are made to the municipalities of Guadalajara and Toledo, adjacent to the Region of Madrid.

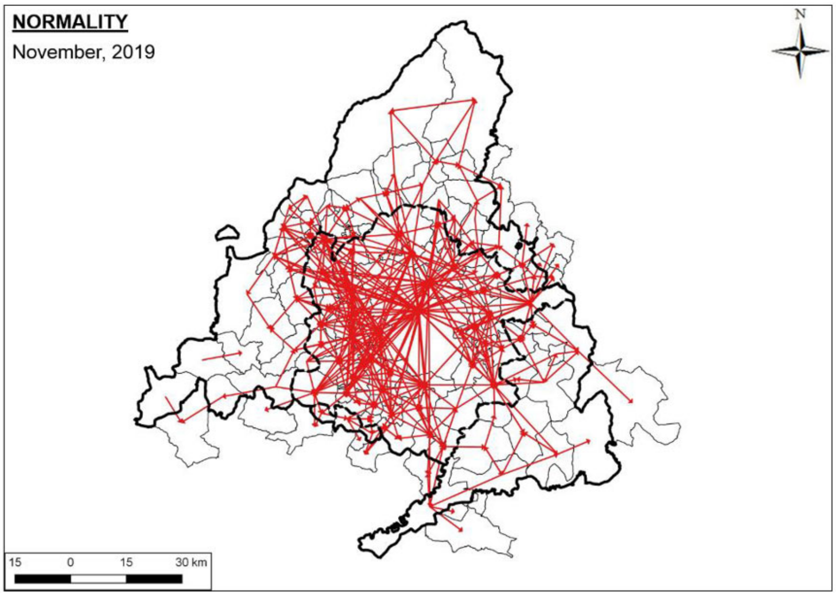

Fig. 6 – Origin-destination flows during the normality period (November 2019). Source: Own elaboration from INE

The flow maps of the trips made during lockdown are shown below. In these, it can be seen that the volume of flows is considerably reduced; practically disappearing trips in the provincial area, as well as in the foreign area.

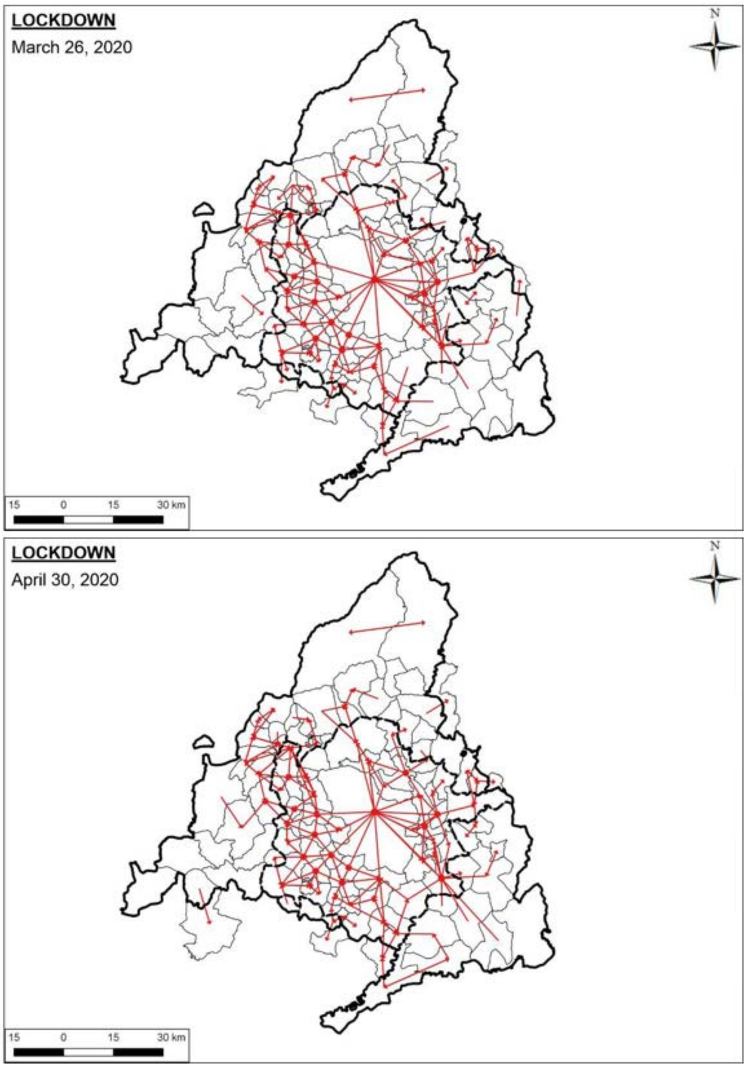

Fig. 7 – Origin-destination flows during the lockdown (March and April 2020). Source: Own elaboration from INE

Finally, flow maps have been made for each phase of the easing of lockdown. It should be noted that, despite the increase in mobility, the provincial and foreign areas do not increase their relationships.

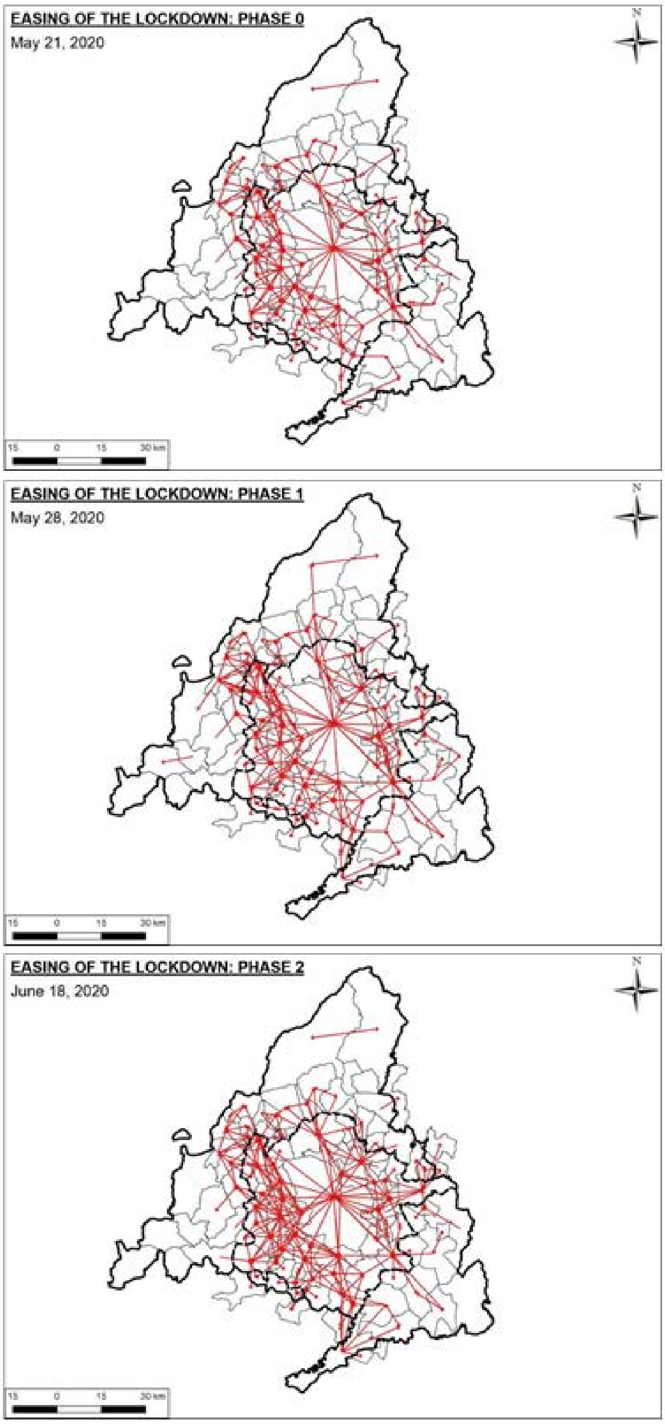

Fig. 8 – Origin-destination flows during the easing of lockdown (May and June 2020). Source: Own elaboration from INE

3.4.2 Outgoing movements

The evolution of the outgoing inter-areal movements has not been uniform in each study area of the Region of Madrid. To see how the effect has been in each area, the same methodology used in the intra-areal movements is followed.

According to the data structure, only flows in which more than 100 trips are made are shown. Due to this restriction, the study areas of Fuentidueña de Tajo and other municipalities, Navalagamella and other municipalities, and Navas del Rey and Chapinería do not have data on outbound trips, so they will not be taken into account in this analysis.

In the analysis of the outgoing inter-areal movements, it can be seen that the most affected areas during the lockdown, for the most part, are within the metropolitan area, in addition to some areas of the northeast of the region and the most rural areas of the southwest.

LEVEL	DECREASES OUTGOING INTER-AREAL	STUDY AREAS
Very high	> 90%	15
High	80-90%	28
Moderate	60-80%	38
Low	< 60%	18

Table 4 – Decreases in outgoing inter-areal mobility during the lockdown. Source: Own elaboration from INE

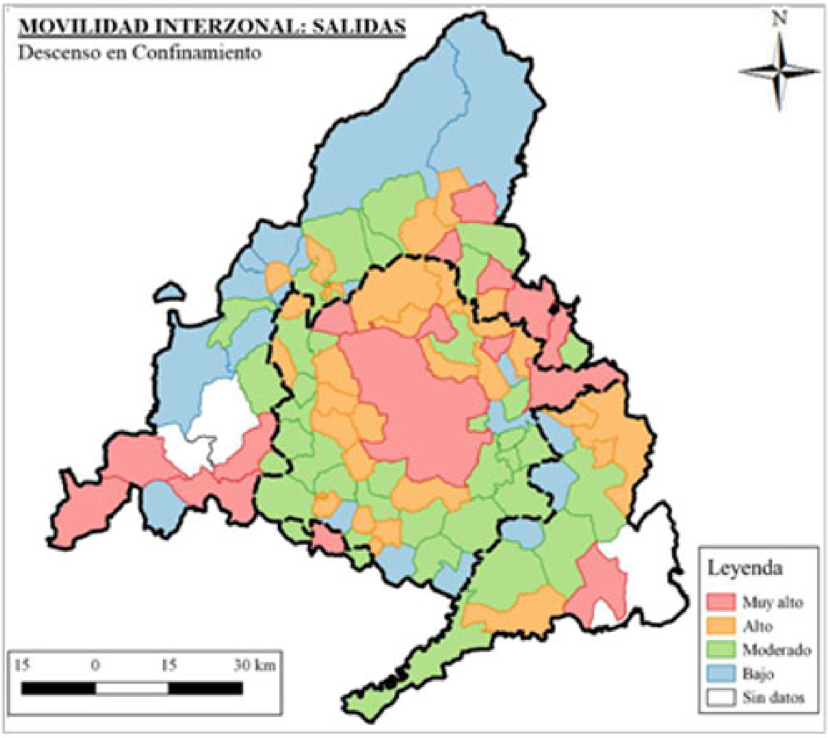

Fig. 9 – Decreases in outgoing inter-areal mobility during the lockdown.
Source: Own elaboration from INE

Outgoing movements increased in a high-moderate way in the metropolitan area during the easing of lockdown, with very high data in Arganda del Rey and San Martín de la Vega.

There were significant increases in the north of the provincial area, contrasting with the low increases in the east and west.

LEVEL	INCREASES OUTGOING INTER-AREAL	STUDY AREAS
Very high	> 50%	9
High	25-50%	30
Moderate	10-25%	32
Low	< 10%	28

Table 5 – Increases in outgoing inter-areal mobility during the lockdown. Source: Own elaboration from INE

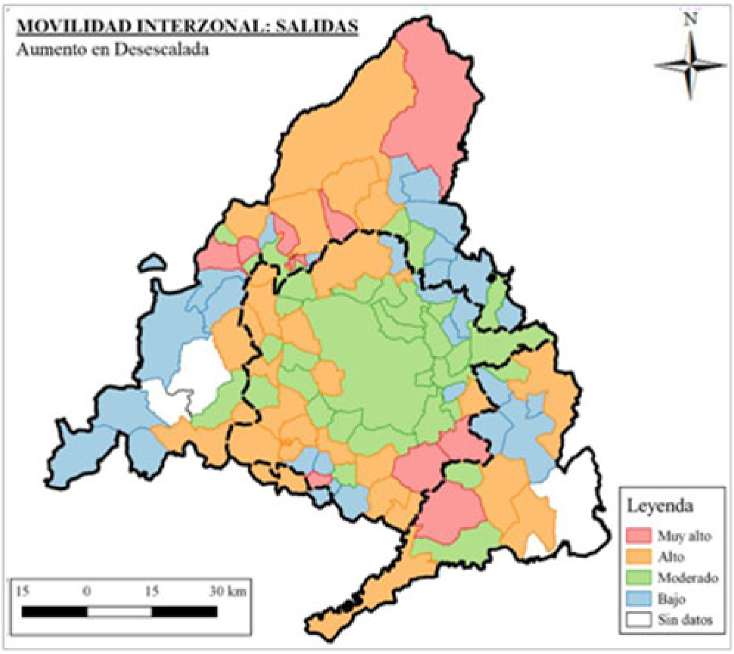

Fig. 10 – Increases in outgoing inter-areal mobility during the easing of lockdown. Source: Own elaboration from INE

3.4.3 Incoming movements

The evolution of the incoming inter-areal movements has not been uniform in each study area of the Region of Madrid. To see how the effect has been in each area, the same methodology used in the intra-areal movements is followed.

According to the data structure, only flows in which more than 100 trips are made are shown. Due to this restriction, the study areas of Aldea del Fresno and Villamanta, Cadalso de los Vidrios and other municipalities, Pedrezuela, San Martín de Valdeiglesias and Pelayos de la Presa, Sevilla la Nueva and Valdetorres de Jarama do not have travel data for input, so they will not be taken into account in this analysis.

The lockdown brought a high decrease in incoming trips in the central and south-eastern areas of the region. It should be noted that the southern regions of the metropolitan area did not undergo significant changes, remaining at low-moderate levels of decrease.

LEVEL	DECREASE INCOMING INTER-AREAL	STUDY AREAS
Very high	> 90%	23
High	80-90%	13
Moderate	60-80%	33
Low	< 60%	27

Table 6 – Decreases in income inter-areal mobility during the lockdown. Source: Own elaboration from INE

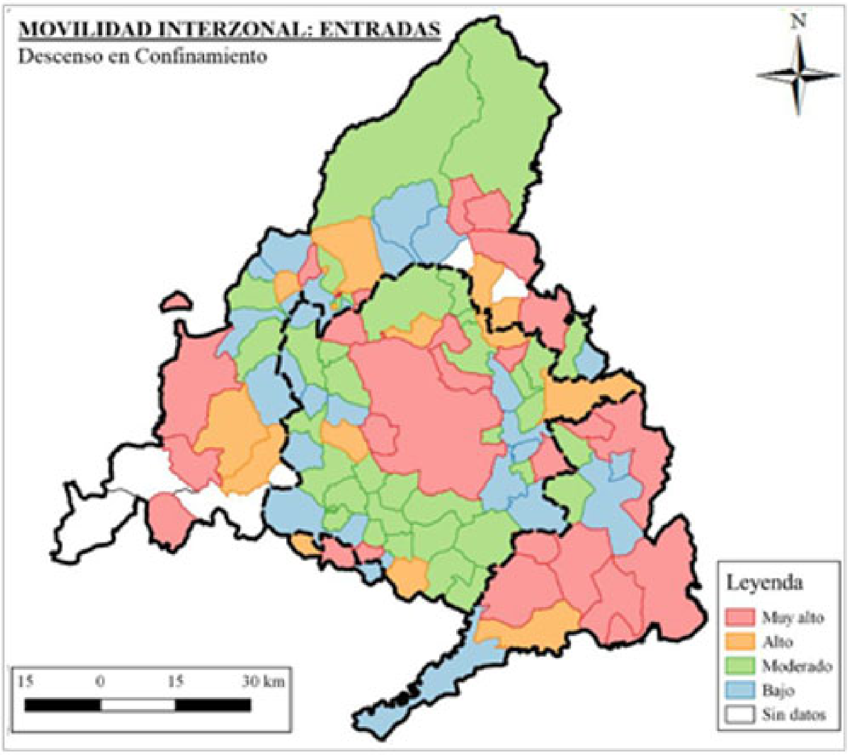

Fig. 11 – Decreases in income inter-areal mobility during the lockdown. Source: Own elaboration from INE

The increase in incoming trips during the easing of lockdown was generally moderate- high. In contrast to the trend of low changes in the south of the region, these areas suffered high increases during the easing of lockdown.

LEVEL	INCREASES INCOME INTER-AREAL	STUDY AREAS
Very high	> 50%	16
High	25-50%	29
Moderate	10-25%	29
Low	< 10%	22

Table 7 – Increases in incoming inter-areal mobility during the easing of lockdown. Source: Own elaboration from INE

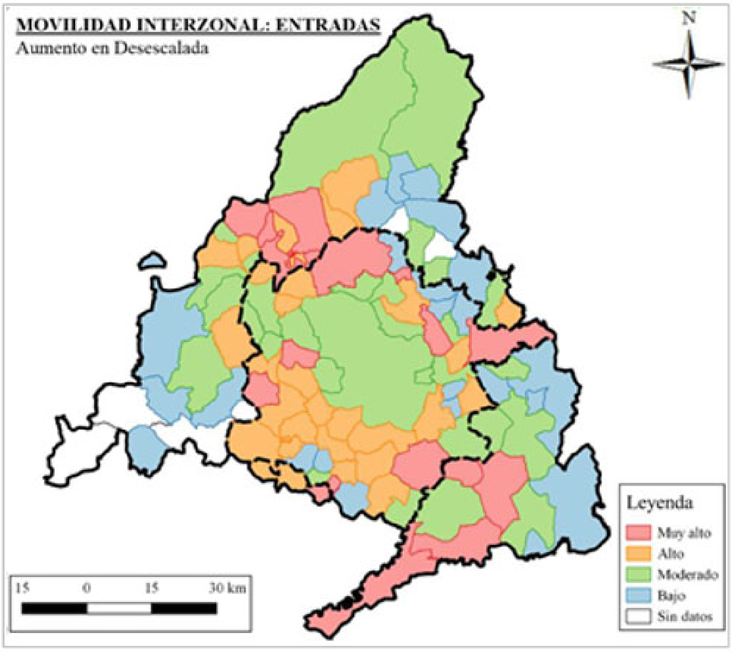

Fig. 12 – Increases in incoming inter-areal mobility during the easing of lockdown. Source: Own elaboration from INE

4. SOCIOECONOMIC, LAND USE AND TRANSPORT STUDY

4.1 Introduction and methodology

The socioeconomic analysis of the different study areas of the Region of Madrid is carried out to contextualize the condition of the lockdown and the easing of lockdown in mobility.

Different socioeconomic variables that will characterize each study area have been analyzed. In the same way that the mobility analysis has been carried out, these variables will be discretized into four categories.

The data that have been used in the analysis have been extracted from ALMUDENA Municipal and Zonal Data Bank of the Region of Madrid and National Geographic Institute (IGN), and it has been added to calculate the data of the study areas used by INE in the collection of mobility data.

4.2 Population density

The Region of Madrid is the most densely populated region with a density of 829.72 people per km2 in 2019. Focusing on the study areas, these densities range between 10 and 7,000 people per km2, concentrating the most densely populated within the metropolitan area.

LEVEL	POPULATION DENSITY	STUDY AREAS
Very high	> 900 people per km^2	27
High	300-900 people per km^2	22
Moderate	100-300 people per km^2	30
Low	< 100 people per km^2	23

Table 8 – Population density. Source: Own elaboration from ALMUDENA

4.3 Per capita income

The Region of Madrid has the highest per capita income data at the national level, with more than 35,000 € per inhabitant. The per capita income data for the region oscillate between 11,000 and 70,000 € per inhabitant, also concentrating the areas with the highest income in the metropolitan area.

LEVEL	PER CAPITA INCOME	STUDY AREAS
Very high	> 25,000 € per inhabitant	27
High	20,000-25,000 € per inhabitant	18
Moderate	15,000-20,000 € per inhabitant	29
Low	< 15,000 € per inhabitant	28

Table 9 – Per capita income. Source: Own elaboration from ALMUDENA

4.4 Employment data

Employment data is a crucial variable to consider since 20% of trips made in the Region of Madrid are associated with work, according to the Home Mobility Survey of the Region of Madrid (EDM2018).

The percentage of the population of each study area affiliated with Social Security has been calculated to see the level of employment of the same. These percentages range from 30% to 50%.

LEVEL	POP. AFFILIATED SOCIAL SECURITY BY RESIDENCE	STUDY AREAS
Very high	> 45%	6
High	40-45%	40
Moderate	35-40%	45
Low	< 35%	11

Table 10 – Population Affiliated to Social Security by Residence. Source: Own elaboration from ALMUDENA

On the other hand, the total number of workers attracted by each study area has been obtained, calculating their percentage concerning the area's population, which varies between 13% and 100%.

LEVEL	POP. AFFILIATED SOCIAL SECURITY BY WORK C.	STUDY AREAS
Very high	> 40%	19
High	25-40%	31
Moderate	20-25%	21
Low	< 20%	31

Table 11 – Population Affiliated to Social Security by Work Centre. Source: Own elaboration from ALMUDENA

From the data of the affiliations, the balance of each study area has also been obtained. This balance is defined as the difference between the workers received by the area and the workers residing in it. In this way, if the balance is positive, the analysis says that the study area needs to attract trips.

BALANCE	STUDY AREAS
Positive	19
Negative	83

Table 12 – Balance of Affiliates to Social Security. Source: Own elaboration from ALMUDENA

The unemployment rate is another variable taken into account as it directly influences the number of trips made in each study area. These rates range from 2.5% to 10%.

LEVEL	UNEMPLOYMENT RATE	STUDY AREAS
Very high	> 6.5%	25
High	5.5-6.5%	27
Moderate	4.5-5.5%	25
Low	< 4.5%	25

Table 13 – Unemployment rate. Source: Own elaboration from ALMUDENA

Finally, the data on the economic activities of each study area have been analyzed, obtaining the majority branches of activity in each of them. The Other Services branch includes Administration, health, education, recreational, personal and associative activities, and households.

BRANCH	RESIDENCE AREAS	WORK AREAS
Construction	1	0
Mining, Industry, and Energy	0	7
Other Services	36	37
Distribution and Hospitality Services	53	50
Business and Financial Services	12	8

Table 14 – Branches of activity. Source: Own elaboration from ALMUDENA

4.5 Land use

Land use in the Region of Madrid has been analyzed, as it is an excellent indicator of job creation and, therefore, of attracting trips.

This analysis has focused on the economic lands in the Region of Madrid: Agriculture, Industry and Mining and Construction.

LAND USE	STUDY AREAS
Agriculture	102
Industry	75
Mining y Construction	51

Table 15 – Land uses. Source: Own elaboration from IGN

Although Agriculture is present in all the study areas, most of it is concentrated in the southern and eastern parts of the region. Industrial land is concentrated in the metropolitan area and, lastly, Mining and Construction in the southeast.

It should be noted that Agriculture is not such an essential sector in the region, the Industrial and Mining and Construction areas attract more trips, on which this analysis will focus

4.6 Transport

The analysis of transport is based on two fundamental axes: motorization and the evolution of the use of Public Transport.

The first one is calculated using the Motorization Index. This index relates the vehicles in a specific area and the population that resides in it. The region is very heterogeneous when it comes to the Motorization Index, with values between 400 and more than 20,000 vehicles per 1,000 inhabitants.

Although it should be mentioned that there is a bias in this variable since the existence of differences in the tax regime between the areas means that in some of them, a large number of vehicles are registered, most of them belonging, for example, to fleets of car-sharing companies. Once this has been clarified, the discretization of the data is presented.

LEVEL	**MOTORIZATION INDEZ**	**STUDY AREAS**
Very high	> 750 vehicles per 1,000 inhabitants	18
High	650-750 vehicles per 1,000 inhabitants	24
Moderate	600-650 vehicles per 1,000 inhabitants	28
Low	< 600 vehicles per 1,000 inhabitants	32

Table 16 – Motorization Index. Source: Own elaboration from ALMUDENA

The second axis of this analysis is, as mentioned previously, the use of Public Transport. INE publishes data on passengers transported monthly by city bus and Metro System. It should be noted that around 85% of the trips made by bus are made within the municipality of Madrid.

The following graph shows the evolution of the use of these two modes of transport. This evolution shows a significant drop with minimum values in April. Mention that the March values are so high since no restrictions were applied to mobility in the first half of this month.

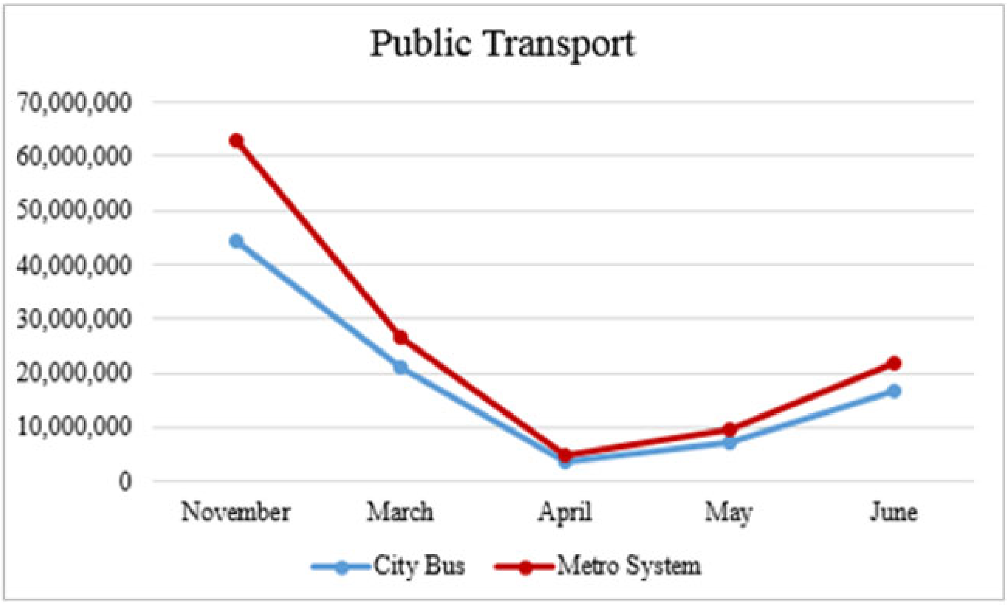

Fig. 13 – Evolution of the use of Public Transport during the state of alarm. Source: Own elaboration from INE

5. DISCUSSION OF RESULTS

This analysis will start from the employment data for mobility analysis, as the main reason for the trips.

The branch to which the population living in each study area is dedicated allows us to analyze the outgoing inter-areal mobility, so the generation of trips in each area.

Thus, it is observed that the areas in which the majority of the population is dedicated to Business and Financial Services, the most economically powerful (Madrid, Alcobendas, Majadahonda, Pozuelo de Alarcón, etc.), suffered a significant decrease during the lockdown and moderate increases after it. This is explained by the fact that the presence of these services was reduced and, after lockdown, a teleworking regime has continued.

On the other hand, the areas in which the population is dedicated to distribution were less affected in lockdown and, therefore, suffered more minor increases in the easing of lockdown. This happened since these services have a high degree of presence and are associated with negative balances, generating many trips.

Incoming inter-areal mobility is given by the branches in each destination area and is highly conditioned by their land uses.

In the same way, the areas that base their activity on business and financial services (Alcobendas, Pozuelo de Alarcón, Tres Cantos, etc.) lost a large percentage of trips and did not recover mobility primarily during the easing of lockdown.

These areas have in common that they present positive balances, that is, they attract many trips, and that they have large areas of industrial land.

Again, areas with heavy distribution services were not significantly affected by the lockdown, receiving practically the same trips as in a normal period.

The per capita income analysis shows that fewer resource areas suffered fewer decreases than those with higher incomes. This may reflect the high unemployment rates in areas with fewer resources, so people who did not work did not make as many trips during normality.

Finally, it should be mentioned that the Motorization Index does not have much impact on this analysis, as it is not an accurate reflection of people's mobility since the Region's Public Transport system is widely used and carries a large number of travelers. However, it has been seen that areas with high Motorization Index are associated with very high decreases and low increases, which leads to the conclusion that the abundance of vehicles in the areas does not ensure low conditions

6. CONCLUSIONS

With this analysis, it has been concluded that the state of alarm brought with it a change in the habits and mobility of the population of Spain and the Region of Madrid. Mobility was drastically reduced during March and April due to lockdown. With the easing of lockdown, mobility grew but, even so, at the end of the state of alarm, the mobility that occurred in normal periods, before the arrival of the pandemic and state of alarm, has not recovered.

Once the condition has been characterized, it has been seen that it is closely related to employment data. The sector most affected by the lockdown was the business and financial industry, which suffered significant declines and did not recover in the easing of lockdown due to the adoption of teleworking.

On the other hand, the distribution sector, the majority in the region, was not significantly impacted due to its degree of presence, so it suffered low decreases and increases, remaining very stable during the state of alarm.

Mention that the municipalities with fewer resources in the region had suffered fewer decreases, related to the high unemployment rates, which meant that the trips before the state of alarm were not very high.

Finally, it has been seen that highly motorized areas have been most affected by mobility restrictions, which can conclude that the abundance of vehicles does not lead to mobility stability.

These conclusions can lead to different strategies, adapted to each branch of activity and study area, to act in the face of new waves of the pandemic in the future

ABSTRACT

The movements to the university campuses bring a challenge to the sustainability and public transportation. Taking into account the EDM2018 (home mobility survey of the Community of Madrid) an analysis of university mobility has been made in order to define global and specific strategies for this segment of recurring trips.

The study perform, divides the survey data according to different type of users: students, workers (PAS) and teachers/researchers (PDI). Each of these groups have different socio-economic profiles, work patterns and availability of their own vehicle, which conditions their daily mobility. Second, the different mobility patterns of the 14 Campuses of the 6 public universities in the region are compared. The results are clearly influenced by location variables (urban, metropolitan, isolated) and their accessibility by public transport.

Therefore, a multiple causal relationship can be established between the above factors, which determine the modal distribution for each campus and each group. The variations are important, going from 78% of trips by public transportation made by students in urban campuses to 14% of trips by public transportation made by workers in isolated fields.

The analysis methodology contrasts the previous results, based on the data obtained from the EDM2018 with the level of infrastructure and transport offer: car parks, entrances, railway stations and bus stops, and their accessibility to the campus.

These analyzes make it possible to propose a series of recommendations to reduce car use and promote the use of collective transport.

All of this will be part of the diagnosis for the development of Sustainable University Mobility Plans, which will be the second phase of this work.

1. INTRODUCTION AND OBJECTIVES

1.1 Issue

There is a big problem with pollution in the city of Madrid. We need to promote sustainable mobility to give a solution to this issue. Nowadays there is talk of using active modes of transport such as bicycles, electric vehicles, walking… but first it is necessary to facilitate their use and make people aware so that they choose to use them.

1.2 Objectives

The main objective of this research is to reduce the CO_2 emissions produced by motor vehicles and improve the mobility of the city, in this case of the university community.

1.3 Structure of paper

The structure of the paper is the following:

First, it will show an analysis of the existing studies that have been carried out on sustainable university mobility will be shown, highlighting proposed solutions and problems that remain to be solved. For this, the mobility of the public universities of Madrid will be taken as a case study.

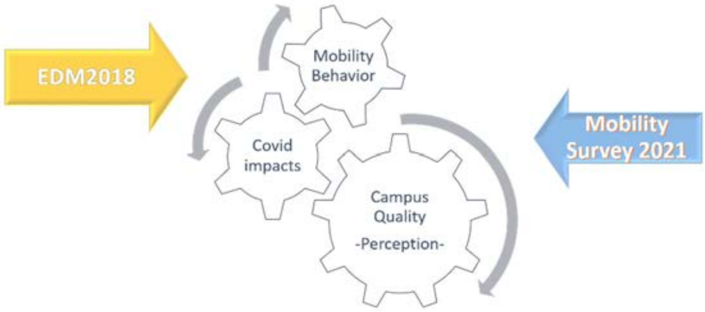
After it will do a recompilation of mobility data with a mobility survey ad hoc EDM2018, where it will obtain the mobility patterns of university users and it will do a comparative analysis with the mobility survey 2021 that was created for this research aimed at students, teachers, administrators, and providers. With the data obtained from the survey 2021, it will do a statistic analysis to identify mobility patterns and to define key factors improving sustainable mobility, in addition to being able to appreciate the incidence of COVID-19.

2. BACKGROUND

2.1 State of the art (key papers <12)

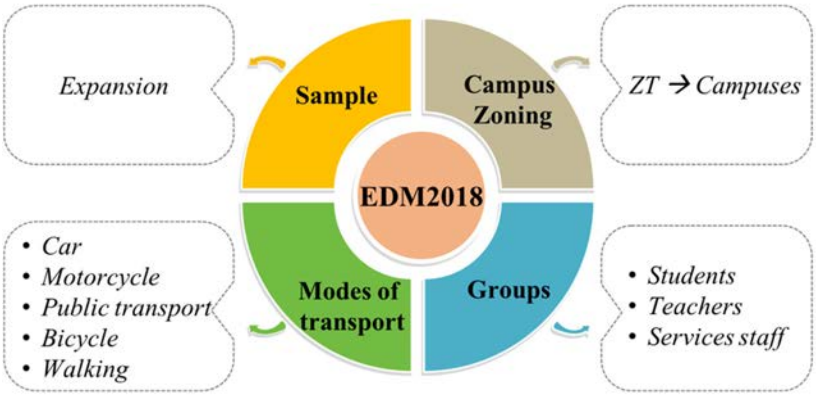
The published literature on sustainable transport is extensive, although it focuses mainly on car use, its impacts, and infrastructure (Balsas, 2003).

3. METHODOLOGY



3.1. Mobility survey ad hoc EDM2018

The mobility survey ad hoc EDM2018 was done by Regional transport consortium of the Community of Madrid to study the mobility general of population of Madrid. This survey was done in person, between February 13 and June 12, 2018 in the Community of Madrid, grouping the areas where the surveys were conducted as transportation areas. For use this data, it has been filtered by age, degree, transportation areas that coincide with our study areas, in this case university campuses and reason for the trip.



The population of the university is made up of students, teachers and service staff that have been identified with the following characteristics:

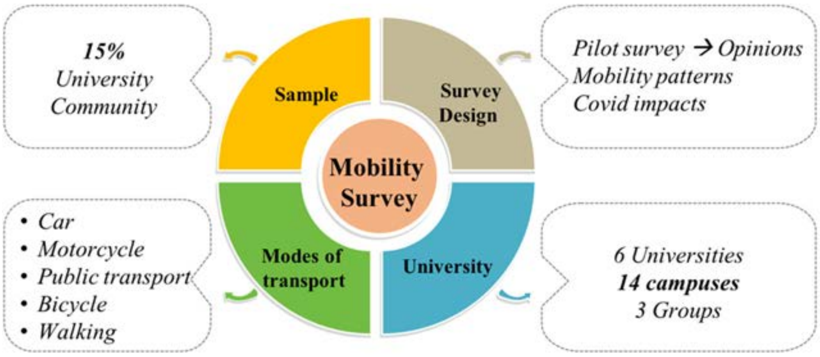
- Students: over 18 years old, with professional or university training, studying or studying and working, study trips.
- Teachers: over 30 years old, with high school studies and/or professional training, public sector employees, work trips.
- Service staff: over 20 years old, public or private sector employees, work trips.

Once the groups have been made with the filters described, the number of trips made by each group is obtained and with this the modes of transport used are classified with the information that EDM2018 provides per trip.

Based on these data, an analysis of trips to university campuses has been made.

3.2. Mobility survey for the university community 2021 (App: survey monkey)

The mobility survey for the sustainable university community 2021 was designed based on the detailed study of the mobility of the university campuses of the 6 public universities of the Community of Madrid in an application called Survey Monkey.



This survey is aimed at students (over 18 years old, studying or studying and working), teachers (over 30 years old, public sector employees) and service staff (over 20 years old, public or private sector employees).

3.2.1 Pilot for students, research teaching staff, and administration and services staff

To prepare it, first of all, a series of pilot surveys were launched, a total of three per group at each campus, with a total of 135 responses throughout the university community. This pilot survey was distributed as follows: three student surveys, two being undergraduate and one master's degree; another three to professors (one to a non-permanent professor and two to permanent professors); and three more to service personnel, two under 30 years old, another over 30 years old.

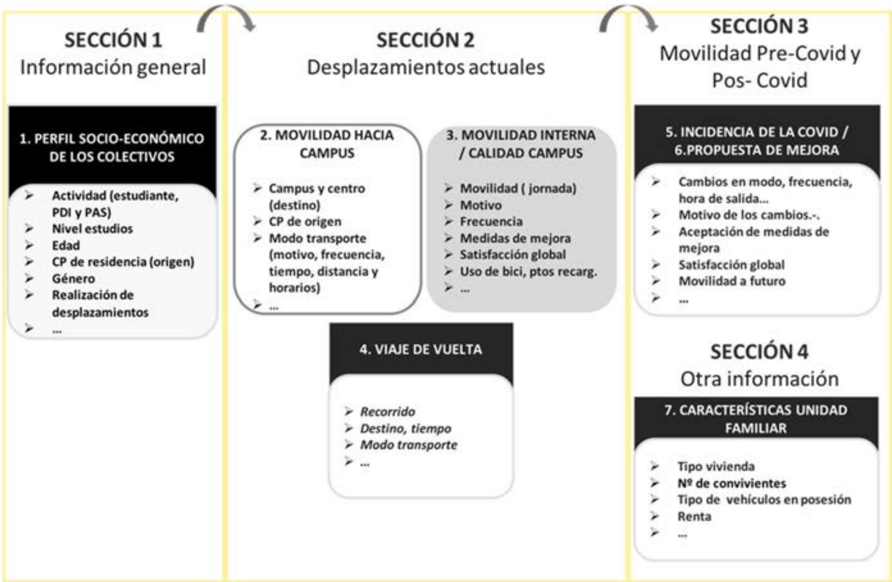
They were able to draw conclusions about the perception of those surveyed with the survey and the aspects to improve.

3.2.2 General survey students, research teaching staff, and administration and services staff (launch communication campaign with posters, screens, complaints management, and recruitment of non-institutional staff with cards)

The general survey consisted of 4 sections, section 1 of general information, section 2 of current trips (including the mode of transport, frequency, origin of the trip, the distance traveled, the trips within the campus and the trip of return), section 3 on pre-Covid and post-Covid mobility (it asks about the perception of quality in their mobility to the campus) and section 4 of other information (where data on the family unit were asked).

For the launch of this survey, a communication campaign was carried out through physical posters and on screens in the buildings of the study universities until March 26, 2021.

During those weeks, an exhaustive control of incidents with the survey was maintained through social networks and email



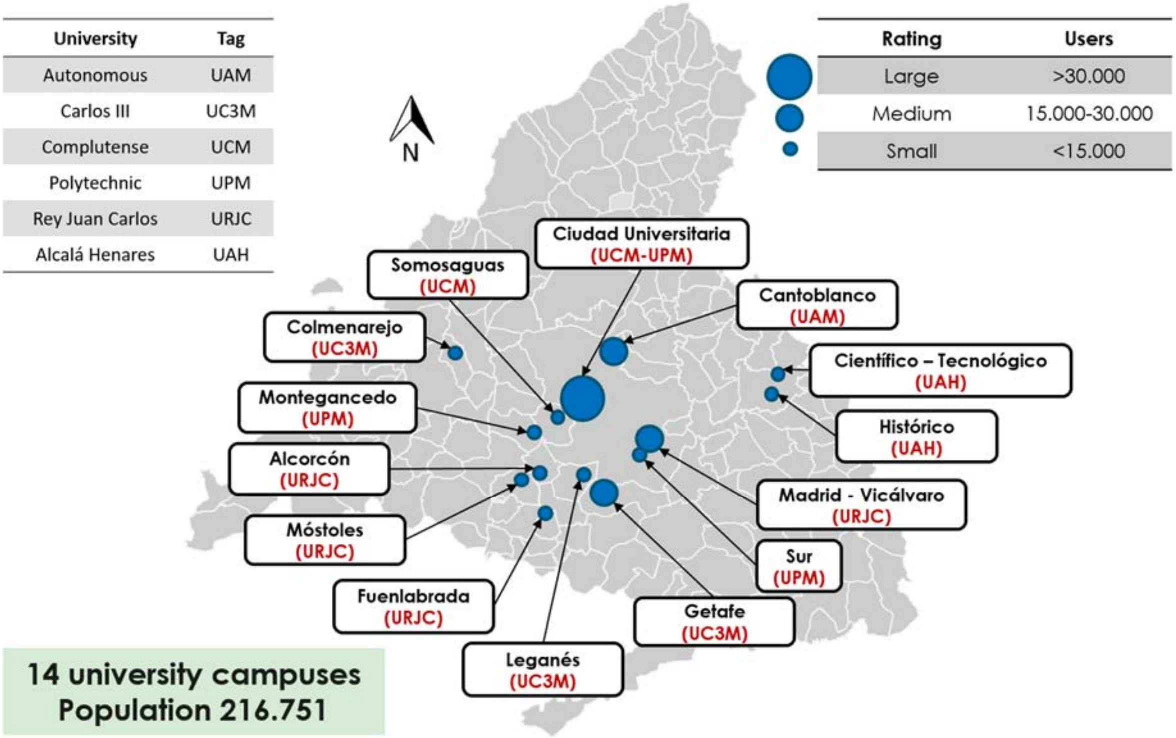
The external contracted service personnel also had access to this survey through cards containing the QR and the survey link, which were sent to them through the management of each university.

4. CASE STUDY

4.1 CAM (public universities of the Community of Madrid)

The objective of the community of Madrid is to acquire a more sustainable mobility in the city and for this purpose a pilot scenario has been created which is the university community, where the main problems in mobility will be collected on a small scale, the main problems in mobility will be determined. majority mobility patterns and a series of recommendations will be provided that will be carried out through the drafting of sustainable university mobility plans that, once completed, can be extrapolated to larger scales, such as the city of Madrid and other cities with similar characteristics.

the universities that have participated in the study are the 6 public universities of the Community of Madrid and the campuses universities study are the following:



There are a total of 14 university campuses, the university campus being shared by the UPM and the UCM.

5. RESULTS

When analyzing the results, this information has been divided into four criteria:

- Socioenomical
- Mobility patterns
- Impacts by Covid
- Perception of mobility and future

5.1 Descriptive analysis (statistic analysis)

The statistical analysis includes the following variables:

Variable	*UPM*	*UCM*	*UAM*	*UAH*	*UC3M*	*URJC*
1. *Activity*						
Students	72%	70%	67%	81%	85%	88%
Teachers	16%	19%	20%	13%	8%	10%
Service Staff	12%	11%	13%	6%	7%	3%
2. Studies						
School	56%	53%	48%	66%	66%	65%
College	6%	7%	4%	8%	10%	11%
Degree	15%	15%	17%	10%	13%	11%
Master	10%	9%	13%	4%	6%	5%
Doctorate	14%	16%	18%	12%	5%	8%
3. Gender						
Man	53%	33%	34%	31%	43%	31%
Woman	45%	65%	64%	67%	56%	68%
I prefer not to specify	2%	2%	2%	1%	1%	1%
4. Monthly income						
1000 – 2500€	44%	48%	44%	51%	40%	55%
2500-5000€	38%	34%	37%	34%	37%	27%
> 5000€	9%	7%	8%	4%	13%	5%
< 1000€	9%	12%	10%	11%	11%	13%
5. Age						
Minimum	18	18	18	18	18	18
Half	35	35	35	29	27	28

Table 1. Socioeconomic characteristics variables

5.2 Mobility patterns

The following variables are used to determine mobility patterns:

Variable	*UPM*	*UCM*	*UAM*	*UAH*	*UC3M*	*URJC*
1. *Current displacements*						
Yes, some day a week	37%	26%	41%	47%	63%	32%
Yes, most of the days	36%	47%	39%	36%	29%	20%
Yes, but less than 1 days a week	27%	19%	19%	17%	8%	48%
2. Transport mode						
Driver car	26%	26%	30%	27%	28%	31%
Accompanying car	3%	2%	3%	3%	3%	3%
Motorcycle	2%	0%	1%	1%	0%	1%
Public transport	59%	65%	63%	58%	52%	61%
Bicycle	2%	1%	1%	1%	0%	0%
Walking	7%	5%	2%	10%	15%	3%
Others	1%	1%	0%	1%	1%	0%
3. Time travel						
0-15min	11%	9%	15%	15%	19%	14%
15-30min	34%	29%	25%	25%	30%	30%
30-60min	37%	41%	38%	29%	33%	34%
>60min	18%	21%	23%	32%	18%	22%
4. Satisfaction	1--6					
Half	4,108	4,058	4,145	3,614	4,082	3,995
5. Campus stay						
Tomorrow	35%	36%	36%	29%	24%	36%
Afternnon	15%	20%	17%	23%	25%	29%
All day	12%	12%	15%	11%	9%	5%
Night	0%	0%	0%	0%	1%	0%
It varies according to the days	38%	32%	32%	38%	41%	29%
6. Moving frequency on campus						
Daily	23%	30%	26%	20%	18%	16%
2 times a week	30%	27%	34%	46%	64%	26%
Occasionally	35%	36%	33%	29%	14%	54%
Never	11%	7%	6%	5%	4%	4%

6. CONCLUSIONS AND RECOMMENDATION

Recommendations based on the characteristics of the campus, where to decide on which campus it would be appropriate to:

- Restrict the access and circulation of private vehicles.
- Promote the electric vehicle, placing recharging points or excluding them from the restrictions of the private vehicle.
- Facilitate the use of the bicycle, or active modes by building more infrastructure or improving the existing one.
- Encouraging the use of dissuasive car parks and the use of shared vehicles.
- Making study and work hours more flexible to reduce the demand curve in public transport at rush hour.

6.1. Key factors improving sustainable mobility (influencing variable in decision making)

The key factors that enhance mobility to universities are: the income of each group, the location and accessibility of the universities, the existing facilities for carpooling.

This analysis shows that it is key to promoting sustainable mobility to know the socio-economic characteristics of university users, which will facilitate access to new, more sustainable modes of transport. The trend and acceptance of the initiatives shown towards the use of bicycles is quite acceptable, which encourages us to continue along this path.

ACKNOWLEDGMENTS

The authors would like to thank the Ministry of Transport, Mobility and Urban Agenda for the agreement signed with the Polytechnic University of Madrid (UPM) for the Metropolitan Mobility Observatory, the 6 public universities of the Community of Madrid, the Regional Transport Consortium of the Community of Madrid, the Ministry of Science, Innovation and Universities and the Ministry of Transport, Mobility and Infrastructures.

ABSTRACT

The growth of the world population indicates that about 70% of the inhabitants will live in cities by 2050. This implies the need for infrastructure, resources, basic services, and transportation available to serve this population and guarantee their quality of life.

To meet these requirements, some cities have adopted technology to obtain data and information that allow for the analysis of these new dynamics from the perspective of smart cities.

Other cities have also involved criteria focused on the well-being of the community-environmental system from the perspective of sustainable cities. There are other cities that transcend the sustainable and intelligent status to become responsive cities where the interpretation and analysis of data is provided by and for citizens. This allows them to become key in the planning and development of their city and the construction of these cities in the future.

Mobility in the development of cities is important and in a responsive city it is no different. It allows for the dynamic action of the population to satisfy their needs. Mobility worldwide is based on the private car and infrastructure grows as a function of this. The associated environmental, economic, and social impacts have wide ranging consequences.

Likewise, the COVID-19 pandemic has revealed an additional motivation to opt for public transport, cycling, or walking instead of the private car. This requires rethinking cities and adapting their physical, technological, and social infrastructure to facilitate this transition.

The evaluation of mobility in cities is based on indicators that allow the monitoring of important aspects from specific practices in each territory. However, the framework of responsive cities is not clearly or comprehensively identified resulting in the need for an investigative process aimed at forming a citizen-centered mobility evaluation model, integrating the holistic precepts of smart and sustainable cities.

1. PLANNING CITIES FOR THE FUTURE

The dynamics of the cities are accelerating their pace according to the urbanization process increase. The emerge of new settlers implies the supply of infrastructure, basic services, transport, employment, dwelling and additional resources that will allow them to improve their quality of life, thus, the conventional planning models are inadequate for the attention of new requests.

Currently, management instruments have been developed which provide a framework to the cities to modify their planning approach, on one hand, to achieve the sustainable urban development (United Nations, 2017), and on the other hand, supported by technology, to attain smart cities (ECLAC, 2020a).

The need to connect the community participation in the city development process has aroused the chance to address a more inclusive urban planning approach that allows to have responsive cities.

Below, the sort of stated cities are contextualized:

1.1 Smart and sustainable cities

The smart city is a concept that implies different meanings, although, it is generally connected with those cities in which information and communication technology – ICT are widely used. A first definition assumes the smart city as a construct to improve the quality of life, it is formulated bearing in mind three concepts: digital city, green city and city of knowledge, which are characterized by the use of data center technology in an ecological sight and a data value-based, information and knowledge production, respectively (Yin et al., 2015).

Another view relates to smart city with a prospective achievement in terms of economy, population, government, mobility, environment and livability (Aletà, Alonso, & Ruiz, 2017), (Albino, Berardi, & Dangelico, 2015), (Manville et al., 2014), therefore, the city is smarter if it is more competitive, preserves natural resources, the community is participatory, generates quality of life, integrates transport and ICT and promotes social and human capital.

The smart city is based on the creation and interaction of human capital, social capital and information and communication technology (ICT) infrastructure to generate greater economic and sustainable development and a better quality of life (Manville et al., 2014).

En este sentido, muchas ciudades están mejorando la calidad y el rendimiento de los servicios urbanos al ser digitalizadas e inteligentes (Kumar et al., 2020). However, “a city may also be smart when investment in social capital and infrastructure are made with a rational management of the natural resources and through a participatory governance” (Schaffers et al., 2011), which does not necessarily mean high investments in technology, bearing in mind resources availability according to the large city. (Manville et al., 2014).

Thus, it is clear that there is a variety of definitions about smart city and it is not possible to establish a universal meaning, nor there is a single way to measure it (Albino et al., 2015).

According to the International Telecommunication Union (ITU) and the Economic Commission for Europe (ECE), “a smart and sustainable city is an innovative city that uses ICT to improve the quality of life, the efficiency of operations, urban services and the competitiveness, at the same time that meets the needs of the current and future generations in economic, social, environmental and cultural features”. Smart and sustainable cities are provided with indicators to determine goals, gather data and evaluate their achievements, they are supported by a telecommunications infrastructure that is stable, secure, reliable and interoperable to provide support ICT-based applications and services (UIT-CEPE, 2016).

In the context of smart and sustainable cities, it is possible to identify the contribution of ICT in the urban setting, which is focused on: i) The advantages of the effectiveness in the operations and urban services, ii) the means to improve the quality of life and iii) encouragement of environmental sustainability (UIT, 2020). It is highlighted the need of smart cities to face challenges such as inequality, insecurity, unemployment and ageing population to contribute to the achievement of the sustainable development goals. (Sharifi, 2019), (Ahvenniemi et al.,2017).

The conceptual evolution of the smart city allows to evidence a different approach, from the use of ICT to maximize the effectiveness of hard urban infrastructure to a style focused on the human being and soft infrastructure (Sharifi, 2019). This is the basis of the responsive city.

1.2 Responsive cities

Taking into account the technological perspective, smart cities are supplied with data to promote information units that support decision-making and the governance (McKenna, 2019a), (von Richthofen et al., 2019), (McKenna, 2019b), such a way to promote knowledge generation in the different actors of the city itself.

At this point, the technological genesis of smart cities has been hatched. However, recent trends based on concepts such as Society 5.0 or people-centered smart society (Hitachi-UTokyo, 2020) urge to advance to citizen-centered cities, thus, “smart” becomes a infrastructure layer in which technological contributions are enclosed by the empowerment of citizens to contribute with their welfare, health, mobility, and other essential criteria of their condition as members of society and inhabitants of the territory; this is the base of responsive cities.

Goldsmith y Crawford (Goldsmith, 2014) established the concept of responsive city based on the citizens commitment and governance during the digital age to encourage cities characterized by their agility, competitiveness and economic resilient, based on the contributions brought by information technologies. The responsive city gives citizens the chance to use smart technology to contribute to the planning, design and management of the city (Yigitcanlar et al., 2019).

The perspective of responsive city is focused on the citizen, so, the processes of the city are supported by technological resources to improve their performance and be more involved with the citizen, decision makers guide their decisions toward problem analysis and opportunities to promote the quality of life in the communities; and finally, local managers use the predictive value of data to make accurate decision. The responsive concept frames a synergy among decision makers, thoughtful citizens and 21st century technologies (Goldsmith, 2014).

While common cities are based on classical planning models where data is emerged, smart cities lay the foundation on technology, proving information; responsive cities are centered on the citizen, building knowledge themselves (Schmitt, 2017).

The responsive city tends to “return the city to its citizens, so, they get involved directly in the planning and management of their habitat. Thus, the citizen responsibility becomes the basis of a responsive city” (Schmitt, 2017).

Bearing in mind the characterization of modern cities, challenges and opportunities that arise regarding mobility will be addressed.

2. MOBILITY IN THE 21ST CENTURY

An increasing trend of population in cities has grown distance journeys (Guasch, 2002) due the expansion of the urban border because of the peripheries settlement and the low coverage of public transport service (Cervero, 2000).

The implementation of encouragement policies to use private vehicles and their reduction prices have caused the increase of motor vehicles (Lizárraga, 2006), (Despacio y ITDP,

2013) and for that reason, problems such as traffic jam, pollution and accident rate have been accentuated (Vasconcellos et al., 2016).

Besides, there are failures in affordability, so, people with lower incomes must assign a high percent of their economic sources to get around (Vasconcellos, 2001), it has a directly impact on social inequity.

Other problems related to transport are connected to security, equity and inclusion, in the same way, the air pollution causes illnesses that can cost around 15% of a person's income (Hidalgo & Huizenga, 2013).

In response to this scenario, the conventional planning mobility approach has been changing toward sustainable smart mobility, where preferences of investments on private vehicle infrastructure are discouraged and active transport modes such as walk or pedal take place articulated with a service quality in the public transport system to guarantee the participation of all social groups and reduce the effects associated with transport such as energy consumption, CO2 release, air quality or wasted space in the streets. (Gillis et al., 2015).

2.1 Sustainable Smart mobility

Mobility makes part of the smart city agenda which is supported by the adoption of sustainable transport practices (Yigitcanlar & Kamruzzaman, 2019).

The context of sustainable mobility includes the objectives of smart mobility: i) reduce pollution, ii) decrease traffic jam, iii) increase people safety, iv) lessen noise and v) improve speeds and cost of movement, which is doable if they are joined to this sort of city (Benevolo et al.,2016). Sustainable mobility also includes four smart perspective which deal with the design, system, infrastructure and usage (Lyons, 2018).

The appropriate proposal about mobility framed within smart cities allows the implementation of projects that aim to answer community needs and tend towards sustainable (Battarra et al., 2018). Thus, sustainability has left to consider specific problems such as resource depletion and pollution to involve economic, social and environmental relations and their impact on solving problems (Litman, 2021).

The sustainability approach is given in mobility addressing the increase of urban congestion and pollution based on substantial changes in terms of logistic and transport affairs, private and public vehicles, as well as behavior and habits changes in order to keep in mind the quality of life, short and long-term impacts, affected population and the city planning (Mozos-Blanco et al.,2018).

According to Banister, sustainable mobility “supplies an alternative paradigm within with the complexity of cities is investigated and links between land use and transport are strengthened”. This requires actions to reduce the number and duration of journeys, promote modal change and encourage greater efficiency transport system. (Banister, 2008).

The main characteristics of the sustainable mobility approach are: i) it focuses on people, ii) it prioritizes accessibility, iii) it is proposed on a local scale, it recognizes the street as a useful space and not only as a vehicular road, v) it finds relevant the inverted mobility pyramid where pedestrians and cyclists are privileged in the upper part and the automobile drivers are placed in the lower part, vi) it is supplied with multi-criteria analysis to contemplate environmental and social concerns, it is focused on management, viii) it has a tendency to integrate people and traffic and, ix) it allows healthy benefits (Holden et al., 2019).

Currently, cities must assume smart and sustainable mobility, not only as a challenge but also as a necessity, taking into account the new requirements imposed by the Covid-19 pandemic.

2.2 COVID 19 and mobility

Coronavirus (COVID 19) has changed the environment sense and new vulnerabilities have emerged, for this reason, territory, distance, time, space and social relationships concepts must be rethought. The actual pandemic has exposed the need to modify people lifestyles as to the risks to health and life of the population, especially in urban areas (Moreno, 2020), this entails changes in city planning and, especially, in the mobility topic.

In this pandemic time, the communities have changed the people displacement modes, caused by virtuality that replaces many journey needs. Thus, technology and connectivity have been increasing to correspond with social distancing. According to this, ECLAC indicates that the Latin American and Caribbean region has the conditions to strengthen its technological capacity to face the consequent challenges through resilience, especially, in the transport, mobility, logistics and energy sectors. (ECLAC, 2020b).

The territory will be the character in these projected changes, then basic transport modes such as bicycles will be promoted, that will require the necessary infrastructure to be developed properly, in this case, bikeways and parking spaces are needed (Universidad de Los Andes, 2020). Likewise, walked displacements will have relevance in the new vision of post-pandemic mobility, it implies the adaptation of areas for the citizens circulation, the public space for its enjoyment and a pleasant environment that motivates them (ECLAC, 2021).

In conclusion, the pandemic has not necessarily had negative effects, as it has undeniably led organizations, families and people to redefine the mobility concept, for example, their transport modes, needs and time value used to fulfill their daily lives; that constitutes in a forced and disruptive process of adaptation for existing models that describe, model and implement sustainable mobility systems.

2.3 Sustainable mobility goals

Mobility in the current context is based on the pillars of sustainability: the social, economic and environmental features; in addition, with the scenario of responsive cities, it is necessary to articulate additional components: planning and governance, that allow to achieve the goals of sustainable and intelligent mobility.

In general terms, the mobility goals of the 21st century are presented as follows. The economic component focuses on the productivity and economic local development, energy efficiency, affordability, and operational efficiency.

The social component includes the equity, safety and human health, as well as, the community cohesion with the preservation of cultural heritage. The environmental component considers the reduction of emissions that contribute to climate change, the prevention of air, water and sound pollution, the reduction of hydric resource damage, the conservation of natural resources, the protection of the biodiversity and open spaces.

The good governance and planning component addresses inclusive, comprehensive and integrated planning (Litman, 2021).

3. MOBILITY EVALUATION

Mobility evaluation for urban context is commonly carried out from indices -or indicators- that consider different aspects of economic, social, environmental and operational issues. Currently, the evaluation models emphasize on sustainability requirements and integrate evaluations of technological types to involve the intelligent aspect in the assessment, to determine a sustainable and smart mobility.

Next, the main characteristics of conventional mobility evaluation models are presented and the most relevant characteristics of a participatory evaluation proposal model are planned in the context of responsive cities, they are obtained from methods focused on documentary research (Geerts, 2011) and bibliometric analysis techniques (Cobo, 2011).

3.1 Conventional evaluation models

Some authors have studied the feasibility to analyze urban mobility based on indicators to: i) transport planning and infrastructure provision (Mihyeon & Parsons, 2016), ii) quality measurement of the public transport network (Zegras, 2006), iii) determination of the relationships between urban planning and transport (Zhang & Guindon, 2006), iv) sustainability measurement of urban transport in different continents (Litman, 2008), (Litman, 2011), (Litman, 2021), (Tanguay et al., 2010), v) measurement of the three dimensions of sustainability (Haghshenas & Vaziri, 2012).

The mobility assessment is carried out by the significant contribution of the transport area through reduced environmental quality of a city. Thus, the transition towards sustainable mobility will contribute to the mitigation of negative impacts, optimization of the transport system and integration with urban planning policies (Battarra et al., 2018).

Since of the 20th century ending, initiatives aimed at achieving sustainable urban mobility were already identified (Commission of the European Communities, 1998). In order to measure and compare the state of urban transport systems in terms of sustainability, the indicators were created, so that different initiatives emerged for reducing the urban mobility effects on human health, environment and economic productivity, in terms of a sustainable development (Alonso & Monzón, 2011).

Sdoukopoulos et al. (2019), proposed a categorization of evaluation indicators for transport sustainability and formulated an index evaluation; however, this research highlights the difficulty in the use of this indicators due to a great variety of indicators that are available, as well as, their structure, the constant monitoring needs and the use context (countries of the First World) (Sdoukopoulos et al., 2019).

Based on the Sdoukopoulos' findings, other related researches about use of indices or indicators to assess sustainable mobility was documented. The number of indicators used by each identified author is presented in Figure 1.

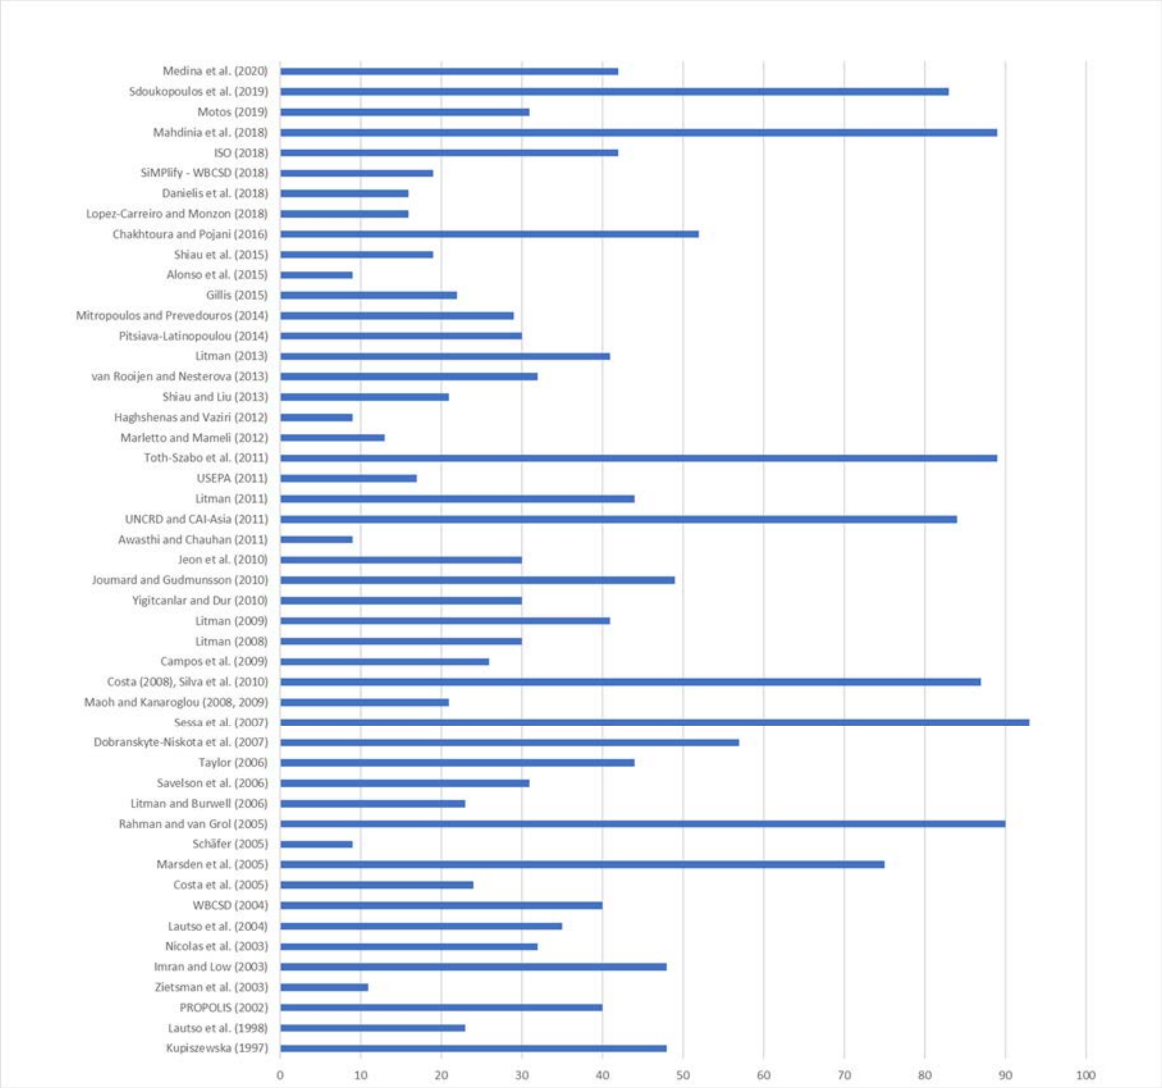

Figure 1: Roadmap regarding the indicator’s quantification in sustainable mobility assessment initiatives

In conclusion, there is a considerable number of alternatives for evaluating the different constitutive aspects of cities, including mobility. These tools allow the evaluation of the main functions of conventional and smart cities. It is expected to obtain a strategy that involves a transition from this type of cities to responsive cities, where the citizen becomes the direct identifier of their needs, besides an information and knowledge contributor through the research solutions, using digital tools or smart technologies that he/she may have at his/her willingness (Levenda et al., 2020).

In order to contribute in the transition towards a smart and sustainable city, the sustainable mobility evaluation is an important factor, because the existing models to achieve this type of city still do not fully include all the aspects that must be taken in this high-level process, this constitutes a knowledge gap (Ibrahim et al., 2018).

3.2 Participatory evaluation model

According to sustainability indicators that can be applied in transport and planning assessment (Litman, 2021), actually, their use is been expanded. However, despite involving economic, social and environment issues like the pillars of sustainability in the environmental mobility evaluation, it is evident that urban dynamics have changed, and both, the active participation of citizens and a greater concern for environmental issues are indispensable in the planning of the future cities.

As evidenced in different worldwide experiences, citizens have the opportunity to change mobility patterns in their cities, promoting an active mobility and demanding changes in that sense (van Laake & Pardo, 2018). Thus, the citizen empowerment allows them to achieve a proactive participation in sustainable and equitable projects, facilitating political changes in their favor to improve their quality of life (Moscoso et al.,2020).

The 2030 agenda also emphasizes two challenges to improve the quality of life in cities: i) not repeating public policies patterns that have not generated a desired impact and ii) include citizens in order to guarantee their rights access. (Naser et al., 2021).

One of the fundamental citizen rights is the right to participation, as part of decision-making in their interest areas. Therefore, the citizenry transition that acts as an observer of their reality is necessary, towards an active and committed citizenry that participates in their city changes processes (Salazar, 2019).

To achieve a participatory evaluation proposal for sustainable and smart mobility, it is necessary to look upon the fundamental principles of citizen participation: Transparency and access information, Voluntariness, Non-exclusion, Equity, Responsiveness, Recognition and respect for the diversity, (Naser et al., 2021).

Likewise, it is necessary to determine a desired level of participation, since it is expected in responsive cities that have an important commitment from citizens, so, they can contribute with their knowledge and live experiences to achieve more effective, efficient, relevant and sustainable to the future.

The first participation level is the informative one, where there is no dialogue with people and a purely information is delivery by the authority. A second level is consultative, where opinions, proposals and interests of citizens are obtained in relation to a public interest subject. The third level is decision-making, where citizens directly influence decision-making on an interest subject. Finally, the fourth level corresponds to co-management, where an articulation between the citizenry and the authority is expected, with the purpose to involve in the design, implementation, control and evaluation of a public interest activity and to influence in an associated decision-making. (Naser et al., 2021).

Currently, research is in progress and it proposes an evaluation model for urban mobility with a participatory approach, it emphasizes in social and environmental mobility aspects, that tries to achieve sustainable and smart mobility. Mobility is being analyzing in the context of sustainable and smart cities that is also responsive, therefore, the importance of the citizens quality of life is highlighted from the new planning of urban mobility.

To achieve this, the need to invest in mobility priorities is accentuated: the first priority is the pedestrian, followed by non-motorized modes, other transport modes, an optimized public transport system and, finally, the private vehicle.

The global context and environmental quality mean a determining aspect in the mobility evaluation, with the criterion that they directly affect the population health and their quality of life. The importance of ecological restoration to achieve green spaces throughout cities to promote active mobility is highlighted.

The built environment constitutes a relevant aspect for evaluation, as the quality public space is required to offer the enough infrastructure for all transport modes and the enjoyment for all social groups.

Connectivity is another important aspect to link-up, because it enables access to the city and its services, regardless of the transport mode used. The purpose is to achieve proximity, balance between time and space, affordability and accessibility.

Urban design becomes relevant, because it allows recovering the social meaning of the city; where safety aims to have streets and safe transport modes, further, urban corridors restored from an ecological point of view, structures and heritage recovered and integrated with the city mobility, where forgotten cultural and historical places are recovered and can be enjoyed on travel routes.

Transport centered on sustainable communities implies the permanent participation of the community in decision-making related to urban mobility and the possibility of discouraging the dependence on private vehicle, searching that infrastructures investments associated with it are reduced.

Financial management is another aspect to consider when evaluating mobility, especially regarding to public transport, that should consider all social groups, including people with physical disabilities, women, people of all ages and low-income people, with the purpose to facilitate their accessibility to the system.

The use of technology to measure some environmental, operational and social parameters is another aspect to consider in the urban mobility evaluation model, where, in participatory processes, the community will be permanently articulated with the local authority to contribute in the decision-making that are necessary, this can be facilitated with this type of technological instruments.

The finished model is expected to be disseminated in 2022 to contribute to the knowledge basis regarding sustainable and smart mobility and to contribute to the transition towards achieving responsive cities based on citizen participation.

4. CONCLUSIONS

Increasing population in cities and its consequent increase in infrastructure, basic services, transportation, employment, housing and those additional resources that allow them to improve their quality of life, make a necessary change in conventional urban planning models, that are insufficient to attend the new requirements.

The need to link-up the community participation in city development processes has given rise to the opportunity to determine an even more inclusive approach to urban planning, which, together with the previous ones, allows achieving responsive cities, that is, centered on the citizen.

For the mobility case, a transition has been taking place in the conventional mobility planning models towards sustainable and intelligent mobility, to guarantee the participation of all social groups and reduce the effects associated with transport, such as the consumption of electricity. energy, CO_2 emissions, air quality, street loss spaces or the impact on public health.

In the current context, Covid-19 pandemic has made it possible to redefine mobility, from transport modes, their needs and the time value used to comply with daily life, that constitutes a forced and disruptive adaptation process of existing models that describe, modeling and implement sustainable mobility systems.

Nowadays, the mobility evaluation in the context is based on the pillars of sustainability: social, economic and environmental issues; furthermore, in the responsive cities’ scenario, it is necessary to articulate an additional component: planning and governance, where the technology integration, knowledge and people participation will make it possible to achieve the goals of sustainable and smart mobility.

To achieve a participatory evaluation proposal for sustainable and smart mobility, it is relevant to bear in mind the fundamental principles of citizen participation and determine the desired level of participation, that in responsive cities the greatest citizen commitment is expected, they can contribute with their knowledge and life experiences to achieve more effective, efficient, relevant and sustainable results over time.

Finally, some of the aspects registered in this proposal for the urban mobility evaluation are related to the invert mobility priorities, the global context and environmental quality, the built environment, connectivity, urban design, and transport-oriented sustainable communities, financial management, the use of technology in the city, among others, to contribute to the proposed objective.

ABSTRACT

The COVID-19 pandemic, which has been ravaging the world since the beginning of 2020, has greatly changed daily habits in terms of mobility, particularly in cities. The fear of prolonged contact with other users on public transport, may cause great changes in citizens' preferences towards transport in private vehicles, motorized or not, and sharing. The aim of this study was to assess the changes in mobility habits based on an online survey in Gijón (Spain) taken at the end of summer 2020, after the first wave, and generation of the so-called "new normality". This document presents a preview of the main results, related to the vehicles most used by Gijon's population. The results have allowed us to observe an increase in the use of private vehicles and, consequently, decrease in use of the bus. In addition, the survey sample also demonstrated the scant insertion of PMVs, motorcycles and bicycles in citizens' preferences. Finally, they also showed gender and age differences in urban mobility.

1. INTRODUCTION AND OBJECTIVE

At the beginning 2020, the virus later known as SARS-CoV-2 began to spread through the city of Wuhan, China. On March 11, 2020, the WHO determined that the situation of the COVID-19 disease caused by SARS-CoV-2 was pandemic. Days later, and in harmony with what occurred in surrounding countries, on March 14th, the Spanish government decreed a state of emergency and home confinement until June 20th.

The effects of this pandemic, and of confinement, caused substantial changes in the habits of millions of people in all walks of life; among others, there are signs that the preferences for use of different means of transportation have been profoundly affected. This relationship is not exclusive to COVID-19, as after a detailed analysis of extant literature, Muley et al. (2020) found a strong relationship between the appearance of contagious diseases and a series of significant changes in the transportation sector, demonstrated by other pandemics in the 21st century before COVID-19: SARS (2003), influenza A (2009) and MERS (2012). However, during the past year, interest in knowing the effect of COVID-19 on mobility habits has generated an enormous amount of information. This was emphasized in surveys and indicators such as Apple's reports on trends in mobility (Apple Maps, 2020); and the Nextdoor app noted that in cities like Madrid and Barcelona, over half of the population has changed its customs for going from place to place (Interempresas, 2020), and other services, such as the Moovit platform (Moovit, 2020) have also suggest this. Likewise, with tremendous immediacy, scientific journals began to publish a considerable number of studies that analyzed the effect of the pandemic on transportation habits in different countries (Awad-Núñez, Julio, Moya-Gómez, Gomez, y Sastre González, 2021; Cartenì, Di Francesco, y Martino, 2020; Gunthe y Patra, 2020; Linka, Peirlinck, Sahli Costabal, y Kuhl, 2020; Orro, Novales, Monteagudo, Pérez-López, y Bugarín, 2020; Tian, An, Chen, y Tian, 2021), and databases focused on future studies of mobility during the pandemic (Barbieri et al. 2020).

The methods for evaluating these changes have been diverse. Thus, Aloi et al. (2020) collected data from traffic counters, ITS public transportation, and recordings from traffic control cameras and environmental sensors, to evaluate the effect in Santander (Spain); Bucsky (2020) took data from official sources to measure the changes in Budapest; Klein et al. (2020) used mobility data from the Cuebiq platform; Brough et al. (2021) combined data from government administrations and own surveys; Khaddar and Fatmi (2021) used data from the 2020 COVID-19 Survey for Assessing Travel Impact (COST); and Bartuska and Masek (2021) analyzed data from traffic surveys.

Along with these methods, some research teams and individuals have chosen to take surveys of their own. Logically, the survey method is widely used for acquiring information on transportation (Ampt y Ortúzar, 2004; Ortúzar, Armoogum, Madre, y Potier, 2011; Plasencia-Lozano, 2021). Table 1 shows a diversity of studies carried out in different places. In general, strong changes in urban mobility are observed in all of them in line with what was noted in the abovementioned study by Muley, who found the following effects on travel behavior: Decrease in the number of trips, in the use of public transportation and in distances covered, and an increase in the use of private vehicles, bicycles and walking. All of them were done before the summer of 2020 and analyzed the effect of COVID-19 during its most complicated moment, due to its novelty, and therefore more in contrast to the prepandemic situation.

Table 3 - Survey studies on variations in mobility habits related to COVID-19.

At the end of spring and beginning of summer 2020, there was a strong descent in contagion, and the authorities in Spain began to talk about remission of the pandemic in a context baptized as “the new normality”. On June 20th, “reconquering mobility” was expressly suggested, and on July 4th, citizens were encouraged to “recover the streets” (Benito, 2021). Although we now know that this first wave was followed by several more, at that moment between the first and following waves, which coincided with the summer of 2020, is of interest for studying mobility habits, at least in Spain, because on those dates, society (or part of it) made decisions within a context of “reconquered mobility” and “recovered streets”. Therefore, it could give us a clue to what were going to be the mobility habits in the final scenario mentioned, when it occurs. With this in mind, on those dates, during the summer and beginning of autumn 2020, we conducted a study using an online survey to evaluate the effect of the pandemic on the mobility habits of the population of Gijón, a middle-sized Spanish city with several transportation options.

2. MATERIALS AND METHODS

2.1. Description of the Case Study

Our study focused on the city of Gijón (Spain), which currently has a population of 271,780 and an area of 181.7 km^2. It is a city with a large urban bus system, with 16 lines with different routes, plus one special line only for workdays and five night-service routes, operating daily from 06:30 to 00:00 making 80,611 trips daily (Gijón City Council, *Plan de movilidad urbana municipal sostenible* [Sustainable Municipal Urban Mobility Plan]). Since 2019, a car-sharing and moped-sharing service has also been in growing demand in the city, and since 2018, the Tucycle e-bike service.

2.2. Procedure

A survey was designed for the study (Table 2) and distributed to the population of Gijón in an online form from August 15, 2020 to November 5, 2020 (date the state of emergency that officially determined the beginning of the second wave was declared) related to mobility habits. A link to the survey was distributed by email, in social networks and in QR codes linked to the form at several different points in the city.

A statement clarified that only those inhabitants of the city aged 18 to 99 who must move around it and need to use a vehicle to do so could answer. Descriptive statistics were used in data processing, although in future these data could be used for developing an inferential statistics research.

	Question	Answer choices
1	State your age	Open answer
2	State your sex	Female, Male
3	Before March 2020, what type of transportation did you mostly use to get around?	Private car, Bicycle, Motorbike (own or sharing), Scooter, Bus, Taxi
4	Before March 2020, did you have a bicycle, motorbike or electric scooter?	Yes, traditional bicycle. Yes, e-bike, Yes, e-scooter. Yes, traditional motorbike. Yes, e-moped. No.
5	After March 2020, what type of transportation did you mostly use to get around?	Private car, bicycle (own or sharing). Motorbike (own or sharing). Scooter. Bus. Taxi.
6	After March 2020, have you acquired some type of bicycle or e-scooter?	Yes, traditional bicycle. Yes, e-bike. Yes, e-scooter. Yes, traditional motorbike. Yes, e-moped. No.
7	Related to the e-bike sharing service “TuCycle”	I was a member and still am. I was a member before March 2020 but am not now. I was not a member before March 2020 and am still not. I was not a member before March 2020, but now I am.
8	Related to the e-moped sharing service “HiMobility”	I was a member before March 2020 and still am. I was a member before March 2020 but am not now. I was not a member before March 2020 and am still not. I was not a member before March 2020, but now I am.

Table 4 – Questions and answer choices in the online form

2.3. Sampling

After the survey was distributed, a total of 630 responses were received as of November 5, 2020, all of them valid. Of these 55.6% were women (350) and 44.4% were men (280); these figures are similar to the social reality of Gijón (Table 3). There were strong differences with respect to reality in age groups, as people aged 18–25 are hardly represented at all, while there is a significant overrepresentation of people over 65.

Category		Sample		Gijón
		Frequency	Percentage	
Gender	Female	350	55.6%	53.5%
	Male	280	44.4%	46.5%
Age	18-25	159	25.2%	7.7%
	26-65	450	71.4%	63.9%
	>65	21	3.4%	28.4%

Table 3. Respondents by gender and age, and comparison with real population in Gijón 18 years and over

The margin of error was found applying the following formula:

$$n = \frac{N \cdot z_{\frac{\alpha}{2}}^2 \cdot p \cdot (1-p)}{e^2 \cdot (N-1) + z_{\frac{\alpha}{2}}^2 \cdot p \cdot (1-p)} \quad (1)$$

The values entered were: size of the population of Gijón over 18 years of age, $N = 235{,}075$; sample size $n = 630$; $p = 0.5$. Following a normal distribution, $z_{\frac{\alpha}{2}} = 1.96$, for a confidence level of $(1 - \alpha) = 95\ \%$. The margin of error was therefore $e = \pm 3{,}9\ \%$.

4. RESULTS

The answers to Question 3 (Table 4) show that the means of transportation most used in Gijón before the pandemic by over 50% of the users, excluding pedestrians, was private vehicle. The bus was used by 36.8% of users, and the rest were hardly used at all.

Comparing this to the answers to Question 5 (Table 5), it may be observed that private car users increased greatly (14.1 points) as did bicycle users (3.8 points), while use of bus diminished (19.5 points). The rest of vehicles increased slightly.

There was an unequal evolution of data by gender: before March 2020, women used private cars less than men, but used the bus to a similar extent. However, after the first wave of the pandemic, their use of the private car was practically the same as men. Men in turn, have chosen to use alternative private vehicles more than women: the set bicycle+moped+scooter rose among men from 12.1% to 17.5%, while in women it went from 2.3% to 5.5%. By age range, the private car was observed to increase greatly in the 18-25 group by 36.1%, and 7.6% in the 26-65 age range, while over 65 remained the same, and this rise was due to the drop in use of the bus, in the group of 18 to 25 by 44.2%, in the 26.65 group by 12.1%, and in the group over 65, the drop is 5.1%.

Table 5: Question 5. Since March 2020, what type of transportation do you mostly use to get around?

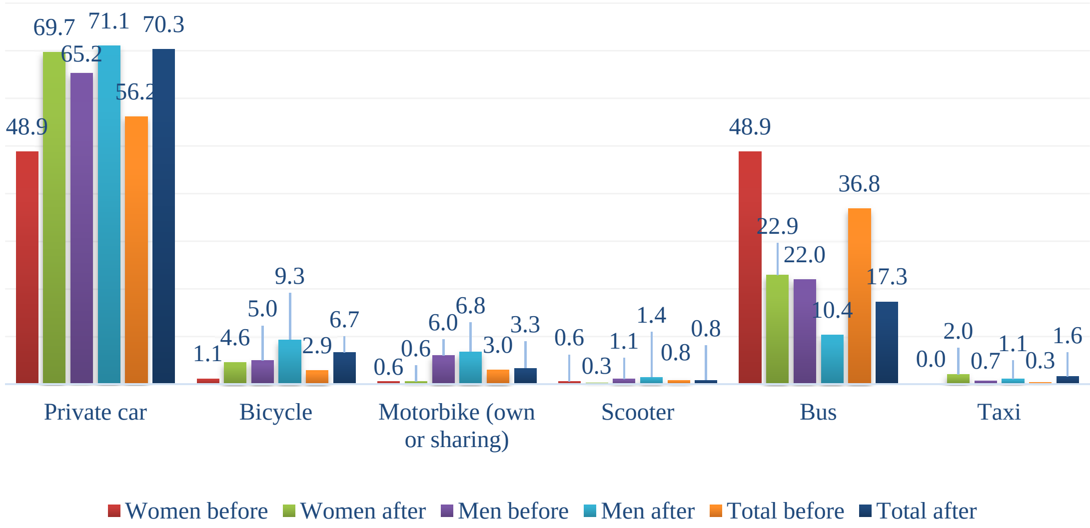

Figure 1. Comparison, in percentage, of means of transportation used before and after March 2020 by gender.

Questions 4 and 6 referred to the evolution of the private vehicle pool other than cars.

Before 2020, over 42% of the population owned some type of vehicle of the following types: bicycle or e-bike, e-moped or motorbike, e-scooter. After March 2020, 6.3% of the population claimed to have acquired a vehicle of this kind. An analysis by gender showed that before the pandemic, a higher percentage of men and women had vehicles of this type (57% vs 30%); after the pandemic, the percentage of men who acquired these vehicles was higher than women (8.9% vs 4.3%). Analyzing these data by age range, over 44% of the group of young people (18-25) had one of the vehicles mentioned, and similar in the 26-65 group (42%), however in the group over 65, only 18% had one of these vehicles. After March 2020, in all of the groups, over 93% had not acquired any of the vehicles mentioned above.

Table 7: Question 6. Since March 2020, Have you acquired a bicycle, moped or e-scooter?

Questions 7 and 8 asked about bicycle and e-moped sharing services. With regard to e-bikes, new and leaving members led to lack of variation in the number of members. e-mopeds went from 2.1% of the population before the pandemic to 3.6% afterwards, for a relative increase of 71%. By age group, in the group of young people, there were 0.6% fewer, while in the group 26-65 there was a 0.4% increase.

Table 9: Question 8. Related to the e-moped sharing service "HiMobility"

5. DISCUSSION

The main conclusion arrived at from the survey responses is that, although the majority of users already used private vehicles as their usual means of transport before the pandemic, there was a large increase in their use, by both men and women, in a higher percentage than the margin of error mentioned above (total of 56% to 70%); at the same time, bus fare increased, and its use fell drastically (from 36% to 17%). In the rest of the means of transport no significant variations were observed (higher than margin of error).

It is also observed that those surveyed acquired one of the following types of vehicle: e-bike or bicycle, e-moped or motorbike, or e-scooter. Only 6.3% said they had acquired one after the pandemic began, and 4.4% were bicycles. Neither is there an increase in sharing services, as only 1.3% said they had become members of the city's bicycle sharing service, and 2.1% of the moped sharing service.

Furthermore, gender was important both before and after the pandemic, observing more use of the bus by women, and more use of private cars, bicycles and motorbikes by men.

This effect has been widely analyzed in the literature (Figueroa Martínez y Waintrub Santibáñez, 2015; Law, 1999) and even related to cities with mild climates (Williams y Larson, 1996) as is the case of Gijón. The gender effect in the city could also be related to women's employment sectors. Before the pandemic, most women worked in sales, healthcare, education and restaurants/hotels (INE, 2019). These establishments are usually in city centers or zones easily accessible by bus, which could be why those workers habitually make use of public transportation.

The reason for the increase in mobility by private vehicle may be fear of contagion in public transportation due to prolonged contact with other riders, especially at rush hour, as well as occasional drop in service level. Users decided to use private vehicles before using a personal mobility vehicle or a sharing service, which reflects the lack of safety of these vehicles, their price or the city's climate, which could be reasons for this deficit of users.

The results of this study are in line with what those cited in the introduction, which were done just before this one. As the Apple and Nextdoor app mobility reports demonstrated, in cities like Madrid and Barcelona, over half of the population had modified their mobility habits. In Gijón, a change in means of transport was also observed, although not as drastic as in Madrid or Barcelona, which are larger cities with more traffic and more public transportation choices. In this case, half of those surveyed were already usually using a private vehicle, so their habits were not modified; nevertheless, the 36% of users who traveled by bus before the pandemic was reduced to 17% after March 2020.

This study had some limitations. In this case, the main problem with the methodology used is the limitation in generating questions asked in the survey, because the form cannot be very long, or respondents will lose interest. This may have led to the omission of some interesting questions, such as those related to users who shared vehicles before and after the pandemic or the usual destination of the respondents, as their usual means of transportation would vary depending on where they work or study, in the city center or in the outskirts or even in another city in the region. Furthermore, the representativeness of the sample was not the most suitable in terms of age, which could affect the results in the 18 to 25 age group.

One of the results that might have been expected was a large increase in the number of users of the bicycle as their usual means of transportation after the pandemic, because the city has a bike lane. This did increase from 2.9% to 6.7%, although this difference is perhaps not as wide as could have been expected: the lack of connectivity between bike lanes in the city might be the reason why this does not seem a safe choice for regular transportation. In fact, at present, the city is working on a Mobility Plan to solve the problems in the current network's continuity (Grande, 2020), and in March 2021 approved a Mobility Ordinance promoting active mobility stead of private vehicles (Ayuntamiento de Gijón, 2021).

Future studies on mobility since the beginning of the pandemic could consider other factors, such as finding out whether people who usually share cars continue to do so or whether on the contrary, many users of public transportation have now decided to share a vehicle; whether there is any difference between mobility in the different waves of the pandemic, since in this case only the period after the first was evaluated; or include pedestrian mobility in the study to quantify its increase. It might also make sense to study a second wave a year after it, or in successive years; and likewise, the results could be combined with changes in the labor market (increase in telecommuting) or unemployment scenarios arising.

6. CONCLUSIONS

This study analyzed the effect of the appearance of the pandemic associated with COVID-19 on mobility habits in the Spanish city of Gijón, with a population of 270,000, where there is currently a good city bus system, and car-sharing, moped-sharing and bike-sharing services. Therefore, a survey was taken from August 2020 to early November 2020. We think that a large part of the value of this study is that it shows a snapshot of a particular moment: that moment at which there was a certain return to normality, in order to evaluate the changes that occurred between the situation before the pandemic and the situation in the summer of 2020, after the first wave.

The survey included eight questions focusing on finding out the variation in type of transportation most used for everyday travel, about possible acquisition of personal mobility vehicles, and joining and leaving bike-sharing and moped-sharing services. This is a pioneer study of the mobility habits related to the pandemic in Gijón, and the results were analyzed based on descriptive statistics.

The main conclusion is a strong increase in the habitual use of the private vehicle, by both men and women, and a decrease in use of the bus. In the rest of the means of transportation, no significant variation was observed.

After the first wave of the pandemic, a certain renewed high in acquisition of personal mobility vehicles by those surveyed was observed. Finally, in regard to shared vehicles, it could only be deduced that there were no important variations.

Gender was demonstrated to affect mobility. Both before and after the pandemic, women used the bus more, and men used private car, bicycle and motorbike more. With regard to the vehicles owned, before the pandemic, more men than women had personal mobility vehicles; after the pandemic, the percentage of men who acquired these vehicles was also higher than women (8.9% vs 4.3%). More people went from public transportation to private in the group of young people (18-25); the group over 65 did not change their habits, because most of them were already using a private vehicle for getting around before the pandemic. Similarly, in regard to owning a PMV, a sharp generational change was observed among those up to 65 years of age compared to those over, as over 42% of the first had a PMB before the pandemic compared to 18% of the latter.

The main limitations of the study were the underrepresentation of young people from 18 to 25, along with the short survey, which did not go into detail so the questionnaire could be answered quickly.

Finally, this study could be a model (both in how it acquired data and the brevity of the survey) for analyzing future modification of mobility habits, as the number of responses was representative (except for underrepresentation of young people), and interesting conclusions were arrived at concerning the objectives set. The possibility of following surveys on the same city to acquire a dataset that can be used to analyze evolution over time of urban mobility habits in Gijón remains open.

ACKNOWLEDGMENTS

This study was carried out in the framework of research project SV-20-GIJÓN-1-21 funded by the IUTA (University of Oviedo and Gijón City Council). The authors wish to recognize the contribution of Dr. Juan Sevilla (University of Oviedo) and Jorge Muriel (Taksee Imbric) for their help during the research.

RESUMEN

El crecimiento del uso de los vehículos de movilidad personal (VMP) en el espacio urbano ha obligado a realizar adaptaciones normativas en distintos niveles de regulación. El tráfico es una materia donde intervienen poderes públicos de ámbito estatal, autonómico y local, con diferentes herramientas de limitación, fomento o servicio público. El retraso en dotarse de unas reglas precisas de ámbito estatal (2020) sobre las características lícitas de producción y uso en el entorno urbano ha provocado un desarrollo desigual de la regulación municipal, cuyas autoridades han tratado de anticiparse, en ocasiones, a los desafíos que este nuevo sistema de movilidad ha provocado: uso de las vías públicas, habilitación de los conductores, interacción con otras formas de movilidad, etc.

El objetivo del estudio ha sido identificar y analizar el régimen jurídico vigente en cinco municipios españoles de similar población (Gijón, Valladolid, Vigo, Hospitalet de Llobregat y Vitoria). Sus normas (también sus proyectos normativos) han sido objeto de la descripción sistemática, y se han contrastado con la regulación estatal adoptada en 2020, y con la normativa generada por las autoridades autonómicas respectivas.

El resultado es una exposición profunda de tres aspectos: el ordenamiento vigente en España a propósito de estos vehículos (VMP), sus principales novedades vigentes a partir de enero de 2021 y el impacto que puede tener en la regulación municipal preexistente; el conjunto de las reglas que podrían resultar de aplicación dadas por los cinco poderes públicos autonómicos que afectan a las ciudades elegidas, con sus principales fortalezas y debilidades actuales; y la comparación específica sobre cómo afrontan los cinco municipios (con sucintas referencias a las normas de otras ciudades españolas) los desafíos en materia de habilitación y permisos de los conductores de VMP, las exigencias materiales sobre los vehículos y las reglas para su uso.

1. INTRODUCCIÓN

El desarrollo de la innovación para el desplazamiento de las personas en el entorno urbano se ha concretado, en los últimos años, en el auge de nuevas herramientas de movilidad alternativas a los vehículos a motor convencionales, que transitan entre la tracción humana (bicicletas tradicionales o con la asistencia de motores eléctricos, patines o patinetes sin motor, etc.) y la total tracción eléctrica, creando una nueva categoría de vehículos que diversifican las formas de utilizar las vías de circulación urbana.

Parte de los nuevos instrumentos para el desplazamiento han sido denominados en España como "vehículos de movilidad personal" (en adelante, VMP), en función de una serie de características técnicas comunes. Morell Aldana (2020) alude a fuentes que cifrarían en alrededor de 20.000 vehículos de estas características los que circularían en España hasta poco antes de la epidemia de la Covid-19. Estos VMP no han sido realmente definidos de forma clara, mediante instrumentos jurídicos que ofrecieran certidumbre, hasta una reciente regulación normativa de ámbito estatal, parcialmente vigente desde enero de 2021.

Hasta entonces, gran parte de las reglas sobre su manejo, sus características y su circulación quedaban en el margen de ordenación de los más de ocho mil municipios.

Cuando iniciamos este estudio aún no se había promulgado la reforma del Reglamento General de Circulación y del Reglamento General de Vehículos, por lo que la mayor parte de las decisiones jurídico-técnicas del uso de los VMP en la vía pública urbana, en España, era competencia municipal, con directrices de la Administración estatal de tráfico manifiestamente insuficientes y de validez jurídica discutida (Vestri, 2018). Tras la reforma de estos reglamentos ejecutivos estatales, se ha elevado el mínimo común denominador de las reglas que afectan al uso urbano de estos vehículos. Nuestro objetivo ha evolucionado con la transformación normativa. Al principio fue solo la identificación y el análisis de las distintas soluciones técnico-jurídicas adoptadas por varias autoridades municipales en España con el fin de ordenar en su ámbito la circulación de los VMP. Sin embargo, la irrupción de las reformas justifica una ampliación del ámbito de estudio, que plantee, primero, cuál es la concreta responsabilidad de los distintos poderes públicos territoriales en la regulación de los VMP, para situar después de forma orientada cuál ha sido el desarrollo específico en los municipios inicialmente seleccionados.

Para desarrollar un análisis comparado eficiente, el ámbito territorial del estudio se ha circunscrito a la comparación entre la regulación (mediante ordenanzas) y la programación (mediante planes de movilidad urbana sostenible) de cinco ciudades de dimensión poblacional equivalente (entre 250.000 y 300.000 habitantes): Gijón, Valladolid, Vigo, Hospitalet de Llobregat y Vitoria. Sus normas y programas serán, además, contrastados con el contenido de las normas europeas, estatales y autonómicas que les son de aplicación específica.

2. MARCO COMPETENCIAL GENERAL

En el sistema político español, los municipios constituyen uno de los tipos de entidades locales (junto a diputaciones provinciales, mancomunidades, cabildos, etc.) que representan el tercer nivel de administración territorial, tras las comunidades autónomas y el Estado.

La Constitución española de 1978 (en adelante, CE) no contiene referencias explícitas a la movilidad ni a la sostenibilidad, aunque aborda tangencialmente estas materias al referirse a las competencias públicas sobre el transporte (por ejemplo, el art. 149.1.21ª CE) o la protección del medio ambiente (arts. 45, 148.1.9ª y 149.1.23ª CE). El enfoque constitucional de estas cuestiones, limitado por el contexto histórico en el que se promulga la Carta Magna (propio de finales de la década de los setenta) no impide un desarrollo normativo inferior acorde a las nuevas realidades y evidencias en estos ámbitos, más de cuarenta años después. La proliferación del uso de los ahora denominados “vehículos de movilidad personal” es una de estas realidades que el Derecho español contemporáneo aborda, aún con notables zonas de incertidumbre.

En todo caso, sobre la movilidad y el uso de medios de transporte, en general, las administraciones públicas de los tres niveles territoriales (Estado, comunidades autónomas y entidades locales –y, entre estas, especialmente los municipios–) disponen, respectivamente, de distintas competencias propias. Este sistema, avoca a una cierta complementariedad de intervenciones, y es el resultado de las previsiones del sistema constitucional.

2.1. Las competencias estatales

El Estado se ha dotado del Real Decreto Legislativo 6/2015, de 30 de octubre, por el que se aprueba el texto refundido de la Ley sobre Tráfico, Circulación de Vehículos a Motor y Seguridad Vial (en adelante, Ley de Tráfico). Esta Ley invoca como título competencial de su contenido lo dispuesto en el artículo 149.1.21ª de la Constitución española de 1978, es decir, la competencia exclusiva del Estado sobre la materia de “tráfico y circulación de vehículos a motor”. En consonancia con la legislación reguladora de las bases del régimen local, y al carácter “bifronte” de la regulación de competencias municipales, esta Ley de Tráfico alude no solo a las competencias ejercidas por la Administración del Estado, sino también al reconocimiento estatal explícito de competencias que corresponden a los municipios sobre las materias objeto de esta norma. En concreto, la Ley de Tráfico dedica su Título I al “(E)jercicio y coordinación de las competencias sobre tráfico, circulación de vehículos a motor y seguridad vial”, y el primer Capítulo de este Título está dedicado a la distribución de las “(C)ompetencias” entre la Administración General del Estado (art. 4) y los municipios (art. 7).

Las competencias que el legislador estatal atribuye a la Administración central del país, a los efectos que interesan en este estudio, pivotan en torno a la potestad para dictar reglamentos administrativos y los actos que correspondan sobre: 1º) la normativa técnica básica en materia de seguridad vial; 2º) las exigencias de homologación previa de los elementos de los vehículos y las directrices en materia de inspecciones técnicas; 3º) la determinación de las condiciones de los sujetos para la conducción de vehículos (reglas y controles sobre consumo de sustancias, causas de inhabilitación, etc.); 4º) la eventual expedición de permisos y licencias, y la determinación de los requisitos para su obtención o pérdida; e) las autorizaciones o permisos (permanentes o temporales) para la circulación de vehículos; 5º) la vigilancia, la disciplina y la regulación (en sentido amplio) del tráfico, en vías interurbanas y en travesías cuando no exista policía local; y 6º) la garantía de la igualdad de oportunidades, no discriminación y accesibilidad universal de las personas con discapacidad, en los ámbitos regulados por la Ley de Tráfico.

Aun cuando veremos que los VMP han sido reconocidos como vehículos propulsados con apoyo motorizado, no son considerados estrictamente "vehículos a motor" en sentido estricto. Pero ello no ha sido obstáculo para que el mencionado Título I de la Ley de Tráfico confiera cobertura a la regulación posterior de los VMP en los reglamentos ejecutivos de desarrollo, conforme a las competencias estatales descritas, quizá asumiendo la inclusión conceptual de los VMP como "vehículos a motor" en un sentido *lato*, o bien porque la circulación de los VMP inciden, de forma notable y obvia, sobre la seguridad vial y el tráfico, aun sin ser estrictamente tal tipo de "vehículos a motor".

Como consecuencia de todo lo expuesto, el Ejecutivo ha podido adoptar una reciente regulación sustantiva explícita (a finales de 2020, parcialmente vigente desde el 2 de enero de 2021) a propósito de los VMP en el Reglamento General de Circulación y en el Reglamento General de Vehículos, sobre la que nos detendremos en el epígrafe siguiente.

En todo caso, tanto las comunidades autónomas como los municipios disponen, también, de un ámbito competencial propio que da pie a una regulación parcialmente diferente en cada territorio autonómico y municipal.

2.2. Las competencias autonómicas con incidencia en la ordenación local

Las comunidades autónomas se ajustan, para regular aspectos que inciden en el uso de los VMP, a lo que prevean sus respectivos estatutos de autonomía en materia de ordenación del tráfico y de las vías para la movilidad terrestre (aun empleando términos distintos). Por el emplazamiento de los municipios que han sido elegidos para el concreto análisis de este estudio, resultan de interés los regímenes competenciales, y el ejercicio de las correspondientes potestades, en las comunidades autónomas del Principado de Asturias (por Gijón), Castilla y León (por Valladolid), Galicia (por Vigo), Cataluña (por Hospitalet de Llobregat) y el País Vasco (por Vitoria).

A título ilustrativo, es frecuente encontrar (en todos los estatutos autonómicos) cláusulas semejantes a las que confieren a la Comunidad Autónoma del Principado de Asturias la competencia exclusiva sobre los "ferrocarriles, carreteras y caminos cuyo itinerario se desarrolle íntegramente en el territorio de la Comunidad Autónoma, y en los mismos términos el transporte terrestre, fluvial, por cable o tubería" (artículo 10.1.5 de la Ley Orgánica 7/1981, de 30 de diciembre, de Estatuto de Autonomía para Asturias). En términos similares se expresa el Proyecto de Ley de Movilidad Sostenible de Euskadi, que señala la "atribución a la Comunidad Autónoma del País Vasco de la competencia exclusiva" en materia de transportes que discurran íntegramente en el territorio del País Vasco, "conforme a lo previsto en el artículo 10.32 del Estatuto de Autonomía para el País Vasco". Previsiones semejantes recoge el artículo 70.1.8º de la Ley Orgánica 14/2007, de 30 de noviembre, de reforma del Estatuto de Autonomía de Castilla y León, o el artículo 27, apartado Ocho, de la Ley Orgánica 1/1981, de 6 de abril, de Estatuto de Autonomía para Galicia.

Sin embargo, merece una atención particular la Ley Orgánica 6/2006, de 19 de julio, de reforma del Estatuto de Autonomía de Cataluña. Este es el único de los estatutos de autonomía que aquí nos interesan que recoge una alusión explícita a la finalidad u orientación que debe guiar el ejercicio de las competencias sobre movilidad sostenible desde los diversos poderes públicos (en este caso, de Cataluña –ya sean poderes públicos autonómicos o locales–), como específico criterio de intervención en materia de las políticas de transporte (el apartado primero del artículo 48 indica que los "poderes públicos deben promover políticas de transporte y de comunicación, basadas en criterios de sostenibilidad", entre otros). Pero, además, el artículo 84.2.h) del estatuto catalán recoge de manera expresa la competencia municipal en esta materia, aun cuando añade poco valor sustantivo directo a las alusiones de la normativa estatal antes mencionada. Este último precepto indica que es de competencia municipal "la circulación y los servicios de movilidad y la gestión del transporte de viajeros municipal".

2.3. El reconocimiento de la competencia municipal

Los municipios pueden regular diversos aspectos del uso directo de los VMP en virtud de sus competencias propias. Estas atribuciones competenciales pueden provenir de tres fuentes distintas, principalmente: a) la legislación básica del Estado en materia de régimen local; b) los expresos reconocimientos de la Ley de Tráfico; o c) de forma matizada, gracias a las previsiones de las normas de ordenación autonómica con efectos sobre las competencias de ámbito municipal.

En primer lugar, la Ley 7/1985, de 2 de abril, Reguladora de las Bases del Régimen Local (LBRL), en su artículo 25.2.g), reconoce de forma expresa que el tráfico, el estacionamiento de vehículos y la movilidad [urbana] son materias sobre las que los municipios ejercen competencias propias. Esta atribución opera con carácter general en todas las Administraciones municipales en el ámbito estatal, aun sin perjuicio de una posible ampliación o precisión de las competencias, por atribución o delegación de la normativa autonómica en cada caso. Aunque el texto de la LBRL no recoge mayor contenido sustantivo sobre el asunto que nos ocupa, esta norma estatal es indispensable para precisar las herramientas de las que disponen los municipios para afrontar esta y las demás competencias propias. Esta Ley marca, precisamente, el instrumento de regulación utilizado con mayor frecuencia por los Ayuntamientos para especificar la regulación del uso de los VMP en sus respectivos términos municipales: las ordenanzas municipales –*vid*. arts. 84.1.a) y 123.1.d) LBRL–. Tales normas delimitan las reglas de la potestad sancionadora atribuida a los alcaldes –art. 21.1.n) LBRL–. No debe obviarse, en cualquier caso, el creciente impacto de la potestad planificadora de los municipios –art. 4.c) LBRL–, que ha favorecido la expansión de los instrumentos denominados Planes de Movilidad Urbana Sostenible (PMUS), bajo el marco de referencia que supuso la Estrategia Española de Movilidad Sostenible de 2009, y la recomendación gubernamental de que todos los municipios de más de 50.000 habitantes se dotaran de su propio PMUS (Movilidad Sostenible: 2019).

En segundo lugar, la Ley de Tráfico, en su artículo 7, indica que "corresponde a los municipios", entre otras competencias: 1º) la "regulación, ordenación, gestión, vigilancia y disciplina (…) del tráfico en las vías urbanas" –art. 7.a)–; 2º) "la regulación mediante ordenanza municipal de circulación, de los usos de las vías urbanas, haciendo compatible la equitativa distribución" del tráfico, las zonas de aparcamiento y "el uso peatonal de las calles" –art. 7.b)–; 3º) la potestad para "la retirada de vehículos de las vías urbanas y su posterior depósito" cuando sean un obstáculo o un peligro para la circulación –art. 7.c) *in fine*–; y 4º) la "restricción de la circulación de determinados vehículos en vías urbanas por motivos medioambientales" –art. 7.g)–.

En tercer lugar, resulta más compleja la identificación de las heterogéneas alusiones de la normativa de proyección autonómica sobre la forma de ejercer estas competencias municipales, que marcan las diferencias entre unos territorios y otros. En las normas estatutarias solo se recoge la referencia del tipo a la ya anticipada del artículo 84.2.h) del Estatuto catalán. Sin embargo, la legislación autonómica específica sobre movilidad o transportes, con independencia de su concreta denominación, también dicta marcos competenciales en los que las comunidades autónomas atribuyen un determinado ámbito de actuación a las administraciones municipales.

Un caso peculiar es el de la Ley 9/2018, de 20 de diciembre, de transporte público de viajeros por carretera de Castilla y León. Esta norma, a pesar de su título alusivo al transporte público, realmente recoge disposiciones relativas a la movilidad personal, ajena a los medios de transporte colectivos. Por ello, su análisis será pertinente en las disposiciones sustantivas. Pero en términos competenciales, el artículo 6 de esta (referido expresamente a las "competencias municipales") carece de relevancia para las potestades de ordenación de los municipios sobre los VMP.

Y, sin embargo, los planes de movilidad sostenible aparecen como una herramienta exhaustivamente regulada (arts. 50 a 59), y en la que las Administraciones municipales desempeñan un papel nuclear.

La Ley asturiana 12/2018, de 23 de noviembre, de Transportes y Movilidad Sostenible no es especialmente generosa en sus previsiones hacia los VMP, ni los denomina así, pero recoge, en su ámbito de aplicación (art. 2), "los transportes activos realizados a pie, en bicicleta, patines u otros de similares características". Esto constituye, a todas luces, una descripción abierta y anticipada de este tipo de vehículos.

3. REGULACIÓN SUSTANTIVA MULTINIVEL EN EL ÁMBITO SUPRAMUNICIPAL

Fruto del esquema competencial antedicho, es imposible determinar con precisión un único ámbito territorial en el que los poderes públicos desplieguen normas jurídicas con efecto directo. Esto, en parte, es habitual en la mayoría de materias que hoy en día son objeto de regulación jurídica. Sin embargo, cobra especial trascendencia en algunas de ellas, cuya ordenación requiere, necesariamente, una complementariedad de normas técnicas industriales y de certificación de productos complejos, y su uso en territorios principalmente acotados a la movilidad en el espacio urbano. Tal es el caso de los VMP.

Aun cuando existe un amplio margen de concreción y discrecionalidad en manos de los Ayuntamientos u otras autoridades municipales para la regulación de la movilidad a través de los VMP, es innegable la incidencia de marcos reguladores de alcance territorial superior. Estos niveles supramunicipales incluyen, a los efectos de este estudio, las disposiciones de la Unión Europea, las normas dictadas por los poderes públicos del Estado en el ejercicio de sus potestades (de legislar, el Parlamento, o de reglamentar, el Ejecutivo), y las comunidades autónomas, en el ámbito de sus respectivas competencias.

3.1. La normativa de la Unión Europea

La principal norma europea digna de ser considerada sobre los VMP es el Reglamento (UE) n ° 168/2013 del Parlamento Europeo y del Consejo, de 15 de enero de 2013, relativo a la homologación de los vehículos de dos o tres ruedas y los cuatriciclos, y a la vigilancia del mercado de dichos vehículos (en particular, este Reglamento de la UE se aplica a los «vehículos de categoría L» definidos en su Anexo I, y que pueden resumirse, a grandes rasgos, como los ciclos de motor y ciclomotores, triciclos de motor y cuatriciclos. La principal diferencia perceptible por sus rasgos externos, al margen del tipo de propulsión del motor y otras características técnicas, es la existencia o no de un sillín –y con o sin sistema de autoequilibrado–).Veremos, más adelante, que esta disposición comunitaria ha sido utilizada como herramienta de delimitación negativa para la definición de los VMP en la normativa estatal española, haciendo que los vehículos objeto de regulación en este Reglamento europeo sean algunos de aquellos que quedan expresamente excluidos de la aplicación de las normas estatales sobre VMP (en el Reglamento General de Vehículos y en el Reglamento General de Circulación, principalmente). Es una distinción que justifica de forma lógica el mismo Reglamento de la UE, en los apartados 2.i) y 2.j) de su artículo 2. No existen otras normas europeas que incidan de forma directa en la regulación del uso de los VMP en el territorio, sin perjuicio de las reglas sobre su producción (SAV-DGT, 2019).

Por tanto, la regulación europea que deben considerar las autoridades municipales es escasa. Ello es acorde al marco competencial de la Unión Europea, que en este ámbito centra el ejercicio de sus potestades normativas en la adopción de "medidas relativas a la aproximación de las disposiciones legales, reglamentarias y administrativas de los Estados miembros que tengan por objeto el establecimiento y el funcionamiento del mercado interior" (art. 114.1 TFUE), y no en la ordenación del uso de vehículos en la específica movilidad "intra-urbana".

3.2. La normativa estatal

La ordenación estatal de los vehículos de movilidad personal se encuentra contenida en varias normas de distinto rango jurídico. Sobresalen una Ley con incidencia directa y sus reglamentos ejecutivos de desarrollo (recientemente reformados en 2020), pero no deben pasar desapercibidas otras disposiciones legales tangenciales, ni una importante iniciativa gubernamental de legislación sobre movilidad sostenible.

Romero *et al*. (2019) señalaban que, en el plano de los Estados europeos, los Países Bajos fueron pioneros al dotarse de una regulación nacional sobre esta cuestión en 2008, si bien han precedido también a España las normas estatales en Alemania, Finlandia, Reino Unido o Suiza (no así Francia, que hasta 2019 seguiría remitiendo la regulación a las normas municipales).

Las reglas de los poderes públicos de ámbito estatal despliegan efectos sobre el marco de competencias sustantivas de todas las autoridades municipales del país. La actual ordenación se encuentra en un momento de transformación: se han adoptado recientes reglas nuevas que inciden en la preservación de la seguridad, que obligan a reconsiderar algunas disposiciones previas dadas por los Ayuntamientos para la circulación en sus ámbitos urbanos.

Al mismo tiempo, está pendiente la adopción de nuevas normas, que pueden incidir en las funciones de fomento de las Administraciones Públicas en materia de movilidad sostenible. Por tanto, es muy probable que los próximos años asistamos a una profunda transformación de la actividad administrativa española en todos los niveles (normativa y planificadora, principalmente) hacia los vehículos de movilidad personal y otras formas de desplazamiento humano considerado "sostenible".

3.2.1. Un esquema básico normativo: leyes y reglamentos estatales que afectan a la ordenación municipal de los VMP

En primer lugar, destacan las previsiones de organización del sector público contenidas en la ya mencionada Ley de Tráfico (el Real Decreto Legislativo 6/2015, de 30 de octubre, por el que se aprueba el texto refundido de la Ley sobre Tráfico, Circulación de Vehículos a Motor y Seguridad Vial).

A raíz de este texto legal (y, en segundo lugar), el Gobierno ha dictado varios reglamentos que concretan las normas aplicables a esta materia. Sobresalen, por la importancia para los VMP de algunos de sus preceptos, dos textos principales: 1) el comúnmente denominado Reglamento General de Circulación (RGC), y 2) el conocido como Reglamento General de Vehículos (RGV).

Ambos reglamentos han sido modificados de forma reciente, precisamente para ser adaptados a la realidad emergente de los vehículos de movilidad personal. Para ello se ha aprobado el Real Decreto 970/2020, de 10 de noviembre [por el que se modifican el Reglamento General de Circulación, aprobado por Real Decreto 1428/2003, de 21 de noviembre y el Reglamento General de Vehículos, aprobado por Real Decreto 2822/1998, de 23 de diciembre, en materia de medidas urbanas de tráfico]. En particular, el texto de 2020 ha modificado, de una parte, los artículos del 38 al 50 del Reglamento General de Circulación. De otra parte, con respecto al RGV, ha modificado los artículos 3, 22.3, 25.1 y 28.1, además de los Anexos II y XVIII, y ha añadido el artículo 22bis.

Con anterioridad a la reforma de 2020, tanto el Reglamento General de Circulación como el Reglamento General de Vehículos ignoraban la realidad de los VMP.

En cambio, las cuestiones relativas a la regulación de estos VMP estaban recogidas de forma muy limitada en la ordenación transitoria efectuada por la Dirección General de Tráfico (DGT), a través de la Instrucción 2019/S-149 TV-108 (esta Instrucción de 2019 clarificaba y adaptaba algunos aspectos de la anterior Instrucción 16/V-124, de la misma autoridad, que hizo una primera clasificación de los VMP, con efectos sobre todo el territorio estatal). Sin embargo, el carácter transitorio y la insuficiencia de las Instrucciones de la DGT (ya sea la de 2019, o la previa de 2016), han sido consideradas insuficientes por la doctrina jurídica.

Así, la reforma de 2020 sobre el RGV y el RGC ha dado carpetazo (en principio) a la reiterada crítica doctrinal sobre la incertidumbre provocada por la falta de regulación común al territorio nacional (véanse, por todos, Perona Gómez, 2019: 26; Vestri, 2018; y Morell Aldana, 2020).

Como cierre del sistema legal estatal, y aunque no inciden de manera explícita en la regulación de los VMP, sí aluden a la movilidad sostenible otra serie de mandatos del Legislador estatal, que deben ser tenidos en consideración por todos los poderes públicos a la hora de dictar sus propias disposiciones sobre la materia. Así sucede, por ejemplo, con la Ley 37/2003, de 17 de noviembre, del Ruido; la Ley 34/2007, de 15 de noviembre, de Calidad del Aire y Protección de la Atmósfera; o la Ley 2/2011, de 4 de marzo, de Economía Sostenible.

Conviene subrayar, en fin, que la regulación estatal mencionada hasta ahora puede verse reforzada y actualizada de manera notable si prospera el (por ahora) Anteproyecto de Ley de Movilidad Sostenible y Financiación del Transporte.

Esta iniciativa legislativa del Gobierno incluye, entre otros aspectos novedosos, la creación de un Sistema Nacional de Movilidad.

3.2.2. Los tres tiempos de la reforma reglamentaria de 2020

La reforma de 2020 sobre el RGV y el RGC significa, de hecho y en la actualidad, que los municipios cuentan con una menor discrecionalidad para regular el uso de los VMP en su territorio a partir de la vigencia de las primeras de sus disposiciones aplicables. Sin embargo, la entrada en vigor de las propias previsiones de esta reforma opera en tres tiempos distintos: uno ya pasado, otro inminente, y un tercero aún indeterminado.

Una parte fundamental de las reformas de 2020 ha entrado en vigor, a los efectos que interesan en este estudio, el 2 de enero de 2021 (las definiciones conceptuales o las relativas a la prohibición de circulación de los VMP por determinadas vías, entre otras). No obstante, la reforma contempla dos medidas específicas cuya vigencia es pospuesta.

La primera obedece a la previsión explícita de la Disposición final única, que retrasa el cambio de los límites de velocidad en vías urbanas y travesías (artículo 50 del Reglamento General de Circulación) hasta los seis meses desde la publicación de la reforma (es decir, el 11 de mayo de 2021).

La segunda vigencia pospuesta remite a una fecha no concretada en el momento de la publicación de la reforma, a propósito de la adición de los párrafos j) y k) en el artículo 3 del Reglamento General de Vehículos, sobre un nuevo régimen de certificación de los VMP. Esta regla se refiere a la obligación de los usuarios de VMP de disponer de un “certificado para la circulación” recabado por los fabricantes para la “identificación” del tipo de vehículo, de acuerdo con un “Manual de características de los vehículos de movilidad personal” que debe elaborar la Dirección General de Tráfico (aún pendiente). En consecuencia, esta exigencia de certificado queda pospuesta hasta el transcurso de veinticuatro meses desde que el Boletín Oficial del Estado publique dicho Manual (podría ser efectivo, por tanto, a mediados de 2023, como pronto).

3.2.3. El nuevo concepto estricto de VMP en el Reglamento General de Vehículos

Desde el 2 de enero de 2021, el Anexo II del RGV (rubricado como "Definiciones y categorías de los vehículos") recoge una serie de definiciones fundamentales que permitirán dar mejor certeza y seguridad jurídica a la ordenación estatal, autonómica y local. La definición anticipada de los VMP es el resultado de dos operaciones normativas. En primer lugar, el RGV define ya un VMP en los siguientes términos:

> "(V)ehículo de una o más ruedas dotado de una única plaza y propulsado exclusivamente por motores eléctricos que pueden proporcionar al vehículo una velocidad máxima por diseño comprendida entre 6 y 25 km/h. Solo pueden estar equipados con un asiento o sillín si están dotados de sistema de autoequilibrado".

Esta definición, utilizada como delimitadora material del objeto de este estudio, refleja las siguientes cualidades que deben ser debidamente apreciadas: a) el número de ruedas, superior a uno, es irrelevante, lo cual flexibiliza el concepto, incluso hacia ámbitos de desarrollo industrial aún desconocidos; b) los aparatos con velocidad máxima inferior a los 6 km/h son considerados juguetes u artilugios no aptos para ser calificados de VMP (posiblemente, porque se asemejen al denominado "paso de persona", y sean susceptibles de uso peatonal); c) la alteración de los productos, o la comercialización formal de ellos, con velocidad máxima superior a los 25 km/h, convierte a estos aparatos en otro tipo distinto de vehículo, ajenos a los VMP, y a los que se aplican otras normas jurídicas o, directamente, sanciones; d) la condicionalidad del sillín al sistema de autoequilibrado parece obedecer a criterios técnicos sobre el riesgo producido por las superficies de impacto, en casos de colisión; e) la propulsión exclusiva a motor va a permitir diferencias en características y en exigencias normativas a los VMP de otros aparatos de propulsión híbrida, como las bicicletas a pedales con pedaleo asistido, que serán asemejadas (en ciertas condiciones) a las tradicionales bicicletas sin motor eléctrico que asista el pedaleo (de hecho todo ello va acompañado de otras adaptaciones conceptuales: en el mismo Anexo II, relativas a las "bicicletas de pedales con pedaleo asistido" –antiguas "bicicletas con pedaleo asistido"–, así como la supresión de los "cuatricilos" y su sustitución por los "cuatriciclos ligeros", "cuatriciclos pesados" y "ciclos de motor") , y f) al ser concebidos como monoplazas, el uso de los VMP por más de una persona de forma simultánea (un conductor y un pasajero, por ejemplo) incurrirá en una infracción administrativa debidamente tipificada.

En segundo lugar, la definición anterior es clarificada mediante tres exclusiones conceptuales explícitas. La primera, al excepcionar los VMP de la categoría estricta de "vehículo a motor". La segunda, al diferenciarlos por sus características técnicas objetivas (no serán VMP aquellos con sillín sin sistema de autoequilibrado, o "con una tensión de trabajo mayor a 100 CV o 240 VAC") o funcionales (los "concebidos para competición" o "para personas con movilidad reducida"). La tercera exclusión opera por la delimitación efectuada en la normativa europea ya mencionada, al no considerar como VMP todo aquel vehículo que encaje en la definición del Reglamento (UE) nº 168/2013 del Parlamento Europeo y del Consejo, de 15 de enero de 2013.

3.2.4. Los efectos directos sobre el uso y la circulación de los VMP a partir del concepto del Reglamento General de Vehículos

Las interpretaciones previas a la reforma de 2020 sugerían sujeciones tales como el eventual sometimiento a pruebas de alcohol y drogas (Perona Gómez, 2019), o la más que razonable toma obligatoria de seguros, aun cuando el sector de las aseguradoras no pareciera preparado para ello (Vestri, 2018: 25). La primera entra ya dentro de la consecuencia indubitada de la regulación vigente. No así la segunda: la explícita exclusión de los VMP como "vehículos a motor" parece debilitar el argumento de Vestri (2018), que presumía la obligatoriedad de los seguros a partir de la consideración de los VMP como vehículos dotados de motor, y dentro, por tanto, del ámbito de aplicación del Real Decreto 1507/2008, de 12 de septiembre, por el que se aprueba el Reglamento del seguro obligatorio de responsabilidad civil en la circulación de vehículos a motor. Sin embargo, expulsados de tal categoría, nada dice al respecto la reforma de los RGC y RGV de 2020, por lo que parece quedar solo en manos de los municipios la exigencia de este tipo de seguros para la circulación en sus respectivos ámbitos. La toma de estos, en fin, parece recomendable en municipios como el de Barcelona, y obligatoria en otros, como Cáceres (Rometo *et al.*, 2019).

La modificación del RGV de 2020 trae consigo, además, una aclaración de sus regímenes de certificación del vehículo y autorizaciones de sus usuarios (que son necesariamente sus conductores, al ser vehículos monoplazas).

De una parte, el RGV incorpora en su artículo 3.j) la exigencia de un nuevo "certificado para la circulación" de los VMP. Es un documento expedido por la Jefatura Central de Tráfico, para acreditar el cumplimiento de los requisitos técnicos de la normativa aplicable, nacional y supranacional. La obtención del mismo es responsabilidad de los fabricantes, importadores o representantes de estos en España.

De otra parte, el artículo 3.k) RGV prevé la implantación de un "Manual de características técnicas" de los VMP. De tal documento, aún no aplicable, el RGV señala: 1º) el órgano competente para aprobarlo (mediante Resolución del Director General de Tráfico –art. 22 bis, apartado 3–); 2º) su contenido mínimo (requisitos técnicos de los VMP que permitan su puesta en circulación, la clasificación de los mismos, los procesos de ensayo para la certificación y una serie de mecanismos empleados para su fácil identificación); y 3º) la necesidad de que sea publicado en el Boletín Oficial del Estado y en la página web de la Dirección General de Tráfico para su plena validez normativa.

Finalmente, el RGV incluye a los VMP (art. 22 bis) junto a los ciclos y la bicicletas a pedales con pedaleo asistido (art. 22.3) en la excepción de la obligatoriedad de obtener una autorización administrativa del artículo 1.1 del RGV, es decir, aquel “permiso de circulación” común, con carácter general, a todos los vehículos objeto de regulación, “dirigida a verificar que estén en perfecto estado de funcionamiento y se ajusten en sus características, equipos, repuestos y accesorios a las prescripciones técnicas que se fijan” en el RGV. Por tanto, los VMP no parecen sujetos a inspecciones periódicas, como el común de los vehículos a motor (salvo que la normativa autonómica o municipal disponga otra cosa, en el ámbito de sus respectivas competencias).

3.2.5. Los nuevos límites derivados de la reforma del Reglamento General de Circulación

Definidos con claridad los VMP en la normativa correspondiente (RGV), la misma reforma de 2020 incorpora dos medidas principales en relación con, por un lado, la circulación general de estos, y, por otro lado, la de todos los vehículos.

La primera de las medidas se introduce mediante la reforma del artículo 38 RGC, incorporando un nuevo apartado 4 con dos prohibiciones. Así, impide a los VMP tanto “circular por travesías, vías interurbanas y autopistas y autovías que transcurren dentro de poblado” como hacerlo “en túneles urbanos”.

La segunda medida supone la reescritura del artículo 50 RGC, alterando los límites genéricos de velocidad en vías urbanas. No es una medida que afecta de forma exclusiva a los VMP, pero sí parece motivada por el interés público de reducir la siniestralidad en el ámbito urbano, al crecer el uso compartido de las vías por otros vehículos distintos de los automóviles (así lo indica el Preámbulo del RD de 2020 que introduce la reforma). Es notorio el esfuerzo en la parte expositiva de esta reforma por subrayar la correlación causal entre la velocidad de los vehículos a motor y la siniestralidad y las probabilidades de sobrevivir en los atropellos. Por ello, el Ejecutivo introduce a partir del 11 de mayo de 2021 (Disposición final única del RD 970/2020) los siguientes límites genéricos: a) hasta 20 km/h para vías de plataforma única (en franca expansión en el diseño urbano); b) hasta 30 km/h en vías de un único carril por sentido de circulación; y c) hasta 50 km/h en las vías de dos o más carriles por sentido. Es relevante señalar, no obstante, que el RGC confiere a las autoridades municipales la potestad de excepcionar al alza el tercer supuesto o rebajar la velocidad en cualquiera de ellos (potestades condicionadas a la correcta señalización, en todo caso).

Al incluir a los VMP en las reglas generales aplicables a los vehículos, sus conductores están sujetos al régimen disciplinario por el incumplimiento también de estos límites, aun considerando que la velocidad máxima absoluta del VMP deba ser, para su homologación, los 25 km/h. Los incumplimientos de los límites de velocidad son considerados infracciones graves o muy graves –el art. 50.8 RGC remite, para su precisión, a los arts. 76.a) y 77.a) de la Ley de Tráfico–.

3.3. La regulación de las comunidades autónomas

Las comunidades autónomas han ejercido una competencia desigual en el ámbito de la movilidad sostenible, o con incidencia directa en la ordenación de los VMP.

De las comunidades autónomas de particular interés para este estudio, solo tres (Asturias, Castilla y León y Cataluña) disponen de normas legales vigentes que aluden, de forma al menos tangencial, al papel de los VMP en la promoción de la movilidad sostenible.

En síntesis, en el caso de Asturias, la regulación está condensada y protagonizada por la Ley 12/2018, de 23 de noviembre, de Transportes y Movilidad Sostenible. Cataluña cuenta con dos normas con rango de Ley que inciden en esta cuestión, a juzgar por el criterio técnico en el que se apoya su Ejecutivo: la Ley 9/2003, de 13 de junio, de movilidad; y el Decreto Legislativo 1/2019, de 3 de agosto, por el que se aprueba el Texto refundido de la Ley de urbanismo. Finalmente, a pesar de una denominación algo confusa, el legislador castellanoleonés incluye disposiciones relativas a la movilidad urbana sostenible y al fomento de un transporte que podría conectar, de forma implícita, con la ordenación de los VMP, a través de la Ley 9/2018, de 20 de diciembre, de transporte público de viajeros por carretera de Castilla y León.

Por otro lado, el Gobierno del País Vasco se encuentra tramitando, desde 2019, un Proyecto de Ley de Movilidad Sostenible de Euskadi (remitido al Parlamento el 17 de enero de 2020). Esta propuesta normativa, en la versión disponible para este estudio, adolece de cualquier alusión a los VMP, de manera directa o implícita. Solo menciona a las bicicletas o el desplazamiento a pie, como únicas alternativas de movilidad individual frente a los estrictos "vehículos a motor". Por su parte, Galicia ha rechazado hasta el momento, de forma explícita, la posibilidad de dotarse de un instrumento jurídico de rango legal sobre la movilidad sostenible en su territorio (su Parlamento se opuso a una iniciativa en tal sentido el 27 de marzo de 2019).

Conviene apuntar que Perona Gómez (2019: 24) ya advirtió de, al menos, dos formas de afrontar la regulación autonómica sobre la movilidad sostenible, bien con leyes específicas (como es el caso, según este autor, del Principado de Asturias, Cataluña y la Comunidad Valenciana), o bien mediante la incorporación de principios jurídicos en otras normas sectoriales distintas, alusivos al valor de la sostenibilidad en la movilidad (como serían las leyes de transporte de la Comunidad de Madrid o la Ley de accesibilidad de Castilla y León, según este autor).

A continuación, detendremos el análisis en dos de las tres comunidades que disponen de una regulación al menos tangencial sobre esta materia, entre sus normas legales. Esta selección se debe, por un lado, a la promulgación reciente (han transcurrido apenas tres años) de las normas asturiana y castellanoleonesa. Por otro lado, también parece pertinente una sucinta exposición que facilite la comparativa entre ambas, dada la proximidad cronológica y geográfica de las leyes y sus territorios de aplicación, respectivamente, y ante la falta de vigencia, aún, de la normativa vasca proyectada.

3.3.1. El silencio de la legislación de Castilla y León con respecto a los VMP como principal debilidad de su normativa sobre movilidad sostenible

Como anticipábamos *ad supra*, la Ley castellanoleonesa del transporte público de viajeros (Ley 9/2018, de 20 de diciembre) va más allá del ámbito objetivo explícito que la norma declara en sus primeros artículos o en su título. En efecto, regula aspectos de movilidad personal (como el deber público de incentivar los desplazamientos peatonales y en bicicleta), que solo conectan con el transporte público de forma tangencial y circunstancial.

Sin embargo, la Ley omite cualquier referencia explícita, o alusión directa implícita, relativa al uso de los VMP, a pesar de ser una norma reciente (de 2018). Así, por ejemplo, el artículo 15.4 de la Ley insta a las Administraciones públicas (autonómica y otras competentes, como podrían ser las municipales) “al fomento y desarrollo de estrategias públicas de uso” de la bicicleta “en combinación con el servicio público de transporte de viajeros”, mediante la creación de una Oficina de la Bicicleta. En esta misma idea incide el artículo 19.2 de la Ley (mediante la difusión en internet de la posibilidad de viajar con bicicletas en los transportes ofrecidos por las administraciones públicas castellanoleonesas). También el artículo 56.2.b).8º incluye, entre las actuaciones mínimas de los planes de movilidad sostenible de competencia municipal, el fomento “de la movilidad a pie y en bicicleta a través de la construcción de espacios para el peatón y el ciclista”. No parece que esta previsión organizativa y de fomento incida de forma explícita en materia de VMP, a pesar de las evidentes conexiones conceptuales con el fin público perseguido para la movilidad personal sostenible entre unas y otras formas de desplazamiento.

No obstante lo anterior, el artículo 8.1.d) contempla como un derechos de los viajeros del transporte público que estos puedan llevar determinados equipajes, incluyendo bicicletas, sin que “suponga un coste adicional para las personas usuarias”. Partiendo de la indeterminación de la cláusula, y de la realidad fáctica de que los VMP suelen ocupar un volumen inferior al de la mayoría de bicicletas convencionales (si tomáramos esta alusión expresa como ejemplo de máximos permitido por el precepto), parece razonable que la legislación autonómica ampare, por analogía, el derecho de los usuarios del transporte público (urbano e interurbano) a hacer uso del mismo cargando con sus posibles VMP.

Esta previsión podría operar como incentivo en el ámbito de influencia metropolitana de Valladolid, en los casos de desplazamientos que puedan combinar transporte público con el uso de VMP, o cuando cambios meteorológicos a lo largo de una jornada puedan hacer aconsejable el uso del VMP durante un tiempo determinado, y el acceso al transporte público en otro horario.

Sea como fuere, el silencio del legislador castellanoleonés sobre los VMP es, tal vez, una de las debilidades más notorias puestas de manifiesto, y con mayor rapidez, en la Ley de 2018. Carece del tratamiento de una obvia realidad de hecho emergente.

En este sentido, sería más que recomendable una revisión puntual de la norma, que incorpore estos nuevos elementos en un plano similar y equiparable al del fomento de la movilidad a pie y en bicicleta, pero atendiendo a las peculiaridades de los VMP que los hacen constituir una categoría diferenciada del resto de vehículos propulsados a motor (esto es, en consonancia con la ordenación estatal mencionada).

3.3.2. La previsión limitada en la legislación sobre movilidad del Principado de Asturias

La principal norma asturiana que aquí interesa es la Ley 12/2018, de 23 de noviembre, de Transportes y Movilidad Sostenible. El artículo 2.1.a) de esta Ley prevé, de forma explícita, la aplicación de sus disposiciones a los desplazamientos personales mediante “transportes activos realizados a pie, en bicicleta, patines u otros de similares características”. No deja de ser extraño el empleo de la expresión “transportes a pie” (en términos de racionalidad lingüística, parece más apropiado haber empleado la expresión “desplazamientos” o “movilidad”), pero es evidente que, aun sin la denominación que se ha generalizado con posterioridad a esta disposición normativa de 2018, el legislador quiso incluir en su ámbito de ordenación el uso de los hoy conocidos como VMP.

A lo largo del texto, la Ley es profusa en alusiones y referencias a estos modelos de transporte llamados “de bajo” o “nulo” impacto, ajenos al uso de combustibles fósiles y equiparables a la movilidad peatonal o en bicicletas.

Las bicicletas son el vehículo alternativo configurado en la Ley como protagonista indiscutible de la movilidad sostenible. Son aludidas de forma explícita en más de cincuenta ocasiones a lo largo de los 153 artículos y múltiples disposiciones de otro tipo, y el legislador dedica, incluso, un Capítulo propio a la “movilidad ciclista” (arts. 132 a 136) dentro del Título X (rubricado “La movilidad ciclista y peatonal”). En definitiva, la norma es exhaustiva en previsiones de toda índole, con el objeto de promover el uso de esta forma de movilidad.

Frente a la movilidad ciclista y peatonal, solo existe una segunda referencia explícita a la terminología alusiva en 2018 a los VMP –“patines a motor, segway y similares”, y aparte de la referida al ámbito de aplicación de la Ley, del artículo 2–. Tal referencia se encuentra en el artículo 18.2.m) de la Ley. En todo caso, este precepto reviste especial valor, ya que obliga a los Planes de Movilidad Sostenible de los municipios a incluir, al menos, la "planificación de una adecuada red de carriles mixtos y para tráfico segregado de vehículos como bicicletas, bicicletas eléctricas" y los VMP. Resulta digno de mención que ya esta Ley autonómica de 2018 recogiera el sentido que sería luego incorporado en la regulación estatal, confirmando la condición de vehículos de estos VMP (posiblemente, en consonancia con la previa Instrucción 16/V-124, de 3 de noviembre de 2016, de la Dirección General de Tráfico).

Por su valor comparativo con la normativa castellanoleonesa, cabe mencionar la distinción nominal de las referencias de la norma asturiana que modifica los preceptos de otra Ley (Ley 1/2002, de 11 de marzo, del Consorcio de Transportes de Asturias), en relación con la Oficina de la Bicicleta y Movilidad Activa, cuya mera denominación ya amplía el ámbito de intervención sustantiva respecto de su homóloga en Castilla y León. Además, esta reforma de la Ley del Consorcio de Transportes hace constar, de forma explícita, aquello que apuntábamos en el caso castellanoleonés de forma implícita: la promoción del uso intermodal entre medios de transporte público y vehículos como la bicicleta con o sin motor (y similares, sobre los que la normativa insta, por ejemplo, a "estudiar, promocionar y estimular la implantación de soluciones de micrologística" –art. 12 *ter*.1.i) de la Ley del Consorcio de Transportes, reformada por el apartado Tres de la Disposición final primera de la Ley de Transportes y Movilidad Sostenible, de 2018–.

4. REGULACIÓN MUNICIPAL COMPARADA

Hemos apuntado ya la competencia de las autoridades municipales para regular un amplio abanico de condicionantes y de elementos de gran relevancia sobre el uso ordinario de estos VMP. Algunos autores, incluso, han llegado a sostener la posible existencia de responsabilidad administrativa municipal en los supuestos de accidentes que involucren a tales vehículos (Perona Gómez, 2019).

La Memoria de la Fiscalía General del Estado 2018 aludía ya entonces a la necesidad de que los Ayuntamientos regularan mediante ordenanzas el uso de los VMP en sus respectivos ámbitos, habida cuenta del creciente riesgo que el crecimiento de su uso estaba produciendo, materializado en accidentes (cfr. Perona Gómez, 2019: 26-27). Sobre la persecución penal a propósito del uso del uso ilícito de estos vehículos se ha pronunciado, también, Morell Aldana (2020), quien cita las instrucciones internas e interpretativas de distintas instancias del Ministerio Fiscal, tratando de ordenar la persecución de los delitos cometidos con ellos.

Las ciudades inicialmente elegidas para la comparativa de su regulación fueron Gijón, Valladolid, Vigo, Hospitalet de Llobregat y Vitoria-Gasteiz. La principal razón de la elección era la similitud de población residente. Sin embargo, la búsqueda (heurística) de sus fuentes normativas, especialmente de sus eventuales ordenanzas sobre VMP, arrojó como resultado la inexistencia de reglamentaciones específicas, adaptadas a estos nuevos vehículos, en tres de las cinco ciudades (carecían de regulación específica vigente, en 2020, Gijón, Valladolid y Vigo, aunque la primera de ellas se ha dotado de una reforma aprobada en marzo de 2021, a la que nos referiremos por su complitud). No obstante, incluso en las ciudades que no cuentan con referencias normativas alusivas al uso de estos vehículos (directa o indirectamente), una sencilla búsqueda de las hemerotecas recientes de la prensa digital local en cada caso evidencia que existen iniciativas municipales tendentes a la regulación.

Las orientaciones de unas y otras encuentran puntos de sinergia, otros de discrepancia, pero todos evidencian algunas innovaciones normativas tratando de adaptarse a nuevas realidades y a situaciones complejas. Sus respuestas pueden servir de inspiración a otras normativas municipales, o para reflejar mejor las zonas más o menos oscuras que aún persisten en otros regímenes jurídicos.

4.1. La implantación de los Planes de Movilidad Urbana Sostenible

Aunque las cinco ciudades objeto de comparación en este estudio disponen de sus propios y vigentes Planes de Movilidad Urbana Sostenible (con esta u otra denominación específica), ninguno de ellos recoge de manera explícita, en sus versiones aplicables a principios de 2021, expectativas de ordenación del uso de los VMP, con esta u otra denominación. Por orden cronológico, el Plan aún vigente más antiguo es el de Valladolid (2004, publicado en BOP-Valladolid el 1 de marzo de 2005), que parece que será sustituido a lo largo de 2021 por uno nuevo. Al vallisoletano le siguió el “Plan de movilidad sostenible y espacio público de Vitoria” (2007), aunque desde 2019 parece haberse iniciado el proceso de reforma, contemplando (esta vez sí) una especial atención tanto a los VMP como a las bicicletas a pedales con pedaleo asistido. Vigo y Hospitalet de Llobregat cuentan con Planes de movilidad sostenible desde 2014, sin que haya evidencias conocidas de su reforma, y sin que hagan mención alguna a los VMP. No obstante, Hospitalet de Llobregat dispone de un específico “Plan director de la bicicleta”, de 2006. Finalmente, Gijón adoptó su vigente “Plan Integral de Movilidad Sostenible y Segura” en 2018, sin mencionar de forma explícita a los VMP, aun cuando una de las propuestas de actuación del mismo sí es una nueva ordenanza municipal de movilidad sostenible (empezada a tramitar formalmente en octubre de 2020 y aprobada en marzo de 2021, aunque no publicada en su versión definitiva al cierre de este artículo), la cual sí contempla la ordenación del uso de los VMP en su espacio urbano.

4.2. Las ordenanzas municipales alusivas a la movilidad y la aplicación de sus normas a los VMP

La promulgación de las normas estatales de 2020, y su vigencia a partir de 2021, marcan una pauta de regulación mínima, confiriendo la potestad a los municipios para excepcionar algunos aspectos (como los límites de velocidad genéricos aludidos), o dictando normas más restrictivas y adaptativas sobre el uso de los VMP, pero no más permisivas de lo que ha previsto el Real Decreto 970/2020.

Gracias a una valiosa labor compiladora de organizaciones de la sociedad civil, resulta fácil constatar la existencia de ordenanzas de movilidad que contemplan el uso específico de los VMP en más de una veintena de municipios de diversa envergadura: A Coruña, Almuñécar, Benidorm, Alicante, Denia, Palma, Burgos, Ciudad Real, Cáceres, San Sebastián, Granada, Logroño, León, Lleida, Alcalá de Henares, Colmenar Viejo, Madrid, Tres Cantos, Pamplona, Valencia, Sevilla, Pozuelo de Alarcón o Aravaca de la Cruz –cfr. AVPE (2021), Romero *et al.* (2019) o la compilación divulgativa de Norauto (2020)–.

La comparación plena de todas estas disposiciones excede, con creces, del tiempo y espacio disponibles para este análisis. Por ello haremos alusiones circunstanciales e ilustrativas a algunas de las normas de estas otras localidades, pero centrando la atención en los modelos vigentes y proyectados de las cinco ciudades elegidas.

En el caso de los municipios seleccionados para un análisis comparativo singular en este estudio, cabe hacer las siguientes precisiones preliminares.

En primer lugar, Gijón dispone de una Ordenanza de Circulación y Transportes, de 2002, que contiene alusiones al uso de las bicicletas pero no de otros vehículos que pudieran interpretarse extensivamente como VMP, pero se ha dotado recientemente de una nueva regulación, a través de la Ordenanza de Movilidad Sostenible del Concejo de Gijón, de 2021, que sí los contempla de forma pormenorizada. Esta Ordenanza no figura publicada al cierre de este artículo, por lo que las referencias se hacen con respecto al texto del proyecto disponible en la web del Excmo. Ayuntamiento de Gijón.

En segundo lugar, Valladolid cuenta con su normativa general de circulación de 2005 (Reglamento general de tráfico, aparcamiento y seguridad, de 2005), otra previa de Movilidad Urbana de 2004, y otra específica sobre el uso de bicicletas, de 2015 (BOP-Valladolid, núm. 67, de 21 de marzo de 2015), pero todas estas normas contienen pocas disposiciones directamente aplicables a los VMP. Además de escasa, la regulación vallisoletana sobre el uso de los VMP es de dudosa validez a partir de la entrada en vigor de la reglamentación estatal de 2021. Esto se debe a que presupone, en parte, una definición ya incompatible con el nuevo marco regulador, porque la Ordenanza municipal de 2015 califica a quienes utilizan patines, monopatines o patinetes como "peatones" (al definir así a los "patinadores" en el anexo de definiciones de aquella normativa). Dado que los objetos que usan pueden abarcar tanto a VMP como a elementos similares, pero sin motor eléctrico, la definición subjetiva puede ser válida para estos últimos sin propulsión motorizada, pero ya no para los VMP, que son conducidos necesariamente por sujetos considerados conductores.

En tercer lugar, Hospitalet de Llobregat reformó su Ordenanza de Circulación (BOP-Barcelona, de 21 de septiembre de 2015), mencionando los VMP mediante la fórmula de "*patins eléctrics i anàles, degudament homologats, i autorizats conforme a la normativa* *vigent*” (art. 19). Esta ordenanza hospitalense de 2015 prevé la aplicación de las reglas dadas para la circulación de bicicletas también a los patines eléctricos y vehículos análogos (en clara alusión a lo que, después, ha sido definido como VMP), haciendo una remisión mínimamente excepcionada desde el artículo 19 (específico de estos vehículos calificados como pre-VMP) al artículo 18. Por tanto, la aplicación debe hacerse matizada por las reglas singulares de las características objetivas de los VMP.

En cuarto lugar, Vitoria adoptó una Ordenanza municipal reguladora de los usos, tráfico, circulación y seguridad en las vías públicas de carácter urbano en 2013 (cfr. BOTHA (Boletín Oficial del Territorio Histórico de Álava) núm. 1, de 3 de enero de 2014), que ha recogido una aparente regulación de los VMP, denominándolos “patines y similares” (en el Capítulo III del Título I de aquella ordenanza). Sin embargo, la mayoría de estas cláusulas, que diferencian el uso de los vehículos de motor de otros vehículos (bicicletas, monopatines, etc.) lo hacen excluyendo expresamente a los VMP, al circunscribir las reglas, en general, a los “patines no motorizados”. En consecuencia, solo podemos deducir algunas normas excepcionales con ciertos ejercicios analógicos, remitiendo el resto a la regulación supletoria que el art. 10.9 de aquella norma prevé (es decir, aplicando la regulación general de los vehículos a motor, aun cuando no lo son en sentido estricto).

En quinto y último lugar, la Ordenanza de Circulación de Vigo data de 1993 (cfr. Boletín Oficial de Pontevedra, núm. 123, de 30 de junio de 1993). No recoge ninguna mención indirecta o directa a los VMP. No obstante, la corporación municipal ha anunciado su intención de reformar tal régimen e incorporar a su ordenamiento local una normativa explícita para estos vehículos (abriendo trámite de consulta pública por acuerdo de la Junta de Gobierno de 25 de marzo de 2021). El interés principal que hoy ofrece el análisis de la situación de Vigo radica en esta programación normativa, que contempla su adopción en el verano de 2021. De la información que es accesible en la actualidad, a través de las comunicaciones de prensa del consistorio y de la apertura del trámite de audiencia pública sobre la norma, extraeremos algunos elementos significativos sobre la previsión de ordenación modal.

Finalmente, conviene anotar un rasgo común: incluso en las propuestas normativas más exhaustivas (como la nueva Ordenanza de Gijón de 2021), el régimen sancionador aplicable a los VMP no difiere de manera significativa de las reglas generales dadas para las infracciones y sanciones en materia de conducción general de vehículos, o en todo caso a las especialidades previstas para las bicicletas y ciclos de transporte.

4.3. Previsiones subjetivas y objetivas para el manejo de vehículos de movilidad personal en las disposiciones normativas municipales

Con independencia de las denominaciones de las ordenanzas, y de la complitud de sus previsiones, el análisis comparado que ya han abordado diversos autores, como Vestri (2018; 2019) o Romero *et al*. (2019), hace evidente una serie de elementos que están dentro de la esfera de competencias de los municipios, y que facilitan apreciar de manera ordenada las sinergias y divergencias de las distintas regulaciones municipales. Esta visión sistematizada de las reglas dadas y de los ámbitos susceptibles de ordenación municipal podría facilitar el ejercicio racional de esta potestad normativa de los Ayuntamientos.

A grandes rasgos, las previsiones del sistema jurídico adoptado en la mayor parte de municipios españoles analizados, hasta el momento, parecen poder reducirse a tres grandes categorías de disposiciones: a) aquellas subjetivas, que regulan las condiciones de los sujetos usuarios-conductores de los VMP, sobre su capacidad para conducirlos y las responsabilidades derivadas; b) las de tipo objetivo, referidas a las características materiales del vehículo, en tanto que objeto; y c) las propiamente modales, o que determinan el modo de uso del objeto, por los sujetos mencionados, en el específico contexto urbano. Estas últimas centrarán la atención del epígrafe siguiente.

4.3.1. Las previsiones sobre las circunstancias de los sujetos: la edad y la diversidad funcional

Con anterioridad a la reforma de 2020, la literatura académica había advertido (fundada en la jurisprudencia disponible y en las instrucciones interpretativas de la Fiscalía, como acredita Perona Gómez, 2019) la sujeción de los conductores de los VMP a las reglas generales de la conducción de vehículos, previstas en la Ley de Tráfico y en su desarrollo reglamentario (RGV y RGC).

Hoy, como nota diferenciadora entre los VMP y los vehículos a motor en sentido estricto, los conductores de los primeros están exentos de contar con una licencia o permiso personal de circulación para su manejo. Así lo prevé la normativa estatal ya mencionada (además, de forma consistente desde la primera Instrucción 16/V-124 hasta el RD 970/2020). Pero ello no impediría, en principio, que los municipios exigieran alguna autorización subjetiva para su uso en las vías de su competencia.

La principal característica subjetiva que ha sido omitida en la regulación estatal es la edad de los potenciales conductores de VMP. Esto da lugar a una actual disparidad notable de previsiones entre unos y otros municipios. Es cierto que el rango no es muy amplio –Pamplona serviría de ejemplo del más bajo, a los catorce años, y Barcelona, Burgos o Cáceres del más alto, a los dieciséis (Norauto, 2020: 7-9; Romero *et al.*, 2019)–. De las ciudades que nos interesan, la edad sirve de criterio no solo para establecer prohibiciones concretas a usuarios por razón de su edad, sino también habilitaciones explícitas u obligaciones circunstanciales.

Las habilitaciones especiales por razón de la edad han sido recogidas, primero, por las ordenanzas de Hospitalet de Llobregat y de Gijón con efectos sobre cualquier tipo de actividad, y, segundo, por la normativa de Vitoria circunscribiendo la restricción etaria al ejercicio de actividades económicas. Las normas e iniciativas normativas de Valladolid y de Vigo guardan silencio en este sentido, por el momento, y sus previsiones sobre la edad para el uso de bicicletas u otros análogos no son extrapolables a los VMP.

La norma hospitalense indica que no existe un claro límite de edad que impida su uso. No obstante, parece que, como excepción, los menores de 12 años (art. 18.16) podrían circular con bicicletas o VMP por las aceras, siempre que respeten el paso de peatón y estén acompañados de adultos (peatones). Reglas similares prevé la ordenanza de Vitoria (de 2013) para el uso de bicicletas, pero sin regla explícita de analogía extensible a los VMP, como es el caso de la ordenanza de Hospitalet de Llobregat (art. 19). Por otro lado, los menores de 16 años están obligados a llevar casco protector, sea cual sea la vía por la que circulen, siendo solo recomendable para el resto de usuarios (igual sucede en Madrid, por ejemplo, o en municipios más pequeños, como Almuñécar –*víd.* Romero *et al.*, 2019–).

La regulación de la edad por la que se ha inclinado el proyecto de ordenanza de Gijón parece un intento de optar por un método avanzado de regulación de los aspectos etarios, y basado en una doble técnica: a) crea un primer rango jurídico que reconoce la capacidad indubitada a los ciudadanos a partir de los quince años para la conducción de los VMP; y b) añade una cláusula de habilitación a los menores de esta edad, basada en circunstancias de su capacidad natural aplicada al caso (esto es, basada en las características aptitudinales propias del sujeto en relación al objeto, como la altura o el peso del menor de quince años).

Sin embargo, aunque esta doble reglamentación debiera favorecer el realismo de la norma, añade también varias condiciones que ya han sido criticadas en normativas vigentes precedentes, por su imprecisión. Resulta que la habilitación a los menores de 15 años exige que deban "ir acompañados de un adulto y bajo la responsabilidad de sus progenitores y/o tutores". Siendo vehículos monoplazas, no resulta del todo claro qué significa el acompañamiento, o cómo opera la asignación de la responsabilidad en exclusiva a unos progenitores/tutores que no parecen ser los únicos adultos habilitados para actuar de acompañantes (pensemos, por ejemplo, en el desplazamiento en grupo con un responsable adulto usando estos vehículos hacia los centros escolares, o en colectivos realizando actividades de tiempo libre educativo). Como cláusula de cierre, los menores 15 años solo podrán conducirlos, además de cumpliendo las condiciones antedichas, "fuera de las zonas de circulación, en espacios cerrados al tráfico" de vehículos a motor.

Entre las ciudades objeto de nuestro análisis, las prohibiciones etarias vinculadas al uso para ciertos fines son expresamente contempladas solo en la norma de Vitoria (en su ordenanza de 2013). Esta norma parece indicar que el uso de VMP para actividades económicas de carga (entendiendo que es viable en el formato de mochila adaptada de algunas marcas de reparto) está limitado a las personas mayores de edad, de acuerdo a lo que indica su artículo 24. Este, aun cuando no alude expresamente a los VMP, establece tal limitación refiriéndose a los vehículos de propulsión eléctrica semejantes pero distintos de las bicicletas.

Finalmente, el elemento de la diversidad funcional, en relación con la discapacidad de cualquier índole, es motivo de especial regulación en varias disposiciones, aunque con previsiones distintas. El proyecto de ordenanza de Gijón prevé, en concreto, la prioridad de las personas con movilidad reducida sobre el resto de peatones, también cuando estas circulen sobre VMP (sin confundirlos con sillas motorizadas u otros vehículos) en vías ciclistas del tipo acera-bici (art. 35.3). Vitoria, en el artículo 21 de su ordenanza de 2013, también alude a la prioridad de las personas con diversidad funcional respecto del resto de usuarios de las vías, con independencia de la forma de desplazarse que tengan.

4.3.3. Los requisitos materiales y otros factores objetivos condicionantes

Las normas de las ciudades objeto de estudio contemplan reglas bastante dispares sobre las exigencias que deben reunir los VMP para circular en su ámbito.

Sobresalen dos conjuntos de previsiones dignas de mención. En primer término, encontraremos las exigencias relativas a elementos que no han sido determinados por la normativa estatal (nótese que el requisito frecuente de sistemas de frenado adecuados para los VMP es de alusión innecesaria en la actualidad, dadas las exigencias de homologación de estos vehículos en el ámbito estatal). En segundo término, identificamos la especificación de condiciones objetivas que justificarían la retirada de estos vehículos por las autoridades municipales, al considerar que están en condiciones de abandono.

Por un lado, la normativa de Hospitalet y de Gijón contempla unos requisitos detallados, equiparables a las exigencias de ciudades como Madrid, Valencia o Pamplona (Norauto, 2020). Este grado máximo de previsión (para Hospitalet de Llobregat y Gijón) es el que prevé la exigencia expresa de sistema de frenado adecuado, timbre, iluminación frontal y trasera, y elementos reflectantes o catadióptricos homologados traseros y laterales (art. 18.11 de la ordenanza hospitalense de 2015, y art. 50.6 del proyecto de Gijón aprobado en 2021). La regulación hospitalense hace especial mención al uso de los elementos de iluminación y reflectantes como requisitos indispensables para circular en ciertas condiciones de visibilidad reducida, sea cual sea la causa –tipo de vía, condición meteorológica u horario nocturno, por ejemplo–.

Por otro lado, Valladolid solo dispone de una cláusula residual, a lo sumo de aplicación por analogía, procedente de la regulación de las bicicletas, acerca del “timbre que los conductores harán sonar siempre que haya viandantes o vehículos a los que puedan alcanzar” –art. 43.f) del Reglamento de circulación de 2005–. El timbre ha sido concebido como elemento recomendable, no obligatorio, por las normativas de otras ciudades aplicables a algunos de los tipos de VMP, ni siquiera a todos ellos (Norauto, 2020).

Finalmente, la actual normativa conocida y proyectada de Vigo y Vitoria no prevén ningún elemento exigible más allá de los mínimos impuestos por la aplicación directa de la normativa estatal. La ordenanza hospitalense es la que recoge una definición más precisa de “estado de abandono” de uno de estos vehículos: cuando, encontrándose en la vía pública, carezca de dos o más elementos indispensables para su funcionamiento. Los arts. 155 al 158 del proyecto gijonés regulan de forma exhaustiva las condiciones de la retidada de los VMP, pero solo anota que el abandono pueda ser presumido “racionalmente” por las autoridades municipales competentes.

En Vigo, por último, es hoy de aplicación a los VMP las mismas reglas sobre consideración del abandono que para el resto de vehículos, según se desprende del artículo 23 de su ordenanza de 1993.

4.4. Las condiciones modales

La insuficiencia de la regulación estatal motivó que no pocas de las ordenanzas que contemplaban la circulación de los VMP antes de 2020 contuvieran aspectos hoy reiterativos, como la prohibición de usar dispositivos móviles o auriculares durante su conducción (Romero *et al.*, 2019), o incluso parcialmente contradictorios, como la prohibición de circular por la calzada. Nos interesan aquellas que suscitan distinciones entre los municipios elegidos.

Algunas reglas municipales sobre la conducción de estos VMP son genéricas e independientes de cualquier factor exógeno. No son muy numerosas, y en ocasiones se aplican por analogía (por indicación explícita o implícita). Pero, por ejemplo, la normativa vallisoletana incluye cláusulas de este tipo, como el deber de los conductores de controlar “en todo momento” el propio vehículo, y “adoptar las precauciones necesarias para la seguridad” del resto de usuarios de las vías (art. 5.2 del Reglamento de 2005), o la obligación de mantener “el campo necesario de visión y la atención permanente a la conducción, que garanticen la propia seguridad (…) y la de los demás usuarios de la vía” (art. 6.1). Por otro lado, algunas reglas son de aplicación discutible a los VMP, o al menos no tan evidente, como las del artículo 43 del mismo Reglamento, que exige a los conductores de bicicletas (quizá teleológicamente extensible a los de VMP) “circular lo más cerca posible de los bordillos de aceras y paseos”, y no pueden circular “sujetos a cualquier otra clase de vehículos” (art. 48.2), algo que también prevé prohibir el consistorio de Vigo, según Melchor (2021). La incipiente propuesta regulatoria de esta última ciudad añade otros dos aspectos generales: la prohibición de la circulación en paralelo de varios VMP (como varias ciudades prevén ya para las bicicletas), y el transporte de animales por parte del conductor.

En todo caso, la mayoría de las normas se aplican en función del uso de los espacios y las condiciones del contexto. En síntesis, sobresalen cuatro conjuntos de regulaciones sobre el modo de uso de los vehículos que nos ocupan, que dependen de factores exógenos. En primer lugar, la materia que es objeto principal de la atención de las normas municipales es la regulación de formas de circulación de los VMP condicionadas a los tipos de vías que existen en cada localidad y a otros factores externos (meteorología, ocupación síncrona del espacio, etc.). En segundo lugar, merecen mención aparte, aunque está estrechamente vinculado con lo anterior, las reglamentaciones alusivas al uso del espacio para el estacionamiento de estos vehículos. En tercer lugar, son frecuentes las previsiones sobre el uso de elementos de protección y visibilización por parte de los conductores, en función de diversas circunstancias del contexto. En cuarto y último lugar, no es extraño encontrar algunas reglas aplicables al uso específico de los VMP para diversas actividades económicas.

4.4.1. Las condiciones de circulación en función de los tipos de vías

El tipo de vías por las que se puede circular aparecen reguladas con tres técnicas: una de preferencia de estos vehículos frente al resto, otra de habilitación del uso de las vías y espacios, y una tercera de prohibición expresa de circulación por otras vías.

En relación el uso preferente de algunas vías por parte de los VMP está asentado en la mayoría de ordenaciones que los contemplan de forma explícita, pero también en aquellas que pueden ser de aplicación por analogía implícita. Este último caso es el de la regulación hospitalense, por ejemplo, donde (si la analogía es válida) ciclistas y conductores de VMP tendrían preferencia frente a los demás vehículos cuando circulen por vías reservadas a bicicletas o en caminos vecinales. Previsión similar recoge el artículo 43 del mismo Reglamento de Valladolid de 2005. Como es habitual, el artículo 32 de esta norma vallisoletana aclara que las bicicletas tienen una prioridad sobre el resto de vehículos en las áreas residenciales, pero no la tienen sobre los peatones. Por su parte, Gijón (en su proyecto) contempla como plataformas especialmente reservadas a los VMP (junto a otros, como bicicletas y ciclos) tres tipos concretos de vías: los carriles-bici, las aceras-bici, y las sendas ciclables (art. 26 del proyecto). También habilita a estos vehículos (VMP, bicis y ciclos) el acceso a áreas de prioridad residencial, excepcionando la restricción horaria prevista con carácter general para el resto de vehículos. Igualmente, y por razones obvias, el artículo 34.5 del proyecto prevé la eventual exclusión de los VMP (entre otros muchos tipos de vehículos) de la aplicación de medidas restrictivas de tráfico o de la prohibición de estacionamiento en los supuestos de ordenaciones temporales por motivos medioambientales.

El grueso de las previsiones normativas se centra en el establecimiento de condiciones específicas para la circulación en función de la vía. El artículo 51.1 del proyecto de Gijón precisa las únicas vías por las que podrán circular los VMP. Esta previsión consta de dos reglas generales, aplicables a todos los VMP, dos reglas particulares condicionadas (que excluyen a los VMP de una sola rueda), y una cláusula de aplicación supletoria de las reglas previstas para las bicicletas y otros ciclos –art. 51.1.e)–. Las dos primeras reglas, aplicables a todos los VMP, suponen que estos pueden circular por: a) carriles bici segregados, sin rebasar la velocidad máxima de 15 km/h también prevista para las bicicletas; y b) por acera bici, a una velocidad no superior a 10 km/h.

Las dos reglas particulares, que excluyen a los VMP de una sola rueda, permiten a los demás circular por otras vías, siempre que “no se haga a una velocidad anormalmente reducida”, y con esta condición pueden circular por: a) las calzadas que tengan la velocidad limitada a 30 km/h; y b) por el carril limitado a 30 km/h, si existe, en aquellas calzadas de varios carriles. En sintonía con este mecanismo, la propuesta normativa de Vigo parece apuntar en la misma dirección. De aprobarse la inicial propuesta del gobierno municipal, parece que el uso de los VMP estaría condicionado a distintos límites de velocidad en función de la vía por la que circulen: a) por las zonas residenciales –de prioridad peatonal– a un máximo de 10 km/h, reduciéndose o desmontando si la falta de espacio lo aconseja; b) por carriles bici y sendas ciclables, a un máximo de 20 km/h; y c) por carriles-bus y por las vías ordinarias con velocidad máxima a 30 km/h, al máximo de su capacidad legal, es decir, a 25 km/h. Distanciándose parcialmente de la pretensión de la DGT, de impedir la circulación de los VMP por las zonas peatonales, con carácter general, la reglamentación de Vitoria permite interpretar un uso autorizado de los VMP de forma excepcional en zonas peatonales, siempre que adapten su conducción a un especial cuidado hacia los peatones (art. 10.9), dada la forma abierta de referirse a vehículos entre los que podrían encontrarse los que nos interesan en este estudio.

Un último factor exógeno que habilita el uso de ciertas vías en determinados momentos, dependiendo del estado específico en el que estas se encuentren, es la reglamentación de la circulación en función de la existencia de aglomeraciones. La regulación de Hospitalet de Llobregat define esta circunstancia como la imposibilidad de guardar un metro de distancia entre vehículos –bicis o VMP– y peatones, o la imposibilidad de circular 5 metros seguidos en línea recta, preferentemente por el centro de la vía. Tal situación permite deducir para los VMP, con las cautelas expuestas, la posibilidad de ser utilizados en dos grandes conjuntos de espacios o vías. Las aglomeraciones no son relevantes para la circulación de los VMP en Hospitalet por vías no peatonales: a) expresamente en pasos reservados exclusivamente a bicicletas (art. 18.5); b) calzadas, pero por la zona más próxima a las aceras (art. 18.4); y c) carriles-acera, aunque con la velocidad limitada a 10 km/h (art. 18.9). *Sensu contrario*, las aglomeraciones impiden la circulación, por lo demás permitida, en: a) parques y áreas peatonales; b) caminos vecinales de plataforma única de preferencia peatonal (siempre que guarden el sentido de circulación de los vehículos); y c) calles vecinales de uso exclusivo de peatones, en ambos sentidos de circulación.

Finalmente, las prohibiciones completan la técnica de reglas que condicionan la circulación de los VMP en las distintas reglas municipales. Una primera prohibición llamativa de las regulaciones analizadas es la relativa a la circulación por las calzadas. Tanto la normativa de Hospitalet de Llobregat expresamente dictada para los VMP (art. 19 de la Ordenanza de 2015), como las disposiciones susceptibles de aplicación teórica a los “patines” y “patinetes” en la reglamentación vallisoletana (art. 48 del Reglamento de 2005), impiden, aparentemente, la circulación de estos vehículos por la calzada, como regla general.

Tal regla contradice la previsión estatal. Esta singularidad, interpretada de forma restrictiva, podría conducir a la práctica imposibilidad de circular por ambas ciudades con VMP, al concurrir las restricciones generales estatales con esta del municipio, sin exista una contradicción invalidante de una sobre otra, en sentido estricto. Por el contrario, si en Valladolid aplicaran las reglas de las bicicletas a los VMP, el artículo 34 de su Reglamento de 2005 prohíbe expresamente "la circulación sobre las zonas destinadas a peatones" (algo ya insistentemente recomendado por la DGT desde 2016, y que el proyecto de Vigo parece contemplar de forma expresa para los VMP).

La interpretación más coherente con el espíritu de la norma vallisoletana de 2005 es, por tanto, que la aplicación de las reglas a los VMP está condicionada a su redefinición como "vehículos" ciertamente conducidos, y no como instrumentos de desplazamiento de "peatones", lo que hace que solo las reglas que sean compatibles con tal conceptualización serán aplicables a estos (la prohibición de circular por la calzada no lo sería).

4.4.2. Las reglas sobre el estacionamiento

En cuanto al estacionamiento de VMP, la tendencia emergente en las regulaciones es reflejo de las normas ya contempladas para las bicicletas, mediante el establecimiento de una regla general de estacionamiento preferente, otra regla subsidiaria y una prohibición explícita. Este es el caso de la Ordenanza de Hospitalet de 2015 (art. 18.14), actualizada en el proyecto de Gijón (art. 110).

La regla de estacionamiento preferente es que se produzca en lugares expresamente habilitados. El artículo 128 de la regulación gijonesa prevé, además, reservas especiales de aparcamiento para bicicletas, ciclos y VMP. Solo cuando estos no existan (regla subsidiaria), "podrán estacionar en las bandas de estacionamiento, en forma oblicua a la línea de acera y ocupando un máximo de 2 metros, de forma que no se impida el acceso a otros vehículos o el paso desde la acera a la calzada".

El mismo precepto hospitalense antedicho impide el estacionamiento donde no puedan hacerlo tampoco los vehículos a motor ordinarios (zonas de carga y descarga, estacionamientos para personas con movilidad reducida, etc.), así como anclándolos al mobiliario urbano, elementos adosados a las fachadas o en los estacionamientos del servicio público de bicicletas. Se distancia de este planteamiento el proyecto de Gijón. Es cierto que la normativa proyectada prohíbe, con carácter general, el anclaje de los VMP (y del resto de vehículos equivalentes mencionados) a "elementos de señalización, elementos vegetales, bancos, marquesinas" u "otros elementos de mobiliario urbano" (art. 110.5).

Pero, "excepcionalmente" ("cuando no existan aparcamientos disponibles en un entorno de 200m"), los VMP y las bicicletas podrán ser ancladas a "callas o elementos del mobiliario urbano" cumpliendo cuatro requisitos: "a) no altere la funcionalidad del elemento del mobiliario urbano; b) no ocasione ningún daño ni implique deterioro del patrimonio público; c) no se entorpezca el tránsito peatonal, la accesibilidad ni la circulación de vehículos; d) no dificulte ni impida la realización por los servicios municipales de tareas de mantenimiento o reparación de tales elementos delimitadores y de mobiliario urbano" (art. 110.6).

La regulación es exhaustiva, más allá de estas previsiones, y añade un régimen de prohibición general de estacionamiento: "a) en el ámbito peatonal de las paradas de transporte público; b) en el ámbito peatonal de las reservas de personas con movilidad reducida; c) en el ámbito peatonal de las paradas de taxi; [y] d) sobre tapas de registro o de servicios". Prueba de la exhaustividad de esta es la cláusula que contempla que los usuarios de VMP están obligados, además, a desmontar del vehículo en aceras y zonas peatonales, hasta llegar al "elemento de anclaje" si este se encuentra en tales espacios (art. 110.4 del proyecto de Gijón).

A diferencia de las previsiones recientes, las normas anteriores a 2010 conservan una equivalencia de regulación del estacionamiento entre los VMP y los vehículos a motor. Este es el caso de la ordenanza de Vigo de 1993, que ordena de forma indistinta el uso que puede dar lugar a la retirada por estacionamiento incorrecto (arts. 20 a 22) o por su abandono (art. 23). Nada distinto significativo aportan las normas de Valladolid o Vitoria.

4.4.3. Los elementos de protección y señalización para la conducción de los VMP

Sobre el uso de elementos de protección, y al margen de las exigencias a ciertos sujetos por razón de su edad, ya mencionadas, el casco es considerado con cada vez más frecuencia como obligatorio (véase, por ejemplo, el artículo 18.19 de la ordenanza hospitalense). El texto de Gijón de 2021, en su artículo 50.5, aboga por una exigencia generalizada de la utilización de casco de protección a las personas conductoras de VMP cuando circulen por la calzada. Además, el apartado 6 del mismo precepto contempla la exigencia, también a los conductores, de portar "alguna prenda o elemento reflectante" cuando "sea obligatorio el uso del alumbrado" (es decir, en función de la visibilidad). La mayoría de estas reglas aplicables a los conductores de los VMP son una trasposición o extensión por analogía de las normas dadas para los ciclistas. Estos, en Valladolid (según el Reglamento de 2005) "deberán ir provistos de un sistema de señalización luminosa delantero y trasero que permita su visibilidad por otros conductores". En el mismo sentido se pronuncia la normativa de Vitoria de 2013, aunque no es fácil determinar la obligatoriedad estricta para los conductores de VMP.

4.4.4. Las exigencias especiales en función del uso económico de los VMP

A juicio de la mayoría de autoridades locales, el uso de los VMP con fines distintos del desplazamiento privado de personas hace aconsejable el establecimiento de reglas diferenciadas, que ordenen un el uso de los mismos para determinadas actividades económicas.

En la normativa de Vitoria de 2013, aun sin mencionarlos expresamente, una cierta apertura expresiva invita a aplicar las reglas sobre el uso de los VMP como vehículo de reparto a las normas generales de horarios y limitación de zonas para estas operaciones de carga y descarga, como prevé el artículo 12.1.2 para las bicicletas y otros vehículos de tracciones eléctricas no convencionales. Esta idea ha sido expresamente incorporada por el proyecto de Gijón (art. 85), reconociendo el papel que ya desempeñan en el abastecimiento de comida a domicilio, o servicios de mensajería, cuando los conductores portan mochilas aptas para tal carga. El Ayuntamiento de Vigo anunciaba su propuesta en similares términos. Este último, sin embargo, contemplaba la posibilidad de exigir la tramitación de una autorización específica para otros usos económicos, como las actividades de ocio o turismo. Sin diferenciar el sector de actividad, Gijón opta por exigir solo la suscripción de un seguro de responsabilidad civil obligatorio, que responda de daños a terceros (art. 50.7), para poder destinar el VMP a cualquier actividad económica. Pero en la línea de la exhaustividad de la que esta normativa hace gala, también ordena de forma pormenorizada el uso de los VMP destinados al arrendamiento, entre los artículos 77 al 79 y 82. Exige a las empresas la existencia de estaciones fijas para su estacionamiento, debidamente reservadas en el suelo público, o el sometimiento periódico a controles y especiales actividades de mantenimiento preventivo, entre otros aspectos. También impone, para su uso turístico, que los titulares de la explotación se responsabilicen de que no accedan al uso del VMP personas que carezcan de la “habilidad mínima” que garantice su seguridad y la de terceras personas, y el apartado 5 del mismo precepto limita a 15 personas el máximo de los desplazamientos organizados por empresas de turismo (art. 82).

5. CONCLUSIONES

La investigación realizada ha permitido esclarecer la maraña jurídica que envuelve a la movilidad urbana sostenible y en particular a los VMP. Así, se ha determinado el esquema básico normativo relacionado con ambos conceptos, desde los artículos de la CE que tocan aspectos relacionados con la movilidad a la situación de la legislación estatal y autonómica en vigor, y concluyendo con la comparativa entre la regulación municipal (Tabla 1).

Tabla 1. Esquema normativo actual de las ciudades estudiadas. Ninguno de los planes de movilidad en vigor alude de forma directa a los vehículos de movilidad personal.

El análisis de la evolución del corpus normativo permite afirmar que la regulación de ámbito estatal en materia de VMP ha llegado tarde, solo precedida por orientaciones y disposiciones administrativas de alcance controvertido y sin aclarar de manera suficiente aspectos esenciales que han provocado confusión a diversas autoridades municipales. No obstante, la reforma del Reglamento General de Vehículos y del Reglamento General de Circulación, mediante el Real Decreto 970/2020, de 10 de noviembre, ha supuesto una importante actualización de alcance estatal, que condiciona la normativa autonómica y municipal. Este punto de inflexión aún no se ha completado, a la espera de la adopción, por la Dirección General de Tráfico, de un importantísimo "Manual de características de los vehículos de movilidad personal", que condicionará la implantación de certificaciones de estos vehículos (por tanto, la plena eficacia de las disposiciones de 2020 es muy probable que se demore hasta 2023, al menos).

En paralelo a este retraso, y en virtud de sus competencias expresamente reconocidas por la legislación aplicable, los municipios se han dotado de normas para hacer frente a los riesgos de la circulación de los VMP o el fomento de formas de movilidad sostenible de manera heterogénea, ya con anterioridad a la promulgación de la reforma reglamentaria estatal. Pero el tamaño de los municipios no parece ser determinante en la diligencia con la que las autoridades locales han abordado la cuestión, ni en las soluciones que han adoptado. Con independencia del tamaño de los municipios, existen casos en los que las reglas específicas sobre los VMP son aún inexistentes o muy limitadas, cuando no directamente incompatibles o incongruentes con la ordenación estatal de 2020, frente a otros que han abordado la cuestión de forma exhaustiva y pormenorizada.

En ese sentido, y de manera no explícita, las regulaciones municipales parecen obedecer a una sistemática de tres ejes: en qué condiciones un individuo puede conducir un VMP (previsiones subjetivas); qué requisitos adicionales a los previstos ya de forma genérica para su comercialización en todo el país deben reunir estos vehículos, materialmente, para poder ser utilizados (previsiones objetivas); y qué reglas rigen para su uso en los distintos espacios públicos urbanos y en qué circunstancias (previsiones modales).

Entre las condiciones subjetivas para el uso de los VMP sobresale la opción mayoritaria por no exigir permisos específicos de circulación a los conductores, aunque la edad puede condicionar su manejo. Tampoco existe un criterio unificado ni coherente sobre tal edad de los sujetos que pueden conducirlos, o en qué condiciones especiales en función de su edad.

Además, de las previsiones técnicas objetivas que estos VMP deben reunir, que no sean obligatorias de forma generalizada por indicación de la normativa estatal, destacan las previsiones relacionadas con la seguridad del vehículo (elementos lumínicos y reflectantes, sistemas de alerta sonora como timbres, etc.).

Por otra parte, las disposiciones que regulan su circulación son las más detalladas en el ámbito de las normas municipales, posiblemente porque los aspectos técnicos de los vehículos son ya considerados de forma detallada por las reglas de certificación europeas y las exigencias estatales reglamentarias, que dejan deliberadamente a las autoridades municipales la regulación de las formas de uso que sean acordes los tipos de vías y condiciones específicas de cada localidad.

El estudio detallado de la normativa municipal analizada ha permitido comprobar que las disposiciones sobre los modos de circular en las ciudades abordan, con carácter general, cuatro conjuntos de previsiones:

a) sobre las condiciones en distintos tipos de vías, adaptando las reglas de seguridad, impidiendo el acceso a algunas de ellas o exigiendo requisitos subjetivos u objetivos especiales según el espacio y o el contexto (visibilidad, aglomeraciones, etc.).
b) sobre el estacionamiento de estos vehículos en la vía pública, tratando de preservar –en las reglas más detalladas– la integridad del mobiliario urbano y la prioridad del uso de las aceras por los peatones.
c) sobre los concretos elementos de protección y señalización para la conducción de los VMP, adaptados al tipo de uso, del usuario y del espacio en el que se use.
d) sobre diversas exigencias específicas en función de la finalidad con la que sean utilizados los VMP, destacando reglas de revisión y control adicionales para usos

económicos, normas de prevención y similares. Conviene apuntar que, en las regulaciones que más atención prestan a estos vehículos, se acude de forma creciente a la técnica autorizatoria para su uso con fines de lucro, en el contexto de actividades económicas tanto de reparto como de turismo o alquiler de corta duración.

En relación a las ciudades analizadas, Gijón se ha dotado (hasta el momento) de la normativa más detallada sobre estos vehículos, y con numerosas previsiones que flexibilizan su uso a diversas circunstancias de los sujetos, de los vehículos y del espacio en el que circulan. Aún pendientes de las evidencias que arroje su aplicación en los próximos años, el grado de detalle y precisión técnica de la normativa gijonesa puede convertirla en un referente para otras ciudades españolas. Tras ella, Hospitalet de Llobregat dispone de la siguiente regulación con más normas directamente aplicables a los VMP, al menos por una regla de analogía explícita, pero con algunas cláusulas ya no plenamente coherentes con la ordenación estatal de 2020. Vitoria, Vigo y Valladolid no cuentan con un régimen jurídico claro para la ordenación eficiente de estos vehículos, y sería más que recomendable la revisión de sus normas de circulación.

Una de las cuestiones llamativas de la regulación estatal es la escasa exigencia hacia los municipios para que se doten de redes especialmente diseñadas para los VMP. Así como hay legislación en materia de accesibilidad universal, y así como hay determinadas exigencias en materia de urbanismo para considerar que un espacio determinado puede ser considerado un solar -por ejemplo, el acceso rodado-, también podrían determinarse una serie de condiciones para garantizar la existencia de redes.

En este sentido sorprende la prohibición de que los VMP no circulen por túneles urbanos, cuando sería más lógico determinar qué requisitos deben cumplir los túneles urbanos para poder ser usados por los VMP, y exigir dichos requisitos a los túneles urbanos futuros. Lo mismo sucede con la prohibición de que puedan circular por travesías, cuando la realidad de muchas poblaciones de pequeño tamaño es que la travesía es de facto la calle principal del municipio -si no la única-. Consideramos, por ello, que la irrupción de los VMP podría ser aprovechada para subsanar el histórico retraso de España en materia de construcción de redes ciclistas (Plasencia Lozano, 2021), impulsando desde los distintos poderes legisladores determinadas reformas de las leyes urbanísticas, de movilidad o accesibilidad que condujeran a la creación de una auténtica tercera malla urbana y regional segregada de las otras dos existentes (peatonal y de tráfico rodado).

Finalmente, la cronología de la normativa de los VMP ha puesto de manifiesto la brecha temporal existente entre el desarrollo tecnológico de estos vehículos y su regulación. Esta cuestión deja el campo abierto a investigar si ese retraso entre la difusión masiva de determinados vehículos y la generación del corpus normativo relativo a su uso también se produjo con otros vehículos (automóviles, autobuses, motocicletas) o si sucede lo mismo en otros modos de transporte (aviones, ferrocarriles), y caso de ser así, qué plazos existieron entre la difusión amplia de la nueva tecnología asociada al transporte y su regulación. Al respecto, podemos recordar que el Plan de Innovación para el transporte y las infraestructuras 2017-2020 sí incluía una sección completa sobre el Hyperloop como nuevo paradigma del transporte, pese a que dicha tecnología estaba dando sus primeros pasos cuando dicho plan fue redactado, y, sin embargo, nada decía de los VMP (aunque sí de las bicicletas).

AGRADECIMIENTOS

Este estudio se desarrolla en el marco del proyecto de investigación SV-20-GIJÓN-1-21 financiado por el IUTA (Universidad de Oviedo) y el Ayuntamiento de Gijón.

RESUMEN

El control de la calidad del aire en las ciudades es uno de los grandes retos en los próximos años. La ciudad de Madrid, como muchas otras ciudades del mundo, cuenta con un sistema de monitorización de la calidad del aire mediante estaciones fijas de medición. Distintos estudios defienden la idea de que los modelos de este tipo presentan ciertas carencias en cuanto a representatividad de la información generada. En este trabajo, se ha evaluado la calidad del aire en ciertas calles de Madrid mediante el uso de sensores móviles. Para ello, se ha diseñado una ruta, analizando las concentraciones de $PM_{2,5}$ agrupadas en los tramos de la ruta. La recopilación de datos mediante un sensor móvil permite una cobertura homogénea de datos en la ruta, gracias a la cual se han mapeado las zonas con mayor riesgo de presentar concentraciones elevadas. Así mismo, se han comparado los resultados dentro y fuera de Madrid Central y se ha estudiado la relación entre las concentraciones de $PM_{2,5}$ con factores meteorológicos y condiciones del tráfico. A pesar del bajo coste de esta tecnología, se han obtenido mediciones de calidad aceptable que pueden ser complementarias a las realizadas con las estaciones fijas del Sistema de vigilancia de la Calidad del Aire del Ayuntamiento de Madrid.

1. INTRODUCCIÓN

1.1 La contaminación en las ciudades

La contaminación se considera uno de los problemas más acuciante en las grandes ciudades, debido a las grandes concentraciones de población expuesta..

Estudios científicos señalan a la contaminación ambiental como causante de la muerte de 6,4 millones de personas en el mundo en 2015 (Landrigan, 2017). Por otro lado, el Banco Mundial estimó unas pérdidas relacionadas con la contaminación de 225.000 millones de dólares en 2016 y la Agencia de Protección Ambiental del Gobierno de los EE.UU. (EPA), la considera un factor de intensificación de las consecuencias del cambio climático.

El tráfico en sí, los atascos y la presencia de bloques continuos de edificios y construcciones altas provocan los llamados *street canyons*, que bloquean la dispersión de las emisiones y dan lugar a altas concentraciones de contaminación (Wu et al., 2017). Esta contaminación atmosférica engloba la presencia de distintos elementos potencialmente peligrosos para los seres vivos que habitan en las ciudades. Estos elementos se presentan en dos estados, gaseoso y sólido (partículas). Los contaminantes gaseosos en los que se centra la OMS en sus Directrices de calidad del aire (OMS, 2005) son el dióxido de nitrógeno (NO_2), el ozono (O_3) y el dióxido de azufre (SO_2). El NO_2 es un gas emitido principalmente en procesos de combustión y fertilizantes y es particularmente peligroso en condiciones de humedad debido a que, en combinación con el agua, genera ácido nítrico, el causante de la lluvia ácida. Por su parte, el O_3 es un fuerte oxidante que se presenta de forma natural en la estratosfera en concentraciones variables, pero su presencia en la troposfera está directamente relacionada con las actividades humanas (Godish et al., 2018) y se considera uno de los contaminantes secundarios más problemáticos de cara al futuro, por sus daños, tanto para el hombre, como para la vegetación (Calderón-Guerrero et al., 2013). Por último, el SO_2 es un gas cuyas principales fuentes de origen son la quema de combustibles fósiles ricos en sulfuro para calefacción doméstica, generación de energía y en vehículos motorizados.

Además, existen otros contaminantes gaseosos que generan preocupación a expertos de todo el mundo, como los compuestos orgánicos volátiles (COVs), importantes precursores del ozono troposférico (Camargo et al., 2015). Todos ellos provocan afecciones al ser humano, relacionadas con problemas respiratorios principalmente.

Las partículas en suspensión que se estudian en materia de contaminación ambiental son las que tienen un tamaño menor a 10 micras (PM_{10}). Según se estima, en Madrid el tráfico rodado constituye la fuente principal de emisiones de partículas. Estas provienen tanto de los tubos de escape de los vehículos a motor, como del levantamiento de capas acumuladas en el firme de rodadura por abrasión mecánica, frenos, obras de construcción y demolición, etc. Así mismo, se considera en Madrid la intrusión de aire africano como fuente probable de episodios de elevadas concentraciones (Ayuntamiento de Madrid, 2004). De ellas, las menores de 2,5 micras ($PM_{2,5}$) son capaces de llegar hasta los bronquios y en el caso de las PM_1 serían transportadas a la sangre a través de los alveolos. Recientemente, un estudio (Soldevilla et al., 2020) ha demostrado que la presencia de partículas ultrafinas está altamente relacionada con el aumento de la presión arterial. También se las relaciona con enfermedades neurodegenerativas, como consecuencia del aumento generalizado de las partículas en suspensión en los ambientes urbanos (Maher et al., 2016).

1.2 Redes de monitorización ambiental

En España, los criterios de medición y evaluación de la calidad del aire quedan dictados por el Real Decreto 39/2017 del 27 de enero, que modifica al RD 102/2011. En las grandes ciudades, de cara a solventar el problema de la contaminación atmosférica se han planteado redes de medición o Air Quality Monitoring Networks (AQMN). Las principales ventajas derivadas de una red efectiva de medición se resumen: (i) poder comparar los niveles monitorizados con los estándares establecidos por el organismo competente; (ii) prevenir el riesgo de exposición a los contaminantes monitorizados; y (iii) mitigar y controlar las emisiones de fuentes conocidas (Afshar-Mohajer et al., 2018). Generalmente, estas redes están compuestas por puestos fijos y suelen contar con mediciones históricas de largos períodos de tiempo. Sin embargo, algunos expertos (Castell et al., 2017; Munir et al., 2019) apuntan que las AQMN generalmente no son suficientemente densas. Además, según Nagendra et al. (2019) las redes de muestreo fijo no proveen variaciones espaciales de las concentraciones de los contaminantes y tienden a subestimar la exposición de los humanos.

Las concentraciones de los contaminantes pueden variar enormemente en el espacio y en el tiempo (Afshar-Mohajer et al., 2018). Consecuentemente, es importante registrar estos picos de polución. Recientes estudios (Nagendra et al, 2019) establecen que los dispositivos de medición basados en sensores *low-cost* pueden ser efectivos para capturar variaciones espaciales y temporales de los contaminantes y constituir un suplemento a las mediciones actuales. En la actualidad, existe una serie de acciones de ciencia ciudadana mediante el empleo de estos sensores *low-cost* dentro de la comunidad escolar (Calderón-Guerrero et al., 2021), que pretenden concienciar a los jóvenes de los niveles de contaminación a nivel local y ser miembros activos en la toma de datos mediante el diseño y empleo de sensores móviles.

2. LA CALIDAD DEL AIRE EN MADRID

2.1 Actuaciones recientes

En los últimos años, la preocupación social y política por la contaminación del aire, ha provocado la puesta en marcha de diversas medidas recogidas en el Plan de Calidad del Aire y Cambio Climático en la ciudad de Madrid de 2017, conocido como Plan A y reestructurado posteriormente y denominado MADRID 360 (Ayuntamiento de Madrid, 2019a). El transporte por carretera es la causa principal de 3 de los 5 contaminantes más relevantes (Ayuntamiento de Madrid, 2019b). En el Plan de 2017, en torno a un 30% del presupuesto se destinaba a las medidas dirigidas a reducir la intensidad del tráfico (154 M€), y un 60% a actuaciones sobre el parque móvil y la ordenación de sectores clave con alto impacto en la movilidad urbana (330 M€) (Ayuntamiento de Madrid, 2017). Plan A de Calidad del Aire y Cambio Climático, 2016).

MADRID 360 pretende cumplir los límites de calidad del aire establecidos en la Directiva 2008/50/CE del Parlamento Europeo y del Consejo, de 21 de mayo de 2008.

Entre otras medidas, se actúa principalmente en la movilidad. Se pretende llevar a cabo nuevas peatonalizaciones; favorecer el transporte público, con líneas cero emisiones y renovación de flotas de autobuses, el uso de la bicicleta y la moto; construir más aparcamientos disuasorios; limitar la entrada de los vehículos más contaminantes en toda la ciudad; y establecer restricciones al tráfico en la zona de emisiones bajas, atendiendo al distintivo ambiental de vehículos.

2.2 Sistema de vigilancia de la Calidad del Aire del Ayuntamiento de Madrid

Sistema de vigilancia forma parte del Sistema Integral de la Calidad del Aire del Ayuntamiento de Madrid (Ayuntamiento de Madrid, 2021). Está compuesto por 24 estaciones de monitorización que miden de forma precisa los niveles de gases y partículas contaminantes. No todas las estaciones miden los mismos contaminantes, lo que repercute en la representatividad de la información. El Sistema de Vigilancia cuenta además con captadores manuales para la determinación de contaminantes específicos y de unidades móviles de vigilancia para la realización de campañas de medición específicas.

3. OBJETIVO

Como se ha visto, la contaminación en las ciudades es uno de los grandes problemas a los que se enfrenta la ciudad de Madrid. El Sistema Integral de la Calidad del Aire está diseñado para permitir al Ayuntamiento una toma de decisiones basada en la información que aportan 24 estaciones de medición. Sin embargo, aunque la calidad de dichas mediciones en cuanto a precisión es indudable, es muy posible que se presenten deficiencias en cuanto a cantidad de puntos de muestreo y representatividad de los datos.

Por tanto, el objetivo general de este trabajo es conocer la concentración de $PM_{2,5}$ en un conjunto de calles de Madrid mediante el uso de sensores móviles. Para ello, se ha diseñado una ruta por la ciudad de Madrid y para conocer el estado de las distintas partes del recorrido, se llevará a cabo un análisis de las concentraciones agrupadas en los tramos de la ruta. Además, se caracterizarán los puntos más controvertidos dentro de los tramos mediante una malla poligonal, algo totalmente imposible mediante los métodos de información de contaminación convencionales. Del mismo modo, la recopilación de datos mediante un sensor móvil permitirá una cobertura homogénea de datos en la ruta, gracias a la cual se mapearán las zonas con mayor riesgo de presentar concentraciones elevadas. En cuanto a Madrid Central, se compararán los niveles medios observados dentro y fuera de sus límites, con el fin de conocer la efectividad de las medidas de regulación del tráfico.

Por último, se tratará de evaluar la relación entre las concentraciones de $PM_{2,5}$ observadas y las variables externas, tales como la meteorología y la velocidad del tráfico.

4. METODOLOGÍA

La metodología seguida consta de 4 fases: (i) una primera fase de selección de componentes y montaje del sensor móvil; (ii) calibración del sensor; (iii) selección del caso de estudio y de las rutas de medición, que recorren distintas calles de la ciudad, tanto dentro como fuera del área de tráfico restringido; (iv) toma de datos; (v) análisis de los datos.

4.1 Selección de componentes y montaje del sensor móvil

Se ha escogido un procesador *ARDUINO UNO*, en el que se ha montado un sensor de PM *BJHIKE HK-A5*. Se trata de un sensor láser que mide partículas desde 0.3 hasta 10 micras y se ha escogido por la sensibilidad que presenta. Además, el sensor debe contar con un GPS que registra en todo momento la latitud, longitud, hora, altitud (m) y velocidad (km/h). El dispositivo escogido ha sido un *Ublox Neo-6M*. Por último, el sensor registra datos de humedad (%) y temperatura (ºC), suministrados por un sensor DHT22 de *Adafruit Industries LCC*. Una vez conectados los diversos componentes a la placa, el sensor *CAELUS*, que es como se ha llamado, se ha montado sobre una carcasa específicamente diseñada para ello.

4.2 Calibración del sensor

Se ha realizado una calibración en campo de los datos registrados por el sensor, comparándolos con a los datos oficiales publicados por el Ayuntamiento de Madrid. Se ha realizado un circuito de tal modo que la ruta coincide con la situación de 2 estaciones con medidores de PM del Sistema de Vigilancia del Ayuntamiento de Madrid (Castellana y Escuelas Aguirre). El dispositivo lleva a cabo mediciones que coinciden en un 75% con los datos oficiales, atendiendo exclusivamente a la clase ICA a la que pertenecen. Las diferencias se deben en parte a que el dato de la estación oficial corresponde a un valor interpolado entre medias horarias. En este proceso se han constatado la capacidad del sensor para captar concentraciones pico frente al sistema de datos promedio del Sistema de Información del Ayuntamiento.

4.3 Selección del caso de estudio y de la ruta de medición

Se ha seleccionado un conjunto de calles de Madrid para realizar las mediciones que se encuentran dentro y fuera de Madrid Central. Por tanto, la ruta de medición planteada alterna salidas y entradas al recinto restringido, así como por su perímetro. Del mismo modo, se considera fundamental el paso por las estaciones del Sistema de Vigilancia del Ayuntamiento, ya que servirán para mantener una calibración de campo y asegurar en todo momento la fiabilidad de nuestras mediciones. De este modo, la ruta diseñada es la que puede observarse en la Figura 1, con un recorrido total de 17,2 km.

4.4 Toma de datos

El sensor se ha colocado en el techo de un *Mitsubishi Outlander Phev* híbrido enchufable y se han tomado datos durante 19 días.

Por otro lado, ya que se trata de factores determinantes en la calidad del aire, es necesario disponer de datos de los factores meteorológicos y el estado del tráfico correspondientes a cada uno de los días de toma de datos. Para los factores meteorológicos (velocidad del viento, temperatura, radiación solar, HR y presión atmosférica) se cuenta con los datos de las estaciones más cercanas a la ruta de medición la red de control meteorológico del Ayuntamiento de Madrid. Los datos de intensidad de tráfico media diaria (IMD) se han obtenido de la Web del Portal de Datos Abiertos del Ayto. de Madrid. En este repositorio se obtienen datos del número de vehículos que pasan por cada estación de medición, en períodos de 15 minutos.

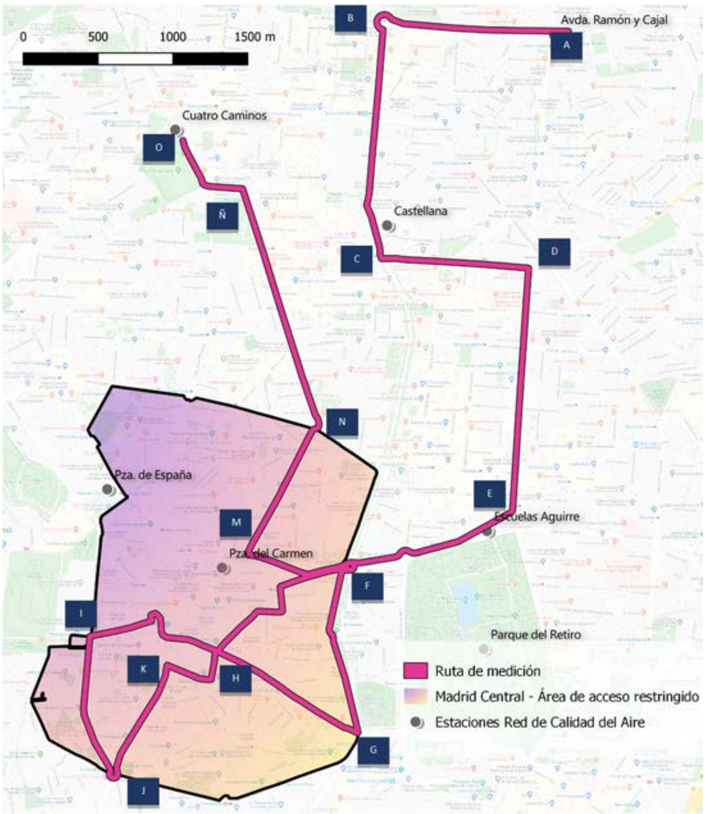

Fig. 1 – Ruta de medición

4.5 Análisis de los datos

Se han realizado varios análisis de las mediciones realizadas: (i) por tramos (Figura 2 izquierda); (ii) mediante malla hexagonal de 50 metros de apotema que contienen puntos de medición (Figura 2 derecha). De este modo, se pretende observar el comportamiento de las diversas concentraciones de contaminantes en puntos más concretos del recorrido; (iii) de altas concentraciones, mediante la generación de mapas de calor que identifiquen las zonas de mayores concentraciones en la ruta de medición; (iv) en Madrid Central, comparando los niveles medios de las concentraciones de $PM_{2,5}$ que aparecen en los tramos interiores del área de bajas emisiones (dentro de Madrid Central) frente a las medias de los tramos externos; y (v) de las variables meteorológicas externas, que pueden condicionar la aparición de patrones de aumento o descenso de las concentraciones de $PM_{2,5}$ en la ciudad.

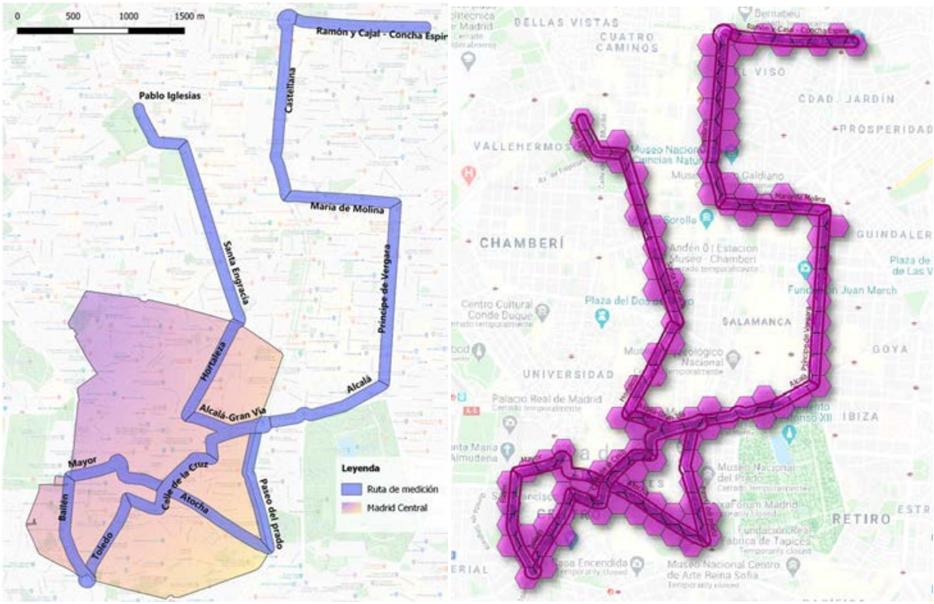

Fig. 2 – izquierda: división de la ruta en tramos; derecha: malla hexagonal

5. RESULTADOS

Atendiendo al estudio de medias por calles, las cuatro calles se superan los promedios globales en un mayor número de ocasiones son: la calle de la Cruz, el Paseo del Prado, la calle Hortaleza y la calle Mayor. Al final de la calle de la Cruz se encuentra la plaza de Canalejas, cuyo acceso está regulado por un semáforo que condiciona plenamente la circulación del único carril de esta calle. Prácticamente todos los días de medición se han encontrado dificultades de acceso a dicha Plaza de Canalejas, con retenciones continuas en la calle de la Cruz en sus 300 metros de recorrido. Este punto concreto, además, supone la sección más estrecha de la ruta, contando con un único carril y apenas cinco metros entre los edificios, lo que puede condicionar la aireación de la zona y el estancamiento de los contaminantes. La suma de los mencionados factores condiciona notablemente la movilidad y la calidad del aire en la calle de la Cruz. Casos similares con los de la calle Hortaleza (supera las concentraciones promedio en 12 ocasiones) y calle Mayor (supera en 8 ocasiones las concentraciones promedio de la ruta), presentando una mayor media global de concentración de $PM_{2,5}$ durante el período de estudio. En ella se producen frecuentes retenciones y la anchura entre edificios es de las menores de la ruta seguida.

En la Figura 3 se muestran los resultados del análisis por malla hexagonal, divididos en mapa de concentraciones medias y mapa de niveles máximos. En los valores promedio del trabajo global de medición se obtienen valores de clase “Buena” (de acuerdo a los valores del índice de calidad del aire (ICA)) de forma predominante, excepto en ciertos puntos de la ruta en los que encontramos promedios de concentraciones superiores, con la clase “Regular” e incluso “Mala”. Cabe destacar que la mayor parte de las concentraciones de tipo “Regular”, posicionadas entre 20 y 25 µg/m3, se encuentran en el interior del área de acceso restringido (Madrid Central). Respecto a los promedios correspondientes a la clase “Mala”, entre 25 y 50 µg/m^3, los principales problemas los encontramos en la calle Príncipe de Vergara, calle de la Cruz y Santa Engracia. El mapa de máximos corrobora dónde se encuentran los principales focos causantes de las altas concentraciones que puedan haberse observado en las distintas calles en el análisis por tramos. Podemos hallar picos máximos puntuales en plaza de Lima, Príncipe de Vergara, calle Atocha, la calle Mayor y la calle de la Cruz.

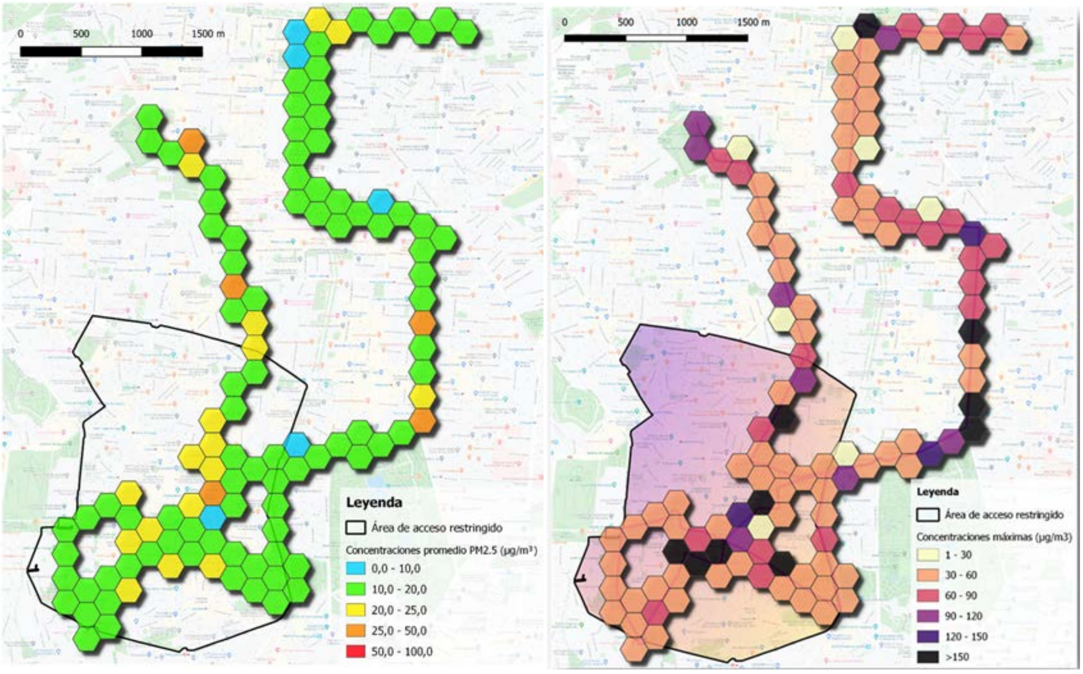

Fig. 3 – Mapas de medias globales y máximos de las concentraciones de PM2,5 sobre malla hexagonal

La Figura 4 representa el histograma de distribución de las concentraciones de PM2,5 durante el recorrido. Esta figura revela que el 30% de todos los valores recogidos se encuentra por encima de 20 µg/m3, es decir, categorías peores que “Buena”. De todos los valores de altas concentraciones, encontramos la máxima frecuencia en la franja entre 20 y 25 µg/m^3, la cual concentra un 7% de todos los valores recogidos. Mientras tanto, la clase “Mala” (entre 25 y 50 µg/m^3) recoge el 18% de las mediciones y la “Muy mala” (de 50 µg/m3 en adelante) tan sólo un 5%. Es reseñable que prácticamente un tercio de todos los datos medidos presentan una concentración entre 0 y 5 µg/m^3, es decir, con niveles de partículas extremadamente bajos.

Los focos principales de las presencias de la clase "Muy Mala" se encuentran en la Plaza de la Lima, la esquina de Príncipe de Vergara con calle Alcalá, la calle de la Cruz, la conexión entre Hortaleza y Santa Engracia (plaza de Alonso Martínez) y en la propia calle Santa Engracia. Con respecto a la situación en Príncipe de Vergara, este análisis pone de manifiesto que este se trata de uno de los puntos más problemáticos de la ruta, corroborando así las conclusiones que pueden obtenerse al analizar los promedios tanto por calle como por la malla hexagonal.

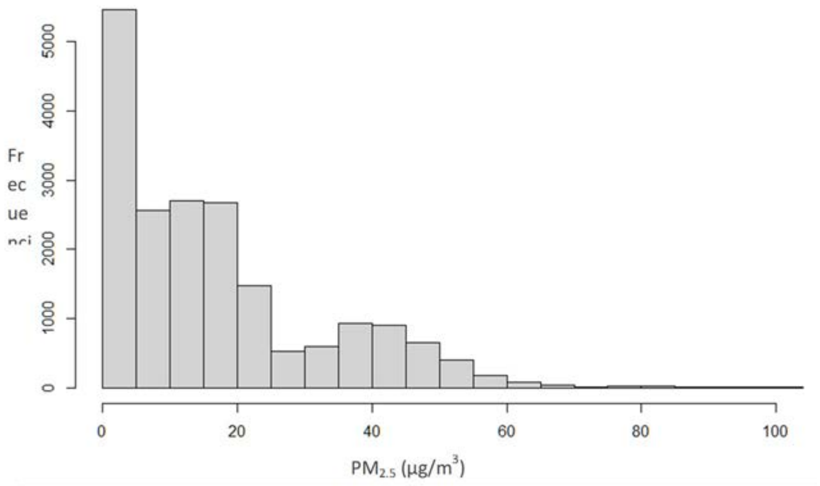

Fig. 4 – Histograma de distribución de las concentraciones de $PM_{2,5}$ durante los trabajos de medición

En cuanto a la comparación entre las medias diarias de los tramos del interior del área de tráfico restringido (Madrid Central) y los tramos externos, no se observan diferencias en los promedios entre ambos. Los datos obtenidos no respaldan una menor concentración de $PM_{2,5}$ en el interior frente al exterior. La Figura 5 muestra una comparativa de los diagramas de cajas y bigotes de las concentraciones de $PM_{2,5}$ para cada uno de los días de estudio.

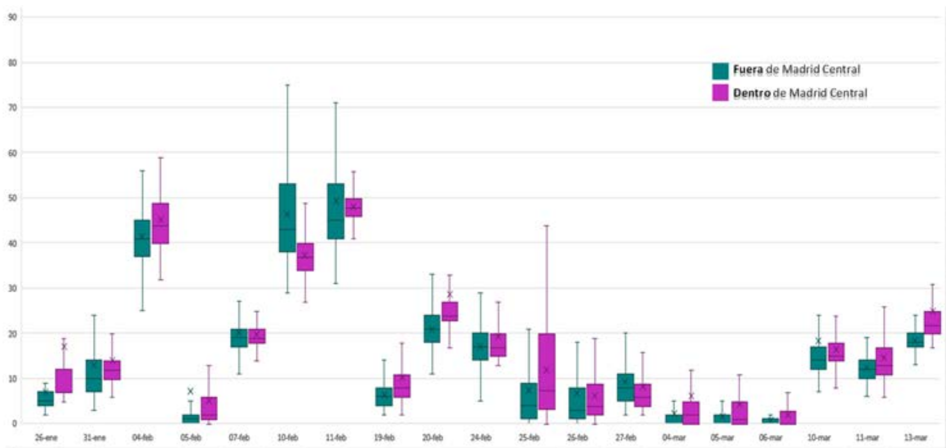

Fig. 5 – Diagramas de distribución de las concentraciones de PM2,5 durante los trabajos de medición

Con respecto a las variables externas evaluadas, el principal resultado obtenido es que únicamente la velocidad del viento muestra una tendencia clara a hacer disminuir las concentraciones de PM, al menos en los rangos de velocidades registrados. Estos resultados coinciden con algunos expertos (Wang y Ogawa, 2015). La temperatura y radiación solar no parecen estar relacionados con el aumento o descenso global de la concentración de $PM_{2,5}$. En el caso de las temperaturas, de hecho, estudios previos obtienen resultados contrarios, ya que mientras que unos aprecian una correlación positiva (Tai et al., 2010), otros defienden la hipótesis contraria (Dawson et al., 2007). La HR y la presión atmosférica deben ser analizadas con mayor profundidad. Aunque también muestran cierta tendencia a ser influyentes en los ascensos y disminuciones de los niveles de PM, la HR afecta a la sensibilidad del sensor de $PM_{2,5}$ y la presión barométrica no describe un abanico suficientemente amplio de valores para sacar conclusiones.

En la comparativa con los valores de IMD, se comprueba de nuevo que las calles con mayor nivel promedio de contaminación por $PM_{2,5}$ no se corresponden con aquellas con menores niveles de IMD. De este modo, encontramos valores promedio de IMD máximos en el Paseo del Prado y Castellana (2200 y 1700, respectivamente) mientras que los mínimos se dan en la calle de la Cruz y la calle Mayor (260 y 290). En cambio, tanto la calle de la Cruz y la calle Mayor como el Paseo del prado han sido evaluadas como algunas de las más problemáticas del recorrido en cuanto a niveles de $PM_{2,5}$. Por tanto, estos aumentos de $PM_{2,5}$ en calles con bajos niveles de IMD deben ser explicados por otros factores, tales como la propia fisionomía de las calles (que en este caso coinciden con las más estrechas de la ruta) y la presencia de elementos perturbadores tales como retenciones constantes en la calle de la Cruz o el túnel de la calle Mayor.

Al comparar los niveles medios de $PM_{2,5}$ con las velocidades de tráfico medias recogidas por el sensor, se puede decir que, al menos a nivel cualitativo, las concentraciones promedio de partículas en el ambiente tienden a verse influidas de forma inversa por la velocidad del tráfico. Es decir, en calles con una elevada tendencia a atascos y retenciones se dan unos promedios generalmente más altos de concentraciones de $PM_{2,5}$. No obstante, mientras que los análisis descriptivos, que comparan las $PM_{2,5}$ con los valores promedio de los factores externos agrupados en días o calles sugieren una alta afinidad de la velocidad del tráfico promedio en cada calle, el análisis de correlación de Pearson no defiende esta aparente tendencia. Esto quiere decir que no se aprecia una correlación lineal entre los aumentos y descensos de $PM_{2,5}$ y los valores de velocidad de tráfico. Esta tendencia podría darse, en parte, por un descenso real de las concentraciones en calles más amplias, con mayor circulación del aire, o por la menor densidad de tráfico presente en el tramo. No obstante, este enfoque también puede estar alterado por una reducción del número de puntos de muestreo debido al menor tiempo de presencia en estas calles.

6. CONCLUSIONES

En este trabajo se ha analizado la concentración de $PM_{2,5}$ en un conjunto de calles de Madrid mediante el uso de sensores móviles. A pesar del bajo coste de esta tecnología, se han obtenido mediciones de calidad aceptable que pueden ser complementarias a las realizadas con las estaciones fijas del Sistema de vigilancia de la Calidad del Aire del Ayuntamiento de Madrid.

Se ha podido comprobar que ciertas calles presentan concentraciones mayores que la media con asiduidad. También cómo la velocidad media del tráfico en cada calle parece afectar a las medias globales de dicho tramo. El método permite caracterizar los puntos problemáticos de la ciudad con un enfoque mucho más minucioso que los sistemas de medición estándar, tal y como se muestra en los resultados por malla y de altas concentraciones. Uno de los factores que más parecen afectar a la aparición de altas concentraciones es la existencia de tramos estrechos de un solo carril, tales como la calle de la Cruz o la calle Hortaleza, donde no circula una gran cantidad de vehículos, pero estos suelen verse sometidos a fuertes retenciones.

De hecho, se han encontrado evidencias de mayores concentraciones de $PM_{2,5}$ promedio en las calles con menor intensidad de tráfico media diaria (IMD), dado que coinciden con los tramos menos amplios, con menos carriles y, en definitiva, mayores dificultades de aireación. Esta valoración del estado de cada una de las calles por las que discurre el recorrido no habría sido posible mediante la recopilación de la información suministrada por estaciones fijas. De hecho, los expertos (Qiu et al., 2017) critican que este es el gran problema de la ciencia de los datos de calidad del aire. Hasta ahora la mayoría de los estudios han recopilado información de estaciones fijas, dejando de lado variables estructurales, tales como el trazado de las carreteras, su anchura, etc.

Hay constancia de otros estudios en la ciudad de Madrid, donde sí se ha considerado otros factores, como la presencia y características del arbolado de las zonas verdes, y la IMD de las calles próximas a los puntos de medición, así como la distancia entre las vías de tránsito y arbolado, y el efecto de los factores meteorológicos sobre estos valores (Calderón-Guerrero, 2014), confirmando la variación de los niveles de contaminación atmosférica en función de la presencia de estas zonas verdes, la distancia y la IMD. De igual modo, en estudios posteriores (Sánchez Martín, 2017), se corroboran estas variaciones de los niveles de partículas (PM_1, $PM_{2.5}$, PM_{10}) en diferentes zonas de la Casa de Campo de Madrid, mediante la adaptación de unos sensores low-cost, similares a los de este estudio, en una aeronave pilotada de forma remota (*DRON*) en las proximidades de las autopistas A-5 y A-6, lo cual avala los resultados de este estudio, y realza la utilidad de estos sensores móviles a la hora de identificar las variaciones de los niveles de contaminantes atmosféricos por otros factores.

En cuanto a Madrid Central, los resultados de este estudio no han identificado una diferencia entre ambas zonas, por lo cual podría establecerse que las restricciones al tráfico no están resultando en un impacto positivo para el interior de dicha área.Se recomienda continuar con investigaciones de esta línea durante los futuros años, para observar posibles cambios con el endurecimiento de las restricciones previstas en la Estrategia MADRID 360.

En la comparativa con los valores de IMD, los resultados indican que las calles con mayor nivel promedio de contaminación por $PM_{2,5}$ no se corresponden con aquellas con menores niveles de IMD. De igual forma, a nivel cualitativo, las concentraciones promedio de partículas en el ambiente tienden a verse influidas de forma inversa por la velocidad del tráfico. Por otra parte, parece claro que las variables meteorológicas como la velocidad del viento y su dirección, la humedad relativa y la presión barométrica tienen un mayor peso que otras variables externas que puedan aplicarse a modelos predictivos en un futuro. Con una mejora futura de los trabajos de medición podrían construirse experimentos con resultados más robustos en este sentido.

Las mayores limitaciones encontradas en el proyecto residen en el diseño del sensor móvil. Por ejemplo, el acabado del prototipo impide su viabilidad de uso en días de lluvia. También se debería incorporar otros sensores como el de O_3 y NO_2, de gran importancia para una ciudad como Madrid.

AGRADECIMIENTOS

Este trabajo ha sido realizado en el marco de los siguientes proyectos: “Efectos de la configuración urbana sobre la movilidad a pie y la contaminación en las ciudades - DESPACIO” (TRA2017-88058-R), financiado por el Ministerio de Economía, Industria y Competitividad de España en el “Programa Estatal de I + D + i Orientada a los Retos de la Sociedad” y “Desarrollo de aplicaciones SIG para la implementación de indicadores de fragmentación urbana y mejora de la movilidad” de la Universidad Politécnica de Madrid, proyecto de investigación núm. RP151320028.

RESUMEN

La Comunidad de Madrid y sus seis universidades públicas presenciales comenzaron la elaboración del primer Plan de Movilidad Universitaria Sostenible (PMUnivS) general a finales de 2019. El plan de trabajo incluye, como parte fundamental de los trabajos a realizar, la toma de datos sobre como la comunidad universitaria madrileña se desplaza hacia los campus y entre campus, y la calidad urbanística de éstos. Esta encuesta, realizada del 22 de febrero al 26 de marzo de 2021, tenía una población objetivo que se estimaba en más de 200.000 personas, entre estudiantes, personal docente e investigador, personal de administración y servicios, y personal de servicios externalizados.

Desafortunadamente, la pandemia de la COVID-19 y las restricciones adoptadas para contenerla, especialmente en materia de movilidad, tuvo un impacto significativo en el objeto de la encuesta, la movilidad a los campus universitarios, y que limitó la estrategia de comunicación. En general, la presencialidad en las universidades presenciales disminuyó en un más del 50%: gran parte de las clases se imparten on-line, muchos servicios están cerrados y el teletrabajo se ha implementado de manera general. Además, cualquier actividad presencial para animar a la participación no se consideraba adecuada. En consecuencia, la campaña de las encuestas debía realizarse, casi por completo, mediante el uso de las vías de comunicación virtual de cada universidad y en el uso de redes sociales, tales como Twitter o Instagram.

En esta comunicación se detalla la estrategia ha sido usada durante la campaña de encuestas, qué decisiones se tomaron desde el punto de comunicación y cuáles fueron sus efectos sobre las tasas de respuestas obtenidas.

El objetivo científico es intentar encontrar una relación causal entre las diferentes actuaciones de comunicación online con cada colectivo de la comunidad universitaria y posibles patrones anormales de participación. Esta experiencia puede ser de utilidad para otras instituciones con la misma problemática.

1. INTRODUCCIÓN

Los campus de las universidades, lugares en los que se concentran varios centros de enseñanzas superiores y centros de investigación, atraen a un gran número de personas a lo largo del día, entre estudiantes (el colectivo generalmente más numeroso), profesores, investigadores y personal de administración y servicios, de diferentes orígenes, estilos de vidas, rentas y actitudes (Balsas 2003). Los campus universitarios, por sí mismos, constituyen espacios urbanísticos propios, con un diseño que tiene a ser diferente al de su entorno, que acoge una gran variedad de actividades a lo largo del día. Además, suelen disponer de infraestructuras y servicios de transporte especialmente diseñadas para su excepcionalidad. En consecuencia, la movilidad a los campus universitarias suele presentar unas pautas propias y muy marcadas por los ritmos de la actividad académica, que deben ser conocidas para realizar una planificación y gestión integral de estos lugares.

La movilidad a los campus universitarios es un tema que ha sido abordado desde diferentes puntos de vista y con diferentes objetivos. Por mencionar algunos de ellos están los estudios que cuyo objetivo era el conocimiento de la movilidad universitaria en general (Albertos et al. 2008), la patrones espaciotemporales de la movilidad universitaria (Delmelle y Delmelle 2012), predisposición a actuaciones con estrategias TDM en los campus (Cherry et al. 2018), la estimación de la utilidad de los modos activos (Lundberg y Weber 2014), la selección modal (Shannon et al. 2006; Hasnine et al. 2018; Etminani-Ghasrodashti, Paydar y Hamidi 2018), cambios de movilidad por cambio de residencia (Haggar, Whitmarsh y Skippon 2019), influencia de la localización del campus y de las características socioeconómicas y comportamiento social para la movilidad em coche (Soria-Lara, Marquet y Miralles-Guasch 2017) o las diferencias entre la movilidad de la universidad y la movilidad en el resto de la ciudad (Danaf, Abou-Zeid y Kaysi 2014).

Generalmente, estos estudios capturaron parte de los datos mediante campañas de encuestas online, salvo Albertos et al. (2008). Algunas de estas campañas fueron propias del estudio y otras fueron realizadas con propósitos generales. La mayoría de dichas encuestas siguieron un muestreo no-probabilístico por cuotas y autoselectivo (Galloway 2005) que incluía, como mínimo, la participación del colectivo de estudiantes, pudiendo estar seleccionados por su vinculación esperada con el campus debido a tipo de estudios y curso. En los casos de Shannon et al. (2006) y de Albertos et al. (2008) la muestra fue aleatoria estratificada al seleccionar previamente a qué personas o grupos académicos se les invitaría a participar en la encuesta. La participación en dichas encuestas se situó en torno al 10%, pudiendo llegar en algunos casos a más del 17%.

Las campañas de encuestas de casi todos los estudios mencionados se dieron a conocer mediante los medios digitales propios de cada universidad, tales como el correo electrónico institucional o los servicios de intranet, salvo los caso de Haggar, Whitmarsh y Skippon (2019), que usaron anuncios de Facebook, y de Shannon et al. (2006) que enviaron correos convencionales. En general, los documentos mencionados previamente no aportan apenas detalles sobre las acciones de comunicación para dar a conocer las respectivas encuestas de movilidad universitaria y animar a su participación. Del mismo modo ninguno de estos documentos realiza valoraciones sobre éxitos y fracasos de dichas acciones y no se especifican si hubo estrategias de seguimiento de la participación para focalizarse en aquellos colectivos con menor número de respuestas de las esperadas a lo largo de la campaña. Estos aspectos que, generalmente, pueden considerarse cuestiones menores para la literatura de las encuestas de movilidad, pueden ser de interés de cara a planificar nuevas campañas de encuestas, sobre todo en aquellas cuya gran parte de población objetivo parece tener unos comportamientos diferenciados en los medios que usan para participar en encuestas online (Bosch, Revilla y Paura 2019).

El objeto de esta comunicación es presentar los efectos observados en la participación en la campaña de encuestas para los grandes colectivos de la comunidad universitaria del Plan de Movilidad Universitaria Sostenible (PMUnivS) de la Comunidad de Madrid que tuvieron las acciones de comunicación usadas y el uso de dichos indicadores relacionados con la participación para la detección de patrones anómalos. Esta encuesta se ha realizado de manera conjuntamente en las seis universidades públicas presenciales de la Comunidad de Madrid durante las primeras semanas del segundo semestre académico del curso 2020/2021. Esta campaña se realizó durante el segundo estado de alarma por la pandemia de la COVID-19 y mientras estaban vigentes una serie de medidas y restricciones para contenerla.

El resto de la comunicación se estructura de la siguiente manera: en la sección 2 se presenta el objeto de la encuesta y las principales características de ésta; en la sección 3 se presentan las características de los campus universitarios en los que se realizó la encuesta y su cuota de presencialidad en tiempos de la COVID-19; en la sección 4 se presenta la campaña de comunicación; en la sección 5 se presentan los indicadores usados para entender el impacto de las acciones de la campaña de comunicación en la participación; la sección 6 se muestran los efectos de las acciones de comunicación sobre la participación; finalmente, la sección 7 presenta las conclusiones y se realizada la discusión.

2. EL PMUNIVS Y LA CAMPAÑA DE ENCUESTAS

El Plan de Movilidad Universitaria Sostenible (PMUnivS) para las seis universidades públicas presenciales de Madrid empezó sus trabajos a finales del año 2019, promovido por las consejerías de Transportes, Movilidad e Infraestructuras, y de Ciencia, Universidades e Innovación de la Comunidad de Madrid y por el Consorcio Regional de Transportes de Madrid (CRTM). Este plan contempla la realización de una serie de encuestas a los diferentes colectivos de la comunidad universitaria para conocer cómo se mueven a los diferentes campus universitarios. La campaña de encuestas se dividió en dos: una primera etapa para las empresas proveedoras de materiales y consumibles y otra etapa en la que se pregunta la movilidad a los grandes colectivos de la comunidad universitaria: estudiantes, personal docente e investigador (PDI), personal de administración y servicios (PAS), y personal de servicios externalizados. Esta comunicación solo hace referencia a las acciones de comunicación y seguimiento de la participación de la segunda etapa.

Estas encuestas debían haberse realizado a lo largo del año 2020 pero la pandemia de la COVID-19 y las diferentes restricciones que se decretaron para contenerla supuso la necesidad de posponer dicha campaña hasta volver a una situación de cierta normalidad. Finalmente se decidió que entre el lunes 22 de febrero y el viernes 26 de marzo de 2021 (antes de las vacaciones de Semana Santa del curso 2020/21) se abriese la campaña de encuestas a los grandes colectivos de la comunidad universitaria de la Comunidad de Madrid. Esta encuesta sería online, mediante SurveyMonkey, previendo inicialmente unos 15 minutos para completarla totalmente. El muestro de esta encuesta responde, por el diseño de las acciones de comunicación para animar a su participación, a un muestreo no-probabilístico con cuotas, por campus y colectivo, y autoselectivo.

La encuesta tenía una parte común y una parte adaptada a la realidad urbanísticas y de la oferta de transporte propia de cada uno de los campus. Además, las preguntas relacionadas con la movilidad no hacían sólo referencia a la movilidad en las circunstancias de la COVID-19 sino también en cómo se movía anteriormente (si tenía desplazamientos al campus) y como estimaba hacerlo en próximos cursos (bajo el supuesto de no necesitar ninguna medida de contención de la pandemia actualmente vigente).

Para animar a la participación se sorteaba, entre las encuestas finalizadas que indicasen un correo electrónico válido de contacto, abonos mensuales para transporte público, cajas de experiencias y diferentes regalos institucionales de cada una de las universidades.

Para conocer más sobre la encuesta, consulte la comunicación (Balsero Martínez, Lamarty Belica y Monzón de Cáceres (2021), presentada en este congreso.

3. LAS UNIVERSIDADES PÚBLICAS PRESENCIALES DE LA COMUNIDAD DE MADRID Y SUS CAMPUS. LA PRESENCIALIDAD EN TIEMPOS DE LA COVID-19

La Comunidad de Madrid tiene seis universidades públicas presenciales: la Universidad de Alcalá (UAH), la Universidad Autónoma de Madrid (UAM), la Universidad Carlos III de Madrid (UC3M), la Universidad Complutense de Madrid (UCM), la Universidad Politécnica de Madrid (UPM), y la Universidad Rey Juan Carlos (URJC).

En total, se estima que el número de personas asociadas a estas universidades es de más de 200.000 personas para el curso 2020/2021, la cual está formada por los estudiantes casi del 90%, el PDI, alrededor del 8,5%, y el PAS, entorno al 4%. A esta comunidad hay que sumarle el personal de servicios externalizados, como son el personal de cafeterías, de seguridad o de limpieza, entre otros, cuyo valor relativo a la población no pudo ser obtenido con precisión.

La gran mayoría de los centros académicos y de investigación de las universidades públicas presenciales están ubicados en alguno de los 14 campus principales de la Comunidad de Madrid (Figura 1), entendiendo campus como áreas en las que se ubican más de un centro académico o de investigación de una misma universidad. Salvo el campus de Ciudad Universitaria, en Madrid y en el que se encuentran centros de la UCM y de la UPM, el resto de los campus son propios de una única universidad. Por tamaño, el que acoge mayor número de personas de la comunidad universitaria es el campus de Ciudad Universitaria, con más del 36% sobre el total. Cabe destacar que, pese a que existen otros centros aislados que se encuentran en Madrid y Aranjuez que no han sido incluidos en esta comunicación.

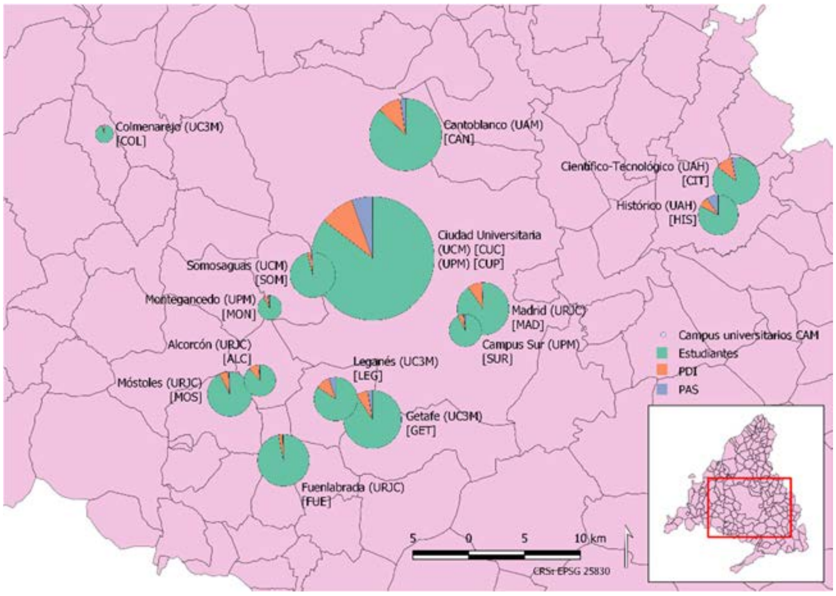

Figura 1. Distribución de los campus universitarios de la Comunidad de Madrid y el porcentaje de estudiantes, PAS, y PDI. A mayor área del diagrama circular, mayor población total de la comunidad universitaria. Entre corchetes está el código asignado en esta comunicación a cada campus.

3.1. La presencialidad durante el segundo semestre del curso 2020/2021

La presencialidad de la comunidad universitaria durante el periodo de la encuesta aún estaba afectada por los planes de contención de la COVID-19 y las restricciones de movilidad. Cada universidad, e incluso cada campus y centro, establecieron sus propias medidas con relación a la presencialidad de cada colectivo.

En general, todos los campus mostraban una importante reducción de los requerimientos de presencialidad, especialmente para los estudiantes. Gran parte de las clases se impartían en formato no presencial o con la posibilidad de seguimiento online, salvo las prácticas y los exámenes; además se diseñaron calendarios y horarios pensados para evitar aglomeraciones y coincidencia de flujos de personas en sentidos opuestos. Esta estrategia hizo que gran parte de la comunidad universitaria tuviese, individualmente, unas pautas de presencialidad relativamente irregulares. De la misma manera, muchos servicios se prestaban de manera telemática, requerían el concertar cita previa o, como en el caso de las cafeterías, estaban cerrados, con horarios reducidos o prestando servicios mínimos, con menor número de personal del que es habitual en situaciones normales.

En la Tabla 1 se muestra la estimación de presencialidad informada por los diferentes responsables de cada universidad o campus.

Universidad	Campus	Código	Presencialidad
UAH	Científico-Tecnológico	CIT	Presencialidad limitada. Grados: sólo prácticas en grupos reducidos (12 personas), Máster depende del máster.
	Histórico	HIS	
UAM	Cantoblanco	CAN	Poca presencialidad.
UC3M	Colmenarejo	COL	Estimada en un 50%
	Getafe	GET	
	Leganés	LEG	
UCM	Ciudad Universitaria	CUC	Depende del centro. Se estima máximo en un 50%.
	Somosaguas	SOM	Estimada entre el 25% al 50%.
UPM	Campus Sur	SUR	Estimada entre el 20% al 30%.
	Ciudad Universitaria	CUP	Depende del centro. Se estima máximo en un 50%
	Montegancedo	MON	Estudiantes: 1º de grado al 100%, el resto sólo prácticas y exámenes. Presencialidad limitada para en el resto de los colectivos.
URJC	Alcorcón	ALC	Estudiantes: Facultad de Odontología al 100% y Facultad de Farmacia sólo prácticas. Presencialidad limitada en los otros colectivos.
	Fuenlabrada	FUE	Estimada en un 25%.
	Madrid	MAD	
	Móstoles	MOS	Estimada entre el 5% y el 10%.

Tabla 1. Resumen de la presencialidad estimada por los responsables de cada campus y universidad durante el segundo semestre del curso 2020/2021.

4. LA CAMPAÑA DE ENCUESTAS DEL PMUNIVS. EL RETO DE LAS RESTRICCIONES POR LA COVID-19

La situación de la COVID-19 afectó a las acciones de comunicación relacionadas con el cómo se podía dar a conocer la campaña de encuesta del PMUS, el porqué de ésta, para qué iban a servir sus respuestas, cómo estas respuestas ayudarían a entender mejor la movilidad a los campus universitarios y ayudar a diseñar propuestas de mejoras. Además, estas acciones de comunicación tendrían también como objetivo fundamental el intentar animar a participar a la mayor parte de la población objetivo.

En situaciones normales, algunas de estas actuaciones pueden ser presenciales tales como la entrega de tarjetones en puntos clave o la instalación de puntos de información temporales que pueden disponer de dispositivos electrónicos, como tabletas digitales u ordenadores portátiles, para que las personas que deseasen contestar la encuesta la pudiesen rellenar en ese mismo lugar. Sin embargo, y debido a las restricciones por la COVID-19, ninguna de estas actuaciones fue considerada como adecuada, tanto por la previsible menor e irregular afluencia de personas a los campus, como para evitar la exposición de las personas encargadas de dichas actividades al virus, por incremento de interacciones de varios minutos con personas ajenas a su círculo de convivencia habitual. En consecuencia, gran parte de las acciones de comunicación de la campaña de encuesta debían basarse con medios no presenciales, sin renunciar al refuerzo puntual con material en soporte físico que no requiriese interacción física.

Se prepararon los siguientes materiales promocionales, siguiendo las recomendaciones del (Instituto para la Diversificación y Ahorro de la Energía 2006) y adaptándolas a las oportunidades que ofrecen las nuevas tecnologías:

1. Nota de prensa: En la cual se anunciaba el inicio de la campaña de encuestas y se comunicaba detalles referentes al porqué de estos trabajos, cuál era la población objetivo y se animaba a participar.
2. Carta: Un documento genérico que se envió a todos los miembros de la comunidad universitaria mediante correo electrónico en la que se daba a conocer la campaña de encuestas, se describía brevemente la motivación de ésta, se anunciaban los premios que a los cuales podía optar al completar la encuesta y se indicaban el enlace propio de su universidad por el cuál podía acceder a la encuesta, el correo electrónico de contacto para dudas y los perfiles en redes sociales. Esta carta podía ser adaptada por cada universidad según considerase conveniente.
3. Póster (Figura 2): Una imagen muy sencilla en la que se anunciaba la campaña de encuestas, la fecha de inicio, los promotores, las universidades participantes y un correo electrónico de contacto para dudas. Este poster fue enviado en formato digital, tanto vertical como horizontal, para presentarlo en pantallas informativas de los campus.
   El póster también fue impreso en tamaño DIN A-1 para ser colocado en diferentes puntos acordados entre el equipo de coordinación de los trabajos y los diferentes responsables de campus durante las visitas de campo para presentar la campaña y la captación de datos necesaria para otros trabajos del PMUnivS. El póster no tenía referencia a ningún enlace de la encuesta, por ser diferente para cada universidad ni a las redes sociales puesto a que se decidió su uso posteriormente a su impresión.

Figura 2. Póster de la campaña de encuestas

4. Tarjetones: Los tarjetones contenía la imagen usada del póster y un texto breve animando a participar. Los tarjetones estaban personalizados para cada una de las universidades, usando sus colores instituciones y presentando el enlace a sus respectivas encuestas mediante un código QR con el logotipo y colores de cada universidad.
5. Correo electrónico: El equipo de coordinación de los trabajos disponía de un correo electrónico que fue referenciado en todos los materiales de promoción usados, para que cualquier miembro de la comunidad universitaria pudiese enviar comentarios, preguntas o sugerencias con relación a la encuesta y al PMUnivS.
6. Redes sociales: Se crearon un perfil de Twitter y otro perfil en Instagram con el mismo nombre (@movunicam) Con estos medios se abría otro medio de comunicación directo entre el equipo coordinador y la comunidad universitaria. La utilización de estos perfiles se fue concebida como una medida adicional a pocos días de iniciar la campaña de encuestas. Sin embargo, estas cuentas sólo alcanzaron unos 23 seguidores y, por lo tanto, tenían poco poder de difusión de la campaña de encuestas.

Las acciones de comunicación de la campaña de encuestas tenían dos objetivos principales.

El primer objetivo era el informar a toda la población, tanto si eran miembros de la comunidad universitaria como si no lo eran, del inicio, los motivos y la evolución de la encuesta. El segundo objetivo consistía en animar a la participación del mayor número de miembros de la comunidad universitaria

Las tareas del primer objetivo fueron desarrolladas principalmente por los equipos de comunicación de las consejerías implicadas y del CRTM, con el apoyo del equipo coordinador de los trabajos. Este equipo fue quien diseño la imagen del póster y el encargado de la rueda de prensa de presentación de las encuestas que se realizó el viernes 19 de febrero de 2021. Parte de estas acciones aún no han empezado a poderse hacer al finalizar los trabajos de redacción del PMUnivS.

El segundo objetivo dependió, principalmente, de cada una de las universidades participantes, y tuvo el apoyo del equipo de coordinación de los trabajos. Se establecieron una serie de reuniones para coordinar las acciones de comunicación que debían asumir cada una de las personas responsables de las universidad y campus, en las cuales se definieron los calendarios de comunicación, los mensajes a transmitir, los medios mínimos y medios deseados que debían usarse. El equipo coordinador fue el encargado de preparar los materiales base comunes y de hacer llegar dicho material a cada universidad para que pudiesen adaptarlo a su realidad. El objetivo de la coordinación de estas acciones era intentar que toda la comunidad universitaria pudiese estar informada al mismo tiempo y, de esta manera, permitir que miembros de la comunidad de diferentes universidades pudiesen estar informados de la campaña de encuestas por cualquier medio abierto de cualquiera de las universidades participantes o por conocidos de otras universidades.

La estrategia principal para cumplir el segundo objetivo se basó, en gran medida en el envío de la carta en varios mensajes a los correos electrónicos institucionales de los miembros de la comunidad universitaria. Cabe señalar que esta acción también pudo requerir la necesidad de coordinación interna de diferentes departamentos de cada universidad y campus puesto que, algunas universidades, no disponían de un listado único de correos: la organización más habitual dichos listados era el disponer del correo de los estudiantes en una lista diferente a la de los correos del PDI y PAS los cuales, a su vez, podían estar en listas centralizados o que dependían de cada centro o campus. A parte, se solicitó que cada universidad comunicase a todas las empresas contratadas para la gestión de los servicios externalizados para que hiciesen llegar el enlace a sus empleados. Ninguna de las actividades de esta acción se podía centralizar a un único punto de envío en el cumplimiento de los Ley Orgánica de Protección de Datos Personales (LOPD).

Las universidades, desde perfiles comunes generales y desde perfiles de centros y delegaciones de estudiantes, complementaron su acción de difusión usando sus redes sociales. Esta acción fue complementada con el uso de los perfiles de Twitter e Instagram (@movunicam) con el que se anunciaban los principales avances de participación, se ponían curiosidades de la movilidad universitaria de las diferentes universidades y se respondían a las dudas y preguntas relacionadas con la encuesta.

En esta comunicación, se entiende perfil general de la universidad las cuentas vinculadas a la propia universidad, a servicios comunes como son la red de bibliotecas (que suelen tener un perfil común) o a vicerrectorados u oficinas relacionadas con la campaña de encuestas, como oficinas verdes o programas relacionados con los ODS.

Se establecieron tres olas principales de comunicación durante todo el periodo de la campaña de encuestas (Tabla 2):

- La primera ola se debía realizar a lo largo de los primeros días de la primera semana de la encuesta (a partir del lunes 22 de febrero de 2021). Esta ola era la que mayor esfuerzo conllevaba puesto a que, además, implicaba la colocación de la cartelería en los puntos acordados durante las visitas de campo realizadas con anterioridad y la programación de las pantallas disponibles para que también mostrasen el póster. En esta ola, todas las universidades optaron por el envío masivo de la carta a los correos electrónicos. Además, tres de ellas también publicaron noticia referente a la campaña de encuestas, con el enlace a sus respectivas encuestas y todas enviaron algún mensaje desde algún perfil general oficial de Twitter.
- La segunda ola se realizó durante la segunda semana de marzo (a partir del lunes 8 de marzo de 2021), cuando ya habían transcurrido más de 15 días desde el inicio de la campaña de encuestas. Esta ola volvió a consistir en el envío de un correo electrónico recordatorio a todos los miembros de la comunidad universitaria. Además, se empezaron a repartir tarjetones todos los campus de la UAM y UCM, y en el campus de Ciudad Universitaria de la UPM para llegar a la parte del colectivo que no pudo ser alcanzada por medios digitales y que acudían a la universidad, en especial, el colectivo de personal de servicios externalizados.
- La tercera ola se llevó a cabo durante la última semana de la campaña de encuestas (a partir del 22 de marzo de 2021). Esta semana era, a su vez, la semana última semana completa de marzo y que coincida con la última semana lectiva antes de las vacaciones de Semana Santa. En esta tercera ola, las universidades debían haber repartido los tarjetones, especialmente en los puntos habituales del personal de servicios externalizados. Además, y de manera opcional, podían volver a enviar correo electrónico recordatorio o enviar mensaje de último aviso en redes sociales.

No se consideró adecuado más olas de comunicación para no generar un rechazo a participar por exceso de recordatorios a todo aquel posible participante que no había participado aún.

Tabla 2. Calendario de actuaciones realizadas en materia de comunicación, de acuerdo con los diferentes responsables de cada universidad y por el seguimiento de su actividad en Twitter.

4.1. Consideraciones que se tuvieron en cuenta en el diseño de las acciones de comunicación

Debido a que la encuesta y las acciones de comunicación se realizaron íntegramente online, existía el riesgo a que se pudiese sufrir un “ataque” cibernético. Una de las principales preocupaciones era que se recibiesen una cantidad elevadas de cuestionarios con respuestas falsas que, en el peor de los casos, pudiese parecer que fuesen respuestas coherentes y, por lo tanto, difícil de filtrar.

Las medidas para reducir la posibilidad de ataque, sin que ello significase que las redujese completamente, fueron:

- Disponer de un enlace propio de cada universidad para acceder al cuestionario. De esta manera se esperaba limitar el alcance de un posible ataque. Sin embargo, pese a que no se publicó ningún material promocional con los seis enlaces, algunos buscadores ofrecían estos enlaces.
  Esta característica de la encuesta fue inicialmente pensada por motivos de diseño y particularización del cuestionario a cada universidad y campus.
- Evitar la publicación del enlace en redes sociales abiertas (tipo Twitter o Instagram) para evitar el rastreo de enlaces por parte de bots.
- Limitar el número de cuestionarios admitidos por dirección IP.

En el período por el cual la encuesta estuvo activa, se realizó un seguimiento de posibles comportamientos anómalos sin haber detectado ningún patrón que indicase un posible ataque masivo y que pudiese invalidar, a priori, la totalidad de la campaña de encuestas

5. MÉTODOS PARA ENTENDER EL EFECTO DE LAS ACCIONES DE COMUNICACIÓN EN LA PARTICIPACIÓN.

Con el fin de comprobar el efecto que han tenido las diferentes acciones de comunicación sobre la participación, se ha realizado el seguimiento día a día, por campus y colectivo, de los siguientes indicadores:

- Número total de encuestas iniciadas, diferenciando entre las encuestas finalizadas y las no finalizadas.
- Horas de inicio de la encuesta por colectivo.
- Tiempo requerido desde que se inicia a responder la encuesta hasta que la finaliza o la abandona.

La evolución de estos indicadores también permitía tener datos de cara a la adopción de nuevas medidas de comunicación orientadas a aquellos colectivos y campus con menor número de respuestas de las esperadas, a la vez que permitía detectar la presencia de comportamientos anómalos.

Los valores de estos indicadores se obtienen de la explotación de los datos de la encuesta.

Debido a que la encuesta tenía preguntas diferentes según lo que contestaba el participante, lo que en SurveyMonkey se llama *Logic Features* (SurveyMonkey [sin fecha]), los ficheros originales contenían varios campos cuyo nombre estaba repetido. En este caso, las primeras preguntas del cuestionario, las relativas sobre cuál es el campus de la actividad del participante y a qué colectivo pertenecía, creaban estos campos repetidos, sin que eso no signifique que hubiesen más de este tipo de campos generados a medida que se respondían otras preguntas. Es por ello por lo que, previamente a analizar los cuestionarios, se tuvo que realizar una tarea de compactación de datos, por la cual se fusionaban todos los campos con el mismo nombre en un mismo campo eligiendo, en caso de discrepancia por error de almacenamiento, el valor del campo moda de registros no nulos para el campus y colectivo de dicho participante. Esta tarea se realizó usando un script de Python 3.7.6 que usa el paquete *pandas* específico para esta comunicación.

Estos indicadores se representan, en el apartado 6.2., en gráficos de barras o de líneas y áreas, cuyo eje abscisas representa cada uno de los días en los que estaba abierta la campaña de encuestas. Además, se han añadido líneas verticales indicando el tipo de acción de comunicación que se ha realizado para poder ver en el gráfico cuál fue el efecto de cada acción sobre la participación (envío de correos electrónicos en negro y con línea discontinua y envío de tweets en azul y con línea punteada) y la duración de dichos efectos. Estos gráficos han sido generados con el paquete *ggplot* de R, versión 4.0.2.

Finalmente, para conocer el detalle de todos los tweets enviados desde las cuentas de interés de las universidades se usó la API de Twitter, versión *Academic Research product track* que permite el acceso a todos los tweets publicados desde el inicio de dicha red social. Para esta comunicación, sólo se preguntó por los tweets twiteados y retwiteados desde el viernes 19 de febrero de 2021 hasta el sábado 27 de marzo de 2021. La captura de los tweets se realizó mediante un script de Python 3.7.6 que usa el paquete *requests* para almacenarlo en un base de datos MongoDB mediante el paquete *pymongo*. Para detectar qué tweets podían hacer referencia a la encuesta, se filtraron aquellos tweets que en el texto tuviesen las palabras “movilidad”, “encuesta”, o “plan”. Estos tweets serían posteriormente leídos por personal del equipo de coordinación para acabar de decidir si eran o no tweets de interés para la presente comunicación.

6. LAS ACCIONES DE COMUNICACIÓN Y LA EVOLUCIÓN DE LA PARTICIPACIÓN

Los resultados mostrados en esta sección son los resultados obtenidos de los primeros análisis preliminares. Dichos resultados podrían variar con respecto a la versión definitiva de los trabajos de redacción del PMUnivS por correcciones que se realicen a medida que se analicen cada encuesta con mayor detenimiento.

6.1. Participación en la campaña de encuestas

Durante la campaña de encuestas del PMUnivS se recibieron un total de 35.538 encuestas en los campus objeto de esta comunicación, lo que representa una participación total entorno al 17,58%, considerando solamente estudiantes, PAS y PDI). Del total de encuestas, el 83,13% estaban completas y, por lo tanto, podían participar en el sorteo de diferentes premios. Este porcentaje de encuestas completadas es similar en todos colectivos de la universidad siendo algo superior para los PDI y siendo algo inferior para el personal del servicio externo. Solamente el 8,29% de las personas que completaron la encuesta rechazaron participar en el sorteo al no facilitar ningún correo electrónico válido de contacto. De los cuestionarios que sí decidieron participar, casi el 85% indicaron usaron el correo institucional de la universidad a la que pertenecían. Hay que señalar que se encontraron 117 participantes usaron exactamente el mismo correo electrónico de contacto en, a lo sumo, 2 encuestas diferentes.

Como se puede ver en la Figura 3, la participación no fue uniforme ni por colectivo ni por universidades ni campus. El colectivo más participativo fue el PAS con más del 40%, seguido del PDI con más del 30% y finalmente los estudiantes con una participación próxima al 15%. En cuanto a universidades, destaca la UCM por ser la que movilizó más participantes de su comunidad y cuyo primer correo fue enviado y firmado por el Rector de la universidad. Por campus, se puede destacar el campus de Colmenarejo (UC3M) destaca por una elevada participación tanto de PAS como de PDI, mientras que los campus de Montegancedo (UPM) y Fuenlabrada (URJC) tuvieron participaciones cercanas al 60% por parte del PDI, y el campus de Ciudad Universitaria (UCM) tuvo una participación de más del 25% del colectivo estudiante. No se ha podido determinar el grado de participación del personal de servicios externalizados debido a que se conoce la población total. Se han excluido de la Figura 3 los campus de Somosaguas (UCM) y Móstoles (URJC) debido a la detección de valores atípicos pendientes de corregir.

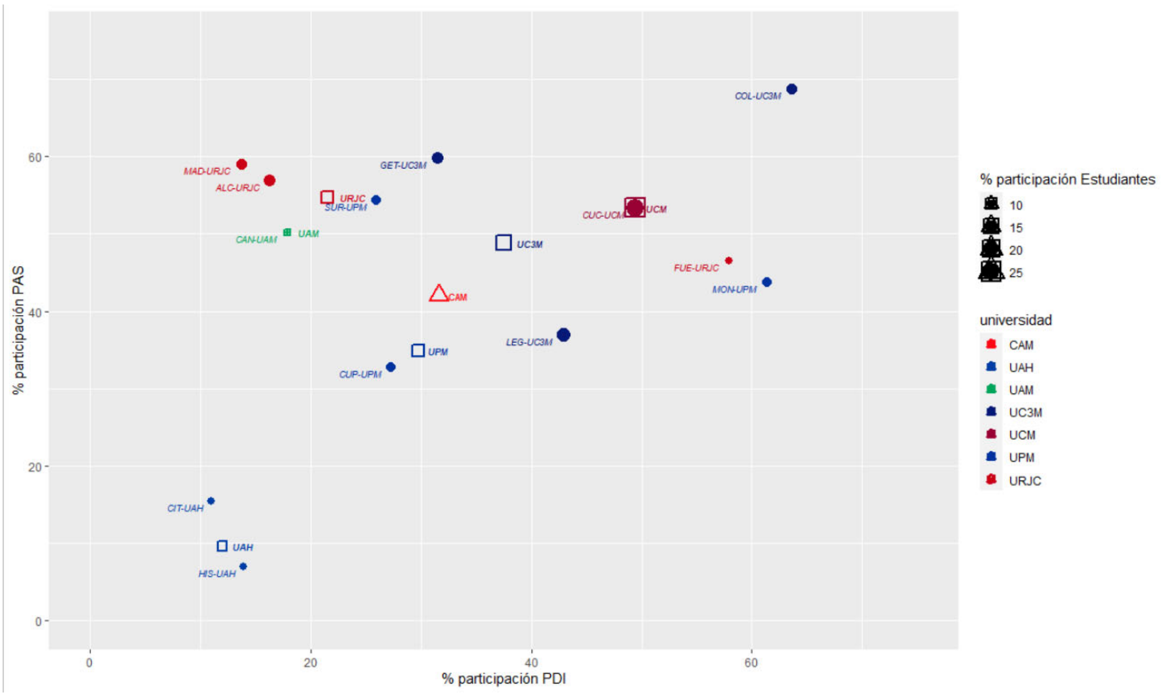

Figura 3. Diagrama del porcentaje de participación de los Estudiantes, PAS y PDI, por campus y por universidad

6.2. Evolución de indicadores de participación, ¿efectos de las acciones de comunicación?

En relación con los días de mayor participación, se puede apreciar en la Figura 4 como estos incrementos son, en general, más prominentes en aquellos días en los que se enviaba algún mensaje mediante correo electrónico de cada una de las olas principales de comunicación y durante el día inmediatamente posterior. El correo electrónico solía enviarse durante el turno de mañana.

Hay que mencionar que, como era de esperar, el incremento de participación es muy destacado en los primeros días de la campaña de encuestas, cuando toda la población objetivo aún no había participado. En estos días no solo se consiguió la más de la mitad de la participación en prácticamente todas las universidades, sino que también se superaron las cuotas mínimas previstas para casi todos los colectivos y campus, no requiriendo tomar casi ninguna medida adicional para dar a conocer la encuesta a segmentos que tuviesen menor participación. También cabe señalar que los primeros días fueron los días que más encuestas no finalizadas se recibieron, en relación con las encuestas finalizadas.

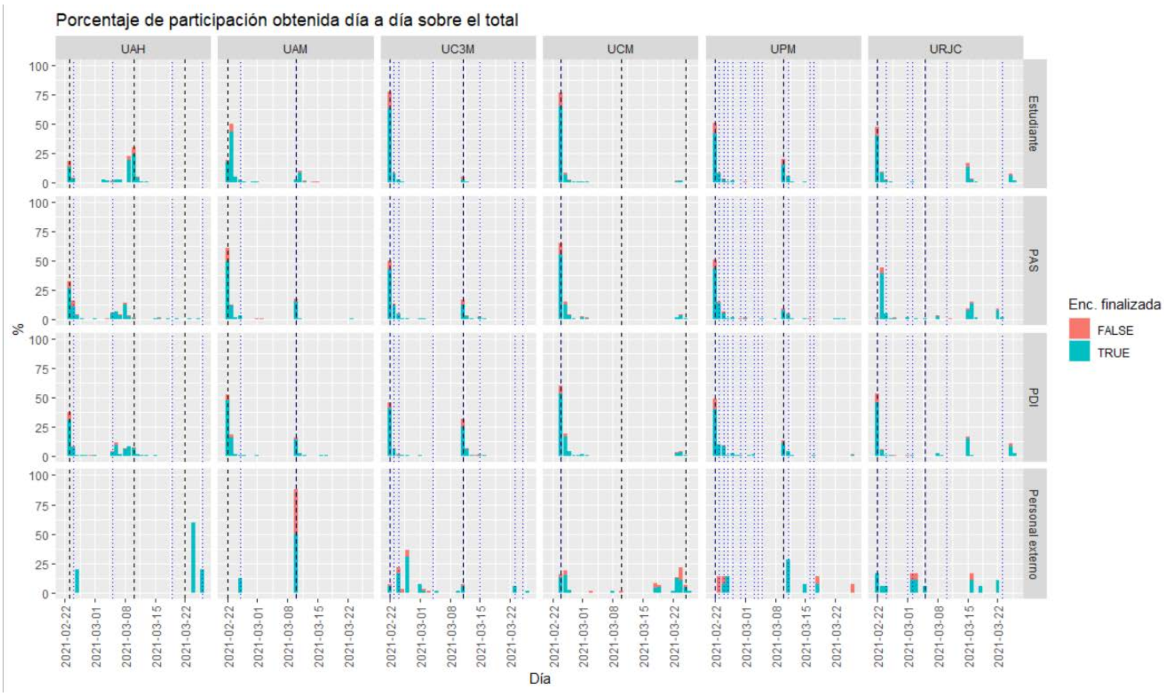

Figura 4. Porcentaje de participación obtenida día a día sobre el total por universidad y colectivo.

Se puede observar cómo los colectivos a los que se les pudo enviar mensaje directamente desde las universidades, es decir todos los colectivos salvo el personal de servicios externos, siguen una pauta similar. Sin embargo, mientras las llamadas de participación tienen un efecto muy puntual y concentrado en el día del envío del mensaje sobre el colectivo de estudiantes, el mismo efecto se prolonga, en cierta manera, a uno o dos días más en los colectivos PAS y PDI.

En relación con el efecto de redes sociales (Twitter) parece ser que estas acciones no han tenido efecto sobre la participación. Las cuentas de interés de las universidades generaron un total de 55 tweets y retweets, de los cuales, el 40% fueron emitidos durante la primera semana de la campaña. Estos mensajes apenas recibieron interacciones que aumentasen la difusión de la comunicación de la encuesta. De media, cada tweet era retwiteado menos de 5 veces, obtenía 3 “me gusta” y apenas tenían interacciones en forma de respuestas o citas; además, gran parte de las interacciones se recibieron durante la primera semana.

Un caso de estudio son las cuentas de interés de la UPM, que enviaron un total de 27 tweets y retweets en todo el periodo de la campaña de la encuesta. La cuenta general de la UPM (@La_UPM) tenía unos 44.500 seguidores durante la campaña, mientras que la cuenta de la biblioteca (@biblioUPM) casi 4.000 seguidores. Los mensajes relacionados con la campaña de encuesta tuvieron la misma reacción en ambas cuentas en cuanto a número de veces que estos fueron retwiterados, no así en cuanto al número de “me gusta” en cuyo caso el que solamente la cuenta @La_UPM recibía este tipo de interacción.

En relación con la hora de inicio de las encuestas (Figura 5), la gran mayoría de las encuestas (90%) se iniciaban entre las 10 y 20 horas, para todos los colectivos y universidades, y tanto para encuestas finalizadas como para las no finalizadas. Este comportamiento era el esperado puesto a que son horas en que hay actividad académica.

Los días cuya hora mediana se acercaba a alguno de los extremos del 90% de respuestas suele coincidir precisamente con días con poca participación. Obsérvese que estos resultados tienen una gran variabilidad, debido precisamente a la disparidad de número de encuestas obtenidas pudiéndose considerar un comportamiento casi aleatorio de la hora de inicio en dicho, y sin envío de correo electrónico.

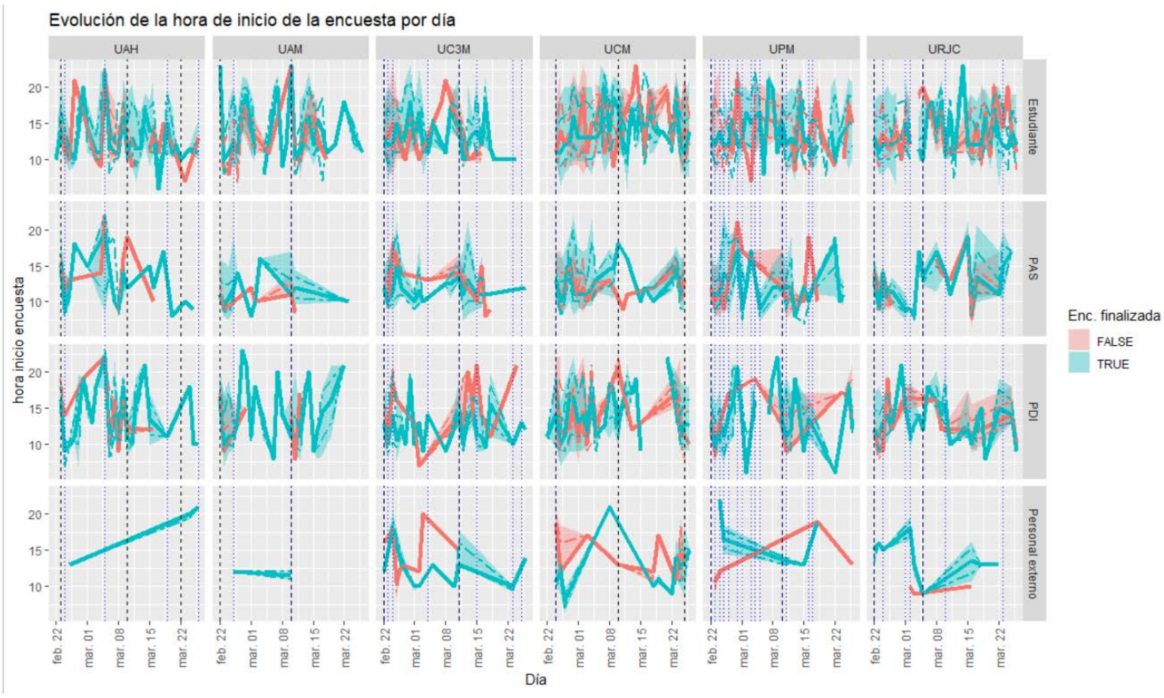

Figura 5. Evolución de la hora de inicio de la encuesta por día, colectivo, universidad y separado entre finalizadas y no finalizadas. La línea gruesa hace referencia a la hora media, las líneas discontinuas hacen referencia al valor del primer cuartil (inferior) y tercer cuartil (superior) y la sombra hace referencia al intervalo de tiempo que contiene el 90% de las respuestas de ese día (P10-P90).

Finalmente, otro indicador de interés era el tiempo que se dedicaba a la encuesta. El 95% de las encuestas necesitaban menos de 60 minutos para completarlas, siendo el 5% restante encuestas no finalizadas hasta que SurveyMonkey cerraba sesión. La evolución del tiempo necesario para las encuestas realizadas en menos de 60 minutos puede verse en la Figura 6.

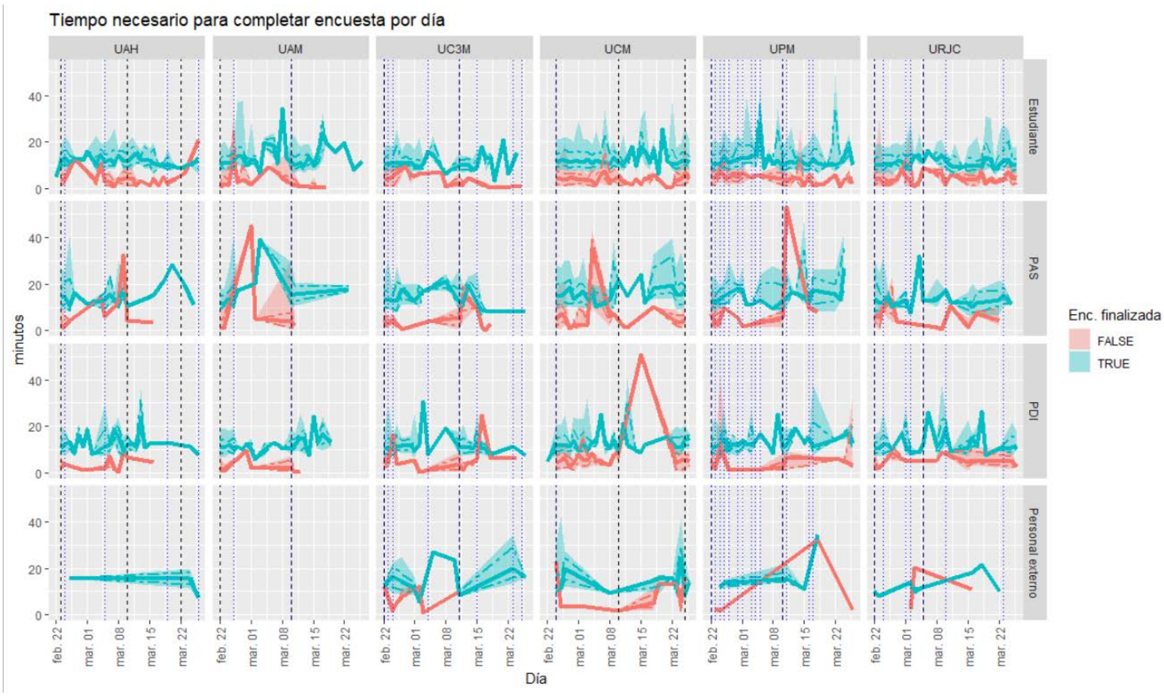

Figura 6. Evolución del tiempo usado en cada encuesta, por día, colectivo, universidad y separado entre encuestas finalizadas y no finalizadas. La línea gruesa hace referencia a valor mediano del tiempo requerido para la encuesta, las líneas discontinuas hacen referencia al valor del primer cuartil (inferior) y tercer cuartil (superior) y la sombra hace referencia al intervalo de tiempo requerido para realizar la encuesta que contiene el 90% de las respuestas de ese día (P10-P90).

Se observa una cierta igualdad en el tiempo de respuestas por colectivo y universidad, no así por si la encuesta se finalizaba o no. El valor medio de las encuestas finalizadas para todos los días rondaba los 15 minutos, que era lo estimado, sin embargo, el colectivo de estudiantes parece que requirieron de un poco menos de tiempo que el resto, salvo en casos muy puntuales en días en los que había poca participación y para los casos en los que se presupone que se cerraba la sesión voluntariamente antes del cierre automático. En el caso de las encuestas no finalizadas solían requerir menos tiempo.

Las campañas de comunicación parecen no tener efecto sobre los tiempos necesarios.

7. DISCUSIÓN Y CONCLUSIONES

La campaña de encuestas del Plan de Movilidad Universitaria Sostenible se realizó en unos tiempos atípicos debido a las restricciones por la pandemia de la COVID-19. Sin embargo, el haber alcanzado más de 35.000 encuestas en los campus presentados en esta comunicación, lo que representa un 17% del total de la comunidad universitaria es un éxito.

En general, parece que el envío masivo de la carta mediante al correo institucional es la acción de comunicación que mayor efecto ha tenido en la participación, especialmente para los grandes colectivos de la comunidad universitaria.

Este hecho puede remarcar la importancia de mostrar públicamente el apoyo a este tipo de encuestas y participar en acciones de comunicación por parte de las máximas autoridades académicas de cada universidad. Por otro lado, se podría considerar que el envío del correo electrónico pudo haber tenido mayor efecto que en otras circunstancias por el hecho de realizar una gran parte de la actividad académica diaria en formato virtual que pudo provocar una mayor atención a dicha vía de comunicación y, en consecuencia, fomentar la participación.

El resto de las acciones de comunicación parecen que no han tenido ningún efecto, tanto por el hecho de no haber visto ningún efecto en los días en los que éstas se aplicaban como por la baja interacción reportada.

La campaña de encuestas del PMUnivS se pueden realizar las siguientes recomendaciones relacionadas con el objeto de esta comunicación de cara a futuras campañas similares:

- En cuanto a las estrategias para animar a la participación, se podría recomendar el implicar a las máximas autoridades de la universidad en las acciones de comunicación puesto a que parece favorecer la participación. De la misma manera, que los perfiles de redes sociales a usar por la campaña de encuesta tengan un elevado número de seguidores antes de comenzar la campaña, esto requeriría ir, poco a poco, generando la red mediante la publicación de tweets que pudiesen convertir a estos perfiles en los referentes de la movilidad universitaria (noticias, avisos y miscelánea relacionada con el objeto de la encuesta). En relación con el material físico de apoyo, éste debería tener tanto el enlace a la encuesta, preferentemente vía código QR, y el nombre de los perfiles de las redes sociales.
- En relación con el seguimiento de las estrategias para animar a la participación y detección de comportamientos anómalos, se podría recomendar el incluir dentro de la encuesta preguntas del tipo para saber cómo ha conocido la encuesta, y si la ha contestado al momento de recibir el enlace o ha esperado, entre otras.
- Finalmente, y en relación con la investigación sobre los efectos de la comunicación, se aconsejaría que en próximas campañas las acciones de comunicación también se diseñasen, desde el principio, incluyendo este tema como objeto propio de la investigación. Especialmente en situaciones de relativa normalidad en la que se pueda comparar el efecto de las acciones físicas con las acciones virtuales.

AGRADECIMIENTOS

Los autores de esta comunicación agradecen a los responsables de los diferentes campus y universidades públicas presenciales de la Comunidad de Madrid participantes las horas dedicadas para garantizar el éxito de la campaña de encuestas del PMUnivS. También agradecen a las consejerías de Transportes, Movilidad e Infraestructuras, y de Ciencia, Universidades e Innovación de la Comunidad de Madrid y al Consorcio Regional de Transportes de Madrid (CRTM) por la iniciativa de redacción del PMUnivS y la financiación de ésta.

ABSTRACT

64% of total trip-km are made in urban environments and these phenomena threaten urban sustainability (Van Audenhove et al. 2014). In the last decades, cities have been applying different policy measures to reduce car use. But they have notable limitations and usually produced small impacts (Sunio y Schmöcker 2017).

Smartphone has emerged as a promising alternative tool to enhance the effects of the policy interventions, because it can overcome several limitations and improve their efficient adoption of sustainable options. Travel apps can be very useful because they provide accurate and real-time information. In addition, user-created information could greatly reinforce information from operators.

A review of the literature of 98 recent papers was performed. It had two main objectives: which factors influence commuters to use travel apps; and second, what persuasive interventions supported by travel apps produce changes towards a more sustainable mobility behavior.

Some facets offered by apps are effective for changing travel behaviour: individualized advice, feedback on one's own behavior and social comparisons between users. The GoEco! experimental travel app, provided feedback and social comparisons on travel behavior among users (Cellina et al. 2019). It was found to produce a statistically significant change in individual mobility patterns.

Travel apps remain underutilized, especially in suburban travel. Scholars found factors that influence app usage: curiosity, expectations of increased utility, attractive design and performance attributes are influence factor for app usage.

In contrast, environmental motives, privacy (desire not to share information) and age (older people are less likely to adopt apps) do not influence or do so not significantly.

The findings of the literature review show that, moreover, to increase apps usage, app design and implementation requires different strategies for each segment of the population.

There are groups of people who are more likely to use apps (e.g., technophiles and young people).

1. INTRODUCTION AND BACKGROUND

This article consists of a systematic literature review on the potential impact of the use of travel apps as a tool to reduce car use in cities, specifically in the periphery.

While in the core of metropolitan areas there is an increased use of travel applications and the modal share of total sustainable travel modes is often important, this not the case in the outskirts.

Almost 50% of the population of OECD (Organisation for Economic Co-operation and Development) countries live in urban areas (OEDC 2016) due to better economic opportunities and the availability of services. Cities are facing an accelerated sprawling process, increasing travel distances, making public transport systems less competitive, and becoming suburban mobility more car dependent. As a consequence, 64% of total trip-km are made in urban environments and is expected to triple by 2050 (Van Audenhove et al., 2014).

These phenomena threaten urban sustainability (Lyons, 2018) because of their well-known impacts, not only on the environment but also on social and economic issues, such as distributive effects, equity and mobility justice (Pereira, Schwanen, Tim y Banister 2017).

Therefore, there has been a challenge for several decades to persuade commuting through sustainable travel modes. And multimodality is an attribute of travel that increases sustainability.

Measures implemented to pursue that challenge have been generally classified as hard and soft. Soft measures started to conduct by public administrations due to hard measures often requires too high investments.

Soft measures look for to change travel behaviour towards sustainability ways. Soft measures have been implemented through, what is most generally called, Travel Behaviour Change Programs (TBCP). TBCP began to be implemented approximately 20 years ago.

At the same time, urban lifestyles and mobility needs are adapting to the requirements and opportunities of the digital age, characterised by the use Information and Communication Technologies-based activities (Mokhtarian 2009). Smartphone arrival has impacted our daily life. In the transportation field, it has emerged as a promising alternative tool to enhance the effects of the TBCP interventions, due to it can overcome several limitations.

This literature review has two goals:

- Firstly, to review the state of the art and practice regarding the factors of travel apps adoption. Two main groups of elements can be identified: the internal, regarding the app itself, and the external related to the user characteristics. The internal ones include aspects such as simplicity, appearance, performance, integration of modes, ticketing, etc. The external factors are related on the user personal traits, social norms, socio-economic and geographical features, etc.
- Secondly, to conduct an exhaustive analysis of the so called 'persuasive interventions' to foster the modal transition. Recent findings suggest that real time informed decisions tend to be sensitive to sustainability and social impacts. We aim to conduct a literature review to extend their impacts as driver for persuasive interventions for motivating changes towards sustainable metropolitan mobility. Apart from public transport information, there is a growing interest to explore the link between public transport and Park & Ride facilities. This option is not properly connected with travel apps, then users do not take informed decisions when accessing by car to city centres.

This article is framed within the U-MOVE research project, funded by the Ministry of Science and Innovation (PID2019-104273RB-100). "U-MOVE" is the acronym for "Intelligent strategies for sustainable urban mobility: the role of travel apps".

2. METHODOLOGY

A systematic literature review was carried out with the aim of working with the most complete sample of available scientific publications. For this purpose, the Scopus database was chosen due to its high scientific impact, the diversity of databases that comprise it and the versatility of the subject matter and formats or types of documents it supports (De las Heras et al. 2021). The literature selection scheme is shown in Figure 1.

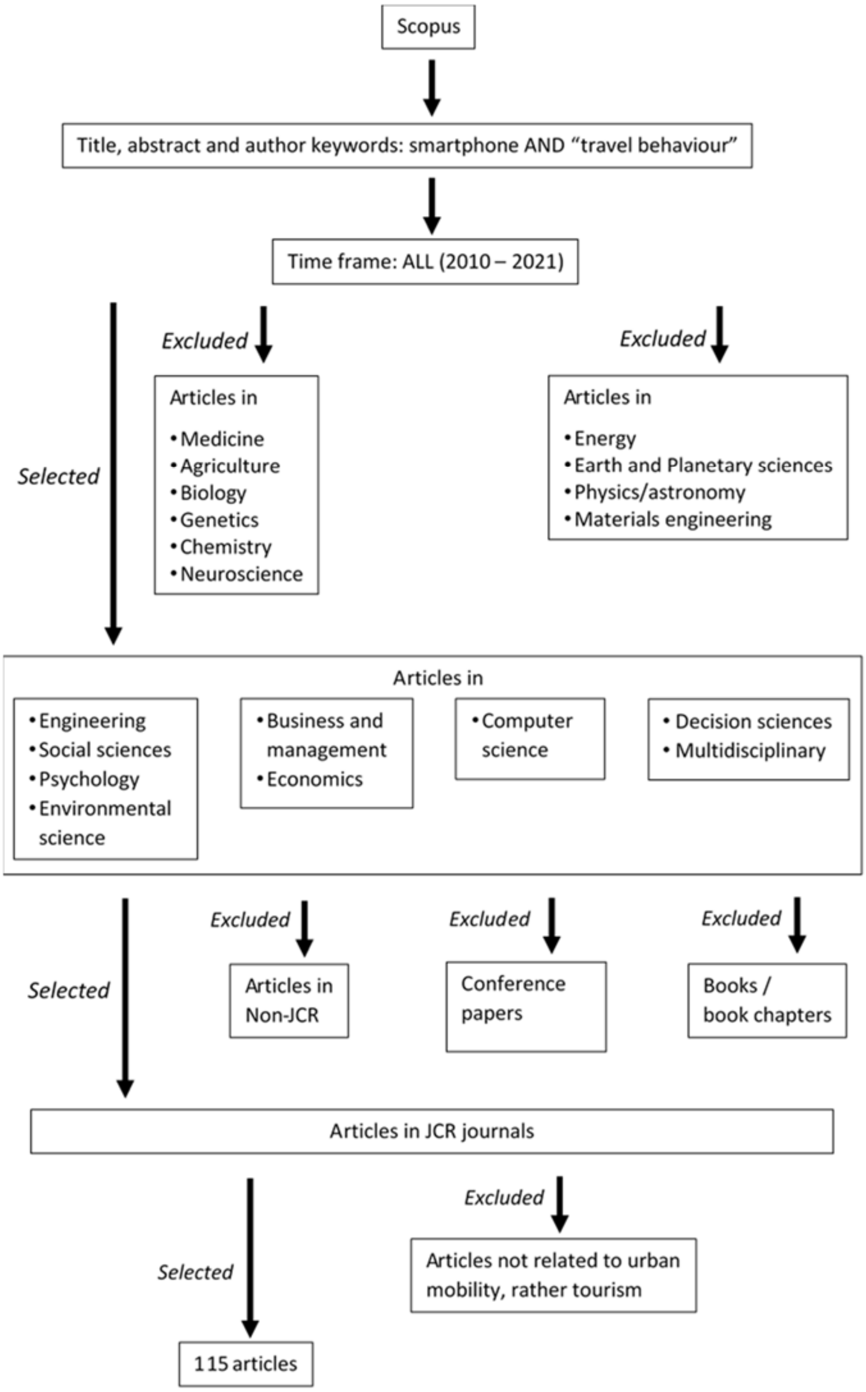

Figure 1 – Process of selection and exclusion of papers indexed in Scopus.

The keywords used in Scopus had to be related to the influence of the use of travel apps on the reduction of car use. The keywords were: 'smartphone', 'travel behaviour'. The query string used was: smartphone AND “travel behaviour”.

Author title, abstract and keywords were used as search fields. Otherwise, articles in which "smartphone" and "travel behavior" are not a key part of their content could have been considered. Further filters were used to select the most relevant articles for this research.

Regarding the subject matter of the articles, those that were considered unrelated to the research were excluded. As for the type of document, only articles published in JCR journals were considered. Finally, an important part of the papers related to 'tourism' and not to mobility were not considered. For this purpose, 'NOT tourism' was added to the query string. Finally, 115 scientific articles were selected for the literature review.

VOSviewer is a bibliometric and network analysis software (van Eck y Waltman 2013). It is a very valuable tool for a literature review and has been widely used for this work.

From the list of 115 papers, the VOSviewer software was used to find out the most relevant keywords. The software has different utilities and, in this case, attention was paid only to the keywords. It was obtained: a) a graph of co-occurrences with the keywords and, b) a list of the keywords and the number of papers (from the list of 115) in which they appear.

In order to ensure that the literature review includes the most studied concepts in the discipline, the keywords with the highest number of occurrences were selected. Finally, of the 115 papers, only those in which one of these keywords appeared (in title or abstract or author keywords) were studied in depth.

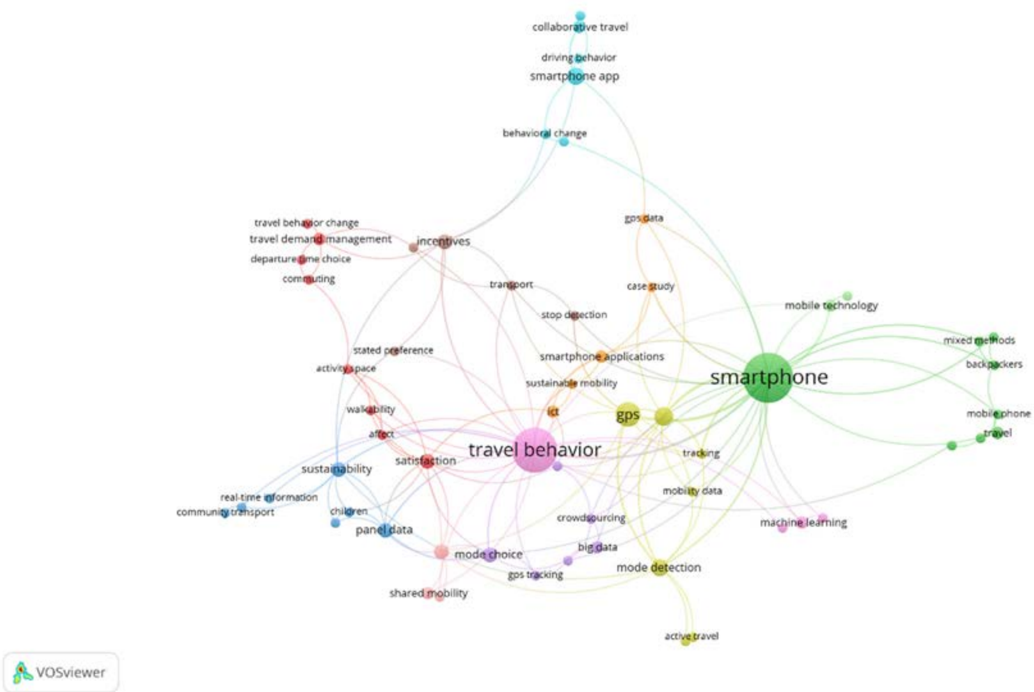

Figure 2 – Map of co-occurrences of keywords (from the title, abstract and author's keywords). Source: VOSviewer.

Figure 2 shows shows the co-occurrence map obtained through VOSviewer. The coloured balls “smartphone”, “travel behavior” and “GPS” are the largest, so these keywords have the highest number of occurrences in the list of 115 papers.

Position	Keyword	Occurrences	Total link strength
1	Smartphone	29	19
2	Travel behavior	24	17
3	GPS	9	13
4	Travel survey	6	11
5	Mode detection	5	9
6	Smartphone app	5	1
7	Incentives	4	4
8	Mode choice	4	7
9	Panel data	4	7
10	Public transportation	4	5
11	Satisfaction	4	4
12	Sustainability	4	5

Table 6. Classification of the occurrence of keywords (in the title, abstract and author keys). Source: own elaboration.

Table 6 shows the number of occurrences of the keywords. "Smartphone", "travel behaviour" and "GPS" have the highest number of occurrences: 29, 24 and 9, respectively.

The keywords "smartphone", "travel behaviour" and "GPS" were selected. 98 of the 115 articles included at least one of these three keywords. These 98 articles were analysed in depth.

3. RESULTS

This section presents the relevant results of the review of the 98 selected documents that have been analysed in depth.

Cities has been planned for a massive use of the car and a lot of resources are needed to revert the situation. Due to changing the urbanization is highly cost, public administrations has been trying to look for other kind of measures to reduce the car usage. Interventions to modify the commuter travel behaviour, as TBCP, has been implemented commonly last decades.

TBCP programs help to reduce the car usage (Arroyo et al. 2018), but only produce small derived effects (Sunio y Schmöcker 2017). Smartphone arrival may dramatically help to change the travel patterns through mobile apps adoption.

Recently some TBCP programs are starting to carry out through smartphones. They are habitually called technology-based interventions.

They consist of persuasive strategies and are carried out through smartphone travel apps.

3.1 Persuasive interventions to foster sustainable mobility

At the same time, the MaaS approach is a new tool to promote smart mobility with a promising perspective (Jittrapirom et al. 2017). Comparing to interventions programs, like TBCP, MaaS projects do not exactly include explicit persuasion strategies. MaaS concept is still under development, but they are commonly developed through an app that integrates the services of multiple travel modes (public and private) with their related information and generally tries to work through packages subscriptions (Arias-Molinares y García-Palomares 2020). These attributes seem to be useful for the commuters but there is still a lack of pilot evidences.

Cost savings is an important factor influencing the decision to switch to public transportation (Abou-Zeid y Ben-Akiva 2012; De Witte, Macharis y Mairesse 2008). Some people were interested to use UbiGo mobility app (MaaS) because expected to reduce costs comparing to the car (Sochor, Strömberg y Karlsson 2015).

Another important factor to switch from car to public transportation is to have a precise and reliable information about travel modes. There are some studies that affirm a notable misperception with public transport (Abou-Zeid y Ben-Akiva 2011; 2012). One study even stated that 50% of citizens have a significant lack of information about transit alternatives (Brög, Erl y Mense 2002). The quality of public transportation service logically has increased along time (Sukor y Basri 2019).

Travel apps can easily offer multimodal, real-time and reliable information. An experiment was proposed to participants to use an existing travel app called Metropia (Li, Chen y Tian 2021). Metropia provides to user real-time traffic information, travel feedback and distributing monetary rewards. It was found that helped users save 5% - 10% of their travel time, due to avoiding traffic peak hours.

On the other hand, Park and Ride facilities are an appropriate measure to reduce car use (Duncan y Cook 2014). Regarding multimodal travel apps, pilots conducted by academics do not typically include P&R in the multimodal travel system.

Also, existing travel apps typically do not include them. Nevertheless, P&R information included in multimodal information affects travel choices (Gan y Ye 2018). Therefore, travel applications should include P&R information to encourage the modal shift from car to public transportation.

Regarding the MaaS implementation, more than a few MaaS pilot projects have been carried out. UbiGo was the first MaaS experience and consisted of a experiment mobility app. It provided an integrated mobility service (public transport, taxi, carsharing, bikesharing, rental cars) and works through a monthly subscription service. 97% of the participants wanted to continue using UbiGo at the end of the test (Sochor, Strömberg y Karlsson 2015).

Two MaaS projects that have started recently in Asia have been assessed (Chang, Chen y Chen 2019). UMAJI is a mobile platform for trip planning and payment services. The app integrates Metro, bus and public bike services in the Taipei-Yilan corridor of 40 kilometers. There is a monthly pass for using the three services. Public transportation has increased 3,2% in the first 6 months (80% of the increased trips are from the existing users). MenGo is an app of MaaS in Kaohsiung metropolitan, and integrates mass transit (city buses, inter-city buses, MRT, light rail, ferries) and shared transportation (public bicycles). There are four types of monthly service packages. Users of motorized vehicles contribute 21% of MaaS MenGo members.

Due to the positive impacts of travel applications, scholars are studying persuasion features, within travel applications, to switch to sustainable modes. For example, a prototype app with motivational features was developed for inducing sustainable travel choices: goal setting (inviting users to set weekly goals), self-monitoring, encouragement (personalized messages according the user profile and travel behavior) and social-sharing features (leaderboard of participants eco-scores weekly provided). An improvement in the use of sustainable modes of 14% was found (Gabrielli y Maimone 2013).

Social comparison is one of the strongest motivational features. Favorable comparisons to others (e.g. shorter commute time than others) enhance commute satisfaction (Abou-Zeid y Ben-Akiva 2012). It has also been featured by a persuasive travel app called GoEco! that exploits information feedback elements and promotes a social comparison of their performance, within a gamified framework. It was found to bring about a statistically significant change in systematic individual mobility patterns, reducing both energy consumption and CO2 emissions in Ticino, where car-dependency is deeply rooted. In Zurich, where individual mobility patterns are already optimized and car-dependency is lower, no significant effects were found (Cellina et al. 2019).

Some authors concluded that including feedback information to the participants in persuasive smartphone applications is a successful factor for promoting a sustainable travel behaviour (Andersson, Winslott Hiselius y Adell 2018; Li, Chen y Tian 2021). Feedback on one's travel history can affect one's awareness of their impact on the environment, intentions to change behavior, and actual behavior change" (Jariyasunant et al. 2012)). Feedback information may include a behaviour comparison among travel app users.

The registered information of the travel application can be processed according to the characteristics of the user and provide personalized/individualized advice. It would be a step beyond simple feedback information. It is known that individualised advice is an effective persuasive technique (Cellina et al. 2019; Fujii y Taniguchi 2006). The reasons behind each person chooses to commute in a specific mode of transport are different from those of the others. (Cellina et al. 2019) experimented the use of GoEco! app that provided "bicycle and walking-friendly suggestions for alternatives and weather-aware personalized recommendations, challenges and badges". (Gabrielli y Maimone 2013) developed a prototype mobile app that sent personalized messages encouraging sustainable travel choices according to his profile and travel behavior. An improvement in the use of sustainable means of transport was observed. (Ahmed et al. 2020) developed an algorithm that determined realistic walking, cycling and public transport potential in an activity-travel routine of an individual by considering constraints related to personal, household, mobility and urban environment.

Individualised advice may be mixed with social comparison techniques. (Jariyasunant et al. 2012) carried out an experiment developing an app which unobstrusively tracked users location and with that collected data participants received feedback (in a website) with trends and comparisons with various peer groups. They observed a significant shift from driving to walking.

Some scholars have assessed planning trips as a proper alternative towards reducing car dependency. Planning a trip consists of basically to evaluate which is the best alternative to arrive to a specific destination. If a Travel Feedback Program (TFP) required participants to create a behavioural plan for their travel behaviour, it resulted in a dramatic increase in TFP effectiveness in terms of behaviour change (Fujii y Taniguchi 2006).

Recorded travel information of the commuter may be a great tool to create and suggest personalized behavioural plans. Based on the recorded travel diary of the individuals, a website was developed with pro-environmental personalized travel plans that were suggested along with pro-environmental and pro-health impacts (Ahmed et al., 2020). It was found a decreasing in car dependency and increasing in physical activity.

Experts agree that market targeting is key to effective persuasion interventions. Persuading interventions to foster public transport may be more effective for non-riders than for frequent riders (Fujii & Taniguchi, 2006). An experiment was carried out encouraging MIT university pupils with free public transportation tickets and was found that free public transportation tickets worked better for commuters more inclined to switch (Abou-Zeid & Ben-Akiva, 2012). Related to this, an study affirmed "it is not fruitful to convince Devoted Drivers to change transport mode with marketing since they oppose messages that promote sustainable transport" (Andersson et al., 2020).

Travel Feedback Programs may be more effective for new residents (Fujii y Taniguchi 2006). Though that statement could be valid for all the persuading interventions. Logically, new residents have not yet developed habits to commute, and habits strongly influence travel patterns (Pronello, Simão y Rappazzo 2017).

In addition, personal health plays an important role over some commuters and they have preference of active travel. Trips with high walking or bicycling rates have priority over public transit. The experimental web with pro-environmental and pro-healthy travel plans suggested (Ahmed et al. 2020) led to the conclusion that public transport options failed to significantly persuade individuals to shift from car to public transport, but active modes did (walking and cycling).

Regarding the sample limitations of the classical intervention programs (TFPs, TBCPs, etc.), a study explored if programs who consists of providing travel feedback information to the participant (Travel Feedback Programs, TFPs) can be replicated without a travel counselor (Jariyasunant et al. 2015). It was developed “a computational system in the mobile cloud” surrogating the travel counselor and the model showed that “the more frequent the interaction with the website, the greater is the increase in the amount of walking/biking”.

3.2 Factors for travel apps adoption

Some experiments showed that smartphone apps influence to change travel choices towards sustainability patterns (Shaheen et al. 2016). A lot of research is being done recently to find out what factors influence the adoption of travel app usage. Although there is a difficulty to quantify the importance of each of the factors studied.

Self-interest was found as the primary interest of trip efficiency improvement for the travel apps adoption intention (Dastjerdi et al. 2019). The main motive (63% of survey respondents) to adopt UbiGo app was the curiosity to know the integrated mobility service could offer them. Many of the respondents stated the desire to not own a car due their work and cost. Ubigo participants expectations regarding the use of travel applications were "To reduce their travel costs, facilitate payment, gain access to more modes of transport, they expected the application to be easy to use and safe" (Sochor, Strömberg y Karlsson 2015).

The app involvement is related to the hedonic and utilitarian benefits perceived (Fang et al. 2017). Hedonic and utilitarian benefits could be classified as self-interest benefits.

Cost and time savings would be utilitarian motives to start to use an app. Real-time and reliable travel information are (also utilitarian motives) an important aspect for commuter travel choice. Travel apps could offer easily that specific information to the commuters. According to (Li, Chen y Tian 2021), “traffic information is strictly in accordance with real-time traffic conditions rather than historical data”.

A survey was carried out for commuters and it revealed that apps like Google Maps do not compete with specific transit apps that include real-time information because daily commuters require that specific information of their routes (Romero et al. 2020).

Regarding the driving time estimation reliability of the apps, Google Maps underestimates the total driving trip time in urban areas when parking places are scarce (Wagner et al. 2021). The estimate does not include the specific time spent parking and walking time to the car from the origin and from the car to the destination. A time estimation model was developed to search for on-street parking (Mannini et al. 2017) and it could supplement the driving time estimate provided by travel apps.

To be entertaining, enjoyable (Gupta y Dogra 2017) and easy to use (Gupta y Dogra 2017; Dastjerdi et al. 2019; Fang et al. 2017) are important factors for using apps. Those aspects are generally called as hedonic motivation, that influences behavioral intention to use apps. These factors are related to the performance app, that is an influential factor for using apps that involves several features. Based on a hedonic motivation perspective, regarding the game elements of app including self-monitoring, information sharing and bonus point collection could be considered as game elements of the app (Seebauer, Stolz y Berger 2015).

There are also individual motivations that come from social aspects. (Seebauer et al., 2015) relate that social motivation to social comparisons and assert the possibility of competition between them if individuals share their information through social media. “In the field of social psychology, sociology and marketing, this is known as social value reflecting the (positive or negative) outcomes of the ownership and use of a product for one’s (self-) identity and social status. It is viewed as the product’s ability to develop social self-concept”. According to (Fang et al. 2017), social interaction is a factor to influence use intention of travel apps.

Social motivation could be also related to the privacy. Maybe it should not be called social motivation, but more precisely privacy barrier. Real-time information is required by the apps, and it could be provided by the transport authorities and operators or by the users. Regarding the users, not all of them share their information or evaluation services. Privacy, safety and even security could be the cause to not share information (Magano y Cunha 2019). Regarding collaborative travel, an study was carried out and concluded that safety has a highly importance, being data privacy a core issue (location data being made available to other users) (Dickinson et al. 2017).

Related to safety, privacy and security in collaborative travel is social trust. The strength of social ties plays a marked role in collaborative travel. Successful implementation is more likely in communities where social ties are established (Dickinson et al. 2017), or in regions where social trust is high.

If the app only suggested traveling with someone who is in your circle of friends, or acquaintances, it might work. But there would be a great difficulty in defining which is each person's circle of friends. The user could define a list of friends, or at least "travel friends".

In addition, environmental-friendly attributes are another notable non-monetary aspect to app adoption (Seebauer, Stolz y Berger 2015). In the specific case of car sharing, (Mattia, Guglielmetti Mugion y Principato 2019) affirm that “Environmental drivers affect the intention to re-use free-floating car sharing to a lesser extent than the utilitarian motives”.

This would confirm (Dastjerdi et al. 2019) when they state that self-interest as the primary interest to app adoption. “Environmental awareness, favorable attitude toward travel information technologies, performing conservation behavior, and a personal desire to participate in organized environmental activities, affect individuals’ perceptions of the benefits of the travel app (Mehdizadeh Dastjerdi et al. 2019).

For increasing the apps usage, segmentation of the target population is recommended to better customize to user’s profiles (Andersson, Winslott Hiselius y Adell 2018). It is important to know the target population, their needs and expectations, and to account for specific groups of users (Dastjerdi et al. 2019). (Dickinson et al. 2015) state the need to identify and attract potential users and illustrate how the travel app might meet their needs and benefit them.

There is an important relationship between the personality of individuals and the degree of acceptance of the technology. The idea of technophilia indicates the affinity for technology. According to (Svendsen et al. 2013),“the pattern of influence (from personality traits to technology acceptance) will differ depending on the technology or service in question”. (Velazquez, Kaplan y Monzon 2018) point out that user’s expectations on the app, affinity for technology (technophilia) and the previous use of other transport apps are factors that influence app use intentions. Technophilia is a statistically significative factor for explaining the willingness to use a travel app both everyday and exceptional trips (Seebauer, Stolz y Berger 2015).

Travel app developers and transport operators could focus their campaigns to strengthen the travel app involvement and transit use on the technophiles (Seebauer, Stolz y Berger 2015), due to those are easier to engage and they may convince to others. The difficulty to approach the individual’s affinity for the technology might be reduced thanks to a study of (Seebauer, Stolz y Berger 2015). They have established the validity of a technophilia measure through a survey of seven questions.

"Public engagement is important in ensuring the success of the system implementation" (Seebauer, Stolz y Berger 2015), due to "public acceptability of sustainable solutions could be triggered by public engagement". Therefore, technophiles are a proper segment to start to use the apps. Psychological involvement is related to the social benefits perceived, and the hedonic and utilitarian too (Fang et al. 2017).

Regarding sociodemographics, the age is a factor that explains the willingness to use a travel app (Seebauer, Stolz y Berger 2015). (Dickinson et al. 2017) tested a collaborative travel app, and age emerges as a smaller barrier to app adoption. In addition, (Seebauer, Stolz y Berger 2015) found that technophilia attribute allows more precise customer segmentation than its sociodemographic proxies age and gender.

According to (Fang et al. 2017), both app design and performance attributes are important factors for the use adoption. (Andersson, Winslott Hiselius y Adell 2018) agreed that appealing design is an essential factor for app usage and (Dastjerdi et al. 2019) remarks that design needs to be implemented from an user's perspective.

In addition, there are some technological factors that also influence to use the apps. Relative advantage is the name of the degree to which an innovation is perceived as being better than the previous ways of performing the same task and (Fang et al. 2017) affirm is a factor that influence potential users to app adoption. Other significant technical factor is what is called as app portability, that is related to use the app through the different mobile operating systems (Android, Mac Os, etc.) (Rogers 1995).

4. DISCUSSION AND CONCLUSIONS

In the last decades, governments have been applying different types of intervention programs in existing transport systems, besides large investments to upgrade service quality, in order to reduce car use. But these interventions have produced usually small impacts.

The advent of smartphones could overcome these limitations and travel apps are a promising tool. Some objective key aspects of travel apps that can improve the current information is manyfold:

- Apps provide a lot of information about travel alternatives (both real and non-real time). Non-users tend to have a notable misperception about public transport and travel apps could easily provide accurate, useful information. Real-time information may be a powerful tool provided by apps and this real time information may be highly enriched if it could reinforce the operators' information with information created by the very users.

- Apps provide personalized advice, based upon registered information. A plan for commuting over a period (for example, each week) is known to be an effective measure.

As a consequence of the previous aspects, apps provide travel time and travel cost savings, usually by means of combination of different modes of travel, this including park and ride.

Apps are a tool of persuasive strategies for sustainable travel behaviour in several aspects:

- Individualized advise is an effective persuasive technique. Apps ~~can~~ provide feedback information about one's behaviour, which is a successful factor for promoting a sustainable travel behaviour.
- Social comparisons can affect notably the individual behaviour.
- comparison of behavior among travel app users could reinforce adoption

Some are strong factors for adoption:

- Curiosity is an initial strong motivation.
- Appealing design, portability and performance attributes are important factors for app adoption. Being entertaining, enjoyable and easy to use are other important factors. Self-monitoring or information sharing can be considered entertainment elements of the application.
- Privacy, and even security, could be the cause not to share information. Many users do not want to share their information. Clear policies in this field are a must.
- Expectations of increased utility (reduce travel costs, have access to more travel modes, etc.) may influence the adoption of apps.
- Social motivation is related to the social comparison and there is a possibility of competition between individuals if they share their information through social networks.
- Social acceptability may be triggered by public engagement.

Environmental motives are not important factors for adoption, although some analyses point out that having a good image of oneself influences behaviour. But compared to utilitarian motives, environmental ones are less important.

In any case, app design and implementation require some population segmentation:

There are groups of people who are more likely to use apps. These groups are suitable segments to start using the applications because they could generate public acceptance or could make an interesting advertisement for the applications. Technophiles are an obvious group to start with.

Regarding sociodemographics, age is a factor that explains most of the willingness to use a travel application. Older people are less prone to app adoption.

RESUMEN

El presente proyecto se plantea como una solución para la disminución de contagio de Covid-19, a partir de la evaluación de diferentes alternativas para el desplazamiento bioseguro desde y hacia el campus de la Universidad Nacional de Colombia Sede Bogotá en el marco de la convocatoria “Hacia el regreso seguro al campus” de la Facultad de Ingeniería. La alta probabilidad de contagio representa un riesgo para las personas que hacen uso del transporte público colectivo dentro de la ciudad, lo que incluye a la mayoría de las personas de la comunidad universitaria que usan este como su principal medio de transporte.

Por ello, se realizó una investigación y estructuración de una aplicación móvil la cual tiene como propósito el uso de carro compartido y se coordinen grupos de bicicletas para movilizarse en estos trayectos.

Como metodología se analizó información de residencia de la comunidad universitaria a partir de bases de datos y encuestas, estas últimas también permitieron identificar vehículos disponibles y disposición para viajar en carro y bicicleta. Por otra parte, se analizaron otras aplicaciones existentes que facilitan la interacción entre las personas para compartir vehículo o generar grupos de ciclistas. Una de las principales razones por las que la gente no usa la bicicleta es la inseguridad, por lo que generar grupos de ciclistas permitiría a los usuarios sentirse más seguros gracias al acompañamiento brindado por otros compañeros. Además, se evidenció un alto interés de los encuestados por participar de estos grupos y se observó que los viajes en bicicleta dentro de la facultad se duplicarían respecto al antes y después de la emergencia sanitaria, pasando del 15% al 30%.

Finalmente, con el apoyo de un profesional especializado se inició la estructuración y generación de una aplicación móvil que contenga las principales funciones necesarias para la creación de grupos para la movilidad segura.

1. INTRODUCCIÓN

La elaboración del proyecto se proyectó para ser una herramienta fundamental como medida de prevención del contagio, de modo que llegado el momento de retornar al campus universitario sea posible hacerlo exitosamente, con la logística implementada.

La metodología de trabajo cumplió con los siguientes objetivos: Recopilar y analizar información de residencia de los miembros de la comunidad universitaria, vehículos disponibles y disposición para realizar viajes en otros modos de transporte (carro y bicicleta) considerando el acompañamiento y la creación de grupos para un viaje bioseguro.

Por otra parte, se planteó analizar aplicativos existentes en el mercado, que facilitan la interacción entre la persona que posee el vehículo particular y aquellos que comparten un origen o destino cercano a su vivienda, sitio de estudio, sitio de trabajo y/o ruta de transporte; y a su vez se propuso comunicar y juntar a aquellas personas que usan la bicicleta como medio de transporte, creando grupos de ciclistas que cumplan con las características mencionadas anteriormente y que puedan realizar su viaje compartido de forma segura, esto con el fin de incentivar el uso de la bicicleta como medio de transporte sostenible; principalmente se busca que estos aplicativos sean adaptables al contexto universitario y la situación de emergencia sanitaria actual.

Una vez realizada toda la investigación, se plantea, con el apoyo de un equipo de trabajo conformado por profesionales, estudiantes o técnicos especializados, la estructuración de un aplicativo móvil con las siguientes funciones:

• Notificar la ubicación de los usuarios, conductor y pasajeros con el mismo origen, destino o cercanos a la ruta, en tiempo real para la opción de carro compartido.
• Notificar el horario de partida y número de cupos dentro del vehículo, para la opción de carro compartido.
• Para viajes que no tienen el mismo punto de origen, notificar sitios de encuentro con su respectivo horario entre el conductor y los usuarios ubicados en un radio cercano al trayecto.
• Notificar la ubicación y horario de partida de los usuarios, que implementan el uso de bicicleta para transportarse desde y hacia el campus.
• Proporcionar información actualizada a los usuarios de los protocolos de bioseguridad establecidos por el Ministerio de Salud, asegurando el cumplimiento de estos.

El proyecto tiene en cuenta las diferentes opciones para la movilidad, por lo que se pueden llevar a cabo este tipo de viajes asegurando el cumplimiento de todos los protocolos de bioseguridad establecidos por el Ministerio de Salud.

1.1 Carro y bicicleta compartida

1.1.1 Carro compartido

El carro compartido, es una alternativa de movilidad en la cual un grupo de personas que presentan orígenes o destinos similares, comparten un vehículo, ya sea para realizar un viaje puntual o recurrente. Esta práctica, genera diferentes beneficios en materia de movilidad, como reducir la congestión vehicular.

Fig. 1 - Semana del carro compartido, Bogotá. Fuente: http://gaia.gobiernobogota.gov.co/noticias/inscr%C3%ADbete-en-las-rutas-de-la-semana-del-carro-compartido

1.1.2 Bicicleta compartida

La bicicleta se considera una opción sostenible de movilidad, que además mejora la salud integral de quienes hacen uso de ella. Sin embargo, la percepción de inseguridad en la ciudad de Bogotá es un limitante para algunos, por lo que generar grupos que permitan una mayor sensación de seguridad favorece el uso de este modo de transporte.

1.2 Alternativas ya existentes para uso de carro compartido y/o grupos de viajes en Bicicleta

Hoy en día existen diferentes alternativas en el mercado para realizar viajes compartidos, por lo cual, es importante resaltar las características principales de cada una de ellas, ya que algunas funcionan en páginas web, y otras utilizan diferentes herramientas como aplicaciones móviles o páginas en redes sociales.

1.2.1 Nivel Nacional

Se presentan algunas aplicaciones existentes en Colombia para realizar viajes compartidos.

a) Wheels Social

Es una aplicación móvil que permite a sus usuarios ponerse en contacto para concretar viajes compartidos en vehículos particulares, servicios de taxi o planes en bicicleta. Es un servicio seguro y confiable ya que solo se permite la interacción entre colegas de la organización que lo implementa.

La herramienta permite que los usuarios se encuentren en uno de los cuatro roles por cada trayecto que quieran realizar: Conductor, Pasajero, Compartidor de Taxi y Ciclista. Para realizar un match o coincidencia, la aplicación muestra la lista de personas que coinciden con sus intereses de movilidad para que puedan coordinar su viaje compartido. De esta forma se generan las métricas de movilidad con reportes de CO2 ahorrado por los miembros de la organización al compartir con Wheels. Actualmente la aplicación móvil no se encuentra disponible para su uso.

Fig. 2 - Wheels Social, movilidad sostenible.

Grupos de personas que interactúan:

- Colegas: Miembros de una comunidad, como, por ejemplo, universidad o trabajo.
- Contactos: Vecinos, personas que desarrollan actividades deportivas en gimnasios u otras actividades.
- Amigos: Círculo de amigos más cercano. Se pueden importar por medio de la información disponible en redes sociales o la lista de contactos del celular.

Beneficios que se presentan en cada rol del usuario:

- Pasajero: Disfruta del confort que brinda el realizar un viaje en carro particular, a su vez, se pueden presentar ahorros en costos de transporte y tiempos de viaje.
- Conductor: Presenta ahorros en costos de combustible y estacionamiento.
- Compartidor de Taxi: Se divide la tarifa entre los que usarán el servicio, generando ahorros en costos de transporte.
- Ciclista: Se realiza el viaje acompañado de otros ciclistas, esto puede representar un mayor respaldo y seguridad durante el trayecto.

Secuencia lógica para realizar el viaje

Al momento de programar un viaje por medio de la aplicación, se tienen en cuenta los siguientes aspectos:

1. Se crea una cuenta, generalmente relacionada con un correo de uso institucional.
2. Se define una red de confianza, esta red se puede definir a partir de un convenio o equipo de trabajo definido previamente entre una organización, como, por ejemplo, en desarrollado en el año 2017 entre la aplicación y la Universidad de Monterrey.
3. Programación de rutas desde y hacia el trabajo, universidad o sitio de interés, ingresando los puntos de origen-destino. Si es miembro de un grupo institucional de la organización correspondiente, el usuario verá las rutas de sus colegas en el mapa. Para definir rutas se tienen en cuenta los siguientes aspectos para cada rol:

a. Conductor: puede diseñar su ruta o seguir la que el sistema de Google Maps le recomienda.
b. Pasajero: puede definir cuanta distancia está dispuesto a caminar hacia el punto de encuentro con otros usuarios.
c. Compartidor de Taxi: el usuario busca conductores o compartidores de taxi para solicitar un cupo.
d. Ciclista: el usuario define cuanto está dispuesto a pedalear y puede diseñar su ruta según sus preferencias o puede seguir las recomendaciones dadas por Google Maps.

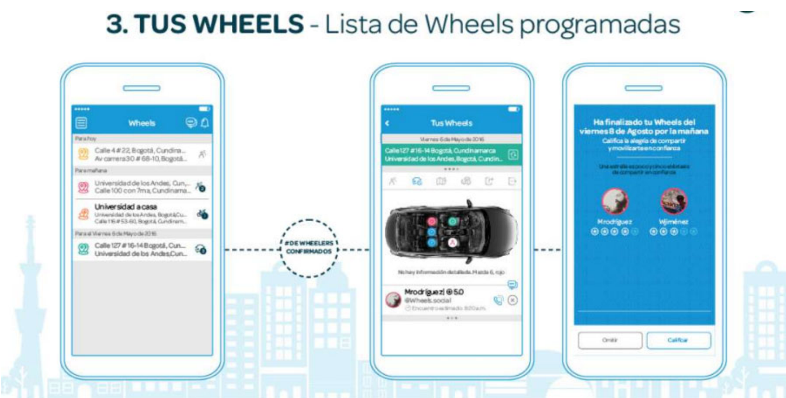

Fig. 3 - Wheels Social, movilidad sostenible.

4. Se escogen los compañeros de viaje y se crea una lista de viajes compartidos programada. En caso de que no se genere un "match", el sistema muestra que no se tienen coincidencias disponibles. En caso de que sí se generen coincidencias, el sistema muestra el número de personas interesadas en compartir el viaje y envía una notificación al conductor informándole el lugar y la hora de encuentro con cada persona. El sistema cuenta con un chat, en donde se confirma el viaje y se pueden realizar algunas sugerencias o consideraciones correspondientes para el viaje.

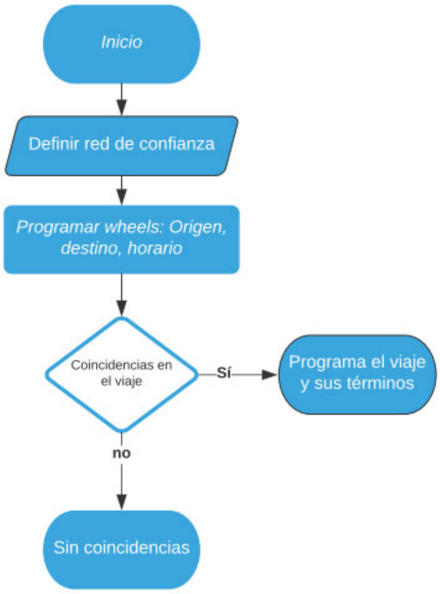

Fig. 4 – Secuencia lógica del funcionamiento de la aplicación Wheels. Fuente: Elaboración propia.

Posibilidad de uso de la plataforma en la universidad Nacional, teniendo como piloto la comunidad de la facultad de ingeniería:

Teniendo en cuenta, que la aplicación Wheels Social, se ha encontrado disponible en Colombia y que se tienen referencias de algunos acercamientos de dicha aplicación con la Alcaldía de Cali, se realizó un contacto directo con uno de sus creadores, el Economista Wilber Jiménez. En la reunión, se evaluó la posibilidad de uso de la plataforma para el desarrollo de este proyecto, sin embargo, actualmente la plataforma no se encuentra disponible para su uso, por lo cual, esta opción se descarta.

b) Transportáme
Es una plataforma que sirve como canal de comunicación entre conductores y pasajeros para que acuerden compartir viajes en sus rutas habituales contribuyendo a la movilidad sostenible. El viaje se puede realizar en la ciudad o entre ciudades de Colombia.

Roles que puede tener el usuario y sus beneficios:

Incluyen los siguientes tipos de viajes en los cuales pueden participar de manera diferente:

Fig. 5 - Opciones de la aplicación

- Carpooling

Al igual que todas las aplicaciones mencionadas Transpórtame cree que una manera de mejorar la movilidad de manera sostenible es el carro compartido. Ellos permiten conectar a personas con el mismo punto de destino, brindan la posibilidad de que los conductores se registren (creación del usuarios y perfiles), registran el vehículo, publican ruta de viaje y los asientos disponibles que poseen. Y los pasajeros realizan la elección a partir de lo publicado por los conductores.

Los beneficios que se tienen como usuario de Carpooling y que implementan la mayoría de las aplicaciones de carro compartido son:

- Asiento propio.
- Compartir los gastos de las rutas con otros usuarios.
- Ayuda a eliminar la contaminación de CO2.

- Motopooling

Al igual que el carro compartido el conductor de la moto indica cuál es su ruta de viaje y si tiene espacio disponible, y de acuerdo con estas decisiones el pasajero decide si tomar el viaje compartido.

Los beneficios de la moto compartida son:

- Viaja en el menor tiempo posible.
- Compartes los gastos de las rutas con otros usuarios.
- Reduce contaminación por CO2
- Evita acumulación de motos en la calle.
- Conecta personas con el mismo destino, creando conexiones.

1.2.2 Nivel Internacional

Se revisaron algunas plataformas existentes a nivel mundial como las que se presentan a continuación.

a) Ciclogreen

Herramienta Española que fomenta la movilidad sostenible en las universidades, empresas y pequeñas ciudades (bicicleta, patineta, transporte público, coche compartido, entre otros). Ayuda a cuantificar y a ahorrar el CO2 originado por los desplazamientos que se realizan a diario. Incentiva a los usuarios con retos y premios.

Funciona en varias plataformas que permiten el suministro de información, registro, y monitoreo dentro de las comunidades que usan la aplicación.

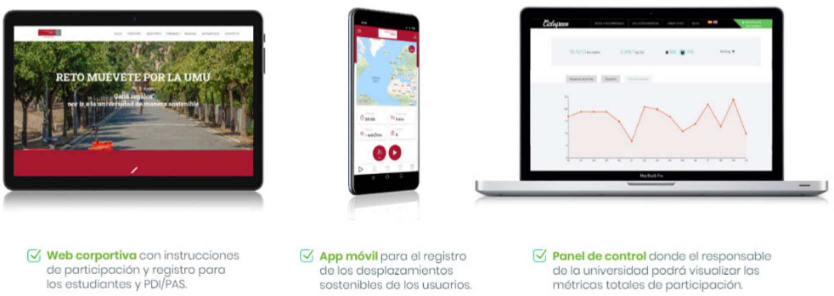

Fig. 6 – Plataformas de Ciclo Green.

Su incentivo al uso por parte de los estudiantes es una de sus grandes fortalezas, pues tienen implementado un sistema de retos que, al momento de cumplirlos, permite la obtención de premios y buenas calificaciones dentro de la aplicación.

Fig.7 - Incentivo de uso de la App.

Su herramienta de carro compartido es similar a las demás, donde el conductor registra ruta, días y hora de llegada, la app le indica a los posibles interesados las opciones que hay para que, por medio de un chat privado, se ponga en contacto con el conductor.

Fig. 8 - Funcionamiento de Ciclo Green.

El uso de un perfil privado con las estadísticas de cada usuario incentiva aún más el transporte sostenible, ya que relaciona cantidad de emisiones ahorradas y la quema de calorías.

Fig. 9 - Perfil privado de los usuarios.

La plataforma recibe gran cantidad de datos de movilidad, que pueden ser visualizados para identificar patrones de movilidad. De igual manera los datos podrían ser utilizados posteriormente para estudios de movilidad.

Fig. 10 - Datos para estudios posteriores de movilidad.

Su éxito se ha demostrado ya en otras universidades españolas.

Fig. 11 - Uso de CicloGreen en otras universidades.

b) BlaBlaCar

Es una aplicación móvil europea para compartir vehículo para viajar entre ciudades. Está presente en España desde enero de 2010, BlaBlaCar se considera la mayor red social de viajes de larga distancia en coche compartido, con más de 90 millones de usuarios en 22 países (5 millones en España). La red social pone en contacto a las personas que quieren realizar un trayecto común y coinciden (conductor y pasajero) para realizarlo el mismo día.

Los usuarios pueden adquirir los siguientes roles:

- Conductor: Ahorran en costos del viaje relacionado con costos del vehículo y reciben acompañamiento durante trayectos largos. Puede escoger cuantos pasajeros está dispuesto a llevar y el punto de partida.
- Pasajero: Se ahorra costo de viaje y algunas veces puede ser menor el tiempo de viaje.

Se puede verificar el perfil de conductores y pasajeros permitiendo tener referencias de los usuarios. Según cifras de BlaBlaCar al implementarse el uso de carro compartido en el 2018 se ahorró la emisión de 16 millones de toneladas de CO2.

Forma de pago:
Los usuarios comparten los gastos del viaje sin obtener beneficio. Para ello, BlaBlaCar recomienda en su plataforma una aportación por usuario y trayecto de 0,06 euros por kilómetro, apropiada para la compartición de gastos inherentes a la conducción (gasolina, peaje, mantenimiento, seguros, impuestos, etc.) y limita la aportación máxima que pueden solicitar los conductores de tal manera que no se superen estos gastos y exista un abuso económico por parte de los usuarios.

Secuencia para realizar el viaje y funcionamiento de comunicación:

El conductor es el encargado de publicar origen destino y número de cupos disponibles, después de esto, por medio de un chat entre el pasajero y el conductor se acuerda el punto de encuentro (punto de inicio del viaje) y el punto de llegada.

Popularidad en el mercado:

Según cifras estipuladas por Blablacar cuentan con más de 90 millones de usuarios en 22 países que actualmente cuentan con el servicio, en los cuales han compartido más de 30 billones de kilómetros ya horrado 1,4 billones de euros. Cuenta con 2.8 millones de opiniones entre los usuarios.

c) 1.5 Socialización de diferentes aplicaciones móviles de viajes compartidos en el mundo

- Universidad Politécnica de Cataluña:

Reunión con el profesor Carles Labraña, el cual es un Ingeniero Civil experto en temas de movilidad compartida en Europa, específicamente en el desarrollo de aplicaciones MaaS. En la reunión se realizó la exposición del proyecto y se obtuvieron diferentes elementos que se deben tener en cuenta para el desarrollo del algoritmo de coincidencias, lo aspectos de seguridad, definición de corredores, funciones de la aplicación y posibles proyecciones.

- Universidad de Brasilia:

Reunión con el profesor Pastor Willy Gonzales Taco, el cual es un Ingeniero Civil experto en desarrollo de aplicación móviles para viajes compartidos en la ciudad de Brasilia, participando en proyectos como Caronaphone y diferentes investigaciones en Carona Solidaria.

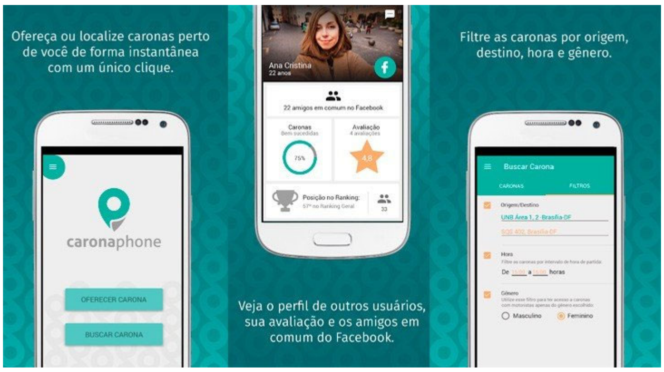

Fig. 12 - Caronaphone.

En esta reunión se realizó una exposición del proyecto UNviaje de la universidad Nacional y el proyecto de Carona solidaria CaronaPhone de la Universidad de Brasilia. En esta reunión, Márcio Batista que fue uno de los creadores de esta aplicación no expuso todos los aspectos tenidos en cuenta para el Design Thinking, los algoritmos de coincidencias, el sistema de interacción con redes sociales, cifras en Brasil de reducción de emisión de contaminantes, entre otros.

2. BASES DE DATOS

2.1 Recolección por medio de encuestas

Como método de participación para la comunidad académica de la Facultad de ingeniería y a modo de actualización de datos, se propuso difundir un formulario en el cual se conociera tanto datos de residencia como preferencias de viaje de acuerdo con los modos de transporte, al igual que el grado de motorización con el que contaríamos para llevar a cabo el proyecto.

Para ello se realizó la pieza gráfica que se muestra a continuación, en la cual como incentivo se promueve la rifa de 3 chaquetas de la TiendaUN que fueron donadas por una empresa externa, y donde también se especifica en qué consiste el proyecto.

Fig. 13 - Póster para viajes compartidos. Fuente: Elaboración propia

Se tuvieron 880 respuestas. Con el apoyo del grupo Ingnova, se realizó una segunda pieza de difusión:

Fig. 14 - Nuevo diseño de Póster para viajes compartidos. Fuente: Elaboración propia

En los resultados obtenidos, se observa el principal vínculo con la universidad de los encuestados:

Fig. 15 - Resultados del formulario vínculo con la universidad. Fuente: Elaboración propia

Dentro de su preferencia, presentan la variación que podemos ver en la siguiente ilustración donde tanto el uso de la bicicleta como del vehículo particular tuvieron prevalencia con aumento de aproximadamente 50% a la hora de desplazarse durante la emergencia sanitaria. Mientras que el transporte público disminuyó igualmente un 50% su uso.

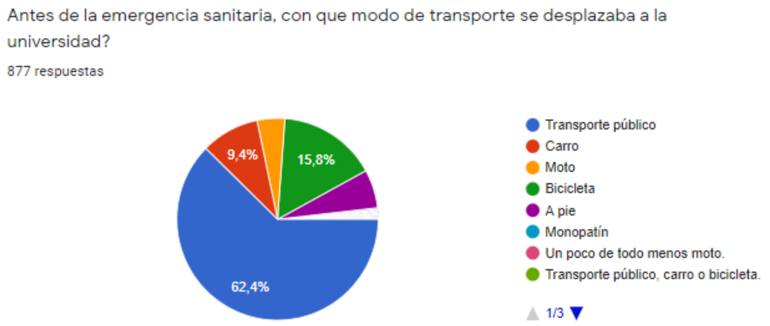

Fig. 16 - Resultados del formulario preferencias declaradas. Fuente: Elaboración propia

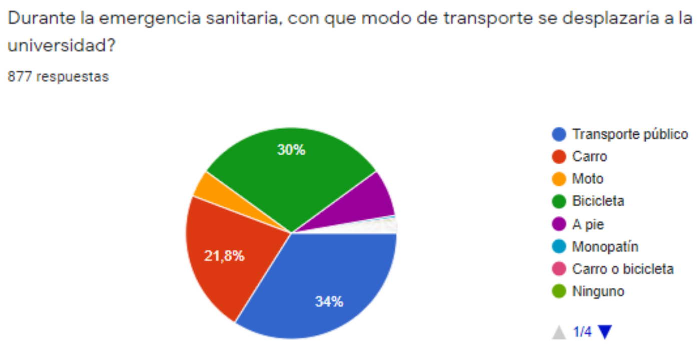

Fig. 17 - Resultados de preferencias de viaje según el modo, antes y ahora en la emergencia sanitaria. Fuente: Elaboración propia

De igual modo, dentro de la encuesta se consultó la intención de participar activamente en el proyecto, obteniendo un resultado positivo con un 85,3% de respuestas afirmativas de participación; a aquellas personas que respondieron que no participarían se les facilitó un espacio en el cual expresaron que su motivo de rechazo era debido a la emergencia sanitaria ya que contaban con familiares de alto riesgo, o el hecho de vivir muy cerca de la universidad para lo cual no requieren ningún tipo de transporte.

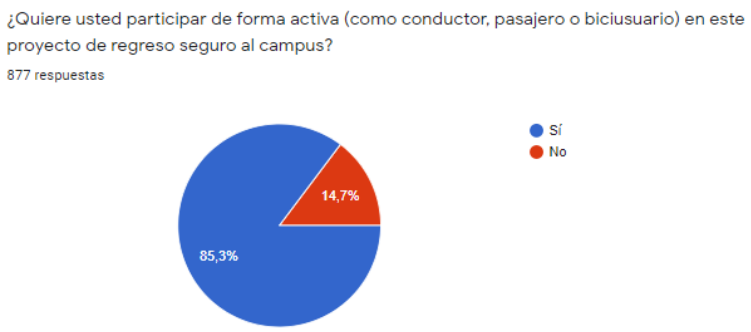

Fig. 18 - Resultados intención de participación. Fuente: Elaboración propia

A partir de las encuestas se realizaron algunos mapas para georreferenciar la ubicación según algunos datos como el tipo de vinculación, disponibilidad de vehículo particular, disposición a movilizarse en bicicleta entre otros. Con el fin de realizar algunos análisis de manera visual.

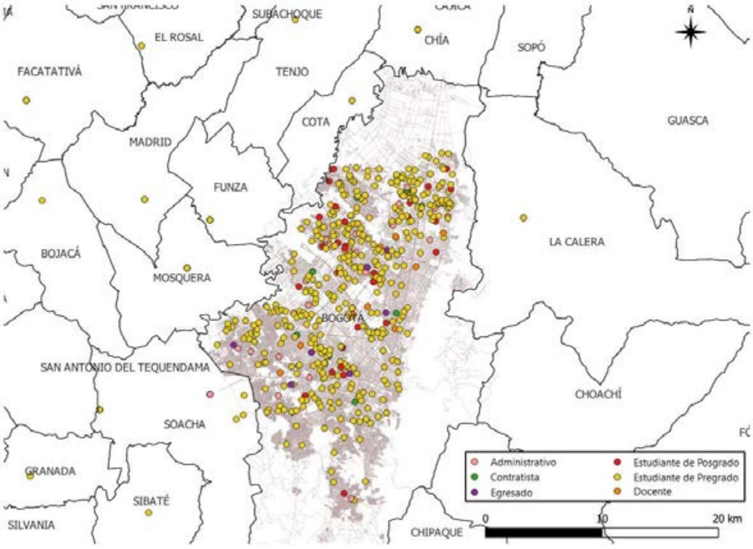

Fig. 19 - Tipo de vinculación de los encuestados. Fuente: Elaboración propia

En la ilustración anterior se evidencia que la mayoría de los encuestados son estudiantes de pregrado y que estos están distribuidos por toda la ciudad y en los municipios aledaños. Por otra parte, como es evidente también de las bases de datos los administrativos y docentes se localizan más hacia el norte y occidente de la ciudad.

En la siguiente ilustración se georreferenciaron los encuestados según el modo de transporte que usaban antes de la emergencia sanitaria, como es lógico alrededor de la universidad se ven en verde algunos miembros que se desplazan a pie. En azul, los que se desplazaban en transporte público, en naranja, aquellos que ya usaban la bicicleta y en negro los que utilizaban el carro particular.

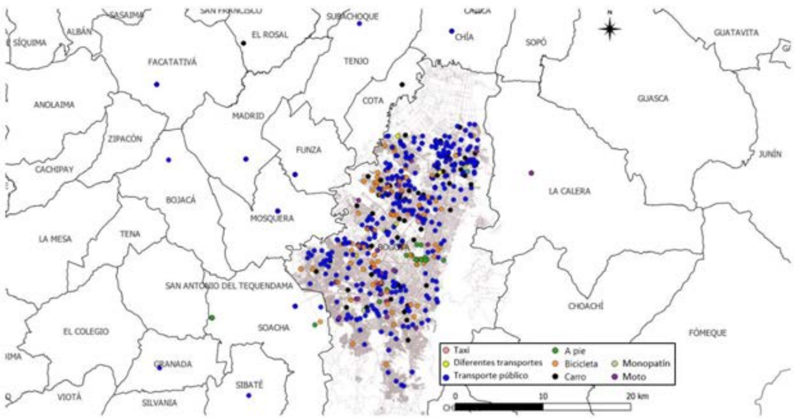

Fig. 20 - Transporte utilizado para los desplazamientos desde/ hacia la Universidad antes de la emergencia sanitaria. Fuente: Elaboración propia

Con la siguiente ilustración podemos ver que quienes tienen una mayor disposición a usar la bicicleta son aquellos que se desplazaban en transporte público, a pie y los que ya hacían uso de la bicicleta.

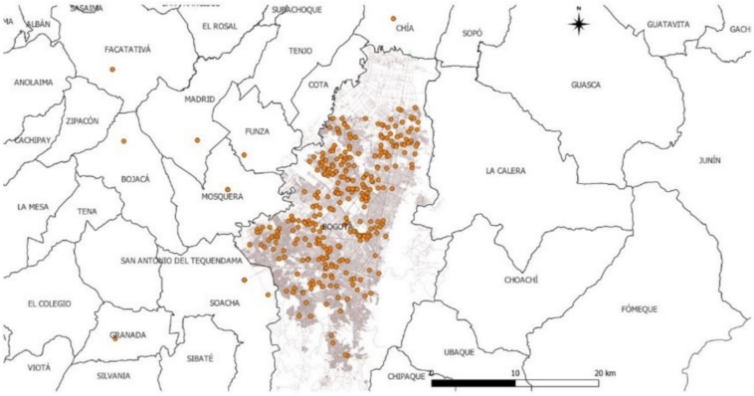

Fig. 21 - Disposición a viajar en bicicleta desde/ hacia la Universidad. Fuente: Elaboración propia

A continuación, se evidencia la disponibilidad de carro de los encuestados, en verde se muestran los que poseen vehículo. Aunque están distribuidos, aún son pocos por lo que se seguirán realizando encuestas e incentivando a los conductores a hacer parte activa de este proyecto.

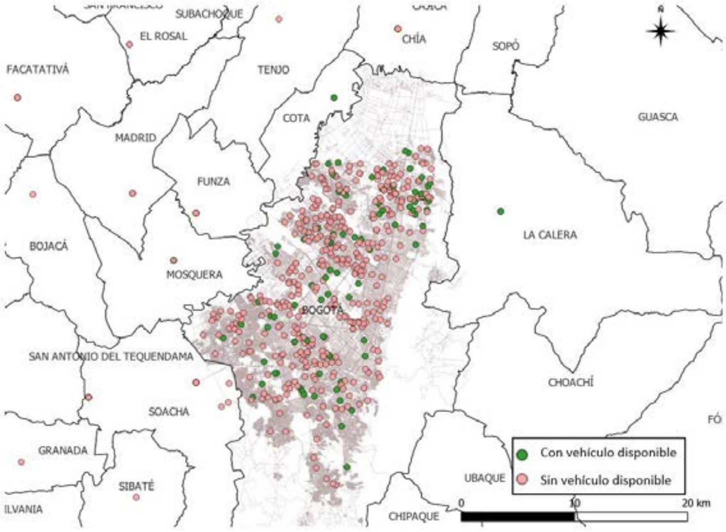

Fig. 22 - Disponibilidad de vehículo particular.Fuente: Elaboración propia

2.2 Bases de datos obtenidas

De acuerdo con las bases de datos suministradas hasta la fecha, se ha avanzado en la georreferenciación de las direcciones para determinar varios indicadores útiles del proyecto, poder realizar análisis espaciales y determinar en cierta medida la viabilidad del proyecto.

La base de datos correspondiente a los contratistas de la facultad de ingeniería cuenta con 620 registros con dirección en Bogotá. La georreferenciación de estas direcciones se presenta en la Fig. 23, donde se puede visualizar la distribución de los lugares de residencia a lo largo de la ciudad.

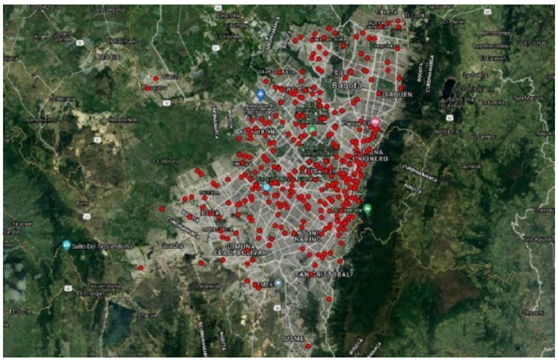

Fig. 23 - Georreferenciación de Contratistas de la Facultad de Ingeniería. Fuente: Elaboración propia

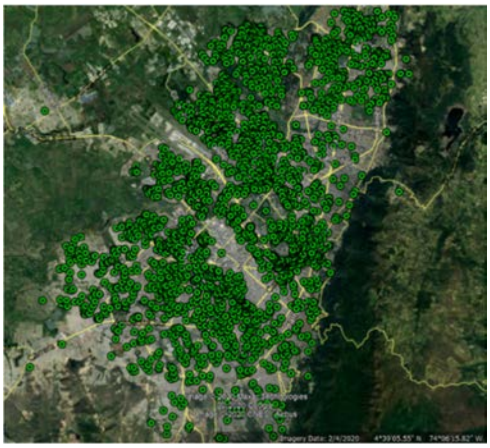

Fig. 24 - Georreferenciación de estudiantes de la Facultad de Ingeniería. Fuente: Elaboración propia

La base de datos de estudiantes de la facultad de ingeniería contenía 8851 registros, de los cuales 2739 tienen como lugar de residencia Bogotá, 2545 de ellos cuentan con dirección y son los que se observan en la imagen. A partir de la georreferenciación de los estudiantes es 1921onsider ver que están distribuidos en toda la ciudad y será 1921onsider la generación de grupos que puedan viajar juntos. Es importante tener en cuenta que las direcciones suministradas son las que tenían los estudiantes al ingresar a la 1921onsiderer1921 por lo que no hay 1921onside de que sean las mismas actualmente, además se debe 1921onsiderer que son solo un cuarto del total de estudiantes inscritos.

3. PROTOCOLOS DE BIOSEGURIDAD

Según la resolución número 000677 del 24 de abril de 2020, se presentan las siguientes acciones para tener en cuenta:

- Realizar una capacitación para aplicar las medidas indicadas en el protocolo.
- Implementar actividades que permitan garantizar la protección integral.
- Proveer a los empleados los elementos de protección personal, que deben utilizarse obligatoriamente durante el desarrollo de sus actividades.

- Registrar su estado de salud en la aplicación Corona App.
- Reportar cualquier caso sospechoso de coronavirus.
- Tener información acerca de algún caso de contagio por parte de la familia, su lugar de trabajo u otro entorno.
- Vigilancia del cumplimiento de los protocolos, (por parte de la entidad a cargo o representante).
- Las medidas propiciadas deben llevarse a cumplimiento mientras dure la declaratoria de la emergencia sanitaria.

3.1 ¿Qué es la bioseguridad?

"El conjunto de medidas preventivas que tienen por objeto eliminar o minimizar el factor de riesgo biológico que pueda llegar a afectar la salud, el medio ambiente o la vida de las personas, asegurando que el desarrollo o producto final de dichos procedimientos no atenten contra la salud y seguridad de los trabajadores".

3.2 Medidas Generales

A. Lavado de manos.
   a. Realizar el lavado de manos con agua limpia, jabón y toallas desechables.
   b. Disponer de alcohol mínimo al 60% y máximo 95%.
   c. Tener un sitio destinado a la ubicación del alcohol, de ubicación fácil de divisar.
   d. Se debe realizar la desinfección de manijas, puertas, junto con todas las superficies con las que es necesario entrar en contacto.
   e. Facilitar la información a los trabajadores.

B. Distanciamiento físico.
   a. Permanecer mínimo a 2 metros de distancia, evitando el contacto directo.
   b. Organizar y optimizar el espacio.
   c. No deben permitirse reuniones sin mantener la distancia mencionada.

C. Elementos de protección personal.
   a. La empresa debe definir los elementos de protección personal a utilizar.
   b. El empleador debe entregar los EPP.
   c. Los EPP no desechables deberán ser lavados y desinfectados, son de uso personal.

D. Manejo del tapabocas.
   a. Es de uso obligatorio en el transporte público y áreas donde se encuentre cualquier otro individuo.
   b. El tapabocas debe cubrir la boca y la nariz (ubicar cubriendo encima de la nariz y debajo del mentón).
   c. Se permite el uso de tapabocas de tela.
   d. Evitar el contacto de las manos con el tapabocas.

E. Limpieza y desinfección
   a. Desarrollar un protocolo de limpieza, definiendo el procedimiento, frecuencia, la persona responsable, los elementos de desinfección empleados, entre otros.
   b. La limpieza de elementos de contacto directo (pisos, paredes, puertas, ventanas, divisiones, muebles, sillas) debe ser de la mayor frecuencia posible.
   c. Procedimiento a realizar a inicio y fin de la jornada.
   d. Elaborar fichas técnicas e instructivos para realizar desinfección.
   e. Especificar las dosis y naturaleza química de los productos a utilizar.

F. Prevención y manejo de situaciones de riesgo de contagio.
   a. Es necesario conocer a organización de la empresa, el proceso ejecutivo de las tareas, tiempo de exposición, características del trabajador (estado de salud, edad, sexo).
   b. Prevenir la transmisión del virus por elementos contaminados (superficies, máquinas, elementos de protección).
   c. Se debe conocer las condiciones de salud de los trabajadores (estado de salud, hábitos, estilo de vida). Y las condiciones de su medio de trabajo.

G. Vigilancia de la salud.
   a. Asegurarse que se cumpla el reglamento de prevención.
   b. No permitir el ingreso de personas con temperatura igual o mayor a 38°C.
   c. Información del trabajador su EPS y ARL.
   d. Se debe señalar el número máximo de personas que estarán en una misma instalación.
   e. Garantizar la correcta circulación del aire.

H. Desplazamiento en Medios de transporte.
   a. Cumplir con el uso de los elementos de protección (Se pueden incluir guantes).
   b. Distancia en vehículo de 1 metro.
   c. Garantizar que el vehículo se encuentre limpio y desinfectado, al iniciar y finalizar la ruta debe realizarse limpieza.
   d. Incentivar el uso de otros medios de transporte como moto, bicicleta, realizando limpieza de cascos, guantes y manubrios.
   e. Planificar las rutas a recorrer.
   f. Retirar del vehículo elementos como alfombras, tapetes, forros acolchados u otro elemento que no puede ser desinfectados o lavados.
   g. Al recibir dinero puede hacerlo con guantes o puede desinfectarse las manos cada vez que realice contacto con dinero, se recomienda al pasajero en lo posible pagar el dinero exacto para evitar cambios y mayor manipulación.
   h. No es permitido consumir alimentos ni bebidas dentro del vehículo.
   i. Reportar si el conductor o el usuario presentan síntomas del covid.
   j. Llevar un kit de prevención personal.

I. Plan de comunicación.

J. Todos los trabajadores o relacionados deben contar con un medio de comunicación para informar acerca de cualquier anormalidad que se presente.

3.3 Propuesta de protocolo para conductores

- Debe proporcionar sus datos personales al registrarse como conductor, para garantizar la seguridad de los usuarios.
- Deben retirarse del vehículo, las alfombras, tapetes o forros que no puedan limpiarse o lavarse.
- Desinfección del vehículo antes y después del recorrido.
- Debe portar con sus propios elementos de protección personal, (Tapabocas, gel anti-bacterial, alcohol del 60%-95%)
- Debe mantener el vehículo con buena ventilación.
- No debe prestar el servicio si su temperatura es igual o superior a 38°C.
- Debe tener el reglamento sobre las medidas de prevención en un lugar visible

3.4 Propuesta protocolo para pasajeros

- Debe registrar sus datos personales al registrarse como pasajero.
- Adquirir y portar su kit de protección personal (tapabocas, gel anti – bacterial)
- No puede usar el servicio si su temperatura es igual o superior a 38°C.
- Debe cumplir con el reglamento de prevención.
- Debe reservar el servicio con anticipación o cancelarlo con considerable anterioridad.

3.5 Propuesta para bici usuarios

- Trazar la ruta de recorrido que se realizará.
- Portar los elementos de kit de protección personal.
- Desinfección del manubrio, casco, guantes, entre otros.

4. ESTRUCTURACIÓN Y DESARROLLO DE LA APLICACIÓN

4.1 Aplicación Web Progresiva o PWA

Una Aplicación Web Progresiva (PWA) permite al usuario tener la experiencia de una aplicación móvil con algunas diferencias y ventajas. Inicialmente está aplicación se descarga directamente desde una página web, generando un acceso directo en la pantalla del móvil similar (o igual) a una aplicación descargada desde la Play Store o App Store.

Entre las ventajas que presenta está aplicación se encuentran el bajo costo de desarrollo, la capacidad de acceder a ella en modo offline o con una conexión “lenta”, ya que almacena alguna información directamente en el dispositivo móvil y puede acceder al GPS del teléfono, puede ser usada en cualquier sistema operativo adaptándose a este. Además, está actualizada sin necesidad de hacer posteriores descargas y permite una navegación segura (HTTPS).

4.2 Historias de Usuario

Los usuarios que ingresen a la aplicación contarán con la posibilidad de seleccionar el rol que desea realizar para el viaje. Existe el rol de pasajero, conductor y bici usuario. En la siguiente imagen se muestran las opciones en la navegación que se tiene según corresponda:

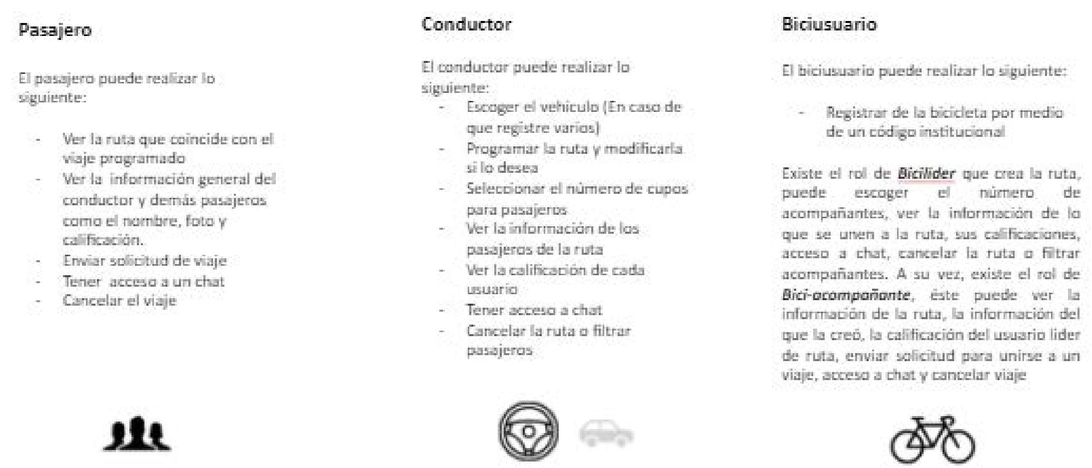

Fig. 25 – Funciones según los roles definidos. Fuente: Elaboración propia

4.3 Nombre de la aplicación

En el formulario que se realizó, se presentó una lista de posible nombre que tendrá la aplicación. A continuación, se presentan los resultados obtenidos:

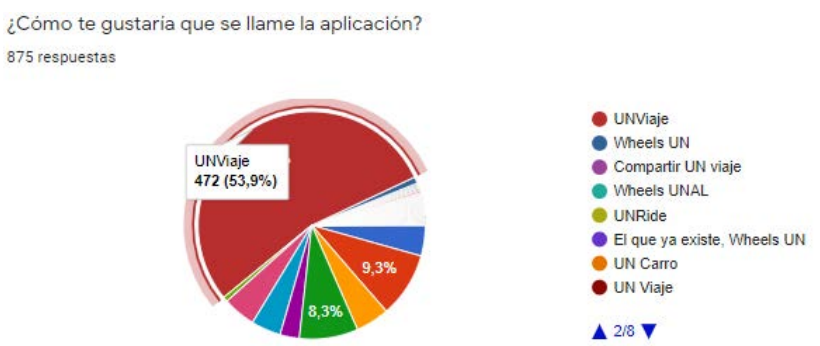

Fig.26 - Resultados del nombre de la aplicación. Fuente: Elaboración propia

El nombre definido para la aplicación es “UNviaje”. A continuación, se presenta un primer diseño del logo propuesto para la aplicación:

Fig. 27 - Logo de la aplicación. Fuente: Elaboración propia

4.4 Diseño del prototipo

Para el diseño del prototipo se realizó la selección de imágenes de dominio público, que se relacionaran con espacios que proporciona la universidad, como son las plazas y edificios que son muy conocidos, con el objetivo de hacer familiar, cercana y asequible la aplicación, para todos los miembros de la comunidad académica. Se propusieron ideas en cuanto al diseño más cómodo y funcional, de manera que en la PWA direccionara al sitio correspondiente y brindara a los usuarios todo lo que necesitan para realizar el proceso de forma adecuada, teniendo en cuenta las características en otras aplicaciones de movilidad.

En primera instancia, la página principal se enfoca en el registro a la aplicación. Ya que nuestro principal interés es el de seguridad en cuanto a la salud e integridad personal, se estructuró como única forma de acceso el registro con usuario institucional, garantizando la identificación de quiénes están usando el servicio. Se solicitan los datos personales, complementando de esta forma las bases de datos ya existentes, inclusive, actualizando las mismas, ya que se le ofrece al usuario actualizar su perfil.

Fig. 28 – Inicio de sesión, registro y acceso. Página principal. Fuente: Elaboración propia

Fig. 29 - Cambio de contraseña. Fuente: Elaboración propia

En la Fig. 29 podemos observar la opción de cambio de contraseña. Como es común en la creación de perfiles es necesario poder tener esa opción para aumentar la seguridad y en caso de que se haya olvidado. Una vez completadas las casillas se mandará un mensaje directamente al correo informando el cambio de contraseña y quedará guardado hasta que se desee volver a realizar el proceso.

Fig. 30 – Registro general complementario. Fuente: Elaboración propia

Fig. 31 - Escoger rol para viaje. Fuente: Elaboración propia

En la Fig. 31, se puede observar que, estando ya registrado como miembro de la aplicación por la condición de pertenencia en la Institución académica, el usuario debe seleccionar su vínculo de participación, con las opciones disponibles, conductor, bici usuario, o pasajero, de acuerdo a lo que considere el propósito de su vinculación, este aspecto es muy importante, ya que hará una nueva clasificación de cuánto es la demanda de vehículos por el número de pasajeros registrados, junto con las coincidencias en cuanto a localidades o puntos de partida estimados para el viaje, esto quiere decir que en cuanto mayor sea el número de usuarios registrados, a su vez el sistema será más óptimo, ya que se contarían con múltiples coincidencias para realizar su transporte, seleccionando la opción que sea más favorable. En el caso de los Bici-usuarios (Fig. 33) según los informes dados por las encuestas, incrementó el número de personas que utilizarían la bicicleta, debido a que su vivienda se encuentra cercana a la Universidad, esto además de ser un beneficio ambiental y sostenible, es una forma de seguirlo fomentando, ya que transportarse en grupo es tener la seguridad de llegar al destino sin posibles situaciones riesgosas como son las que se registran por robos o asaltos, además se pide como parte de la vinculación el registrar la bicicleta con el protocolo propio de la universidad para la protección de los elementos personales. Para quienes seleccionen la opción de conductor (Fig. 32) deben ingresar la placa y el color del vehículo como parte obligatoria del registro, ya que así se hará una rápida distinción de este, puede seleccionar más de una opción de vinculación, si solamente desea hacerlo como pasajero, al únicamente seleccionar esta opción ya quedará completo su registro.

Fig. 32 – Perfil solicitado para registrarse como conductor. Fuente: Elaboración propia

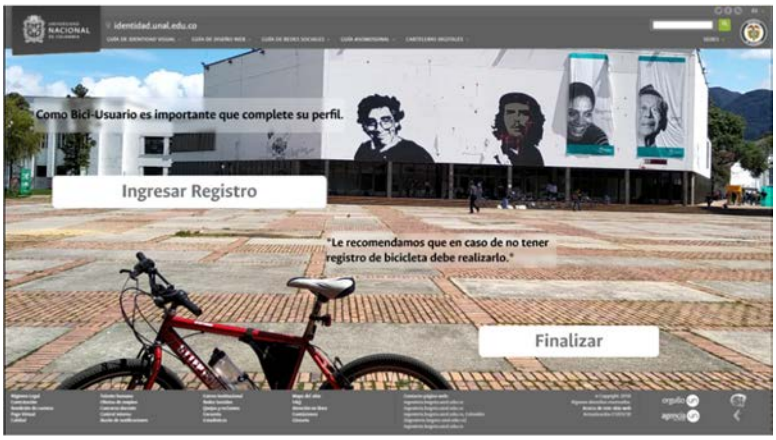

Fig. 33 – Perfil solicitado para registrarse como Bici – usuario. Fuente: Elaboración propia

Fig. 34 - Perfil solicitado para navegación. Fuente: Elaboración propia

En la Fig. 34 anterior se puede observar el mapa principal, el cual consta de un mapa de geolocalización (GoogleMaps) que permite visualizar la localización actual dentro de la zona de Bogotá y algunos de sus municipios aledaños. Tenemos las opciones básicas de punto origen y hora de salida, claves para lograr el match entre los usuarios. En el punto de origen se puede variar entre la dirección ingresada inicialmente en el registro y la ubicación proporcionada por el mapa; y en la hora de salida se visualizará opciones de 5 am a 8 pm en un rango de 15 min entre cada opción de salida. Finalmente se puede ver el destino, este incluye las diferentes entradas de la universidad y la modalidad de usuario con la que desea iniciar su viaje.

Finalmente se puede ver el número de coincidencias con los conductores (Fig. 35), el perfil de la persona con la que deseas viajar (Fig. 36) y finalmente el mensaje de confirmación (Fig. 37).

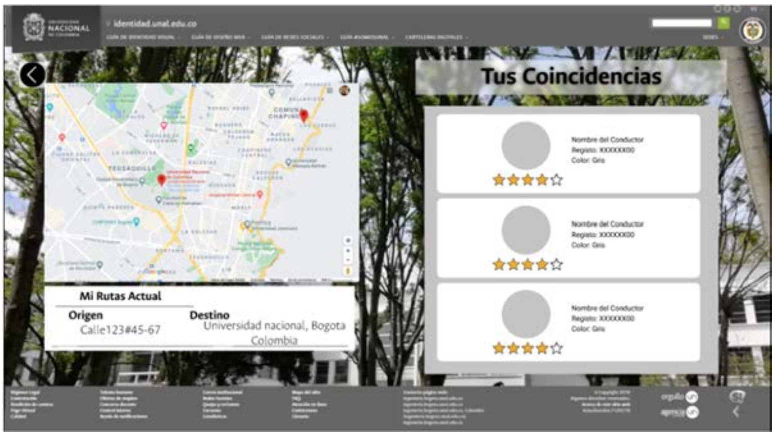

Fig. 35 – Coincidencias. Fuente: Elaboración propia

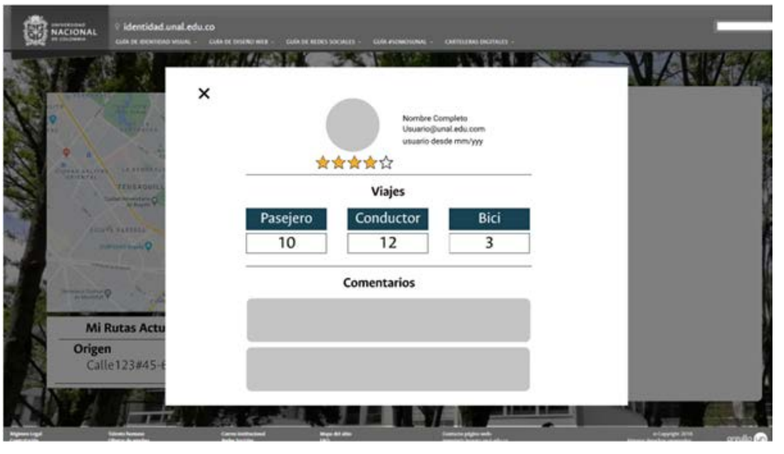

Fig. 36 - Perfil compañero de viaje. Fuente: Elaboración propia

Fig. 37 - Confirmación de viaje. Fuente: Elaboración propia

4.5 Programación

La base de programación que usamos para la PWA es un entorno de NodeJs, con la arquitectura del paquete ExpressJs y otros paquetes como firebase, PM2 y otros para la organización de accesos atreves de Parse (es un motor de NoSQL Basado en MongoDB) entre otras comunicaciones esto con el fin de tener una aplicación web con la mejor adaptación multiplataforma (PWA) orgánica y funcional sobre cualquier tipo de dispositivo.

Actualmente se cuenta con 2 servidores, uno de pruebas y uno master para producción, el cual cuenta con un sistema operativo Ubuntu 18.04, El segundo server es una réplica que consta con sistema operativo igual que el de producción, el cual tiene capacidad de 1GB en RAM y 8GB en disco duro, los deploy constan con Travis CI, el cual nos permite un manejo sobre las publicaciones y continuo monitoreo de cambio en código entre el servidor y el repositorio para soporte entre otros ajustes sobre código fuente.

Internamente entre los servidores tenemos un sistema simple NGINX que cumple su función de servidor web también esta NodeJs como entorno de ejecución y NPM para la instalación y ejecución de paquetes Javascript como secundario se está usando YARN como gestor de paquetes de respaldo el cual está ejecutando al tiempo con NPM para no generar error entre estos gestores de paquetes, en cuanto a GIT se está usando el GIT oficial de Ubuntu, y se está trabajando con Travis CI para testing code y continuous deployments.

En la siguiente imagen podemos ver gráficamente la arquitectura de la PWA.

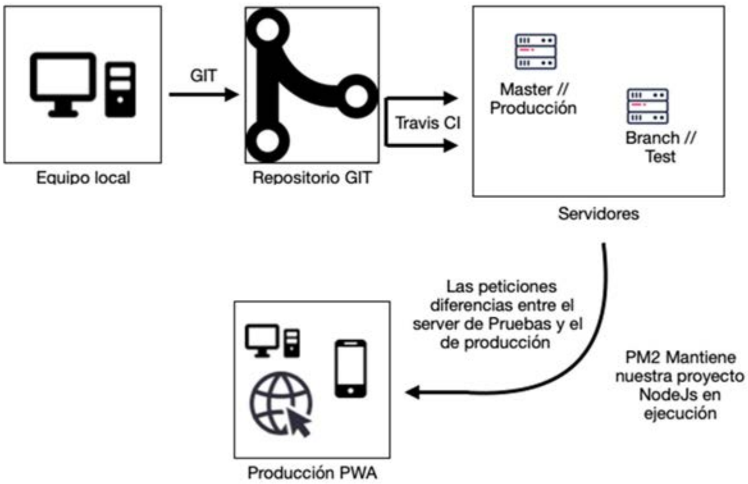

Fig. 38 – Arquitectura PWA. Fuente: Elaboración propia

5. ANÁLISIS ESTADÍSTICO DE LOS RESULTADOS OBTENIDOS

La base de datos utilizada fue obtenida a partir del desarrollo de una encuesta divulgada por correo masivo al personal administrativo, docentes, estudiantes, egresados, investigadores, empleados y contratistas de la Universidad Nacional de Colombia

De la encuesta realizada se obtuvieron un total de 880 respuestas, contando con registros de desde el mes de septiembre hasta el mes de diciembre del año 2020. Para del desarrollo de los análisis estadísticos de las respuestas obtenidas, es importe definir el estudio a realizar. El estudio para la creación de la aplicación define las posibles rutas de viaje que se comparten entre individuos que se desplazan desde y hacia el campus de la Universidad Nacional, es por esta razón, que los análisis se dividen por zonas de la ciudad, en este caso por localidades, tomando que referencia los individuos que se desplazan desde el sur, norte, oriente y occidente.

Teniendo en cuenta que los individuos que se ubiquen, por ejemplo, en el sector norte de la ciudad, pueden compartir su viaje con otros individuos que se ubiquen en este sector próximos a la ruta de viaje, en la Fig. 7.1 se define la división de los análisis estadísticos a realizar de la base de datos de estudio, partiendo principalmente de la georreferenciación de las respuestas obtenidas. Dado esto, a partir del análisis espacial de los datos, se divide la base de datos, obteniendo como resultado lo siguiente:

a. Zona norte: comprendida por los individuos que viven en las localidades de Barrios Unidos, Chapinero, Engativá, Suba, Teusaquillo y Usaquén y los municipios del área metropolitana de Bogotá: Cajicá, Chía, Cogua, Cota, El Rosal, la Calera, Sopó, Subachoque, Tenjo, Tocancipá y Zipaquirá.

b. Zona Sur: comprendida por los individuos que vienen las localidades de Tunjuelito, Usme, Puente Aranda, Kennedy, Ciudad Bolívar, Fontibón, Bosa, Candelaria, San Cristóbal, Antonio Nariño, Mártires, Rafael Uribe, Santa Fe y los municipios del área metropolitana de Bogotá: Bojacá, Facatativá, Funza, Granada, Madrid, Mosquera, Sibaté y Soacha.

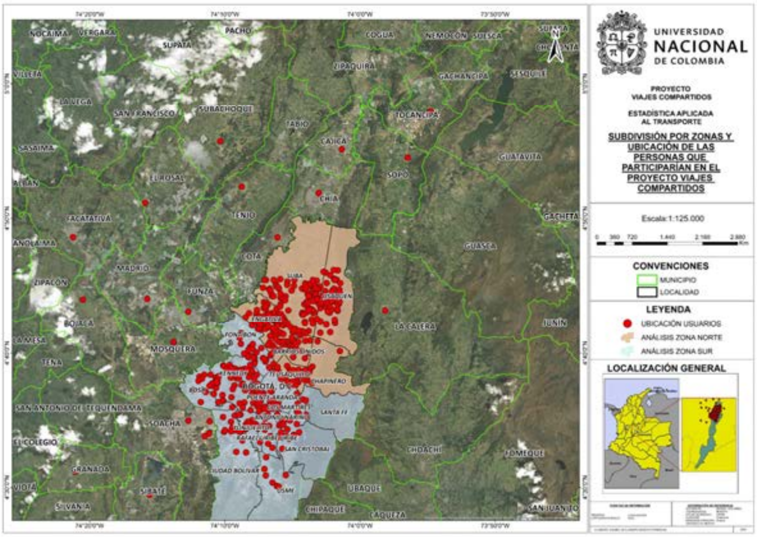

Fig. 39 - Subdivisión por zonas del análisis estadístico. Fuente: Elaboración propia.

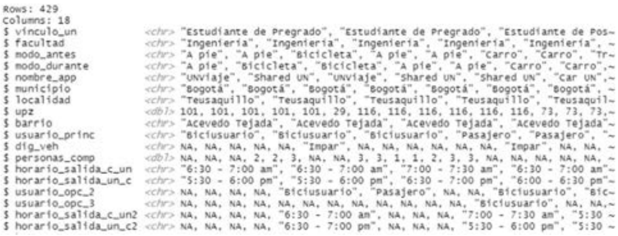
El alcance definido comprende un análisis en la **zona norte** de la ciudad de Bogotá y su área metropolitana. A continuación, se presenta una descripción de la base de datos seleccionada:

- Individuo o unidad de análisis: usuario de la aplicación.
- Población: La población objetivo para este proyecto son los 7408 estudiantes de la facultad de ingeniería, incluyendo también personal administrativo, contratistas, empleados, investigadores, egresados y docentes, teniendo alrededor de 9000 personas en total.
- Muestra: Respuestas de la encuesta realizada. Se tiene un total de 429 respuestas de personas pertenecientes a la universidad Nacional de Colombia, que se ubican en la zona norte descrita anteriormente y respondieron que si estarían interesadas en participar en la aplicación.
- Variable: Vínculo con la universidad, Facultad a la que pertenece, Municipio en que vive, Localidad, UPZ, Barrio, hora de salida desde el hogar, hora de salida desde la universidad, modo de transporte antes de la emergencia sanitaria, modo de transporte que usaría durante la emergencia sanitaria, rol principal, secundario y terciario que desarrollaría dentro de la aplicación.

Las variables contenidas dentro de la base de datos son variables categóricas, excepto la upz y con cuantas personas estaría dispuesto a compartir el vehículo, estas dos son variables cuantitativas, como se muestra en la Fig. 40. En total se tienen 18 variables, de las cuales se realizó una selección de las que podrían caracterizar de una mejor forma el análisis planteado en la pregunta del primer punto, encontrándose así en el desarrollo de gráficos de frecuencias, matriz de correlación de Pearson y ACM.

Algunas de las respuestas obtenidas en el formulario presentaban pequeñas variaciones, por ejemplo, para el caso de modo de transporte que utilizaba antes de la emergencia sanitaria, fue necesario depurar y uniformizar la base de datos, ya que algunas personas tenían respuestas que no se encontraban dentro de las opciones definidas o escritas de otra forma, por ejemplo: la palabra “Carro” y “carro”, aunque signifiquen lo mismo, una está escrita con la primera letra en mayúscula y la otra no, por lo cual, al momento de realizar el análisis estadístico en R, se toman como dos variables categóricas diferentes, lo mismo ocurre con el municipio, localidad, el vínculo y el rol; ya que por ejemplo, “Bogotá”, se encontraba escrita con tilde o sin tilde, o también se encontraron 2 municipios de residencia en zonas alejadas del área de influencia, por lo cual, estos datos se descartaron dentro del análisis realizado.



```

Fig. 40 - Estructura de la base de datos inicial. Fuente: Elaboración propia.

De las 18 variables presentadas anteriormente, se seleccionaron las siguientes variables categóricas para el análisis estadístico:

- vinculo_un
- facultad
- modo_antes
- modo_durante
- municipio
- localidad
- usuario_princ
- usuario_opc_2
- usuario_opc_3

5.1 Tablas y gráficas de frecuencias

5.1.1 Vinculo de cada uno de los usuarios con la Universidad Nacional

Considerando los vínculos obtenidos en la zona de influencia norte definida anteriormente, se realiza la respectiva tabla de frecuencias:

	Variable	Frecuencia	Frec. Relativa	Porcentajes%
1	Administrativo	17	0.039627040	3.96
2	Contratista	5	0.011655012	1.17
3	Docente	11	0.025641026	2.56
4	Egresado	3	0.006993007	0.70
5	Estudiante de Posgrado	30	0.069930070	6.99
6	Estudiante de Pregrado	363	0.846153846	84.62

Tabla 1 - Tabla de frecuencias vinculo_UN. Fuente: Elaboración propia.

De la tabla 1 se resalta que la variable "Estudiante de pregrado" es la que más se presenta dentro de la base de datos realizada, teniendo esta una frecuencia relativa en porcentaje de 84%. Dado esto, los análisis que se van a realizar con respecto a los modos de transporte y lugares de residencia representan un tamaño de la muestra mayor para esta variable, generando así mayores correspondencias con la variable "vinculo_un Estudiante de pregrado", observada como una de las representativas para el modelo.

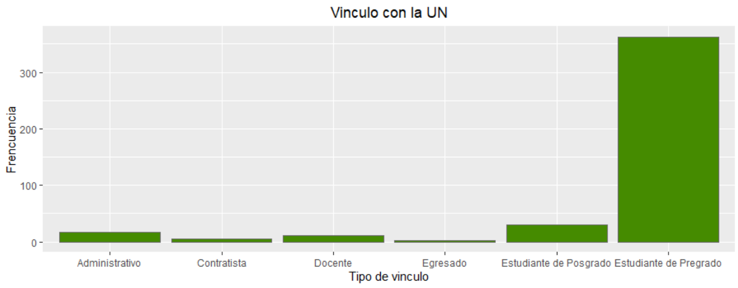

Fig. 41 - Gráfico de frecuencias vinculo_UN. Fuente: Elaboración propia

Como aporte al problema de investigación, se tiene que los resultados obtenidos en cuanto a la relación de los modos de transporte vienen en mayor medida por las respuestas a la encuesta realizada de los estudiantes de pregrado de la universidad Nacional, según se observa en la figura 7.2.

5.1.2 Facultad a la que pertenecen

Considerando la facultad a la que pertenecen los individuos presentes en la zona de influencia norte definida anteriormente, se realiza la respectiva tabla de frecuencias:

	Variable	Frecuencia	Frec. Relativa	Porcentajes%
1	Artes	15	0.034965035	3.50
2	Ciencias	15	0.034965035	3.50
3	Ciencias Agrarias	9	0.020979021	2.10
4	Ciencias Económicas	14	0.032634033	3.26
5	Ciencias Humanas	7	0.016317016	1.63
6	Derecho, Ciencias Políticas y Sociales	5	0.011655012	1.17
7	Ingeniería	358	0.834498834	83.45
8	Medicina	4	0.009324009	0.93
9	Medicina Veterinaria y de Zootecnia	1	0.002331002	0.23
10	Nivel Central	1	0.002331002	0.23

Tabla 2 - Tabla de frecuencias facultad. Fuente: Elaboración propia

Teniendo en cuenta que uno de los objetivos principales del proyecto es que en la primera etapa se caracterice de forma aproximada a los usuarios de la facultad de ingeniería; la tabla 1, muestra que los análisis a realizar en cuanto a modo de transporte, representan en mayor medida a personas que pertenecen a dicha facultad, teniendo esta un frecuencia de 358 y una frecuencia relativa en porcentaje de 83,45%, por lo cual, se cumple con uno de los primeros objetivos definidos para la población de análisis, obteniendo así, un tamaño de la muestra que genera mayores correspondencias con la variable facultad de ingeniería, observada como una de las representativas para el modelo.

En la figura 42 se observa la representación gráfica de la variable "facultad", donde se resalta la diferencia que presenta la facultad de "Ingeniería" respecto a las demás, siendo esta, representativa en el desarrollo del problema estadístico planteado.

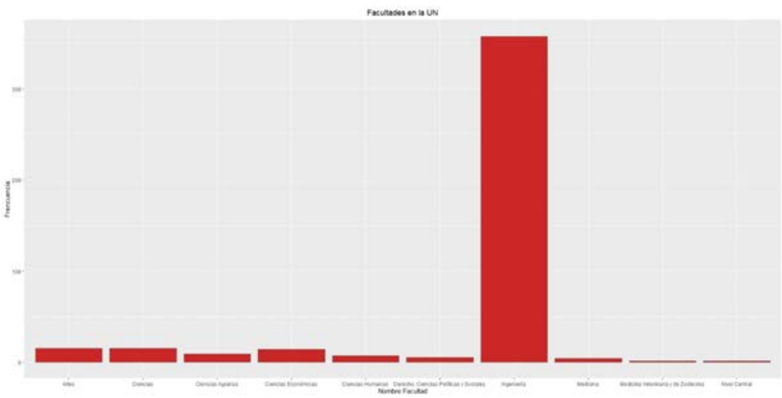

Fig. 42 - Gráfico de frecuencias facultad. Fuente: Elaboración propia.

5.1.3 Modo de transporte con el cual se desplazaba antes de la emergencia sanitaria ocasionada por el covid-19

Considerando los modos de transporte con los cuales se desplazaban los individuos en la zona de influencia norte definida anteriormente, se realiza la respectiva tabla de frecuencias:

	Variable	Frecuencia	Frec. Relativa	Porcentajes%
1	A pie	19	0.044289044	4.43
2	Bicicleta	72	0.167832168	16.78
3	Carro	56	0.130536131	13.05
4	Monopatín	2	0.004662005	0.47
5	Moto	10	0.023310023	2.33
6	Taxi	1	0.002331002	0.23
7	Transporte público	269	0.627039627	62.70

Tabla 3 - Tabla de frecuencias modo_antes. Fuente: Elaboración propia

Se observa que el transporte público es el modo de transporte más utilizan quienes respondieron la encuesta, presentando una frecuencia de 269, con una frecuencia relativa en porcentaje de 62,70 %. Esta información es importante para contrastar los cambios de modo de transporte que se pueden presentar durante la emergencia sanitaria, con el fin de atacar estos frentes a partir del desarrollo de la aplicación móvil. Se observa una frecuencia relevante de personas que se movilizan en bicicleta y carro, los cuales pueden ser usuarios potenciales de la aplicación móvil.

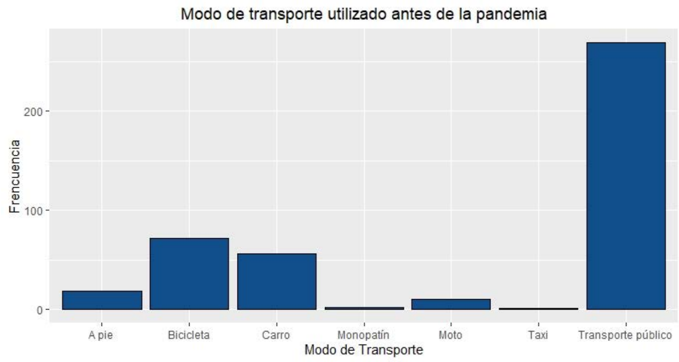

Fig. 43 - Gráfico de frecuencias modo_antes. Fuente: Elaboración propia

En la fig. 43 se presenta de manera gráfica lo mencionado anteriormente, donde sobresale el modo de transporte público, bicicleta y carro.

5.1.4 Modo de transporte con el cual se desplazaría durante la emergencia sanitaria ocasionada por el covid-19

Considerando los modos de transporte con los cuales se desplazarían los individuos en la zona de influencia norte definida anteriormente, se realiza la respectiva tabla de frecuencias:

	Variable	Frecuencia	Frec. Relativa	Porcentajes%
1	A pie	21	0.048951049	4.90
2	Bicicleta	138	0.321678322	32.17
3	Carro	119	0.277389277	27.74
4	Monopatín	2	0.004662005	0.47
5	Moto	8	0.018648019	1.86
6	Transporte público	141	0.328671329	32.87

Tabla 4 - Tabla de frecuencias modo_durante. Fuente: Elaboración propia

Se observa un aumento significativo en las personas que se movilizarían en bicicleta, pasando de una frecuencia de 72 a 138; lo mismo ocurre con carro pasando de una frecuencia de 56 a 119 y una reducción en el uso de transporte publico pasando de una frecuencia 269 a 141. Esta información es un insumo fundamental ya que se observa un cambio significativo en los modos de transporte, aumentando así considerablemente los usuarios que se movilizarían en carro y bicicleta, los cuales serían usuarios potenciales de la aplicación móvil.

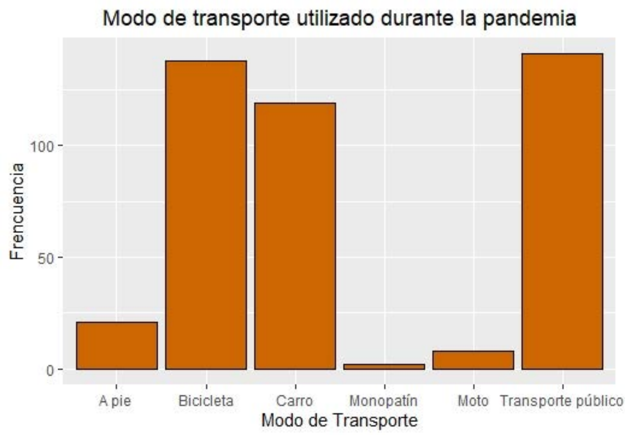

Fig. 44 - Gráfico de frecuencias modo_durante. Fuente: Elaboración propia

La fig. 44 contiene el gráfico de frecuencias que representa lo mencionado anteriormente, siendo esto un insumo fundamental para resolver el problema estadístico planteado, ya que caracteriza los cambios en modos de transporte presentados.

5.1.5 Localidad en la que vive

Considerando la localidad en la que viven los individuos en la zona de influencia norte definida anteriormente, se realiza la respectiva tabla de frecuencias:

	Variable	Frecuencia	Frec. Relativa	Porcentajes%
1	Barrios Unidos	26	0.06060606	6.06
2	Chapinero	8	0.01864802	1.86
3	Engativa	118	0.27505828	27.51
4	Municipios externos	47	0.10955711	10.96
5	Suba	127	0.29603730	29.60
6	Teusaquillo	40	0.09324009	9.32
7	Usaquén	63	0.14685315	14.69

Tabla 5 - Tabla de frecuencias localidad. Fuente: Elaboración propia

Se resalta que las localidades de Suba y Engativá son las que presentan una mayor frecuencia respecto a las demás localidades, teniendo así un valor de frecuencia de 127 y 118 respectivamente, junto con un valor de frecuencia en porcentaje de 29,60 % y 27,51 %. A partir de este análisis, se puede concluir las localidades con las cuales, a partir del estudio de los modos de transporte de los individuos que las habitan, pueden presentar una relación con la cual se puedan obtener correspondencias para realizar viajes compartidos.

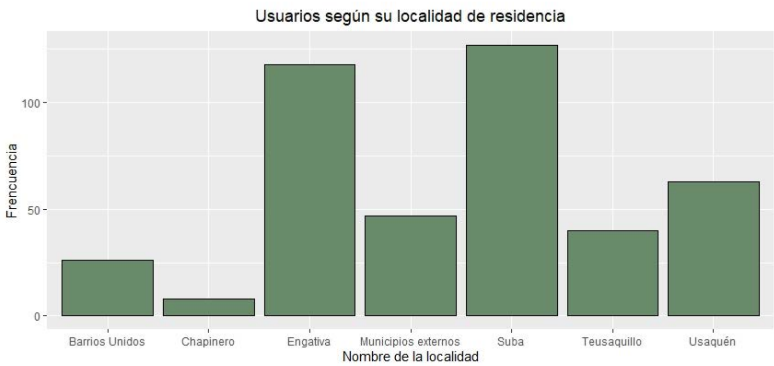

Fig. 45 - Gráfico de frecuencias localidad. Fuente: Elaboración propia

En el gráfico 45 se presenta el gráfico de frecuencias obtenido donde se sobresalen laslocalidades de Suba y Engativá.

5.1.6 Usuario principal de uso de la aplicación

Considerando el rol principal de uso de la aplicación los individuos en la zona de influencia norte definida anteriormente, se realiza la respectiva tabla de frecuencias:

	Variable	Frecuencia	Frec. Relativa	Porcentajes%
1	Biciusuario	132	0.3076923	30.77
2	Conductor (Con vehiculo disponible)	71	0.1655012	16.55
3	Pasajero	226	0.5268065	52.68

Tabla 6 - Tabla de frecuencias usuario principal. Fuente: Elaboración propia

Se observa que el usuario "pasajero" presenta una mayor frecuencia, con una frecuencia de 226 y una frecuencia relativa en porcentaje de 52,68 %. Este análisis es importante ya que el número de vehículos particulares debe satisfacer la demanda de pasajeros observada y su aporte a la solución del problema estadístico es importante, ya que se deriva de los modos de transporte que el individuo usa.

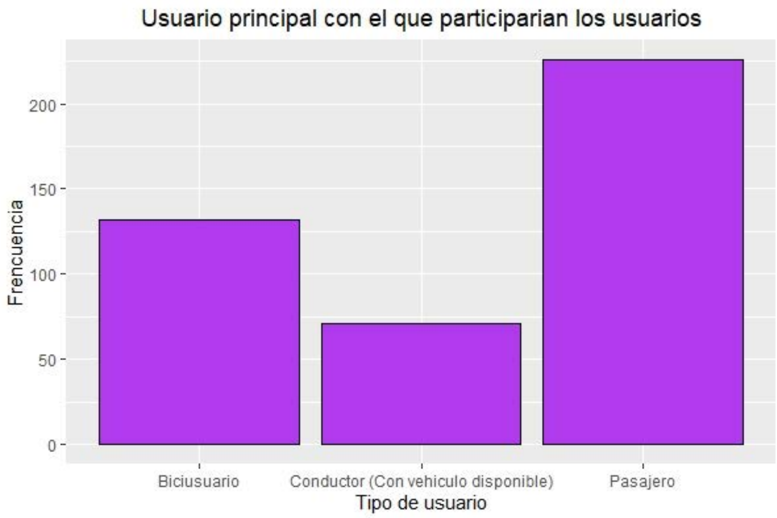

Fig. 46 - Gráfico de frecuencias usuario principal. Fuente: Elaboración propia

5.1.7 Segundo rol de Usuario en la aplicación

Considerando el segundo rol de uso de la aplicación los individuos en la zona de influencia norte definida anteriormente, se realiza la respectiva tabla de frecuencias:

	Variable	Frecuencia	Frec. Relativa	Porcentajes%
1	Biciusuario	95	0.2214452	22.14
2	No interesado	271	0.6317016	63.17
3	Pasajero	63	0.1468531	14.69

Tabla 7 - Tabla de frecuencias segundo rol. Fuente: Elaboración propia

A partir de la tabla de frecuencias obtenida se puede concluir que 271 individuos (63,17%), no están interesados en ejercer un segundo rol dentro de la aplicación, mientras que biciusuario, es el segundo rol que predomina, con un total de 95 individuos (22,14 %).

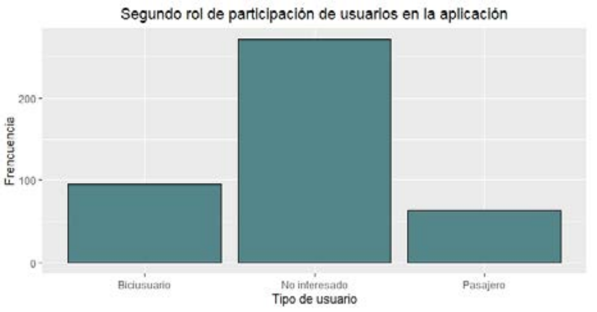

Fig. 47 - Gráfico de frecuencias segundo rol. Fuente: Elaboración propia

En la figura 47 se presenta el gráfico obtenido, donde se resalta un alto porcentaje de usuarios no interesados en desarrollar un segundo rol en la aplicación, siendo esto un insumo relevante para resolver el problema estadístico debido a su relación directa con los modos de transporte que el individuo utilizaría.

5.1.8 Tercer rol de Usuario en la aplicación

Considerando el tercer rol de uso de la aplicación los individuos en la zona de influencia norte definida anteriormente, se realiza la respectiva tabla de frecuencias:

	Variable	Frecuencia	Frec. Relativa	Porcentajes%
1	Biciusuario	26	0.06060606	6.06
2	No interesado	403	0.93939394	93.94

Tabla 8 - Tabla de frecuencias tercer rol. Fuente: Elaboración propia

A partir de la tabla de frecuencias obtenida se puede concluir que 403 individuos (93,94%), no están interesados en ejercer un tercer rol dentro de la aplicación, mientras que biciusuario, es el rol que se mantiene, con un total de 26 individuos (6,06 %). Esto permite identificar que los modos de transporte, objeto de análisis del problema estadístico planteado, presentan una alta relación con el rol principal seleccionado.

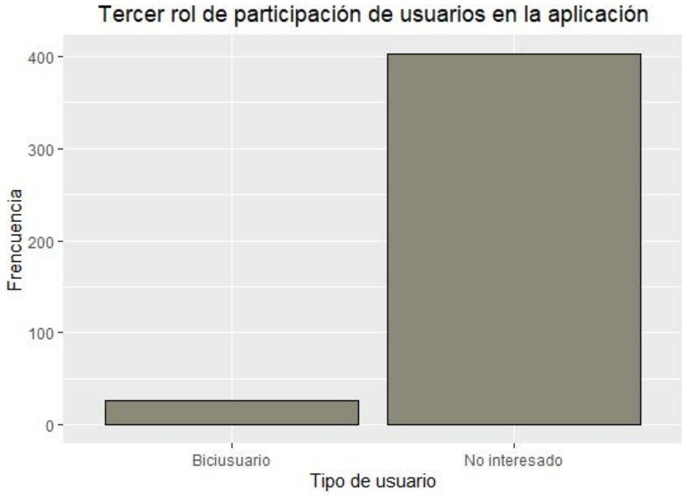

Fig. 48 - Gráfico de frecuencias tercer rol. Fuente: Elaboración propia

5.1.9 Municipios de residencia – Zona Norte

Considerando el tercer rol de uso de la aplicación los individuos en la zona de influencia norte definida anteriormente, se realiza la respectiva tabla de frecuencias:

	Variable	Frecuencia	Frec. Relativa	Porcentajes%
1	Cajicá	6	0.12765957	12.77
2	Chía	10	0.21276596	21.28
3	Cogua	1	0.02127660	2.13
4	Cota	3	0.06382979	6.38
5	El Rosal	2	0.04255319	4.26
6	La Calera	3	0.06382979	6.38
7	Sopó	2	0.04255319	4.26
8	Subachoque	1	0.02127660	2.13
9	Tenjo	1	0.02127660	2.13
10	Tocancipá	1	0.02127660	2.13
11	Zipaquirá	17	0.36170213	36.17

Tabla 9 - Tabla de frecuencias municipios de residencia. Fuente: Elaboración propia

Aunque se observa una baja frecuencia para los municipios analizados, se resalta el municipio de Zipaquirá, con una frecuencia de 17 y una frecuencia relativa en porcentaje de 36,17 %. Esto es un insumo importante ya que en estos municipios se pueden analizar los diferentes modos de transporte partiendo de que debido a su alta distancia con el campus universitario, los modos de transporte tienden a ser transporte público, moto y automóvil.

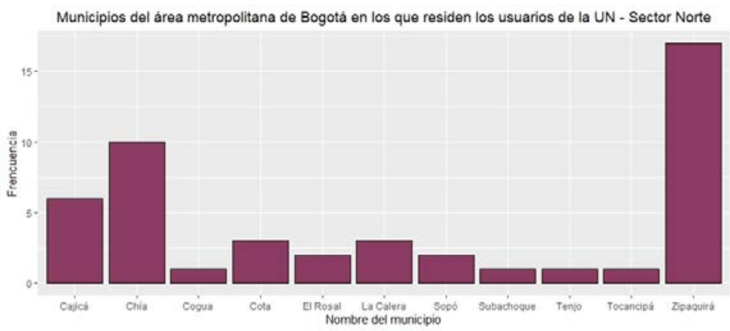

Fig. 49 - Municipio de residencia. Fuente: Elaboración propia

5.2 Tablas y gráficos de contingencias

5.2.1 Localidad vs vinculo

Considerando que dentro del objetivo del problema estadístico se tiene analizar los modos de transporte antes y durante la emergencia sanitaria presentada por el covid-19, teniendo en cuenta su localidad de residencia y el vínculo que este tiene con la universidad, es importante relacionar estas variables a partir de una tabla de contingencias, tal como se ve en la siguiente tabla:

	Barrios Unidos	Chapinero	Engativa	Municipios externos	Suba	Teusaquillo	Usaquén
Administrativo	0	0	10	1	4	2	0
Contratista	0	0	0	0	2	2	1
Docente	1	1	0	0	4	3	2
Egresado	0	0	1	0	1	1	0
Estudiante de Posgrado	2	0	9	0	9	4	6
Estudiante de Pregrado	23	7	98	46	107	28	54

Tabla 10 - Tabla de contingencia localidad vs vinculo. Fuente: Elaboración propia

Nuevamente se destaca que “estudiante de pregrado” es la variable que presenta un mayor número de registros, esto contrastado con las localidades de Engativá y Suba. Municipios externos se incluye dentro de este análisis, sin embargo, este se estudia con una mayor profundidad más adelante. Para realizar un análisis más a fondo, es importante relacionar las variables de localidad y vinculo, con los modos de transporte usados antes y durante la emergencia sanitaria.

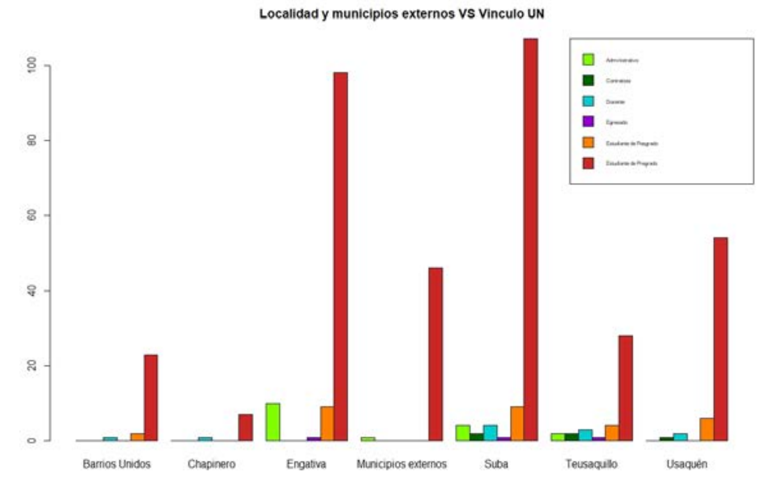

Fig. 50 - Gráfico de contingencias localidad vs municipio. Fuente: Elaboración propia

En el gráfico anterior se resalta lo mencionado con respecto al mayor número de registros para estudiantes de pregrado en las localidades de Suba, Engativá, Usaquén, Municipios externos y Teusaquillo. Es importante considerar la cercanía que estas localidades tienen al campus universitario, por ejemplo, las personas que residen próximas a la universidad nacional que viven en la localidad de Teusaquillo, tienden a desplazarse a pie o en bicicleta, mientras que las personas que residen los municipios externos tienden a desplazarse en trasporte público, moto o carro. Estos análisis se desarrollan a profundidad en las siguientes tablas de contingencias.

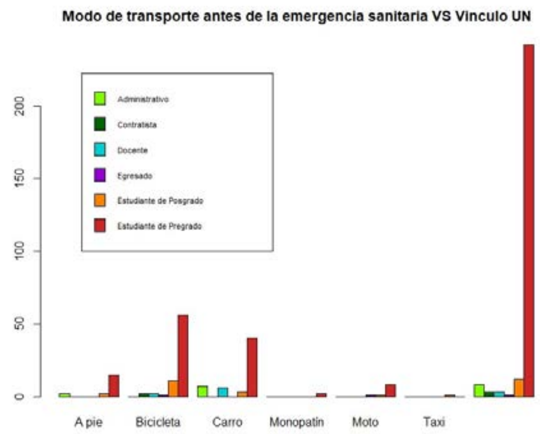
5.2.2 Vinculo vs modo antes

Considerando que dentro del objetivo del problema estadístico se tiene analizar los modos de transporte antes y durante la emergencia sanitaria presentada por el covid-19, teniendo en cuenta el vínculo que el usuario tiene con la universidad, es importante relacionar estas variables a partir de una tabla de contingencias, tal como se ve en la siguiente tabla:

	A pie	Bicicleta	Carro	Monopatín	Moto	Taxi	Transporte público
Administrativo	2	0	7	0	0	0	8
Contratista	0	2	0	0	0	0	3
Docente	0	2	6	0	0	0	3
Egresado	0	1	0	0	1	0	1
Estudiante de Posgrado	2	11	3	0	1	1	12
Estudiante de Pregrado	15	56	40	2	8	0	242

Tabla 11 - Tabla de contingencia Vinculo vs modo antes. Fuente: Elaboración propia

Según lo presentado en la tabla de contingencias anterior, los estudiantes de pregrado tienden a desplazarse más en transporte público, caso contrario a los docentes, ya que según los resultados estos tienden a desplazarse más en carro particular. Esta tabla refleja un frente importante a trabajar en el desarrollo del proyecto y es el de incentivar a que más docentes se unan al proyecto de carro compartido, ya que estos pueden aportar más vehículos particulares para satisfacer la demanda de pasajeros. En el siguiente gráfico se presenta la información descrita en la Tabla 11, donde se resalta que una vez describan los resultados obtenidos en el modo de transporte que usaría durante la emergencia sanitaria, se realiza análisis del problema estadístico planteado.



TP

Fig. 51 - Gráfico de contingencias Modo antes vs vinculo. Fuente: Elaboración propia

5.2.3 Vinculo vs modo durante

Considerando que dentro del objetivo del problema estadístico se tiene analizar los modos de transporte antes y durante la emergencia sanitaria presentada por el covid-19, teniendo en cuenta el vínculo que el usuario tiene con la universidad, es importante relacionar estas variables a partir de una tabla de contingencias, tal como se ve en la siguiente tabla:

	A pie	Bicicleta	Carro	Monopatín	Moto	Transporte público
Administrativo	1	2	8	0	0	6
Contratista	0	2	2	0	0	1
Docente	0	2	7	0	0	2
Egresado	0	3	0	0	0	0
Estudiante de Posgrado	2	16	3	0	1	8
Estudiante de Pregrado	18	113	99	2	7	124

TP

Tabla 12 - Tabla de contingencia Vinculo vs modo durante. Fuente: Elaboración propia

Según los registros presentados en la tabla de contingencias anterior, se observa que los estudiantes de pregrado reducirían considerablemente el uso del transporte público durante la emergencia sanitaria hacia un eventual regreso a las actividades presenciales pasando de 242 a 124 registros, y a su vez, estos migran al uso de carro particular pasando de 40 a 99 registros. Se observa que, para los demás vínculos, no se presenta un cambio significativo en el modo de transporte utilizado antes y durante la emergencia sanitaria, por lo cual, se puede concluir que el vínculo “estudiante de pregrado”, es el que presenta una mayor relación en cuanto a los cambios que se pueden presentar en los desplazamientos.

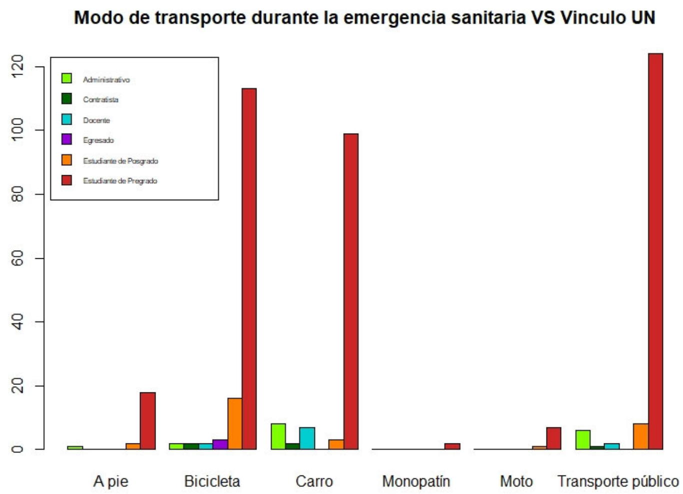


Fig. 52 - Gráfico de contingencias Modo durante vs vinculo. Fuente: Elaboración propia

Los análisis descritos anteriormente se pueden visualizar de una mejor forma comparando las figuras 51 y 52, donde se observa el cambio de las alturas de las barras según el modo de transporte.

5.2.4 Localidad vs modo antes

Considerando que dentro del objetivo del problema estadístico se tiene analizar los modos de transporte antes y durante la emergencia sanitaria presentada por el covid-19, teniendo en cuenta la localidad de residencia del usuario, es importante relacionar estas variables a partir de una tabla de contingencias, tal como se ve en la siguiente tabla:

	A pie	Bicicleta	Carro	Monopatín	Moto	Taxi	Transporte público
Barrios Unidos	0	7	4	0	1	1	13
Chapinero	1	0	1	0	0	0	6
Engativa	0	33	16	0	2	0	67
Municipios externos	0	0	3	0	4	0	40
Suba	0	16	17	0	1	0	93
Teusaquillo	18	14	1	2	1	0	4
Usaquén	0	2	14	0	1	0	46

Tabla 13. - Tabla de contingencia localidad vs modo antes. Fuente: Elaboración propia

Se observa que antes de la emergencia sanitaria, el modo de transporte público es el que se utiliza mayormente por cada localidad, excepto en la localidad de Teusaquillo, ya que como se había analizado anteriormente, su proximidad con la universidad hace que la mayoría de las personas se desplace a pie o en bicicleta. Se resalta que las localidades de Suba, Engativá, y Usaquén son las que presentan un mayor número de registros en cuanto a modos de transporte como el transporte público y carro particular.

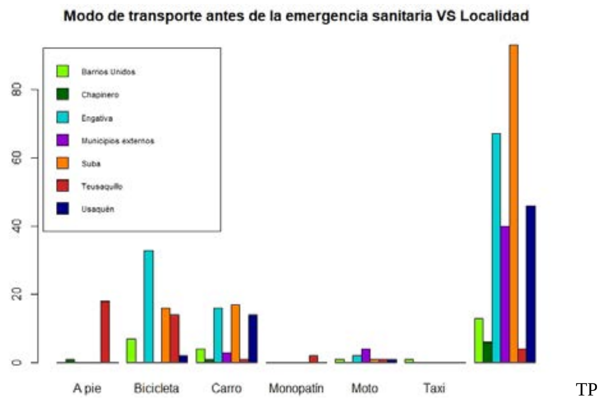

Fig. 53 - Gráfico de contingencias Modo antes vs localidad. Fuente: Elaboración propia

Es importante analizar la localidad vs el modo de transporte durante la emergencia sanitaria con el fin de obtener una respuesta al problema estadístico planteado

5.2.5 Localidad vs modo durante

Considerando que dentro del objetivo del problema estadístico se tiene analizar los modos de transporte antes y durante la emergencia sanitaria presentada por el covid-19, teniendo en cuenta la localidad de residencia del usuario, es importante relacionar estas variables a partir de una tabla de contingencias, tal como se ve en la siguiente tabla:

	A pie	Bicicleta	Carro	Monopatín	Moto	Transporte público
Barrios Unidos	0	17	5	0	0	4
Chapinero	2	2	1	0	0	3
Engativa	4	53	26	0	1	34
Municipios externos	0	0	10	0	4	33
Suba	1	34	43	0	2	47
Teusaquillo	14	19	2	2	0	3
Usaquén	0	13	32	0	1	17

Tabla 14 - Tabla de contingencia localidad vs modo durante. Fuente: Elaboración propia

Según los registros presentados en la tabla de contingencias anterior, se observa que los usuarios de las localidades de Suba, Engativá y Usaquén reducirían considerablemente el uso del transporte público durante la emergencia sanitaria hacia un eventual regreso a las actividades presenciales pasando de 93 a 47, 67 a 34 y 46 a 17 registros respectivamente, y a su vez, estos migran al uso de carro particular pasando de 17 a 34, 16 a 26 y 14 a 32 registros respectivamente.

También se observa un importante aumento del uso de la bicicleta en localidades como Engativá, Suba, Barrios unidos y Usaquén; por lo cual, estas localidades presentarían una gran posibilidad de uso del aplicativo para realizar viajes compartidos en carro particular y la conformación de grupos de ciclistas.

Si se compara la Fig. 53 con respecto a la Fig. 54, se observa el contraste que se presenta con respecto a los modos de transporte por localidad utilizados antes y durante la emergencia sanitaria, siendo este un insumo relevante para resolver el problema estadístico planteado.

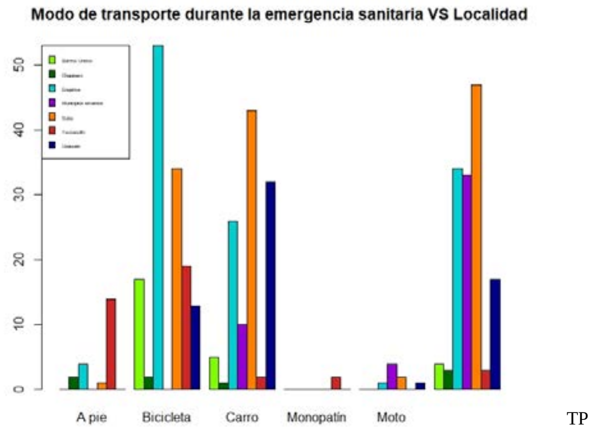

Fig. 54 - Gráfico de contingencias Modo durante vs localidad. Fuente: Elaboración propia

5.2.6 Municipio vs modo antes

Considerando que dentro del objetivo del problema estadístico se tiene analizar los modos de transporte antes y durante la emergencia sanitaria presentada por el covid-19, teniendo en cuenta el municipio de residencia del usuario, es importante relacionar estas variables a partir de una tabla de contingencias, tal como se ve en la siguiente tabla:

	Carro	Moto	Transporte público
Cajicá	0	0	6
Chía	0	0	10
Cogua	0	0	1
Cota	1	0	2
El Rosal	1	0	1
La Calera	0	1	2
Sopó	0	0	2
Subachoque	0	1	0
Tenjo	0	0	1
Tocancipá	0	0	1
Zipaquirá	1	2	14

Tabla 14 - Tabla de contingencia Municipio vs modo antes. Fuente: Elaboración propia

Para poder analizar la tabla anterior, es importante revisar la tabla que relacione el modo de transporte durante la emergencia sanitaria vs el municipio.

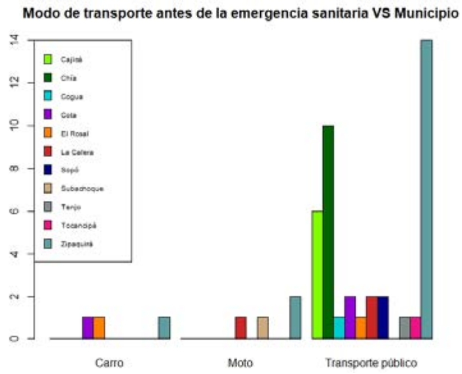

Fig. 55 - Gráfico de contingencias Modo antes vs Municipio. Fuente: Elaboración propia

5.2.7 Municipio vs modo durante

Considerando que dentro del objetivo del problema estadístico se tiene analizar los modos de transporte antes y durante la emergencia sanitaria presentada por el covid-19, teniendo en cuenta el municipio de residencia del usuario, es importante relacionar estas variables a partir de una tabla de contingencias, tal como se ve en la siguiente tabla:

	Carro	Moto	Transporte público
Cajicá	0	0	6
Chía	1	0	9
Cogua	0	0	1
Cota	1	0	2
El Rosal	1	0	1
La Calera	1	1	1
Sopó	0	0	2
Subachoque	0	1	0
Tenjo	1	0	0
Tocancipá	0	0	1
Zipaquirá	5	2	10

Tabla 15 - Tabla de contingencia Municipio vs modo durante. Fuente: Elaboración propia

Se observa que se presenta poca diferencia entre el modo de transporte utilizado antes de la emergencia sanitaria y después de la misma. Aunque se resalta que se presenta un leve aumento del uso del carro particular durante la emergencia sanitaria como se puede observar si se compara la Fig. 55 y Fig. 56.

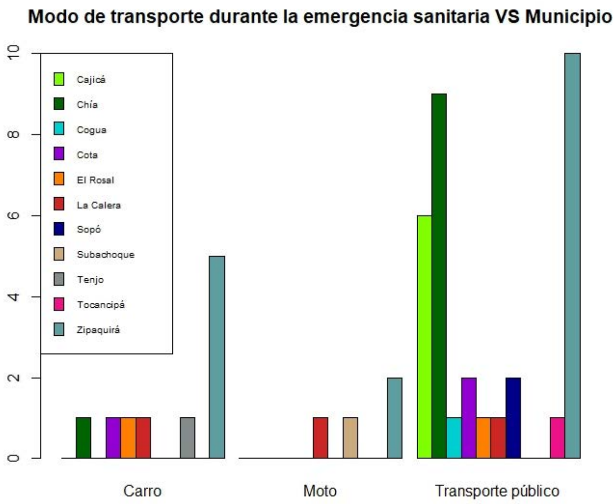

Fig. 56 - Gráfico de contingencias Modo durante vs Municipio. Fuente: Elaboración propia

5.3 Matriz de correlación de Pearson

En el anexo A, se presenta la tabla de Burt de frecuencias relativas realizada para desarrollar los análisis estadísticos de correlación de Pearson. Realizando una exploración inicial de las potenciales relaciones que se pueden presentar entre las variables, considerando también los análisis realizados por medio de tablas y gráficos de contingencias y de frecuencias, en la Fig. 57, se presenta el resultado de los análisis de correlación obtenidos:

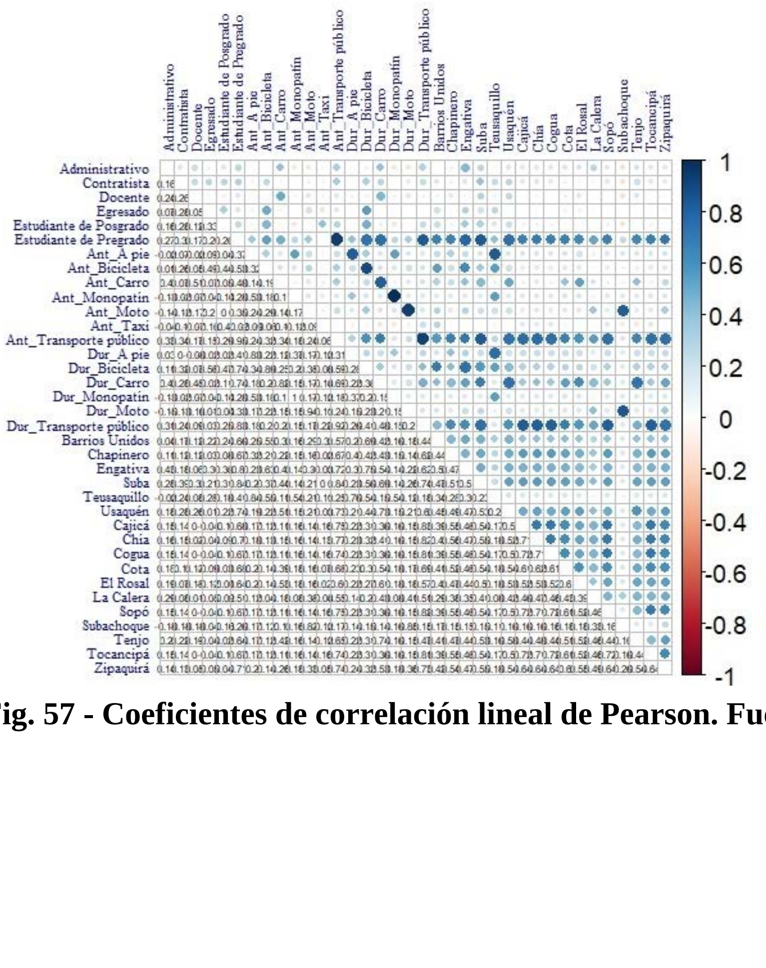

Fig. 57 - Coeficientes de correlación lineal de Pearson. Fuente: Elaboración propia

Observando las diferentes correlaciones obtenidas, se reafirma los supuestos planteados anteriormente, ya que se evidencia que la variable “estudiante de pregrado”, presenta una mayor correlación con la mayoría de las demás variables analizadas, esto corrobora los resultados obtenidos en cuanto a frecuencias y contingencia. Si analizamos los modos de transporte que son el objetivo principal de este análisis, se observa que transporte publico presenta una alta correlación con las demás variables. Por su parte, algunas variables como moto, monopatín, vinculo administrativo, egresado, docente y contratista, presentan poca correlación con la mayoría de las variables de análisis, por lo cual, su uso es poco relevante dentro de la solución del problema estadístico. También se evidencia una alta correlación de localidades como Engativá y Usaquén con respecto a varias de las variables utilizadas, aunque, a manera general, las localidades y municipios si son relevantes dentro de los análisis realizados.

5.4 Análisis de Correspondencias Múltiples (ACM)

Contrastando los resultados obtenidos anteriormente en cada uno de los análisis estadísticos realizados anteriormente, es importante aplicar un análisis de correspondencias múltiples con el fin de corroborar la relación existente entre las variables categóricas, esto de forma gráfica, a partir de los respectivos gráficos biplot obtenidos. Para este análisis, se utilizan las variables de vinculo_un, modo_antes, modo_durante, municipio y localidad. El siguiente gráfico muestra la varianza representada en cada una de las dimensiones contenidas dentro del ACM:

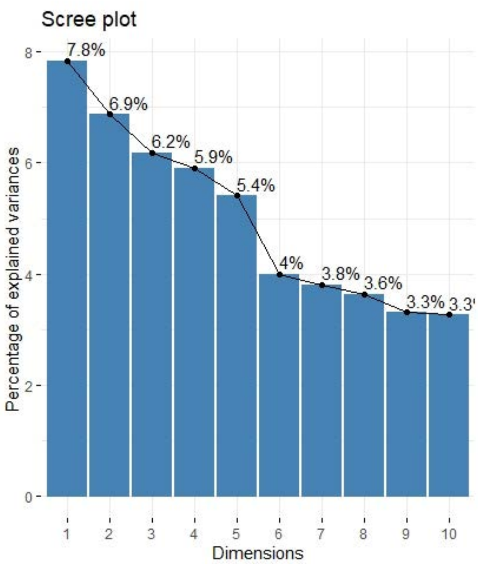

Fig. 58 - Varianza para cada dimensión. Fuente: Elaboración propia

El gráfico Biplot de correspondencias múltiples agrupa los análisis estadísticos de las primeras dos dimensiones.

	Dim 1	Dim 2	Dim 3	Dim 4	Dim 5
vinculo_un	0.0507050	0.01492978	0.07443590	0.01029841	0.1851428
modo_antes	0.5658525	0.75377881	0.80494832	0.88195720	0.6578468
modo_durante	0.6078269	0.70638982	0.81772441	0.87771447	0.6724284
municipio	0.5545850	0.25726166	0.24445404	0.07255927	0.1206911
localidad	0.8087095	0.53478565	0.09692396	0.10372327	0.1482212

Tabla 16 - Varianza por cada dimensión. Fuente: Elaboración propia

Teniendo en cuenta lo explicado anteriormente, a continuación, se presenta el respectivo gráfico biplot de ACM:

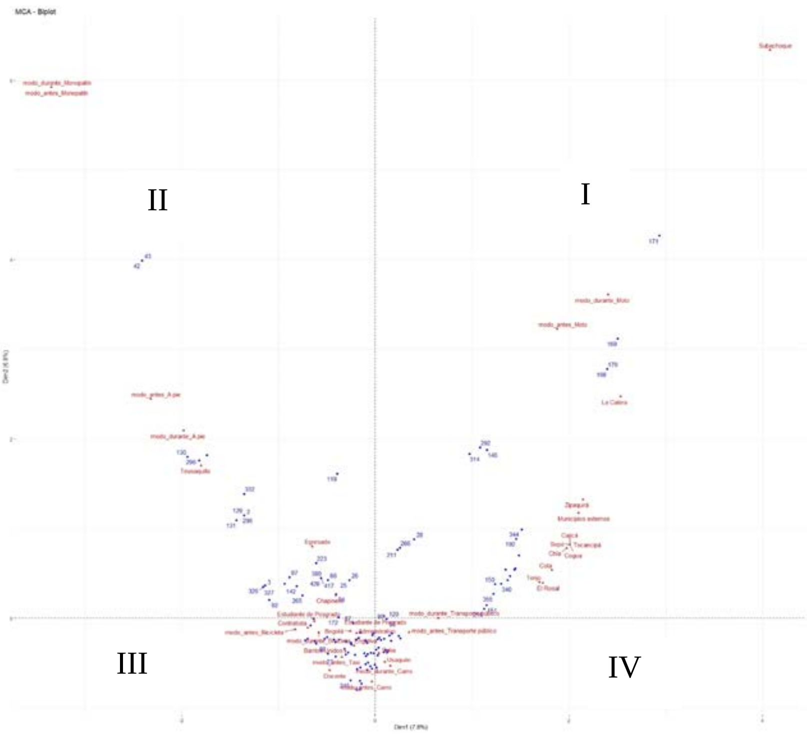

Fig. 59 - Biplot de correspondencias. Fuente: Elaboración propia

Analizando los planos factoriales obtenidos se presenta una relación entre los resultados estadísticos obtenidos anteriormente, ya que "estudiante de pregrado", se encuentra próximo al punto donde cortan el eje de la dimensión 1 y 2, esto se traduce a que esta variable forma un clúster con las demás variables, por lo cual, se evidencia una relación directa entre estas variables que se encuentran agrupadas. Teniendo en cuenta esto, analizamos las variables principales para saber la relación que existe entre estas:

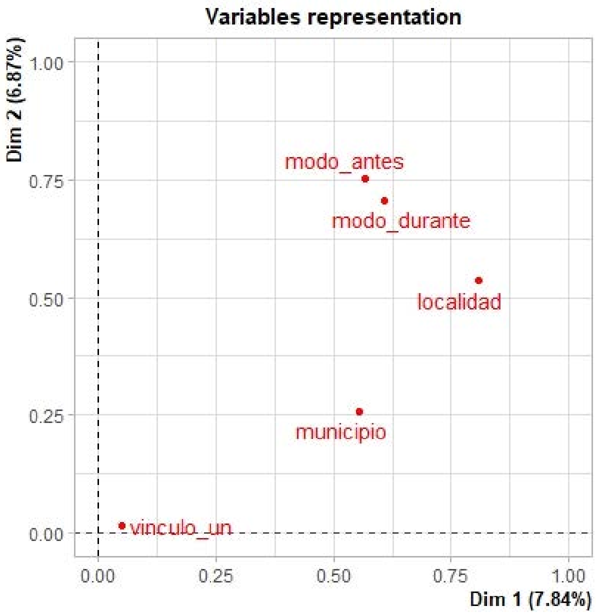

Fig. 60 - Representación de las variables. Fuente: Elaboración propia

Se observa que las variables se ubican en el mismo cuadrante, presentando una cercanía entre los modos de transporte utilizados como se espera que suceda. El siguiente gráfico muestra la relación existente entre los registros analizados, donde se destaca una estrecha relación entre la mayoría de los registros presentados, sin embargo, se observan algunos registros que se encuentra bastante alejados con respecto a los demás, por lo cual, se concluye que estos no son relevantes dentro de la solución del problema estadístico:

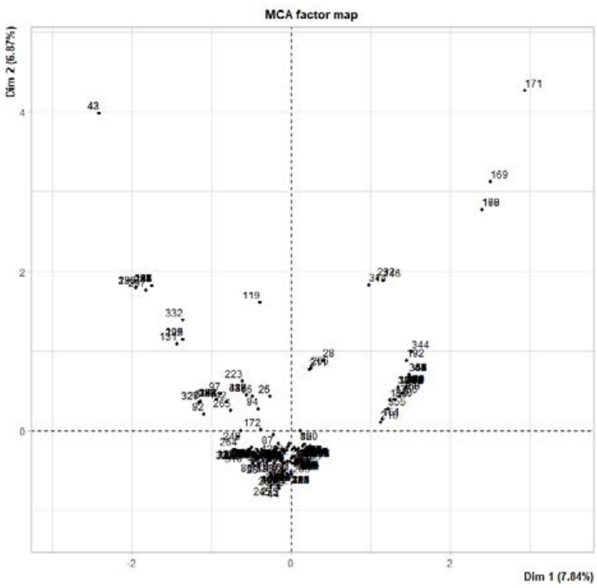

Fig. 61 - Representación de los registros. Fuente: Elaboración propia

En la siguiente imagen se presenta la información del biplot de correspondencias, en el cual se destaca la conformación de clusters y también se descartan variables como modo de transporte a pie o transporte en moto dentro del análisis ya que no son relevantes.

Se destaca también la agrupación que se refleja en el cuadrante 4 de los municipios del área metropolitana, ya que como era de esperarse, existe una estrecha correlación entre estos, por lo cual, el análisis de modos de transporte es relevante para los clusters que se identificaron.

6. CONCLUSIONES

- Se evidencia un interés por parte de la comunidad académica en formar parte del proyecto compartiendo su vehículo o formando grupos de bicicleta para desplazarse hacia el campus universitario, contando con respuestas positivas en las encuestas de un 85.3% de los encuestados.
- Con ayuda de herramientas tecnológicas como lo son la PWA podemos generar soluciones modernas a problemas relacionados con movilidad, que además se acomodan a inconvenientes actuales como lo es la pandemia provocada por el COVID-19.
- Se presenta un interfaz amigable y fácil de usar, adaptable a usuarios sin experiencia tecnológica y que evidencias que es una app que puede ser usada por una comunidad mucho mayor que incluya desde niños mayores de 10 años hasta adultos mayores.
- Este proyecto busca ampliarse a las demás facultades de la Universidad y se contempla la posibilidad de que sea útil también en otros entornos como otras universidades, empresas o entidades.
- Debido a que no se han retomado actividades presenciales dentro de la Universidad, no ha sido posible contar con viajes que hagan uso de esta herramienta, pero tiene la ventaja de ser útil, también cuando se normalice la situación por COVID-19.
- El análisis estadístico realizado arroja una alta correlación entre la variable "estudiante de pregrado" con la mayoría de las demás variables tenidas en cuenta. Es importante para posteriores análisis tratar de ampliar la información recolectada con los demás vínculos de la universidad con el fin de poder caracterizar de una manera más amplia el comportamiento de otros individuos.

ABSTRACT

The 6 public universities od Madrid Region are developing a coordinated strategy to implement Sustainable University Mobility Plans (SUMPs) in their 14 campuses. To this end, a combination of mobility survey and data collection inventory were carried out to set a common methodological basis.

Based on data obtained in the inventory, indicators were designed to measure the accessibility and quality of urban space (for instance, pedestrian and cycling areas with respect to total area, percentage of the campus area occupied by parking facilities, etc), combining quantitative and qualitative aspects adapted to the reality of each campus.

Then, taking these indicators as reference, a comparative analysis of the 14 campuses was performed to identify mobility weaknesses and strengths to support the efficient implementation of the SUMPs.

The results showed that campuses with higher accessibility and compactness have a more integrated and higher quality public space, besides a stricter parking control policy. These characteristics are associated with a lower proportion of trips by car and a higher number of walking trips.

1. INTRODUCTION

The university campuses of the 20th century provided an opportunity for the application of modern theories regarding the city and the building. Campuses occupied vast non-central areas, despite being easily accessible by public transport. They gathered all the necessary attributes of a functionally well-defined urban community.

However, the distorted evolution of this model has generated increasingly segregated and dispersed spaces, which are difficult to access. Currently, the unsustainable mobility pattern of university campuses, in which the large number of trips attracted by individual vehicles stands out, requires strategic actions to foster the use of public transport and active mobility.

On the other hand, universities are a good experimentation ground for innovative ideas in the field of sustainable mobility. Most students do not own their own vehicle, and are more open to alternative ways of transport, especially non-motorised modes (Whalen et al., 2013).

Aligned with the effort fostered by the Community of Madrid to decarbonise urban mobility, the 6 public universities od Madrid Region are developing a coordinated strategy to implement Sustainable University Mobility Plans (SUMPs) in their 14 campuses.

The aim of this study is to perform a comparative analysis of the accessibility and spatial characteristics of these 14 campuses. To this end, they were classified and separated in three groups, according to public transport accessibility and urban configuration. As a second step, quantitative and qualitative indicators were employed to analyse the strengths and weaknesses of the mobility infrastructure of each type of campus. Finally, this technical analysis was contrasted with the perceived quality of the campuses by their users, to establish guidelines to support the design and effective implementation of the SUMPs.

1.1 Background

In recent decades, an increasing number of researchers have questioned the possibility of reducing travel demand, mainly by single-occupancy vehicle, through changes in the built environment (Arellana et al., 2020; Bozovic et al., 2020; Koszowski et al., 2019; P. J. Lamíquiz-Daudén & López-Domínguez, 2015; Lee & Moudon, 2006; Valenzuela-Montes & Talavera-García, 2015). As seminal papers, stand out the pioneer study of Newman & Kenworthy (1989) about the association between urban density and car dependence, and the study of Cervero y Kockelman (1997), concerning the influence of the built environment on travel demand and modal choice through three main dimensions, so-called '3 Ds': ‘density’, ‘diversity’ and ‘design’.

Density combined with diversity approaches the origin to the destination, allows for better quality transport infrastructure, reduces the need for parking and foster a more diversified urban environment. (Cervero & Duncan, 2003; Lehmann, 2016). On the other hand, urban design characteristics such as street network density, block size, sidewalk width, urban furniture and tree-lined streets qualify the urban space and distinguish car-oriented environments from pedestrian ones (Ewing et al., 2006; Ewing & Handy, 2009).

Ewing & Cervero (2001) added two more dimensions to the ‘3 Ds’: ‘destination accessibility’, which measures the ease of access to travel attractions, and ‘distance to transit’, related to proximity to rail stations or bus stops. ‘Demand management’, such as parking supply and cost, would be a sixth ‘D’ (Ewing & Cervero, 2010).

Despite the extensive literature on the subject, there are few studies on university campuses, major traffic generators that demands large parking areas. Balsas (2003) highlights that campuses layout varies according to their urban or peripheral location: suburban campuses generally have a more horizontal and dispersed configuration, apart from being more automobile dependent than urban ones. The distance to the city centre also affects the possibility of walking, cycling and use the public transport.

Accessibility plays a key role in the choice of more sustainable modes of commuting to the campus: 32% of the public transport users of the Autonomous University of Barcelona justify their modal choice by the existence of good public transport service options connecting their place of residence with the university, 30% by comfort, 12% by travel time and 10% by lack of private car or motorbike (Miralles-Guasch & Domene, 2010).

Built environment factors associated with campus active mobility includes proximity, mixed use development, street connectivity and accessibility (Ramakreshnan et al., 2020), as well as bicycle and pedestrian facilities, such as continuity and width of pedestrian paths, lighting, pedestrian signage, disabled-users accessibility, shading elements, safe and separate bike lines, bicycle parking lots, showering facilities, and traffic-calming schemes (Bonham & Koth, 2010; Menini et al., 2021). This schemes must be combined with transportation demand management (TDM) strategies, which include parking policies, subsidies for public modes of transit, rideshare programs, park and ride facilities, etc (Balsas, 2003; Delmelle & Delmelle, 2012).

The combination of the active modes with public transport, providing a well-defined walking and cycling network, has been shown to be effective in the case of longer travels: commuters to university campuses use public transport more often when such facilities are properly provided (Dehghanmongabadi & Hoşkara, 2018). Still, walking and cycling continue to play a marginal role as means of transport, and their infrastructure is continuously neglected in the planning of the campuses. Due to insufficient infrastructure, empirical findings show that there is an unsatisfied demand for non-motorised modes, especially for cycling (Miralles- Guasch & Domene, 2010).

2. CASE STUDY

The case study relies on the 14 campuses of the 6 public universities of Madrid Region: Universidad Autónoma de Madrid (UAM), Universidad Complutense de Madrid (UCM), Universidad Politécnica de Madrid (UPM), Universidad Carlos III de Madrid (UC3M), Universidad Rey Juan Carlos (URJC) and Universidad de Alcalá de Henares (UAH).

Table 1 presents the university population and area of each campus, as well as the modal split.

Name of the campus	University	University population	Area (ha)	Modal shift (%)			
				Car / motorbike	PT	Walking	Cycling
Cantoblanco	UAM	3220	125	36	61	3	0
Somosaguas	UCM	9840	36	32	65	2	1
Ciudad Universitaria	UPM / UCM	25774	480	28	63	7	2
Montegancedo	UPM	2720	23,5	51	47	1	1
Campus Sur	UPM	5062	25	34	61	3	2

Histórico	UAH	10194	82,9	23	58	18	0

Table 1 – Public University Campuses in Madrid

3. METHODOLOGY

In order to obtain information and data on the existing mobility infrastructures, a form was sent to the universities, requesting general data on the campuses. This data was checked and complemented through technical visits and orthophoto analysis to produce a complete inventory, including data such as number of public transport stops, parking places, pedestrian and motorized traffic area, length of cycle paths, etc.

From this inventory, a series of quantitative indicators were generated. Qualitative indicators were also defined to assess the spatial configuration and quality of public spaces on the campuses. The table 2 in the section 4 shows all the quantitative and qualitative indicators used in this study, as well as their results.

In the case of qualitative indicators, reference values from 1 to 6 were used: from “Poor” to “Excellent”. The spatial configuration (compact or dispersed) was defined based on the average of two qualitative indicators: “Density of users” and “Mixed use”. The quality of public spaces was determined by the average of 4 indicators: “Street furniture”, “Continuity and maintenance of the pedestrian network”, “Percentage of tree-lined streets” and “Landscape maintenance”.

Finally, to contrast this technical analysis with the perception of campus users, a survey among the university community was carried out to find out about mobility patterns and users' opinion regarding mobility infrastructure and services. For this study, two questions of the survey related to campus infrastructure were used:

The question “F1: Value the quality of your campus' infrastructure and transportation services” provided a rating from 1 to 6 (from poor to excellent) for the following items:

- Good road access (A)
- Availability of car parking spaces (B)
- Availability of charging points for electric vehicles (C)
- Availability of motorbike parking spaces (D)
- Good access by public transport (E)
- Good access by bicycle (F)
- Availability of bicycle parking spaces (G)
- Good condition of sidewalks and pedestrian tracks (H)
- Proper lighting (I)
- Sufficient vegetation and shade (J)
- Security in accesses and parking (K)

The question “S7: Write down any improvements you deem necessary for your campus” requested a complementary point of view to the previous question (F1), while making it possible to particularize the answer for each campus.

3.1 Campus typology according to accessibility and spatial configuration

For subsequent analysis, campuses have been classified into three types, according to their accessibility to public transport and spatial configuration.

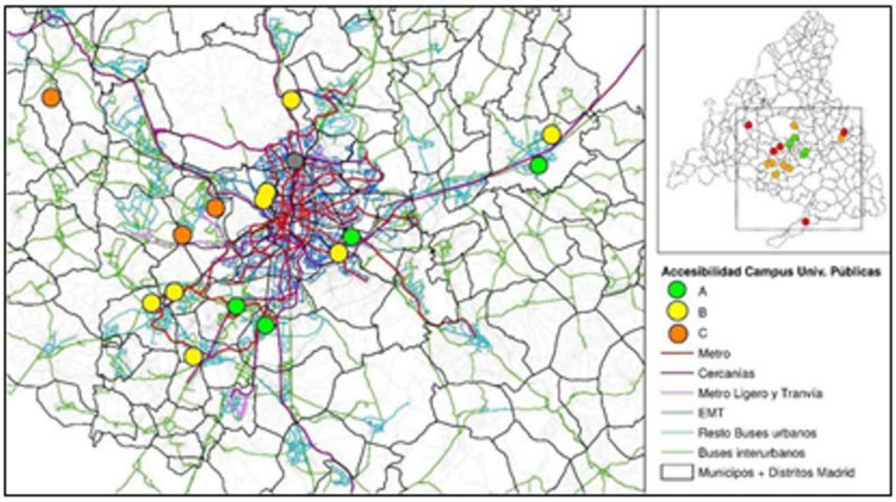

Fig. 1 – Campus typology according to accessibility and spatial configuration

- Type A: Compact urban campuses with access to the Metro/Cercanías: Leganés (UC3M), Getafe (UC3M), Madrid-Vicálvaro (URJC) and Campus Histórico (UAH).
- Type B: Dispersed urban campuses with access to the Metro/Cercanías: Ciudad Universitaria (UPM + UCM), Campus Sur (UPM), Cantoblanco (UAM), Alcorcón (URJC), Fuenlabrada (URJC), Móstoles (URJC) and Científico-Tecnológico (UAH).
- Type C: Dispersed peri-urban campuses without access to Metro/Cercanías: Colmenarejo Campus (UC3M), Somosaguas Campus (UCM) and Montegancedo (UPM).

According to this classification, the analysis of the indicators identified the strengths and weaknesses of the mobility infrastructure and quality of public spaces of each type of campus.

4. RESULTS

Type A campuses have high density of construction and users, as well as other uses other than educational one (housing, cultural, commerce and support services). They are located in areas of higher density and mixture of uses, as is the case of the historic centre of Leganés and Alcalá de Henares.

Furthermore, they have greater connection with the surrounding areas, maintaining a dialogue with the surrounding infrastructure and proposing activities open to the neighbouring population. Compared to the other groups, it presents a lower percentage of trips by car or motorbike, and a higher proportion of walking trips.

Type B campuses occupy larger terrains and have low density, as well as few uses other than educational ones. This classification includes both central campuses of Madrid (Ciudad Universitaria and Campus Sur) and located in subcentres of the Madrid Region (e.g. Alcorcón, Móstoles and Fuenlabrada).

Except for the Ciudad Universitaria, which is open and maintains a good connection with the dense and diversified district of Moncloa, the others have little relation to the surrounding area. This connection is hampered by perimeter closures and large metropolitan infrastructures, such as motorways and train lines.

Type C campuses occupy large areas in transition zones between urban and rural/natural environment, presenting low density, as well as an accentuated monofunctionality: apart from educational and administrative use there have few support services such as cafeteria and reprographics. The connection with the surrounding area is virtually non-existent.

However, this problem is more related to the distance separating these campuses from the nearest centralities than to the existence of barriers or lack of access. The absence of adequate support services to the university community makes it difficult to stay long periods of time on campus and acts as another factor, apart from distance, that encourages people to travel by car. Compared to the others, this group presents a higher proportion of trips by car or motorbike, and a lower proportion of walking trips.

These results are in line with the references consulted (Balsas, 2003; P. J. Lamíquiz-Daudén & López-Domínguez, 2015; Newman, P. and Kenworthy, 1989; Ramakreshnan et al., 2020).

Table 2 summarizes the result of each indicator by university campus, integrating quantitative and qualitative indicators. In green: type A campuses, in yellow: type B campuses and orange: type C campuses.

	INDICATOR	UAM	UCM	UCM + UPM	UPM		UC3M			URJC				UAH	
		Cantoblanco	Somosaguas	Ciudad Universitaria	Montegancedo	Campus Sur	Getafe	Leganés	Colmenarejo	Alcorcón	Fuenlabrada	Móstoles	Madrid Vicálvaro	Científico-tecnológico	Campus Histórico
Quantitative indicators	Nº of public transport stops - less than 1000m	25	44	196	45	82	100	124	6	54	39	74	81	65	201
	Number of parking places/100 campus users	21	24	10	34	19	6	7	14	14	11	10	3	20	2

	Landscape maintenance	4	3	3	4	3	5	6	6	4	3	3	4	2	4

Table 2 – Results of indicators by university campus.

4.1 Accessibility to public transport

Both type A and type B campuses have good accessibility due to the proximity of the Metro and Cercanías train station, as well as numerous urban and intercity bus lines. Type Cs do not have good accessibility. Usually, there are few bus lines departing from specific locations in Madrid city or other parts of the Madrid Region. The frequency of these buses is low, and users spend a lot of time on the journey.

4.2 Parking facilities

The parking offer changes significantly according to the type of campus. Type A campuses stand out for the low number of parking spaces per user and a higher percentage of parking spaces with access restriction.

Despite good accessibility by public transport, especially in the case of the URJC and UPM campuses, which are accessible by Metro, Type B campuses have a wide range of parking and little or no restriction policy. Naturally, this is also the case for Type C campuses, justified by poor accessibility by public transport.

These results reinforce the results obtained by Balsas (2003) Delmelle & Delmelle (2012) and Ewing & Cervero (2010) regarding parking control policy and lower proportion of car trips

All campuses offer more than 87% of their parking spaces for cars, at the expense of spaces reserved for motorbikes and people with disabilities. None have a parking policy based on HOV criteria (High Occupancy Vehicles). They also do not have a significant number of parking spaces reserved for electric vehicles and/or equipped with electric charging points.

4.3 Pedestrian and cycling infrastructure

Due to their compact configuration, type A campuses prioritize the pedestrian space. This situation varies for type Bs and Cs. The campuses of the Universidad Rey Juan Carlos y Colmenarejo (UC3M) concentrate most of the road system, as well as parking lots in the peripheral area. In contrast, the interior preserves large fully pedestrian areas. This configuration has the advantage of maintaining the continuity of the pedestrian zone and establishing a balance between the road system and the pedestrian space.

On the other hand, the UAM, UCM, UPM and Científico-Tecnológico (UAH) campuses prioritise the road system, which impairs the continuity and fluidity of the pedestrian space.

Regarding cycling infrastructure, although none of the campuses have a suitable cycling network, that is, continuous and extended, some stand out for a greater extension and balance between segregated cycle lanes and road system, as well as more bicycle storage facilities, as for example, Ciudad Universitaria (UCM + UPM).

Most campuses prioritise the shared use of road space with bicycles without adopting calm traffic strategies and proper signage. Type A campuses and those of the URJC that belong to group B are cyclable over most of their surface, without the need to compete for space with vehicles. However, in a scenario of greater use of bicycles to commute to campus, measures should be adopted to avoid conflicts with pedestrians, such as bicycle dismounting zones.

The Getafe and Leganés (UC3M) campuses have a higher supply of bicycle parking spaces than the others. This is possibly the result of a combination of factors: central location, more developed cycling infrastructure in the surrounding area and parking restriction policy, which mainly affects students.

Bicycle-friendly campuses also have more safety concern, locating the facilities in high-traffic locations and adopting surveillance and access control strategies.

4.4 Quality of public space

The quality of the public space is the result of the combined analysis of 4 indicators: 'urban furniture', 'continuity and conservation of the pedestrian network', 'percentage of tree-lined streets’ and 'landscape maintenance'.

Being more compact, type A campuses have a more integrated space that favours the creation of convivial areas. On the other hand, these campuses spend fewer resources in the care of public space: they stand out for the quantity and quality of urban furniture, diversity of herbaceous plants with a high level of maintenance and good condition of the sidewalks.

In this sense, the Campus Histórico (UAH), for example, benefited from the pedestrianization plan developed by the City Council of Alcalá de Henares for the historic centre.

Unlike the previous case, the dispersed configuration of the campuses of groups B and C makes it difficult to create convivial spaces, as well as install and maintain urban furniture and the landscaping. The great distance between buildings and the excess of public space do not favour the appropriation of space by people. In the case of the UPM, UAM and Científico-Tecnológico (UAH) campuses, the car-oriented design prioritises the road system and fragments the space.

These results are in line with Cervero & Kockelman (1997); Ewing et al. (2006) and Ewing & Handy (2009).

In contrast, Colmenarejo (UC3M) stands out for its high quality of public space: the campus concentrates educational and administrative activities in a limited space, while the rest of the campus integrates a green area (Botanical Garden) with impeccable maintenance that also acts as a convivial space.

4.5 Perceived quality of campuses according to users

Table 3 shows the results of the assessment of campus infrastructure according to the perception of its users, according to a rating from 1 to 6 (from poor to excellent).

Name of the campus	University	A	B	C	D	E	F	G	H	I	J	K
Cantonlanco	UAM	5	5,1	2	3,9	4,7	3,9	3,8	4,5	4,5	4,8	4,6
Somosaguas	UCM	4,8	5,1	1,8	4	4,3	3,2	3,4	4,2	4	4	4,3
Ciudad Universitaria	UCM / UPM	4,8	3,8	2	3,6	4,8	4,2	3,8	4,3	4,3	4,3	4,2
Montegancedo	UPM	4,6	4,9	1,5	3,9	3,1	2,3	2,9	3,9	4	4,6	4,3
Campus Sur	UPM	4,8	5,2	1,7	4,1	4	3,3	3,3	4	3,7	4,5	3,7
Getafe	UC3M	4,9	4,5	2,5	3,4	4,5	3,8	3,9	4,7	4,6	4,3	4,5
