CONNECTIONS BETWEEN MOBILITY AND URBAN FABRICS IN THE CITY OF BURGOS (SPAIN)

Roberto Serrano-López

Alaitz Linares-Unamunzaga
Civil Engineering Department. University of Burgos

RESUMEN

Previous research has studied possible links between different urban environments and induced mobility. The traditional Spanish city patterns have specific features that promote the use of soft modes, mainly favouring pedestrian presence in the streets. Nevertheless the last twenty years development has changed the previous urban reality in many towns, following some sprawl characteristics and occupying much more land than strictly necessary. Accordingly, we have analyzed the morphology of Burgos using the perspective of urban fabric differences. Focusing in some parameters such as density of dwellings, population and compactness, we have tried to understand the underlying correlation between urban environment and private car trip generation.

However, although some of these urban variables can be considered as quantitative and quick indicators for unsustainable modes of transport, the effects of compact or diffuse development cannot be figured without taking into consideration other parallel factors that configure urban vitality. A previous qualitative analysis of urban growth and development may help to grasp this reality, connected with design criteria trends and urban planning policies. Likewise, mobility cannot be completely understood if only quantitative correlation is prosecuted. The retail distribution or concentration, the presence of malls, the excessive streets broadness, the existence and size of open spaces, or the residential building typologies have verifiable impact on the final modal share. Our results show clear correspondence between low dense urban fabrics and higher number of car trips. Hence, future urban development and reform policies must be oriented if sustainable mobility objectives want to be fulfilled. We suggest some final recommendations with this aim.

1. INTRODUCTION

Multiple studies have tried to understand the underlying connection between urban morphology features and mobility, many of them trying to find the best practices to achieve sustainable solutions and policies. Research has used different statistical and modelling tools and approaches to tackle this. An important part of the results have shown that compactness and density are initial indicators of a lower use of car in terms of kilometres travelled (Ewing et al., 2018; De Vos, 2015; Ewing and Cervero, 2010).

However, some others have evinced no significant influence, no direct effect reflected in the analysis, or an increased complexity due to regional differences (Maat et al., 2005; M. G. Boarnet and Sarmiento, 1998; Ewing et al., 1996; M. Boarnet and Crane, 2001; Lin and Yang, 2009). Anyway, we can accept an academic consensus about the convenience of the so called 5D-variables explained by Ewing and Cervero (2010) in terms of sustainable urban development: density, diversity, design, distance to transit, and destination accessibility.

Critically reviewed, we can argue that in many of previously referenced works there is a strictly statistic use of data. Neighbourhoods, districts, towns, suburban areas, travelled kilometres, shopping areas, citizens, and number of trips are numerically adopted by a more simple or complex model to study the possible correlations. Nevertheless, spatial differences are usually forgotten, even when important variances can be observed in very near zones or neighbours. We find here a gap in this kind of studies that must be accordingly revised and which plays a special role in small and medium cities (SMCs) due to the reduced trip distances.

Moreover, density and compactness cannot be analyzed as isolated variables. Counterbalance effects were identified in large cities when high congestion may be provoked by origin-destination concentration, where increased investment on highways is consequently required (Ewing et al., 2018). A carefully design of land use distribution added to parking control measures were identified as requirements to reduce car dependence, seeking for polycentric distributions and adequate mix of uses (Choi, 2018).

On the other hand, low density and compactness have been previously identified as key factors in many other negative factors: health problems (Hamidi et al., 2018); local urban service and facilities costs (Sole-Olle and Hortas-Rico, 2008); and ecological or pollution drawbacks (Cárdenas Rodríguez et al., 2016; Chen et al., 2019). The important impact that transport and urban planning policies has on climate change mitigation strategies has been also recognized by the Intergovernmental Panel on Climate Change (Sims et al., 2014), which suggested a reduction in private cars use as a major contribution to achieve these objectives.

In summary, research has shown the potential of urban planning decisions on mobility, and their implication on health and other important issues. However, we consider that the particular urban morphology of each city plays an essential role in the understanding of this connections and possible effects. Therefore, we introduce here a novel path to perform a locally oriented study of theses links, as an alternative o complement to mere statistical or numerical approaches that forget the city singularities. For this aim, we suggest an urban pattern and tissue analysis to find out possible expected differences when similar values of density or compactness are compared.

2. URBAN TISSUES ANALYSIS

For the purpose of this work, we have selected the city of Burgos as an example of Spanish SMC. Due to its population of 175821 inhabitants (Spanish Statistical Office, 2019) we can consider it as a representative MC according to European statistics. Burgos, placed in the north of Spain between Madrid and Bilbao, experienced a quick increase in number of inhabitants between 1996 and 2012, and after a slight reduction is now in a plateau situation (fig. 1). Burgos has an important heritage ensemble and is crossed by Arlanzón River in the east-west axis. Current local land-use regulation was planned in 2008 and reviewed in 2013, including a set of developable zones denoted as sectors by regional laws.

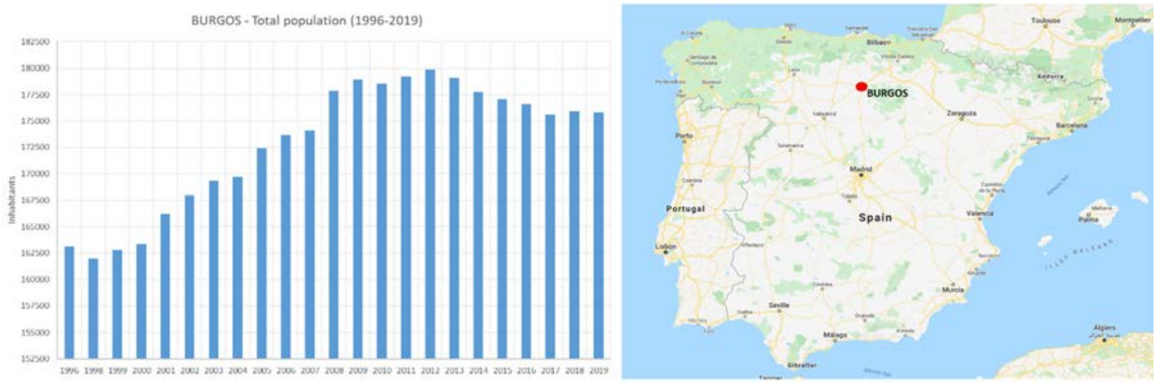

Fig. 1 – Population and location of Burgos (Spain). Source: Google Maps

Fig. 2 – A selection examples for the different urban tissues identified in the city of Burgos. A: historic centre; b: the garden city concept; c: traditional popular area (type 1); d: traditional popular area (type 2); e: first extension; f: second extension, compact; g: second extension, ultra-compact; h: second extension, open type; i: third extension. Source: Google Maps.

Regarding to the already built land, the growth of the city has experienced different phases. This growing mode is very linked with the urban tissue distribution and contrasts. In fact, we can distinguish the following fabrics in parallel to the historical spread of the residential uses. We here generally agree with previous selection criteria by other authors (Andrés López, 2013), but grouping part of them in homogenous sets: Historic centre and near surroundings, Garden city, Traditional popular areas, First extension (1930-1964), Second extension (1960-1980), Third extension (1980-nowadays). Performing a brief analysis of planning features of each of them is an unavoidable step to understand the daily movements of neighbours.

2.1 Historic centre and near surroundings

Although the city was founded around 884 A.D., many buildings in this area were erected between the endings of 19^{th} century and the fifties of 20^{th} century (Andrés López, 2004), and an important part of them have been internally refurbished or adapted in the near past (Fig. 2a). However, the singularities of this district and tissue are intrinsically connected to its origin: a medieval urban pattern with narrow and irregular streets, very compact small-buildings distribution, outdated services, and lack of parking lots. Burgos centre is, since many years ago, partially pedestrian. Nowadays the district is focused on tertiary sector, attracting a vast part of city population to its restaurants and bars, and very connected to the tourism due to the heritage richness.

2.2 Garden city

This special tissue is not a follower of the original Garden City movement spirit, but nearer from the Garden Suburb concept (Andrés López, 2000). Like in other Spanish cities, mainly during the twenties of 20th century, the emergent bourgeoisie was offered to live in specially designed areas for high-income families. These types were commonly placed in the periphery, and the use of vegetation played an important role in the concept. Initially disconnected from the urban core and designed with very low density of detached single-family houses, the growth of Burgos has engulfed this neighbourhood (Fig. 2b).

2.3 Traditional popular areas

Inside this tissue we want to distinguish two different types or groups of popular areas. The first (type 1 in Fig. 2c) are related with the so called Low-income houses law (*Ley de casas baratas*), which were built in Burgos during different phases between 1911 and 1936 (Delgado Viñas, 1992). The main characteristic is the typology: semi-detached or attached single-family houses, with small gross floor area, a little garden included, and reduced budget. Most of these have been already demolished to build multifamily buildings during the 20^{th} century. However, some of them continue in the same position and configuration, although many have been refurbished to be adapted to current building and isolation standards.

The second group (type 2 in Fig. 2d) consists of three low density small popular neighbourhoods built around the thirties of 20th century. Generally speaking they have with very similar features than the first group, but the number of houses is bigger forming each one a sort of core, like a very small village. The size of dwellings is usually bigger in this case. Even though they were initially built far away from urban core, the growth of the city has reached them.

2.4 First extension (1930-1964)

A reduced residential multifamily development was produced during the post Civil War period. The closed block is the used typology (Fig. 2e), with a very compact distribution of dwellings and relatively high population density. A not fully regular gridiron plan was used for the street pattern. Commerce is placed in the ground level.

2.5 Second extension (1960-1980)

An important growth occurred in this period, affecting to several zones of the city. We can distinguish here differences depending on the year of design. First, a compact (Fig. 2f) or ultra-compact (Fig. 2g) closed block solution was extensively used, reaching an exceptionally high population density. Here a lack of parking lots and open spaces is often found, but the compactness promote on foot daily trips. On the other hand, open types like blocks and towers were built (Fig. 2h), with open spaces or parking areas around them.

Sometimes the buildings are distanced each other, extending pedestrian distance. This tissue was also affected by the intersection of big mono-functional zones (mainly sports and schools). Although buildings by itself are densely populated, the distances and interspaces reduce global values for this variable. The ground floor includes space for tertiary sector.

2.6 Third extension (1980-nowadays)

The latest developments are usually featured by oversized carriageways, commonly using a grid pattern (Fig. 2i). Regarding to typologies, a mix of possibilities is found. The open block is revisited, and the closed block has been erected sometimes with a bigger horizontal dimension. Internal block areas include occasionally private services (sport yards, green zones, swimming pools…). Open spaces are often underused due to size, design or placement. Although a mix of used is promoted by regulations, it is usually formalized using detached buildings, while ground floors are sometimes devoted to residential uses. In some cases the planned density has been not reached due to incomplete development, or the presence of half-empty buildings.

2.7 Tissues summary

Table 1 qualitatively summarizes the basic characteristics of Burgos urban tissues.

	Tissue	Density	Open spaces	Commerce
a	Historic centre	M	M	H
b	Garden city	VL	L	VL
c	Traditional popular area (type 1)	L	VL	VL
d	Traditional popular area (type 2)	L	L	VL
e	First extension	M - H	L	H – VH
f	Second extension (compact)	H	L – M	H - VH
g	Second extension (ultra-compact)	H -VH	L – VL	VH
h	Second extension (open type)	M - H	H – VH	L- M
i	Third extension	M	M - H	L - M

Table 1 – Tissues features as a glance (VL= Very Low, L=Low; M=Medium; H=High; VH= Very High).

3. URBAN PARAMETERS AND GENERATED CAR MOBILITY

The use of official statistics and cadastral data for population and dwellings (Spanish Statistical Office, 2011; Spanish Cadastral Office, 2017) was combined with a GIS software (QGIS Development Team, 2017). To compute density and compactness, postal sections were used as geographical divisions. Population was randomly placed in each section. To calculate compactness, a total buildings volume estimation was divided by section area. OpenStreetMap database (OpenStreetMap, 2019) was consulted to gather the distribution of common commercial uses: small shops and offices, cafeterias, bars, retail business, bank offices…. Number of private car trips generated were also extracted from the origin/destination matrix from a mobility study included in the city General Plan (Burgos City Hall, 2014), which were later coherently and randomly dumped in the already mentioned sections. Different maps were performed as layers using QGIS tools as a result of these operations (Fig. 3), generating heat maps for population density, commerce and trips. Number of trips was normalized using population and areas of each section for comparison purposes.

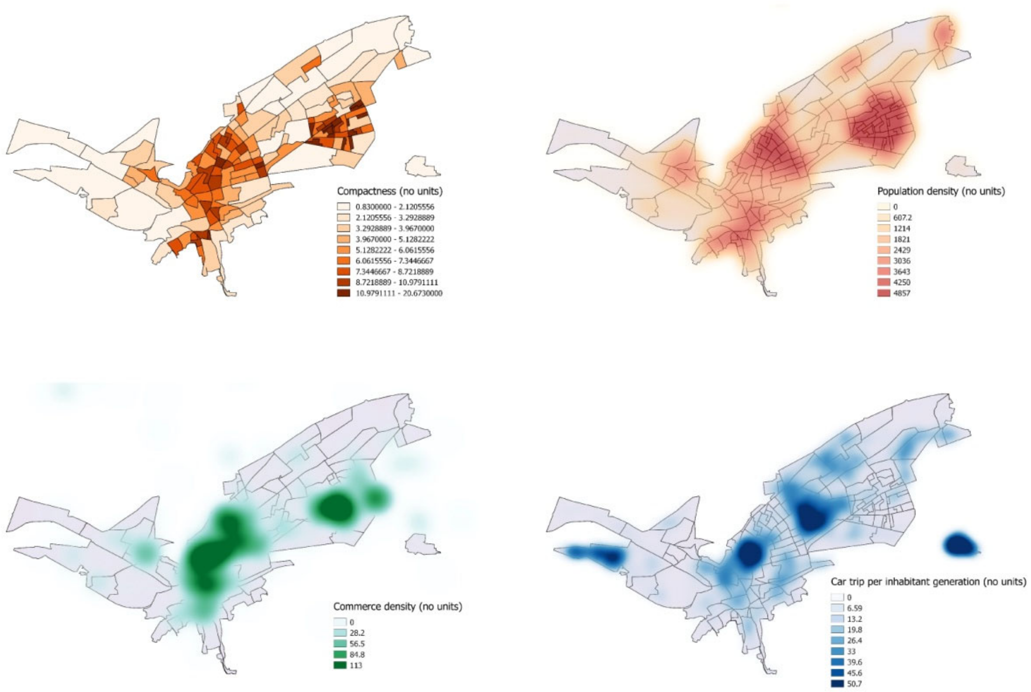

Fig. 3 – Top left: compactness density. Top right: population density. Down left: commerce density. Down right: generated private car trips density. In all cases, densities have no units but represent clearly the differences among the different sections.

As a result, a noticeable correlation can be identified between compactness and density, and also with the retail business distribution pattern. Regarding to mobility, zones with lower commerce presence are those with a higher generation of car trips. Moreover, the features of the urban tissues (Table 1) and the position on the city map are very connected with the generation of private car trips. The mentioned features have to be joined with some other section variables as the age of population and number of young families. Fig. 4 includes the map of the city and car trips, superimposing the characteristic tissue of each part of the city.

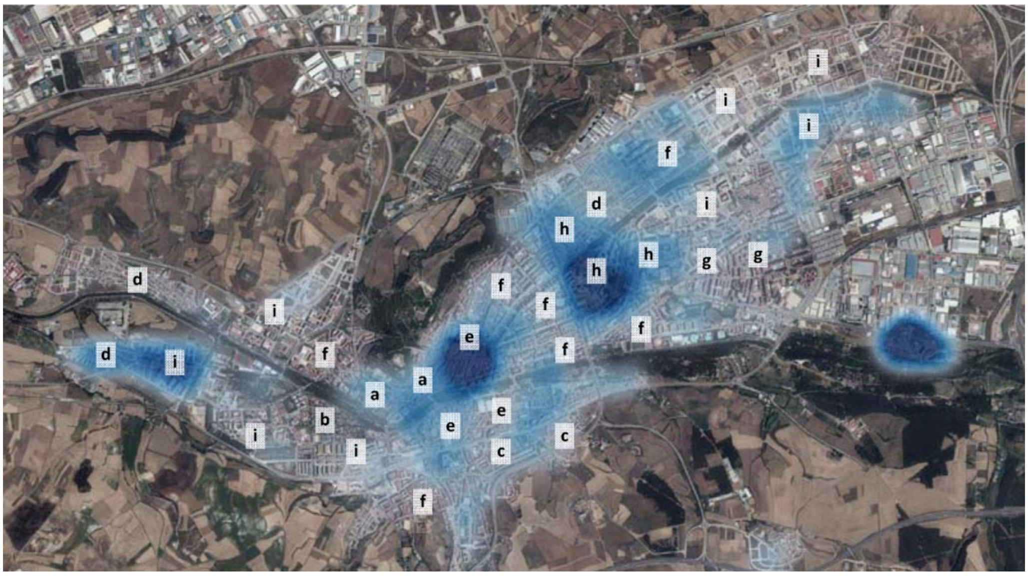

Fig. 4 – Density of generated car trips over the tissue map distribution.

4. PLANNING RECOMMENDATIONS

The links between urban environment characteristics and mobility shown by our results allow inferring a set of recommendations for future planning decisions in SMCs development:

- Regulation may be not enough to achieve sustainable mobility results if not clear objectives are prosecuted and implemented For instance, a minimum mix of uses can be applied in a development area without avoiding segregation of commerce.
- To obtain adequate results in diversity of uses, a minimum density of 80-90 dwellings per hectare may be considered as the standard.
- Although important, high density is not enough to reach adequate values of compactness and variety in the area where are placed. Additional requirements must be applied in addition to mere density, because it can be distorted by the use of high density buildings (e.g., tall towers) in a low density area. However, density may be a good indicator when compactness and short distance mix of uses are fulfilled.
- Number and position of parking lots must be strictly studied to avoid attraction of unnecessary car trips.
- Pedestrian friendly environments, and short trip distances by adequate mix of uses are adequate policies to promote. Open spaces are needed and coherent with these principles, but the size and position must be carefully designed in a bigger scale. Too big open spaces may become counter-productive, underused or empty islands, increasing also pedestrian distances.

4. CONCLUSIONS

Previous research has applied statistical models to huge databases in large metropolises or urban regions.

We have oriented our work to a visual mapping and comparison in a particular city reality, to identify local particularities in its daily trip context. Our study has shown not negligible links between urban planning decisions (i.e. urban tissues) and induced unsustainable mobility in a SMC. Therefore, we suggest a set of recommendations to promote active travel modes and reduce car dependence.

GREENHOUSE GAS EMISSION IN URBAN PASSENGER TRANSPORT

Héctor Rubén Tarcaya
National University of Salta, Faculty of Engineering, IIDISA. Argentina.
Angélica Noemí Arenas
National University of Salta, Faculty of Engineering, IIDISA, INIQUI. Argentina.

ABSTRACT

Public transport of passengers is one of the development axis of the communities, due to the positive impact on socio-economic activities and its link between central and peripheral communities. In the city of Salta this situation also occurs, where public passenger transport is conceived as a metropolitan service. Such transport meets the population's need for mobility and, among its impact, contributes to the generation of greenhouse gases from combustion engine emissions. This paper presents an estimate of CO2 emissions in urban passenger transport in Salta, based on the collection of data on fuel consumption and distances. At the same time, it analyzes the CO2 emissions as a consequence of the COVID-19 pandemic. The results allow to visualize a trend of this emissions.

1. INTRODUCTION

1.1 Objet of Study

In fulfilling its main objective of providing mobility, transportation generates numerous impacts, including the generation of greenhouse gases. Globally, emissions from the transport sector correspond to 73% to road transport, 9% to international maritime transport, 11% to aviation (international and cabotage), and only 2% to rail (Barbero and Rodríguez Tornquist, 2012). In Argentina, road transport has a greater share than the word average and the national emissions of the transport sector calculated by mode reach a 90% share for road transport, followed by a distance by 5% corresponding to navigation, 4% for the air transport and 1% for rail. If road transport emissions are discriminated according to the type of demand, it is estimated that freight transport generates 61%, and passenger transport 39% (Secretaría de Ambiente y Desarrollo Sustentable, 2007).

The present work has the purpose of estimating the amount of greenhouse gases, with regard to carbon dioxide, emitted by urban passenger transport in the city of Salta. For this, the amount of fuel consumed and the factor of GHG emission is considered. It is a descriptive work, based on documentary research and field research. On the documentary side, research antecedents on the subject of this work, were firstly analyzed. The field research was based on data collection and interviews in public transport companies of the city of Salta. This article is structured as follows: in section 1 a brief introduction is presented. Section 2 presents the results and same good practices to reduce emissions. The paper ends with conclusions and references.

1.2 Characteristics of the operation of passenger transport in the city of Salta

The city of Salta, capital of the homonymous province, is located in the northwest of the Argentine Republic, and concentrates 44% of the provincial population. It constitutes the center of the so-called metropolitan area with 536.113 inhabitants (INDEC, 2010). Its population has grown by 46% in a period of 19 years. The Salta Metropolitan Area is made up of four departments, which includes eight municipalities. The public transport service is provided through a private state-owned company that unifies the management of the contracted companies for 8 corridors. It operates the 49 lines of the route network that cross the metropolitan area. The service operations include a fleet of 618 units (1,2 units per 100.000 inhabitants) with an average urban frequency in peak time of 7 minutes between bus units, which carry 650.000 passengers per day and more than 183 million per year (Arenas et al, 2016; Tarcaya et al, 2018).

2. RESULTS AND DISCUSSION

2.1 Estimation of CO2 emissions

The total number of passenger transport units is 618 vehicles powered by diesel engines that use diesel as fuel. This total is distributed in 8 transport companies. Of the aforementioned fleet of public transport vehicles for the study, two companies, called “A” and “B” were considered (Transportation companies, 2021). They have 105 and 58 units respectively. The sample considered makes a total of 163 units, representing 26,4% of the fleet of transport vehicles. In both cases, data was taken on kilometer travelled and fuel consumed, detailed per month during the years 2019 and 2020.

For the estimation of carbon dioxide emission, the conversion factor proposed by the Secretary for the Environment and Sustainable Development (2008) in version 1.0 of the document “The carbon footprint of the average Argentinian” as considered. Such conversion factor is expressed in Equation (1):

$$\text{Diesel emission factor} = 2{,}77\ (KgCO2\text{-}e\ /litre) \qquad (1)$$

Based on the data collected, we proceeded to the estimation of carbon dioxide emissions during the years 2019 and 2020, which is presented in Tables 1 and 2.

Table 4 - CO2 emissions in company "B" during 2020

In Figure 2, a comparison of carbon dioxide emissions during the years 2019 and 2020 in company "B" is shown. As in company "A", the fall caused by the isolation measures as a consequence of the COVID-19 pandemic is also observed, starting in the second half of March 2020.

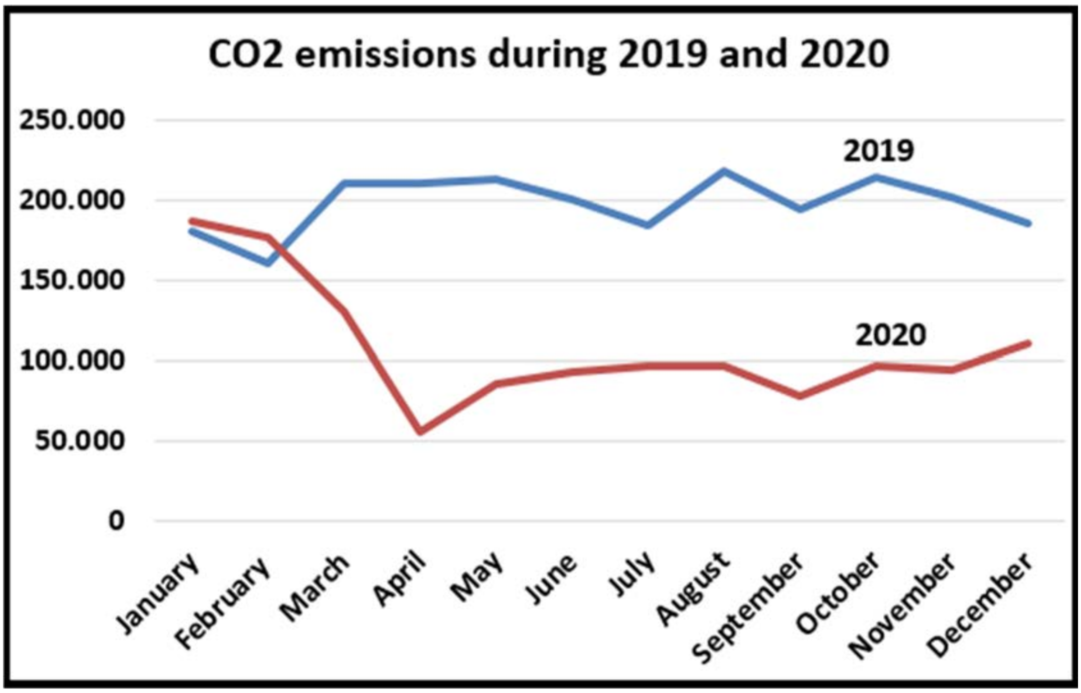

Figure 2 - CO2 emissions in company "B" during 2019 and 2020 years

In both companies, a similar trend is observed in carbon dioxide emissions proportional to the liters of fuel consumed.

This can be considered as the bases for an estimate for the entire fleet of transport vehicles.

Since the isolation measures were stablished in the city of Salta, mobility has not been the same again, since at first only essential workers could travel by public transport. This caused the buses to circulate with few passenger and, in many cases, without passenger at bus stops. This changes in mobility also caused reductions in CO_2 emissions per kilometer travelled, since driving with fewer stops, the fuel efficiency was higher, as it is observed in Figure 3.

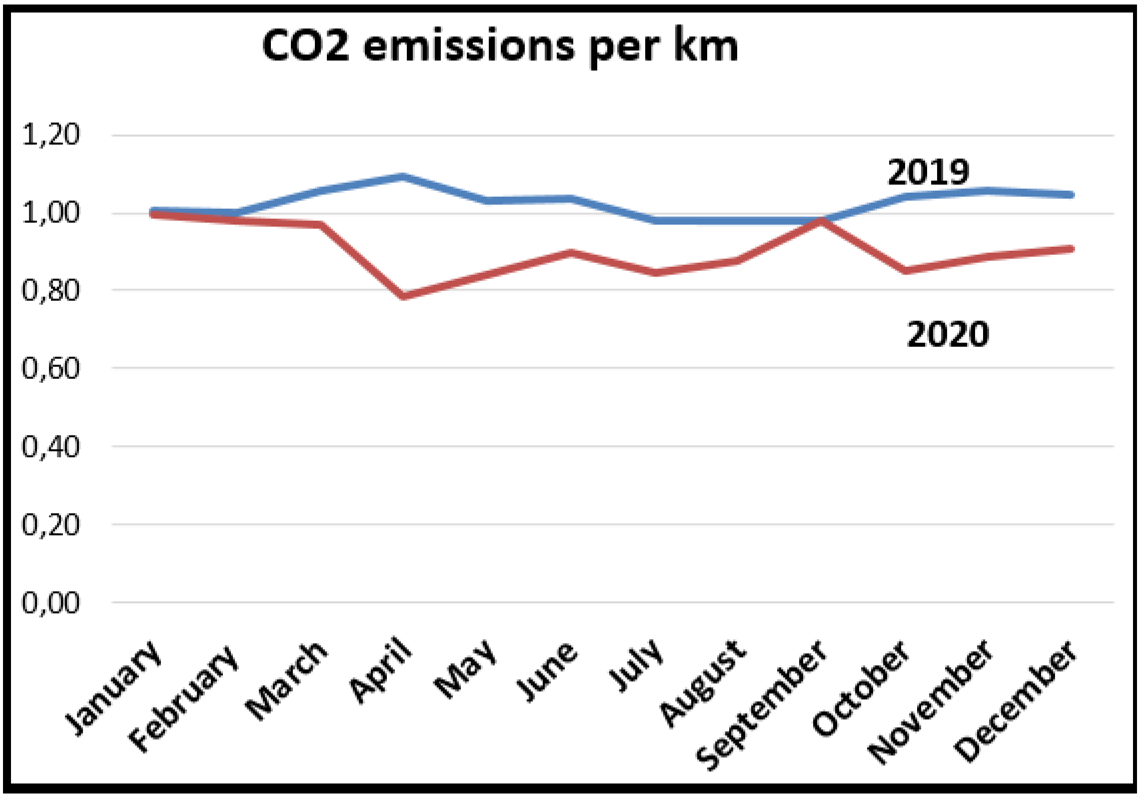

Figure 3 - CO2 emissions per km during 2019 and 2020 years

2.2 Good practices to reduce emissions

Among the good practices that are recommended to reduce carbon dioxide emissions in buss transports we can mention:

Maintenance controls: Maintenance is not only a strategy for reducing fuel consumption, but it also a key aspect of vehicles safety. Tires pressure control is substantive, since in case of being deflated they have greater resistance to rolling. Greater pressure translates into less flattening, reducing the area of contact with the pavement and reducing the resistance force (Instituto del Transporte, 2016). Air and fuel filter controls are also recommended, leading to a richer mixture in combustion, with a more rational use of fuel.

Efficient driving: Considering that fuel consumption increases at high and low speeds, it is recommended to ride in the longest possible gearbox and at low revolutions. It is also recommended to keep the speed of circulation as uniform as possible and driving with anticipation and foresight, avoiding sudden accelerations (Instituto del Transporte, 2016).

Fuel change: Public transport vehicles using compressed natural gas (CNG) engines is a pilot test in Argentina. The change from diesel fuel to CNG is an important mechanism not only to reduce emissions, but also to reduce total costs (Puliafito and Castesana, 2010; Montero Sanz and Díaz López, 2014; Scania, 2019).

3. CONCLUSIONS

The work shows a first approximation of the estimates of carbon dioxide emissions in part of the fleet of public transport of passenger vehicles, with the limitations and the availability of data and information by the time of doing it. However, even with these restrictions, it was possible to identify trends and good practices to improve fuel efficiency, and therefore reduce the emissions.

Some aspects of this study might be limited. For example, the sample considered represents only 26,4% of the fleet of transport vehicles. This and other limitations of the work will be the focus of further research.

This work is a starting point for future research to complement it, in order to reduce carbon dioxide emissions and thus contribute to the preservation of the environment.

RESUMEN

La descarbonización de la movilidad urbana se ha convertido en uno de los principales objetivos de las ciudades, que ven cómo florecen diferentes planes y estrategias para hacer frente al cambio climático. Dentro de las ciudades, las universidades son áreas que propician la concienciación sobre estilos de vida respetuosos con el medio ambiente. El presente trabajo describe una acción que se puso en práctica en la Semana de la Movilidad Europea de 2019 en la Universidad Politécnica Madrid (UPM).

El objetivo fue que toda la comunidad UPM (más de 40.000 personas) conociese las emisiones de CO_2 diarias de sus desplazamientos a la UPM. Para ello, se realizó una sencilla encuesta de movilidad online en la que los encuestados indicaban los modos de transporte que utilizaban para llegar a los centros UPM, la distancia que recorrían y el motivo de escoger dichos modos. En 3 días que duró la campaña, se recogieron 2.149 respuestas.

El estudio incluye una metodología para calcular los factores de emisión de dióxido de carbono por modo de transporte del área metropolitana de Madrid. Los resultados demuestran que el transporte público es el modo principal utilizado por la comunidad UPM con más del 75% de viajes realizados, los modos privados representan el 17% y los modos blandos un 8%. Sin embargo, son los modos privados quienes emiten más del 55% de las emisiones de CO_2 totales de la UPM.

Tras un análisis en profundidad de los motivos que llevan a utilizar un modo u otro, se proponen un conjunto de políticas para la reducción de las emisiones. Se destaca la campaña de concienciación que se realizó en la Semana de la Movilidad con la difusión de los resultados en Ciudad Universitaria para hacer partícipe a la ciudadanía de los impactos al clima que tienen nuestras decisiones individuales.

1. NTRODUCCIÓN

El crecimiento de la población en las áreas urbanas -en 2018 el 55% de la población mundial residía en áreas urbanas y se prevé que para el 2050 más del 70% de la población mundial se concentre en áreas urbanas (United Nations, 2019)- conlleva un aumento de la movilidad urbana con sus derivados impactos medioambientales, como son las emisiones de Gases de Efecto Invernadero (GEI). Una de las consecuencias es que la descarbonización de la movilidad urbana se ha convertido en uno de los principales objetivos de las ciudades, con la implementación de planes y estrategias para hacer frente al cambio climático.

Este es el caso de España, donde las principales ciudades están tomando medidas para frenar las emisiones GEI y la contaminación en las áreas urbanas a través de planes de acción y estrategias de cambio climático y energía limpia, que se complementan con planes de calidad del aire y eficiencia energética. Una de las medidas que lleva implementándose desde la aprobación de la Estrategia Española de Eficiencia Energética 2004-2012 (E4) (IDAE, 2003) y el siguiente Plan de Acción 2011-2020 de la E4 son los Planes de Movilidad Urbana Sostenible (PMUS) junto con los Planes de Transporte al Trabajo (PTT) cuyos objetivos de reducción de emisiones son del 10% en las áreas urbanas. Entre muchas acciones, en el caso de la capital de España, en 2017 se aprobó el Plan de Calidad del Aire *PLAN A* (Ayuntamiento de Madrid, 2017) para cumplir con los objetivos de calidad del aire de la Unión Europea. Dentro de dicho plan se enmarca la *Zona de Bajas Emisiones (ZBE) Madrid Central* pionera en España, que comenzó a funcionar en diciembre de 2018, y donde se restringe el acceso libre de los vehículos en una amplia zona. Madrid Central tiene el doble objetivo de reducir la contaminación atmosférica y las emisiones GEI. Según apunta un estudio preliminar de Blázquez (2019), en los primeros meses demostró ser útil para mejorar la calidad del aire, aunque eran necesarias medidas más fuertes para logar reducir de forma más notable las emisiones.

Otra medida son las campañas de información y comunicación a la ciudadanía. Diversas fuentes señalan que si los ciudadanos son más conscientes de las posibilidades de estilos de vida y hábitos de consumo respetuosos con el medio ambiente, se les puede alentar a experimentar en su vida diaria acciones que ayuden a reducir las emisiones de dióxido de carbono (Delmas et al. 2013; Klöckner, 2015). Sobre estas campañas de sensibilización e información a la población trata de enfocarse el presente trabajo. Aprovechando la Semana de Movilidad Europea de 2019 se puso en marcha una acción en la Universidad Politécnica de Madrid (UPM) preguntando a la comunidad universitaria qué modo de transporte utilizan para ir a la universidad, su distancia de recorrido y el motivo de escoger ese modo de transporte. Se calcularon sus emisiones asociadas, y se informó en una campaña de concienciación en el campus de *Ciudad Universitaria* la huella de carbono de su viaje diario a la universidad (Global Challenge, 2019).

El objetivo principal de este estudio es doble: en primer lugar, proponer una metodología para estimar las emisiones totales de dióxido de carbono (CO_2) generadas por la comunidad UPM en su viaje diario a los campus, y en segundo lugar, comprender mejor las características del colectivo y cómo se viaja a la UPM para proponer una serie de políticas que den lugar a la reducción de la huella de carbono en la UPM. Esta comunicación se divide en varias secciones. A continuación se recogen estudios similares que analizan la movilidad en los campus universitarios y los impactos sobre el cambio climático (Sección 2). Seguidamente, se describe el caso de estudio de la UPM y la metodología llevada a cabo para la estimación de las emisiones de CO_2 de la movilidad en la UPM a partir de una sencilla encuesta online (Sección 3). Con la aplicación de dicha metodología al caso de estudio de la UPM, se analizan los resultados y se reflexiona sobre diferentes acciones que ayuden a la comunidad universitaria a reducir el impacto sobre el cambio climático de los movimientos diarios que se realizan a los centros de atracción de población, como son las áreas universitarias de las ciudades (Sección 4). Por último, se realizan las conclusiones y futuras investigaciones.

2. MOVILIDAD EN LOS CAMPUS UNIVERSITARIOS E IMPACTOS SOBRE EL CAMBIO CLIMÁTICO

Recientemente, las universidades están desarrollando un creciente interés en políticas institucionales que promuevan la movilidad sostenible (Leona et al. 2018). En efecto, las universidades son lugares ideales para explorar el impacto de medidas que promuevan hábitos de transporte más saludables, debido a la mayor predisposición de los estudiantes universitarios y su personal a utilizar medios de transporte activos (Balsas et al. 2003). Este es el motivo por el que las universidades alrededor del mundo están promoviendo iniciativas sostenibles, donde las medidas sobre la movilidad son importantes.

Para poder proponer medidas se necesita, en primer lugar, conocer los impactos sobre el cambio climático que la movilidad en las áreas universitarias genera. Son varios los trabajos de investigación que han analizado las emisiones de GEI de la movilidad en las universidades por todo el mundo y que se recogen a continuación.

En Canadá, Mathez et al. (2013) analizaron las emisiones diarias al campus del centro de la ciudad de la universidad McGill en Montreal a través de una encuesta online a los estudiantes y trabajadores. Entre sus resultados cabe destacar que las diferencias de género no obtienen grandes disparidades de emisiones, sin embargo, sí que hay grandes diferencias entre estudiantes y personal de la universidad. Los estudiantes generan 3,6 veces menos de gCO_2eq/persona-viaje que el personal de la universidad. Por modo de transporte utilizado, los conductores de vehículo privado son los que más emiten. Más recientemente, Hafezi et al. (2019) estimaron las emisiones de CO_2 de la universidad Dalhousie en Nova Scotia a toda su comunidad. Entre los resultados encontraron que el personal de administración y servicios son los que más emiten por persona y día

(370,23gCO_2/persona-día), siendo los resultados consistentes con los del estudio de Mathez et al. (2013).

En Estados Unidos, Appleyard et al. (2018) desarrollaron una metodología para calcular las emisiones anuales generadas por el transporte de sus viajeros a la universidad estatal de San Diego, en California, a través de una encuesta online. Los resultados con consistentes con investigaciones en otras universidades, y es que los que emiten más CO_2 per cápita son los miembros del colectivo de personal de la universidad, que en el caso de San Diego está explicado porque recorren más distancias para ir al campus y, además, más del 75% utiliza el vehículo privado. El estudio también incluye la evaluación de diferentes políticas, donde se destacan la utilización de vehículos eléctricos como una acción que podría reducir el 60% de las emisiones.

En Reino Unido e Irlanda, Davison et al. (2015) estudiaron los impactos sobre las emisiones del comportamiento modal de los estudiantes en 17 universidades de Irlanda y Reino Unido. Entre los resultados se destacó que los estudiantes que utilizan más el vehículo privado, y por ende lo que más emiten, corresponden a mujeres que estudian a tiempo parcial, mientras que los hombres tienden a utilizar más los modos activos. Las diferencias entre estudiantes de diferentes regiones son notables, siendo los estudiantes de Irlanda del Norte los más dependientes del coche y que recorren más distancias, con lo que son los más emisores. Por el contrario, los estudiantes escoceses emiten menos, pues son los que más utilizan los modos ferroviarios y modos activos.

Por último, en España, Pérez-Neira et al. (2020) analizaron los patrones de la movilidad de la Universidad de León y su potencial para mitigar las emisiones GEI. Los resultados son similares a los de estudios anteriores, el personal universitario emite el doble de emisiones de CO_2eq por viaje a la universidad (728 gCO_2eq/persona-viaje de los estudiantes frente a los 1531 gCO_2eq/persona-viaje del personal de universidad). Además, aquellos que utilizan el coche son los que emiten el 95% de las emisiones totales por movilidad de la comunidad universitaria. Se proponen en el estudio diferentes medidas para reducir los impactos al cambio climático, como estrategias de educación y concienciación del personal, estimular el uso de modos activos, mejorar las infraestructuras de transporte público entre otras.

Como se recoge de los estudios anteriores, las universidades tienen la extraordinaria capacidad de generar conciencia sobre todos los aspectos de la sostenibilidad en las comunidades, siendo el transporte un sector clave en la sostenibilidad. El efecto del uso de los diferentes modos de transporte para ir a la universidad sobre las emisiones es significativo y demuestra la importancia de la educación y difusión del impacto de los viajes a la universidad para el desarrollo de una política sostenible de transporte.

3. METODOLOGÍA

3.1 Ámbito de estudio: campus universitarios de la UPM

La Universidad Politécnica de Madrid (UPM) es una universidad pública con diferentes sedes en el área metropolitana de Madrid, área que ocupa unos 8.030km^2 y cuenta con una población total de 6.663.394 habitantes repartidos en 179 municipios en 2019. La ciudad de Madrid es la capital de España, con una población total de 3.226.126 en 2016, cubriendo 605km^2 (Comunidad de Madrid, 2020). La UPM se reparte en cuatro campus principales (Figura 1): *Campus Ciudad Universitaria* (que incluye 9 escuelas y el complejo del rectorado), *Campus Madrid Ciudad* (que incluye 4 escuelas cercanas a la Zona de Bajas Emisiones de Madrid –Madrid Central-), *Campus Sur* (justo al lado de la carretera de circunvalación M-40 y que incluye 4 escuelas, 2 centros/institutos de investigación y 1 biblioteca) y *Campus Montegancedo* (en el municipio de Pozuelo de Alarcón, que incluye 1 escuela y 7 centros/institutos de investigación). La accesibilidad del transporte público cercano a estos campus, así como la presencia de áreas de estacionamiento gratuitas son factores que impactan directamente en la elección modal de los viajeros hacia estos campus (Tyrinopoulos y Antoniou, 2013). La Tabla 1 resume las principales características de los cuatro campus de la UPM, incluyendo el transporte público cercano o infraestructuras de transporte. Como es de esperar, los campus cercanos al centro de la ciudad de Madrid tienen una mejor conexión en transporte público y menos áreas de estacionamiento para vehículo privado que los que se encuentran a las afueras de la capital.

La comunidad de la UPM son más de 40.000 personas, representando el 1,37% de la población total de la ciudad de Madrid. Sus principales colectivos son: 39.000 estudiantes (incluyendo estudiantes de grado, postgrado y movilidad internacional), personal docente e investigador (PDI) con 3.300 personas y el personal de administración y servicios (PAS) con 1.890. En noviembre de 2019, la UPM plasmó su compromiso de lucha contra el cambio climático creando “Comité para la Descarbonización de la UPM”, por el cual la universidad ha fijado la meta intermedia de anular sus emisiones directas netas de gases de efecto invernadero en el año 2030, con el fin de alcanzar la neutralidad climática en 2040 (UPM, 2020).

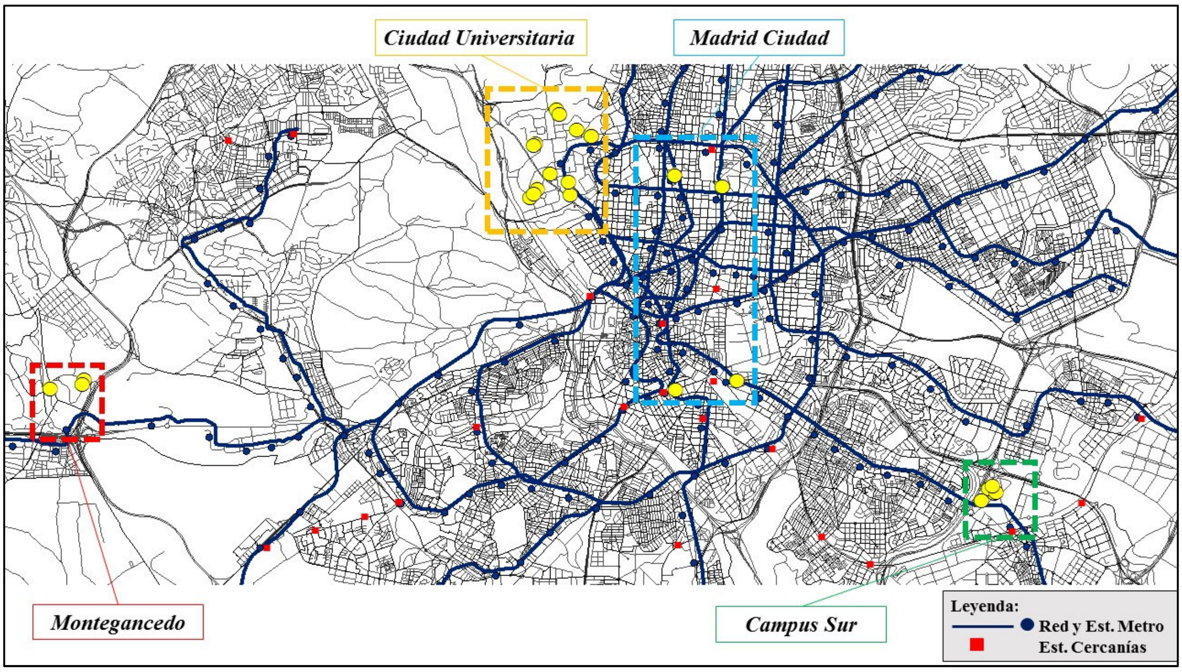

Fig. 1 – Mapa de los campus universitarios de la UPM en Madrid.

CAMPUS UPM	Nº EDIFICIOS	ESTACIONES DE METRO/CER-CANÍAS	LÍNEAS DE AUTOBUS	SISTEMA DE BICICLETA PÚBLICA	PARKING GRATUITO	DISTANCIA AL CENTRO DE LA CIUDAD
Ciudad Universitaria	9 Escuelas y rectorado	2 estaciones de metro	Si, líneas urbana e interurbana	No	Si	4km
Madrid Ciudad	4 Escuelas cercanas a “Madrid Central”	4 estaciones de metro & 3 estaciones de cercanías	Si, urbanas	Si	Parcialmente	2km
Campus Sur	4 Escuelas & 2 centros/ institutos de investigación, 1 biblioteca	1 estación de metro & 1 estación de cercanías	Si, líneas urbana e interurbana	No	Si	7km
Campus Montegancedo	1 Escuela & 7 centros/ institutos de investigación	No	Si, línea interurbana y 1 línea exclusiva para personal UPM	No	Si	11,5km

Tabla 1 – Características de los campus UPM en 2019

3.2 Encuesta de movilidad online en la Semana de la Movilidad Europea 2019

En la celebración de la Semana de la Movilidad Europea 2019, la UPM dentro del programa *Global Challenge* realizó en septiembre de 2019 una sencilla encuesta online de tres días (martes 10, miércoles 11 y jueves 12 de septiembre de 2019) preguntando a toda la comunidad UPM qué modo de transporte utiliza para ir a los campus UPM (Global Challenge, 2019). La participación fue voluntaria y anónima. Un cuarto día (el 19 de septiembre) se realizó la difusión de los resultados (después de aplicar la metodología, ver Sección 3.3) de la encuesta en la salida del Metro de Ciudad Universitaria con el objetivo de concienciar de los impactos del cambio climático al viajar a la universidad. El propósito de la encuesta fue comprender la elección modal diaria de la comunidad universitaria hacia los campus UPM y las principales razones de las elecciones modales (ver Tabla 2).

Preguntas	Respuestas
1. Género	Hombre / Mujer / No declara
2. ¿Cómo vienes a la universidad?	Pie / Bicicleta / Coche / Moto / Metro / Autobús Urbano (EMT) / Autobús interurbano / Tren - Cercanías / Otro (ej. Patinete)
3. ¿Por qué utilizas esos modos?	*Texto libre*
4. ¿A qué campus UPM vas?	Ciudad Universitaria / Madrid Ciudad / Campus Sur / Campus Montegancedo
5. ¿Podrías estimar los kilómetros que recorres para llegar a la UPM?	Hasta 5km / 5km-10km / 10-20km / Más de 20km
6. ¿A qué colectivo perteneces?	Estudiante / Personal Docente e Investigador / Personal de Administración y Servicios / Otros (proveedores, operarios, etc.).

Tabla 2 – Diseño de la encuesta online

3.2.1 Características de la encuesta

La encuesta fue respondida por un total de 2.142 personas de la UPM, siendo la tasa de respuesta del 4,8%. Para verificar si el número de encuestados cumple con los requisitos del tamaño mínimo de muestra, se utiliza la fórmula de Smith (Smith, 1979).

$$N_{min} = \frac{p(1-p)}{\frac{d^2}{Z^2}+\frac{p(1-p)}{N}} \quad (1)$$

Donde N_{min} es el tamaño de muestra mínimo, N es el tamaño de la población objetivo, p es la distribución de la respuesta desconocida (p=50%), Z es la normal para un 95% de confianza (Z=1,96) y d es un nivel absoluto de precisión (se aplica d=5%). Según la ecuación [1], el tamaño mínimo de la muestra para la población de 44.190 de la UPM es de 381. Por lo tanto, el número total de encuestados cumple con los requisitos de un tamaño mínimo de la muestra.

Aunque se tiene una sub-representación de los estudiantes en la encuesta, y una sobrerrepresentación del PDI y del PAS (ver Tabla 3), lo cual es común en encuestas universitarias (Mathez et al. 2013; Appleyard et al. 2018).

	Actual (absoluto; %)	Encuesta (absoluto; %)
Estudiantes	39.000; 88,3%	1.641; 76.6%
PDI	3.300; 7.5%	273; 12.7%
PAS	1.890; 4,3%	228; 10.4%
Total	44.190	2.142

Tabla 3 – Comparación del tamaño de la muestra con la población universitaria real.

3.3 Estimación de las emisiones de CO_2 por modo de transporte en el área metropolitana de Madrid

La estimación de los impactos sobre el cambio climático de los desplazamientos diarios individuales a los campus universitarios de la UPM se realiza combinando la distancia recorrida por diferentes modos de transporte y el factor de emisión medio específico de cada modo. De tal forma, que las emisiones diarias medias de CO_2 relacionadas con cada viaje se calculan de la siguiente forma (Stead, 1999; Nicolas y David, 2009; Ko et al. 2011; Sobrino & Monzon, 2013):

$$C_i = \sum_m D_{i,m} \times FE_m \quad (2)$$

Donde C_i representa las emisiones individuales de CO_2 de los viajes diarios al campus (gCO_2/persona-viaje), i denota el individuo y m es el modo de transporte utilizado. $D_{i,m}$ (km) es la distancia recorrida por el individuo i en el modo m que se deriva de la encuesta online (Sección 3.2.1, tomando el promedio de la distancia estimada), FE_m (gCO_2/pas-km) es el factor de emisión medio del modo principal m. En el presente estudio se considera modo principal siguiendo la siguiente jerarquía de modos: transporte público (tren>autobús interurbano>metro>autobús urbano)>coche>moto>bicicleta>pie.

Dependiendo del modo de transporte y los datos disponibles, la estimación del factor de emisión podrá tener dos enfoques (*top-down o bottom-upm*), ver Tabla 4. El enfoque *top-down* se basa en datos agregados a nivel macro (consumo total anual de energía, distancia total anual recorrida, tasa de ocupación anual). En el presente estudio, los factores de emisión se han estimado para el año 2017 (resultados en la Figura 2), que es el último año del que se dispone de datos suficientes para estimar dichos factores.

Se ha utilizado el enfoque *top-down* para estimar los factores de emisión del tren-cercanías, el metro y el autobús interurbano. En estos casos, el consumo anual de energía o las emisiones de CO_2 anuales de la flota se divide entre la distancia total recorrida en km y la tasa de ocupación media de la flota para obtener el factor de emisión por pasajero y kilómetro. La principal fuente de datos es el *Informe Anual del Consorcio Regional de Transportes de Madrid* (CRTM, 2019), ya que son modos de transporte público.

Por otro lado, en el enfoque *bottom-upm* se tienen en cuenta datos desagregados más detallados (tipo de la flota de vehículo, velocidad media, factor de emisión específico de cada vehículo, etc.). Se ha empleado este enfoque utilizando la metodología oficial de la Agencia Europea de Medioambiente (EEA, 2019) para estimar los factores de emisión de los autobuses urbanos, coches y motos empleando los siguientes pasos:

1. Obtener las características del tipo de vehículo utilizando el último estudio de la flota de vehículos circulantes en Madrid en 2017 para motos y coches, así como el Informe anual de operaciones de EMT para autobuses urbanos (Ayuntamiento de Madrid, 2018; EMT 2018, respectivamente).
2. Para cada categoría de vehículo se ha estimado el factor de consumo (MJ/km) utilizando la guía EEA (2019) considerando una velocidad promedio en áreas urbanas de 13km/h para autobuses urbanos, 35km/h para motocicletas y 40km/h para automóviles (según estudios de tráfico en la ciudad de Madrid).
3. El factor de consumo estimado se transforma en emisiones de CO_2 utilizando la fórmula de la densidad del combustible de cada categoría de vehículo (MJ/g), así como el factor de emisión de combustión de cada combustible (gCO_2/g de combustible) (EEA, 2019)
4. En función de la ponderación de todas las categorías de vehículos, se obtiene los gCO_2 por kilómetro por cada modo de transporte.
5. Finalmente, aplicando las tasas de ocupación, se obtienen los factores de emisión GEI por pasajero y kilómetro. Las tasas de ocupación son las siguientes: 13,6 para autobuses urbano; 1,1 para motocicletas y 1,2 para automóviles (según EMT 2018 y estudios de tráfico en la ciudad de Madrid).

MODO	TIPO DE ENFOQUE	FUENTE DE DATOS
Metro	*Top-Down*	- Para el consumo total de energía y las características de los trenes: *Informe anual de Metro Madrid* (Metro Madrid, 2018). - Para la producción y la demanda: *Informe Anual del Consorcio Regional de Transportes de Madrid* (CRTM, 2019)
Tren-Cercanías		- Para el consumo total de energía y las características de los trenes: *Observatorio del Ferrocarril en España* (OFE, 2018). - Para la producción y la demanda: *Informe Anual del Consorcio Regional de Transportes de Madrid* (CRTM, 2019).
Autobús interurbano		- Para el consume total de energía, características de la flota de autobuses, producción y demanda: Para la producción y la demanda: *Informe Anual del Consorcio Regional de Transportes de Madrid* (CRTM, 2019).
Autobús urbano	*Bottom-Up*	- Tipo de vehículo, velocidad media, ratio de ocupación: *Informe Anual de Operaciones de la EMT* (EMT, 2018). - Factor de consume y emisión por tipo de vehículo: *EMEP/EEA Air Pollutant Emission Inventory Guidebook* (EEA, 2019).
Moto		- Tipo de vehículo, velocidad media, ratio de ocupación: *Estudio del parque circulante en la ciudad de Madrid en 2017* (Ayuntamiento de Madrid, 2018). - Factor de consume y emisión por tipo de vehículo: *EMEP/EEA Air Pollutant Emission Inventory Guidebook* (EEA, 2019).
Coche		

Tabla 4 – Estimación de los factores de emisión de CO_2 por modo: tipo de enfoque y fuente de datos.

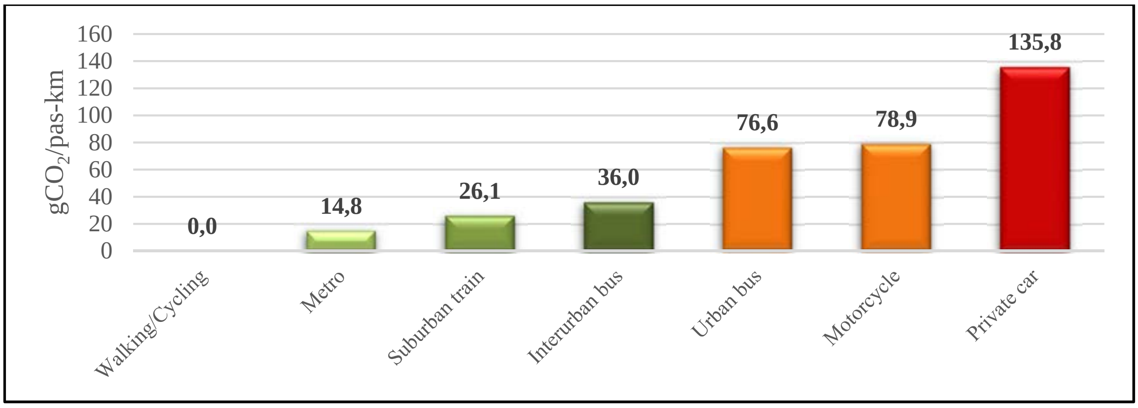

Fig. 2 – Factores de emisión de CO_2 medios para los principales modos de transporte en Madrid en 2017 (Fuente: elaboración propia).

4. RESULTADOS Y DISCUSIONES

4.1 Características de los viajes a los campus UPM

Distribución modal. Los resultados mostrados en la Tabla 5 son similares a las conclusiones de investigaciones anteriores (Mathez et al. 2013, Davison et al. 2015, Appleyard, 2018, Pérez-Neira et al. 2020). Si observamos a toda la comunidad de la UPM, en la cual los estudiantes representan el 88% de la población total, se obtiene que el transporte público es el modo principal para viajar a los campus de la UPM (75,4%), seguido de los modos privados (automóvil y moto, 16,9%), y modos blandos (a pie y bicicleta, 7,6%). Por colectivos, la mayoría del personal contratado en la UPM realiza su viaje en automóvil (45,4% y 41,2% del PDI y PAS, respectivamente). Sólo el 39,2% del PDI usa el transporte público, un modo predominantemente utilizado por el 85,2% de los estudiantes. En proporción, los modos blandos (a pie y bicicleta) son más utilizados por el PDI que los estudiantes (a pie: 7,7% versus 5,7% respectivamente) y en el caso de la bicicleta es el 4% versus 1,3%, respectivamente. En cuanto al género (Tabla 6), no existe una clara diferencia causada por cuestiones de género, solo que los que los hombres viajan más en bicicleta que las mujeres (3,1% versus 0,6), y las mujeres viajan más en metro y autobús urbano que los hombres (46,3% versus 38,4%, respectivamente). Las personas que no declaran su género caminan más a la universidad que el resto. Con respecto a la distribución modal por campus, la Tabla 7 muestra que en los desplazamientos a los campus cercanos al centro de la ciudad, como Madrid Ciudad o Ciudad Universitaria, se utilizan más el transporte público y modos blandos que los que están a las afueras de la ciudad, con menos accesibilidad al transporte público. Se observa que cuanto más cerca está el campus al centro de la ciudad, menor es la proporción de viajes en modos privados (Figura 3). Esto significa que la ubicación y la buena accesibilidad al transporte público son clave cuando se busca la movilidad sostenible (Soria-Lara et al. 2017).

Colectivo UPM	A pie	Bicicleta	Tren - Cercanías	Bus interurbano	Metro	Bus Urbano	Coche	Moto	Otros
Estudiantes	5,7%	1,3%	20,5%	19,0%	35,7%	10,0%	6,6%	1,0%	0,2%
PDI	7,7%	4,0%	7,3%	4,8%	21,2%	5,9%	45,4%	3,7%	0,0%

Tabla 7 – Distribución modal por campus

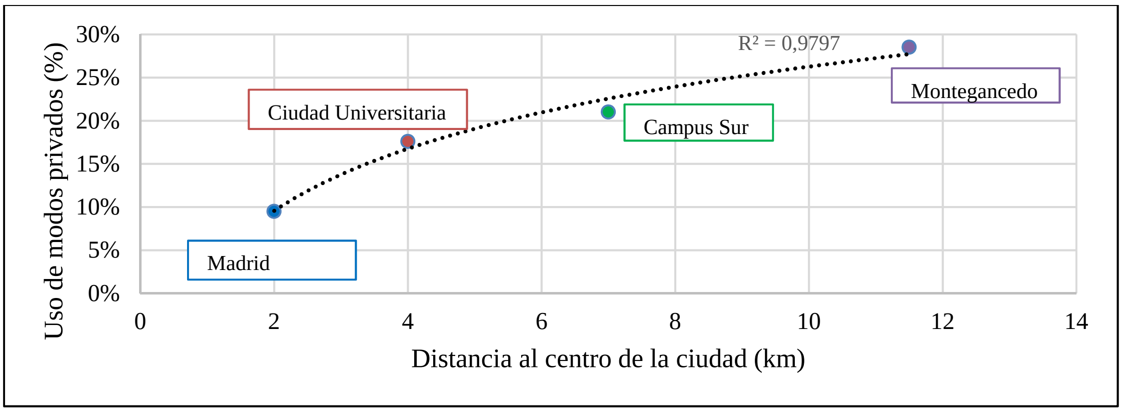

Fig. 3 – Relación entre la distancia del campus al centro de la ciudad y la distribución modal en viajes privados.

Criterios de selección del modo de transporte. La gran mayoría de los encuestados respondieron a la pregunta de cuál es su principal motivo de elección del modo de transporte para los viajes a la universidad. Se puede comprobar (Tabla 8) que los encuestados en el que su modo principal es el modo blando están relacionados principalmente con vivir cerca de los campus universitarios. Por otro lado, el colectivo que utiliza el transporte público aprecia el tiempo, la comodidad y el coste del transporte como motivos principales de su elección. Los usuarios de los modos privados valoran muy notablemente el tiempo, la comodidad y la accesibilidad directa a los campus. Cabe destacar que el compromiso o concienciación por el medio ambiente no se encuentra entre los principales criterios de elección de modo de transporte. Se debería, pues, realizar un mayor esfuerzo en el colectivo universitario en la concienciación medio ambiental respecto a las elecciones diarias de movilidad.

Criterios	Modos Blandos	Transporte Público	Modos Privados
Tiempo	10,4%	31,1%	61,7%
Comodidad	9,7%	17,6%	14,1%
Costes	3,5%	12,7%	3,4%
Accesibilidad	0,7%	5,9%	9,8%
No tengo otra opción	0,7%	9,7%	2,5%
Medio Ambiente	8,3%	6,3%	0,9%
Accesibilidad directa	1,4%	5,3%	4,3%
Vivir cerca	50,0%	0,7%	0,3%
Seguridad	0%	2,7%	0%
No hay parking gratis	0%	0,3%	0%
No dispone de coche	0%	3,9%	0%
Salud y Actividad Física	11,1%	0,5%	0%
No hay bicicleta compartida	0%	0%	0,3%
Eficiencia	0%	2,2%	1,2%
Disfrute / Placer	4,2%	0,2%	1,5%

Tabla 8 - Criterios declarados de elección de modo de transporte por parte del colectivo de la UPM

4.2 Resultados de las emisiones de CO_2 medias en los viajes diarios a la UPM

Esta sección presenta los principales resultados del análisis de las emisiones de CO_2 medias generadas en los desplazamientos diarios a la UPM a partir de la información recogida en la encuesta y utilizando la metodología propuesta. De acuerdo con esto, los 2.142 encuestados en la UPM son responsables de la emisión de 1.532,2kgCO_2 en un día por todos los viajes desde sus hogares a la universidad, lo que significa un promedio de 715,3gCO_2/viaje-persona. Sin embargo, estas emisiones se distribuyen de manera desigual dependiendo del colectivo de la UPM, la distancia al campus o el modo principal.

Comprender quién está emitiendo más ayudará a generar políticas que puedan reducir los impactos al cambio climático de los mayores emisores de dióxido de carbono.

Entre los diferentes colectivos de la UPM, la Figura 4 muestra los diferentes colectivos en el eje X y las emisiones GEI medias por viaje emitido por los individuos de cada colectivo en el eje Y. El eje secundario Y muestra el número de encuestados de la encuesta que pertenecen a esta categoría. Los mayores emisores son el personal de la universidad, con un promedio de 1.303,8gCO_2/viaje-pers y 1.159 gCO_2/viaje-pers, PAS y PDI, respectivamente. Estas cifras son más del doble del promedio de emisiones GEI de los estudiantes (559,7 gCO_2/viaje-pers). Estos resultados son consistentes con los obtenidos en estudios similares anteriores como Mathez et al. (2013), Appleyard et al. (2018) y Pérez-Neira et al. (2020). Como se adelantaba en el subcapítulo 4.1, el personal de la UPM viaja más en vehículos privados que los estudiantes, modo más contaminante, y por lo tanto aumentan sus emisiones medias. En este caso, se deberían poner en práctica medidas específicas para este colectivo.

Si nos centramos en los cuatro campus UPM, la Figura 5 muestra que para los que viajan a los campus más distantes del centro de la ciudad las emisiones medias por viaje son más altas que para los que viajan a los campus más cercanos al centro de la ciudad (1.301,3gCO_2/viaje-pers al *Campus de Montegancedo* a 11.5km del centro de la ciudad frente a 559,7 gCO_2/viaje-pers al *Campus Madrid Ciudad* a tan solo 2 km del centro). Son necesarias, por tanto, medidas concretas para mejorar o reforzar la accesibilidad en transporte público en campus alejados de la ciudad.

Con respecto al modo principal, la Figura 6 muestra la distribución de las emisiones totales de CO_2 por modo y la distribución modal de los encuestados UPM. Los resultados confirman que solo el 16% de los viajeros usan los modos privados (coche y moto), pero emiten más de la mitad de las emisiones de CO_2 totales estimadas.

Finalmente, usamos la Curva de Lorenz para explorar la variabilidad de las emisiones de CO_2 de los encuestados en sus viajes diarios a la UPM. Encontramos que el 10% de los emisores principales son responsables del 54% de las emisiones totales (con una media de 3,4 kgCO_2/viaje-pers), mientras que si tomamos el 30% de los emisores principales contribuyen con el 76% del total de las emisiones de CO_2 (ver Figura 7). Por tanto, esta desigualdad pone en evidencia que son necesarias medidas más contundentes para los pequeños colectivos que, sin embargo, son los más contaminantes.

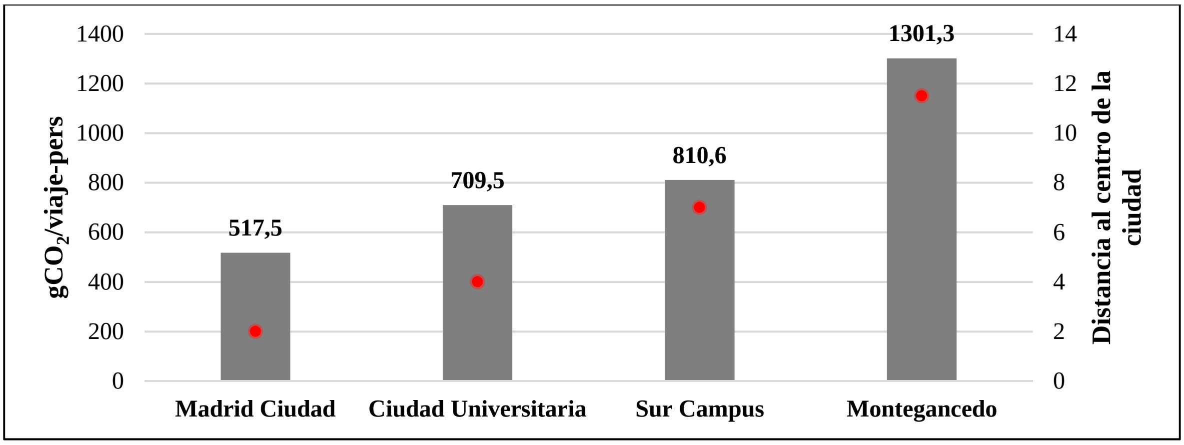

Fig. 5 – Emisiones medias de CO_2 por viaje a los cuatro campus y persona

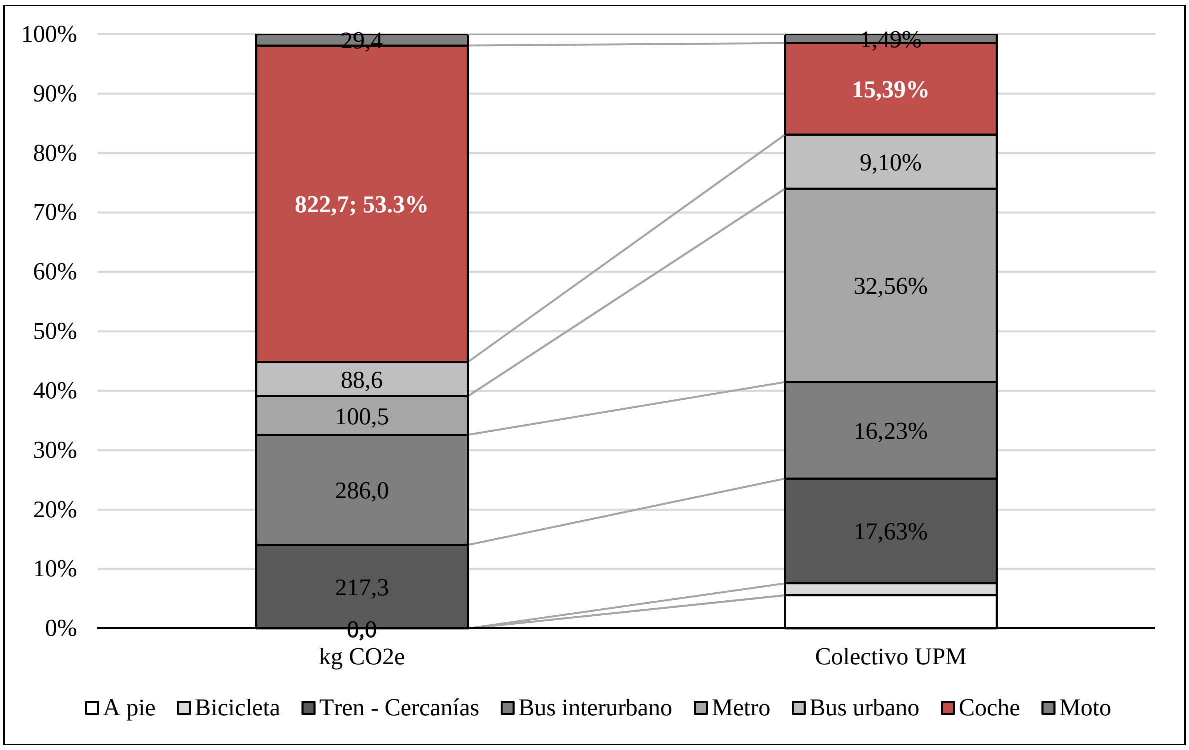

Fig. 6 – Emisiones de CO_2 totales diarias por distribución modal de los encuestados UPM y distribución modal UPM.

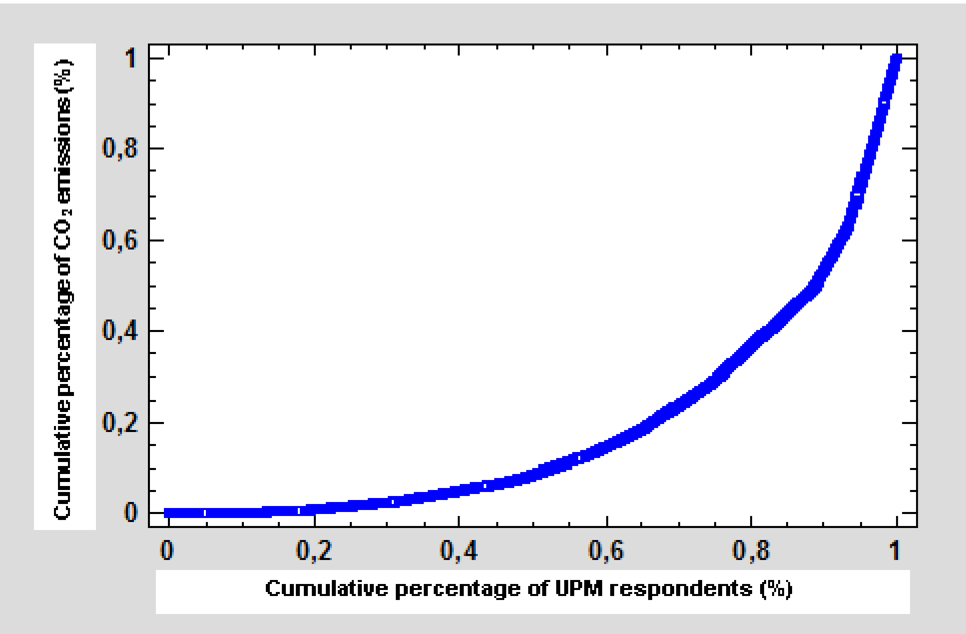

Fig. 7 – Curva de Lorenz de las emisiones de CO_2 de los viajes diarios a la UPM

4.3. Discusión y políticas universitarias

De los datos y resultados obtenidos para la comunidad universitaria de la UPM se deduce que el uso del coche privado para ir a la universidad genera más de la mitad de las emisiones, y solo representa el 15% de los viajes, por lo que es una prioridad que hay que atender. La reducción de los viajes en vehículo privado es el primer objetivo que debe conseguir la UPM.

Para hacer una mejor propuesta de acciones orientadas a reducir el uso del vehículo privado es importante, por un lado, destacar cuáles son los principales motivos del uso de vehículo privado en el colectivo UPM, en concreto, el menor tiempo de viaje, seguido de comodidad y accesibilidad directa entre el origen y destino (ver Tabla 8), y, por otro lado, analizar las opciones disponibles al vehículo privado. Por ello, una de las acciones que se pueden poder en marcha es el uso de coche compartido (car pooling) para las personas que vayan al mismo centro de destino mediante medios apps (similar a *BlaBlaCar,* pero exclusivo para la comunidad de la UPM). También, para frenar el uso del vehículo privado, se podría limitar el uso de los aparcamientos de vehículos privados en los centros de la UPM. Otra acción es el fomento del transporte público. Mediante ayudas y mejorando las frecuencias y accesibilidad en aquellos campus que están más alejados del centro de la ciudad. Aunque ya se vienen fomentando las ayudas al personal de la UPM para el uso del transporte público, que dichas ayudas sean mayores -por ejemplo, pagando el 50% del abono transporte).

Otra línea de acción es la educación: las universidades son espacios privilegiados para la creación de conocimiento y la introducción del concepto de "movilidad sostenible" en los planes de estudio y los procesos de aprendizaje de facultades, escuelas y otras instituciones públicas de gran valor (Larsen et al. 2013). Entre las medidas pueden estar campañas promocionales de modos alternativos (uso durante un tiempo gratuito de sistemas de bicicleta pública, sistemas de coches compartidos, vehículos eléctricos, etc.) que lleven a los usuarios a tener experiencias reales que les hagan cambiar sus hábitos. También sería interesante la difusión del impacto que generan sobre la sociedad sus acciones individuales.

En conclusión, es necesario establecer objetivos y estrategias para reducir las emisiones de carbono en las universidades. Esto es aún más importante dados los efectos de la COVID 19 en los patrones de movilidad, como es la reducción en el uso del transporte público debido al miedo al hacinamiento y la transmisión de virus (véase por ejemplo el estudio Jenelius y Cebecauer, 2020 en Suecia). Entonces, los planificadores de transporte tendrán la oportunidad de reformular la movilidad después de la pandemia de COVID-19 (Gutiérrez et al. 2020).

5. CONCLUSIONES

Pocas son las acciones que se han abordado hasta el momento para descarbonizar las universidades, pero el interés de las mismas por reducir sus emisiones tiene que vincularse a actuaciones importantes sobre la movilidad. Es verdad que sería necesario conocer la participación de la movilidad en el conjunto de las emisiones totales de la universidad, y ello debería ser objeto de investigación en un futuro próximo, pero, con carácter general, cabe pensar que el sector transporte representa un alto porcentaje de las emisiones de CO_2 derivadas de la actividad en los campus.

Solamente con actuaciones decididas en varios frentes puede llegar a conseguirse un resultado de disminución de emisiones apreciable. Probablemente en las zonas en las que hay más posibilidades de uso de transporte público, las acciones habrán de ser de concienciación e incentivación. Sin embargo, en los campus más alejados del centro, las actuaciones ofrecen más posibilidades, porque el transporte público es, actualmente, una opción inexistente o escasa y es donde más posibilidades de mejora existen.

Es preciso plantear objetivos de reducción y medidas que los acompañen, buscando buenas prácticas y buscando los puntos y las acciones con las que se pueden obtener mejores resultados. Para ello, sería necesaria una investigación detallada de la contribución de cada campus, por un lado, y la aplicación de medidas inspiradas en las guías de movilidad sostenible al trabajo diseñadas para las empresas.

AGRADECIMIENTOS

A la iniciativa *Global Challenge de la UPM* por proponer la acción de difusión de la huella de carbono de la UPM en la Semana de la Movilidad Europea 2019.

IMPLEMENTATION OF ASSET MANAGEMENT SYSTEMS AS A GUARANTEE OF SUSTAINABILITY WITHIN THE FRAMEWORK OF THE SOCIAL, BUSINESS AND FINANCIAL OBJECTIVES OF TRANSPORT COMPANIES. CASE OF APPLICATION TO RAILWAY ADMINISTRATORS AND OPERATORS

David Maté Sanz
Senior Expert, Economic and Transport Policy Area, INECO, Spain

ABSTRACT

Asset Management, internationally, is a mature discipline with strong support in database processing, automation, and organizational change management systems being launched by numerous infrastructure managers (ADIF, AENA, DB).

Recently the UIC has issued guidelines for the application of Railway application guide: *Practical Implementation of Asset Management through ISO 55001 (2016)*. It is a document that sets out guidance on international standards for the railway sector.

INECO is a provider of railway managers and operators in the field of asset management, in the development of railway technical regulations and in the analysis of the economic and financial sustainability of companies and projects in different geographical areas.

Asset Management is a set of systematic and coordinated activities and practices, through which a company manages its assets in an optimal way and the performance, risks and expenses associated with them, throughout its life cycle, with the purpose of achieving the business goals of the organization.

The objective of this paper is to present those actions and starting bases that, according to what has been published by other agents and institutions of the railway market and according to INECO's experience, are the keys to implementing an Asset Management System based on the UNE Standards - ISO 55000 in Railway Administrators and Managers.

1. SOSTENIBILIDAD ECONÓMICA, SOCIAL Y MEDIOAMBIENTAL COMO NUEVO PARADIGMA EN LA CREACIÓN DE VALOR DE LAS ORGANIZACIONES

La sostenibilidad económica tiene numerosas definiciones, pero en términos generales existe el consenso de que es la capacidad que tiene una organización o institución de administrar sus activos generando una rentabilidad de largo plazo de manera responsable.

Las organizaciones empresariales, al diseñar sus estrategias empresariales y los planes de negocio que las soportan han de fijar una estructura de inversiones, costes e ingresos que garanticen estar por encima del punto de equilibrio económico y financiero.

En paralelo a este objetivo económico, es comúnmente aceptado, que la responsabilidad de una organización desborda el ámbito económico y son muchas las iniciativas que promueven la sostenibilidad económica, social y medioambiental. En el sector de la movilidad estas iniciativas forman parte estructurante de cualquier estrategia nacional y se impulsa de manera efectiva por todos los agentes implicados.

En 2015, 193 estados miembros de Naciones Unidas aprobaron la Agenda 2030 para el Desarrollo Sostenible. Esta Agenda define 17 Objetivos de Desarrollo Sostenible para luchar contra cuestiones como la pobreza, la desigualdad, la injusticia o el cambio climático en el mundo, NACIONES UNIDAS A/70/L.1 (2015). Estos objetivos proporcionaron un marco común para que las partes interesadas públicas y privadas establezcan sus agendas y definan sus políticas y estrategias durante los siguientes 15 años.

En INECO nos sumamos al reto y nos comprometemos con la Agenda 2030 y los 17 ODS, pero no somos la única organización que asumió esta responsabilidad. Como consultora e ingeniería de transporte, INECO ha visto cómo sus principales clientes internacionales y nacionales han integrado estos ODS en sus estrategias y se están acostumbrando a desarrollarlos.

Con este punto de partida, lo que está resultando más difícil es llegar a protocolos comunes para asegurar y medir el impacto que consigue de la inversión necesaria para lograr esos objetivos de desarrollo sostenible. La Tercera Conferencia Internacional sobre Financiamiento para el Desarrollo, NACIONES UNIDAS. A/RES/ 69/313. (2015), estableció la Agenda de Acción de Addis Abeba que apoya y complementa el logro de los 17 Objetivos de Desarrollo Sostenible (ODS) y ayuda a contextualizar sus medios de implementación con políticas y acciones concretas.

En 2017, el Comité de Innovación, Competitividad y Asociaciones Público-Privadas, de Naciones unidas, NACIONES UNIDAS. ECE/CECI/2017/CRP.1 (2017), organizó su sesión anual en Ginebra focalizadas en la Financiación de la innovación y asociaciones público-privadas prioritarias para el desarrollo sostenible. Se aprobó un documento de posición denominado. En dicha sesión se corroboraba esta apreciación de que hace tiempo que existen métodos, normas y regulaciones bien establecidos para contabilizar e informar sobre el desempeño financiero, pero, por el contrario, la medición del impacto social y ambiental aún se encuentra en una etapa relativamente temprana.

Muchas empresas, especialmente las grandes, y los inversores de impacto utilizan sus propias medidas idiosincrásicas, y muchas no miden el impacto de forma coherente. En lugar de intentar medir el impacto real ex post, algunos inversores se dirigen a sectores y modelos de negocio en los que, ex ante, esperan generar un gran impacto positivo.

Si bien el desarrollo de estándares más armonizados para la medición y la presentación de informes de impacto está siendo impulsado por la propia industria, estas iniciativas también han generado desarrollos regulatorios y legislativos para cumplir los objetivos energéticos y climáticos de la UE para 2030 y alcanzar los objetivos del Pacto Verde Europeo, a efectos de orientar las inversiones hacia proyectos y actividades sostenibles.

Para lograrlo, la UE consideró que se necesita un lenguaje común y una definición clara de lo que es "sostenible". Por eso, el plan de acción sobre la financiación del crecimiento sostenible pedía la creación de un sistema de clasificación común para las actividades económicas sostenibles, o una “taxonomía de la UE”. Recientemente la Unión Europea ha publicado el Reglamento sobre taxonomía UNIÓN EUROPEA (2020) que establece los criterios para determinar si una actividad económica y cualquier producto de inversión asociado a ella pueden o no clasificarse como ambientalmente sostenibles. Antes de esta normativa no existía un estándar armonizado en Europa para clasificar las inversiones sostenibles.

Recientemente, UNEP FI (2021), organización de las Naciones Unidas y la Federación Europea Bancaria (EBF), lanzaron una propuesta para que el Sistema Bancario internacional pusiese en uso esta taxonomía como la columna vertebral de una agenda que aumente la transparencia del mercado y se emplee para señalar lo que es "suficientemente bueno" desde una perspectiva de sostenibilidad, la taxonomía de la UE tiene el potencial de dirigir el flujo de financiación necesario hacia la innovación verde y sostenible en la economía.

El proyecto fue esponsorizado por bancos comprometidos a andar un camino hacia la sostenibilidad y hacia la implementación de la taxonomía de la UE de acuerdo con la agenda europea para las finanzas sostenibles (https://www.unepfi.org/banking/high-level-recommendations-on-the-voluntary-application-of-the-eu-taxonomy-to-core-banking-products/ UNEP FI (2021) asss Testing the application of the EU Taxonomy to core banking products: High level recommendations).

También hay especialistas que exponen su escepticismo sobre los mismos, SOLVERE (2020). Donde identifican como una reserva a tener en cuenta es que la normativa deja los aspectos sociales y de gobernanza de las inversiones al arbitrio de estándares mundiales.

Según este autor el aumento de la desigualdad en muchas economías avanzadas apunta a deficiencias considerables en estos estándares, en su aplicación, o en ambos.

SOLVERE (2020) detecta un problema aún más fundamental: los datos disponibles. El autor considera que son muy pocos los datos disponibles para probar y validar los criterios y, más aún, para evaluar una amplia gama de actividades y activos económicos según estos criterios. Sin unos estándares adecuados para el intercambio de datos, tanto sobre las inversiones en sí mismas como sobre los mecanismos de gobernanza (públicos y privados), la estandarización puede disolverse en un sistema tecnocrático, o una máquina de "greenwashing" masiva, o ambas cosas.

Volviendo al sector de infraestructura, varios estándares y métodos voluntarios se están utilizando actualmente en la industria, por ejemplo, INECO ha estado involucrado con las instituciones financieras evaluando los Principios de Ecuador como un marco de gestión de riesgos, adoptado por las instituciones financieras, para determinar, evaluar y Gestión del riesgo ambiental y social en la financiación de proyectos de infraestructura.

En este artículo se considera que la implantación de sistemas de Gestión de Activos de normas ISO 55000, permite implantar un sistema estructurado para las gestión de activos con el fin de resolver prioridades que compiten entre sí, garantizar que los beneficios a largo plazo no se sacrifiquen en pos de necesidades inmediatas y generar un sistema de registro y documentación que de soporte al cumplimiento de los objetivos estratégicos que se fijen las organizaciones.

Un Sistema de Gestión de Activos (SGA) basado en la familia de normas ISO 55000 ayuda a una organización a establecer un enfoque coherente y la asignación coordinada de recursos y ejecución de actividades apropiadas. También incorpora el seguimiento y elementos de mejora continua para asegurar el logro sostenido de los objetivos estratégicos.

La Gestion de Activos puede generar valor al optimizar criterios financieros, ambientales, de impacto social, de gestión de riesgos, calidad de servicio y desempeño a lo largo de la vida de un activo.

Una buena Gestion de Activos asegura que los activos satisfarán la responsabilidad de una organización porque requiere:

- desarrollar e implementar procesos que conecten los propósitos y el desempeño requeridos de los activos con los objetivos de la organización;
- implementar procesos para garantizar la capacidad en todas las etapas del ciclo de vida;
- implementar procesos de seguimiento y mejora continua; y proveer los recursos y el personal competente necesarios para lograr el éxito.

2. GESTIÓN DE ACTIVOS EN EL SECTOR FERROVIARIO COMO MODELO DE GOBERNANZA EN EL DISEÑO DE LA MOVILIDAD SOSTENIBLE Y EL CUMPLIMIENTO DE LOS OBJETIVOS DE DESARROLLO SOSTENIBLE

En el sector transporte, recientemente la Ley de Movilidad Sostenible y Financiación del Transporte, MITMA (2020), considera la movilidad como un derecho, un elemento de cohesión social y de crecimiento económico. Entre los principales objetivos a alcanzar se ha destacado establecer un modelo de gobernanza que permita un diseño coherente de las políticas de movilidad y, en definitiva, avanzar hacia un modelo de transporte y movilidad sostenible como factor clave para el futuro de nuestro país.

Como se ha comentado, los indicadores clásicos del buen gobierno corporativo son, entre otros, los de índole económica y de gestión, pero estos se han de ampliar con indicadores tales que permitan conocer labor que realizan los activos de la compañía en el cumplimiento de los objetivos de sostenibilidad económica, social y medioambiental.

Siendo cierto que la sostenibilidad empieza por la viabilidad de las organizaciones, que es lo que permite conseguir que a los beneficios económicos que se generen se puedan añadir los beneficios sociales y ambientales, se considera práctica común que la empresa haya de certificar los resultados de su Gobernanza ante los agentes interesados en el gobierno corporativo, midiendo su participación en los criterios de sostenibilidad social y ambiental y económica.

Para muchos administradores de infraestructuras europeos, esta evolución conduce a una situación en la que las partes interesadas (como el Gobierno y las autoridades locales, las empresas ferroviarias y el público en general) empiezan a imponer requisitos más estrictos que los rendimientos y los costes, lo que obliga a los administradores de infraestructuras a tomar nuevas y transparentes medidas para poder tomar las decisiones correctas.

Esta forma alternativa de gestionar la infraestructura y los servicios de transporte en mi opinión desemboca en la implantación de sistemas de gestión de activos. La gestión de activos comprende todos los sistemas, métodos, procedimientos y herramientas necesarios para optimizar los costes, el rendimiento y los riesgos durante todo el ciclo de vida de la infraestructura ferroviaria. El objetivo es conseguir la mejor relación objetivo-precio.

Estas optimizaciones se referirán a todas las actividades de infraestructura (construcción, mantenimiento y renovación, incluidas las máquinas y los materiales) a lo largo de todo el ciclo de vida, así como a las consecuencias de estas actividades para el gobierno en su calidad de propietario y para los operadores ferroviarios y los viajeros en su calidad de usuarios.

Por lo tanto, la gestión de activos que impulso los objetivos de sostenibilidad fijados se ha de apoyar en los siguientes instrumentos:

- Definición clara de la misión de la empresa, valores compartidos y aspectos liderazgo y comunicación.
- Gestión de la información y gestión del conocimiento: acceso directo a todos los datos relevantes, en el nivel correcto de integración, en el formato correcto.
- Conciencia del riesgo: la realización de análisis de riesgos y la evaluación de los resultados será una práctica habitual en el proceso de toma de decisiones para el cumplimiento de los objetivos de desarrollo sostenible.
- Visión a largo plazo: tener en cuenta los efectos a largo plazo a la hora de tomar decisiones a corto plazo (Análisis de costes del ciclo de vida),
- Instrumentos adecuados: registro de objetos, métodos de análisis de riesgos, conceptos de mantenimiento, planificación del trabajo, control, medición y monitorización de infracondición y archivo de historial de mantenimiento de activos e historial de estado de activos.

El Objetivo de la Gestión de Activos como técnica, o Asset Management (AM), es la coordinación de las actividades y aspectos organizacionales que permiten optimizar el valor de los activos durante todo su ciclo de vida para el cumplimiento de objetivos estratégicos.

3. CARACTERÍSTICAS DIFERENCIALES DE UN SISTEMA DE ASSET MANAGEMENT SEGÚN EL ESTÁNDAR 55000

Según a UIC (UIC Railway Application Guide (2016)) las razones que llevan al sector ferroviario a impulsar la aplicación de los estándares ISO 55000, 55001 y 55002 son:

- Mejora el resultado del ferrocarril poniendo el foco de la gestión de iniciativas de confiabilidad de activos en las partes críticas de la red ferroviaria, soportada por información sobre las condiciones de los activos y una mejor comprensión de la probabilidad y las consecuencias del fallo a lo largo de su ciclo de vida.
- Reduce los costes al hacer el trabajo correcto, en el lugar correcto y en el momento correcto, con intervenciones de coordinación para conseguir el balance óptimo entre mantenimiento, renovación y mejora en toda la base de activos.

- Brindar a los clientes y a los financiadores opciones informadas basadas en escenarios que describen cómo funcionará la infraestructura a largo plazo, bajo diferentes niveles de gasto, crecimiento del tráfico, longitud de las obras de ingeniería e implementación de la automatización.

Bajo esta consideración la UIC entiende que los ferrocarriles no están aún operando a su total potencial en términos de proveer a sus clientes con un seguro servicio de calidad que sea eficiente en términos de coste beneficio o valor por dinero y que esto se conseguiría en esta Industria implementando técnicas de gestión de activos.

La norma 55000 provee los aspectos generales para la gestión de activos y sistemas de gestión de activos. La Norma ISO 55001 especifica los requisitos para establecer, implementar, mantener y mejorar un sistema de gestión de activos, mientras que la ISO 55002 proporciona directrices para clarificar los requisitos especificados en la Norma ISO 55001 y proporciona ejemplos para apoyar la implementación.

La ISO 55000 de Gestión de Activos es una evolución de los modelos tradicionales aunque tiene tres características diferenciales:

1.- Que las actividades de mantenimiento, renovación y mejora se hacen con el menor coste posible del ciclo de vida completo no solo de los activos físicos, sino también de resto de activos de la compañía
2.- Genera mecanismos de integración entre administrador de infraestructuras y empresas de contratación
3.- Da mayor énfasis en la toma de decisiones basada en la evidencia (utilizando conocimiento sobre degradación y fallo de los activos)

4. ELEMENTOS PARA DIAGNOSTICAR EL GRADO DE IMPLANTACIÓN DE LA ISO 55000, 55001 Y 55002 EN EL SECTOR FERROVIARIO

El sector ferroviario suele disponer de una estructura de gestión de activos apoyada en la Ingeniería de Mantenimiento y en la Ingeniería de Confiabilidad o RMAS. Lo cual fija una excelente situación de partida.

Para dar el salto a un Sistema de Gestión de Activos, si aún no se ha dado, habría de dotarse de directrices estratégicas que le aporten un conjunto de elementos interrelacionados para establecer políticas, objetivos y procesos para alcanzar esos objetivos de Gestión de Activos.

Es de destacar que los Planes Programas de los Administradores de Infraestructuras y Operadores de Transporte púbicos definen, en cierto grado, un Marco de Gestión de Activos que podría homologarse en el marco de la ISO 55001, y fijarían la senda para generar sistemas de gestión de activos (SGA) al solicitar modelos e indicadores sobre los proyectos de inversión y / o actuaciones empresariales que integren tanto los costes de capital (CAPEX) como de operación (OPEX) de las actuaciones incluyendo el ciclo de vida completo de los activos (LCC o análisis por ciclo de vida).

Aunque estos programas no resuelven un elemento clave como es la gobernanza del Sistema de Gestion de Activos y su encaje dentro de la estructura de la organización, los roles y las responsabilidades, la planificación, la operación, y los objetivos fijados por una parte de los agentes interesados sí que podrían quedar fijados.

A efectos de poder diagnosticar de forma efectiva y justificada el grado de implantación de los criterios definidos por la ISO 55000 se considera fundamental analizar los siguientes elementos constitutivos del sistema de Gestión de activos de una compañía:

- Si se fijan los objetivos para los activos requeridos por clientes
- Si se fijan objetivos para los activos requeridos por los propietarios de las infraestructuras
- Si se fijan criterios de sostenibilidad con el menor coste posible en el ciclo de vida total de los activos
- Si se incluyen acciones de integración de la Gestión de Activos en el contexto de la organización
- Si se incluye acciones de Liderazgo y RRHH de la Gestión de Activos
- Si se incluye acciones de Planificación de la Gestión de Activos
- Si se incluye acciones facilitadoras de Apoyo y Operación de la Gestión de Activos
- Si se incluye acciones de evaluación y mejora continua de la Gestión de Activos
- Si se define la gobernanza de la gestión de activos y del alcance de esta
- Si se define la Política de gestión de activos
- Si se define el Plan Estratégico de Gestion de Activos (PEGA)
- Si se documenta el Marco de gestión de activo. Planes gestión de activos
- Si se define la Implementación, evaluación y mejora de la GA: Decisiones y Mecanismos de habilitación y revisión

5. RECOMENDACIONES GENERALES PARA LA IMPLEMENTACIÓN PARA LA IMPLEMENTACIÓN

La Gestión de Activos es el conjunto de actividades y prácticas sistemáticas y coordinadas a través de las cuales una empresa ferroviaria gestiona de manera óptima sus activos y el rendimiento, riesgos y gastos asociados a los mismos, a lo largo de su ciclo de vida, con el propósito de alcanzar los objetivos de negocio fijados en su Contrato Programa y en su Plan de Actuación.

Los pilares fundamentales en los que se basaría la propuesta de implementación de la Gestión de Activos serían:

1. Planes y objetivos organizacionales: definir el alcance de la gestión de activos en la organización, la filosofía y misión de la empresa para evaluar el estado actual de los activos.
2. Políticas y estrategias: establecer objetivos a corto y largo plazo, definiendo las actividades de negocios presentes y futuras de la organización.
3. Marco de la Gestión de Activos: formular estrategias posibles, planes de gestión y elegir la que será adecuada para conseguir los objetivos establecidos en la misión de la empresa, así como desarrollar una estructura organizativa para conseguir la estrategia.
4. Implementación y operación: asegurar las actividades necesarias para lograr que la estrategia se cumpla con efectividad.
5. Verificación y acciones correctivas: controlar la eficacia de la estrategia para conseguir los objetivos de la organización.

El siguiente flujograma conecta adecuadamente todos estos elementos:

Fig. 1 - Relación entre los elementos clave de un sistema de gestión de activos. Fuente: Elaborado a partir de Anexos B de ISO 55000.

El Sistema de Gestión de Activos incluirá:

- La Política de gestión de activos
- Los objetivos de la gestión de activos
- El Plan estratégico de la gestión de activos (PEGA)

El plan o planes de gestión de activos, que se implementa en: planificación y control operacional, las actividades de apoyo, actividades de control y otros procesos pertinentes

5.1 Definición de planes y objetivos organizacionales

El sistema de gestión de activos es una parte integrante del sistema de gestión de la organización y posee una estructura preestablecida. Debería estar alineado y ser coherente con los objetivos de la organización.

Se recomienda definir dos categorías de alcance:

- ✓ Activos físicos de aplicación
- ✓ Decisiones, procesos y actividades (relativos a mantenimiento, renovación y mejora y explotación de la red) que relacionan la Estrategia a Alto Nivel con el trabajo sobre el terreno

5.2 Políticas y Estrategias

Para establecer objetivos a corto y largo plazo, definiendo las actividades de negocios presentes y futuras de la organización.

El objeto de la Política de gestión de activos es una declaración de intenciones a alto nivel por parte de la dirección de la empresa. El documento debería ser reducido en su extensión y por él se comunica a empleados, clientes y grupos de interés:

- Visión de la organización
- Papel de gestión de activos
- Principios esenciales
- Cómo se va a implantar el sistema de GA

En cambio, la Estrategia de gestión de activos define el modelo de gestión de la empresa a medio y largo plazo. Según la UIC se recomienda que establezca:

- requisitos de rendimiento (frecuencia de servicio, rendimiento de trenes, seguridad, impacto ambiental,)
- Cómo se va a implantar el sistema de GA
- Conviene que incluya las Interfaces con otros departamentos y grupos externos.

5.3 Marco de la gestión de activos

La UIC caracteriza con acierto el marco de gestión de los activos mediante la formulación de estrategias posibles para el sector ferroviario identificando la dualidad entre gestión de los activos y condiciones de operación de los mismos. Recomienda definir objetivos de red y por itinerarios o rutas, elegir los que sean adecuados para conseguir los objetivos establecidos en la misión de la empresa, así como desarrollar una estructura organizativa para conseguir su desarrollo para la cartera de activos que serán objeto de atención por el Sistema de Gestión.

A efectos de gestión de activos, es común que, en el sector ferroviario, al menos en el europeo y algunos latinoamericanos, se haya definido un Contrato Programa, un plan de negocio o un Plan de Actuación con los Objetivos que se han de seguir en la red, entendidos como los requisitos de alto nivel para el ferrocarril desde la perspectiva de los clientes, el gobierno y los usuarios y clientes de los activos.

Dichos documentos ya incluyen especificaciones sobre el nivel de financiación disponible.

Las estrategias de itinerarios deberían especificar los objetivos a nivel de itinerarios, la financiación y las limitaciones a lo largo de un período de al menos 5 años, coherentes con los objetivos de red. Es una tarea que podría desarrollarse de una forma más sistemática y homogénea. En esta tarea se podría:

- Mantener las prioridades señaladas por el Plan de Actuación diferenciando entre el escenario “compromiso", el escenario "base", y el escenario potencial
- Traducir los objetivos de red a nivel de itinerarios, con un presupuesto basado en rendimientos
- Incluir especificaciones de los itinerarios

La definición de estrategia de activos sería la conexión entre requisitos cliente/financiador y la planificación y finalización de los trabajos. Debería de incluir criterios de intervención y mantenimiento, umbrales y estrategia de costes.

Los Planes activos por itinerarios definirían, como ya hace el Plan de negocio o planes de actuación, ubicación de actuaciones de mejora específica, necesidades de renovación/mantenimiento, asegurando a la alta dirección y a grupos de interés externos una justificación de costes y de resultados finales para la infraestructura.

Los Planes de explotación por itinerarios en los que debería estar basada la gestión de activos deberían de incluir requisitos de los operadores ferroviarios, planes detallados/asignación de surcos, y así como una planificación detallada, al menos de 10 años, que incluya intervalos entre trenes para trabajo en infraestructura.

5.4 Planes de gestión de activos

Estos planes detallados están relacionados o con activos muy concretos o con rutas específicas, y aseguran las actividades necesarias para lograr que la estrategia se cumpla con efectividad.

Una vez esté desarrollado el plan estratégico de gestión de activos, se ha de evaluar cuáles son los activos y qué aspectos de los mismos son más relevantes para redactar un posible plan de gestión de dichos activos.

Tampoco se puede olvidar el sector ferroviario de las Herramientas LCC (coste del ciclo de vida) y predictivas que deben apoyar la optimización de las decisiones y la previsión de volúmenes de trabajo, costes y resultados.

El Plan de gestión de activos debe abordar tanto riesgos estratégicos como operativos dentro de un solo marco e incluir procesos de negocio_claros para sustentar y ligar componentes del Marco de gestión de activos.

Los planes de gestión de activos dan soporte al diseño de la estructura organizativa y facilitan una estrategia de comunicación clara.

5.5 Verificación y acciones correctivas

Los trabajos de verificación y acciones correctivas permiten controlar la eficacia de la estrategia para conseguir los objetivos de la organización.

Apoyándose en el Sistema de gestión de la calidad ya implantado desde hace tiempo en numerosas empresas ferroviarias la verificación se apoyaría en la implantación de un programa sistemático de auditorías basado en riesgos, centrándose en áreas en las que las carencias o los incumplimientos en gestión de activos tengan efecto fundamentalmente en Objetivos de Negocio.

También se recomienda implantar un conjunto completo de KPIs, Key Performance Indicators, que proporcionen información detallada sobre impactos de las decisiones estratégicas y sobre su implantación táctica. Al igual que otros resultados de los procesos de auditoría del Sistema de Gestión de Calidad, los resultados de auditorías y revisiones de KPIs son revisados regularmente por el equipo directivo.

Lo cual permitirá mejoras del rendimiento de la infraestructura a corto plazo y mejoras a largo plazo en componentes de gestión de activos. Incluso podría producirse cambios en el marco de gestión de activos propiamente dicho.

6. RECOMENDACIONES ESPECÍFICAS. INFORMACIÓN DOCUMENTADA

Del proceso de valoración y conciliación contable de activos surgen áreas de mejora y recomendaciones que pueden aportar mejoras a los procedimientos actuales de alta y baja de los activos identificados en las etapas anteriores así como en el proceso de dotar de información fiable al modelo económico sobre los proyectos de inversión y / o actuaciones empresariales que integre tanto los costes de capital (CAPEX) como de operación (OPEX) de las actuaciones incluyendo el ciclo de vida completo de los activos (LCC o análisis por ciclo de vida).

6.1 Mejorar la información sobre los activos

La cuantificación de los costes vinculados a la gestión de activos puede representar un peso muy relevante en la cuenta de una compañía ferroviaria, como compañía con uso intensivo de capital. Por lo tanto, identificar el coste del proyecto por ciclo de Vida del Activo es fundamental de cara a **maximizar su valor y aumentar su contribución al negocio**.

La piedra angular para la optimación de la gestión y que los objetivos de la organización estén alineados correctamente con los objetivos de Gestión de Activos es el **conocimiento de los activos** a lo largo de todo el ciclo de vida, de forma que pueda sacarse el mayor partido a los activos de la empresa desde el concepto inicial del proyecto.

En este sentido la Información sobre los activos es esencial para desarrollar estrategias de activos apropiadas e implantar planes de trabajo y planes de explotación (tipo, localización, fecha instalación, capacidad, estado, historial de fallos, historial y planes de mantenimiento, costes unitarios,).

Se cree conveniente incorporar y completar estos conceptos a los sistemas contables de los administradores y operadores ferroviarios, ya que serán de gran utilidad para las futuras tareas de valoración.

Otro aspecto a destacar en relación a la información de los activos es que los principales activos que constituyen el material rodante suelen están dados de alta en el inventario contable como unidades y no como las partes o elementos que lo componen. Para una correcta identificación taxonómica que permita a su vez la asignación del método de valoración a aplicar, se recomienda desagregar los activos de material rodante actuales, generando nuevos números de activo que hagan referencia a los elementos y no al todo.

En relación con el punto anterior, sería interesante disponer en los inventarios de las compañías de registros agregadores de las unidades de material rodante que permita de forma sencilla agrupar todos los números de activo relacionados con una misma unidad, y que además sirva para categorizarla dentro de la tipología de material rodante a la que pertenece (unidad de tren, vagón de carga, coche de pasajeros, etc).

6.2 Trabajar en la conexión de las bases de datos de activos

De cara a enriquecer y facilitar la mecanización y sistematización de procesos y de mantenimiento predictivo, sería de vital importancia incorporar a las bases de datos contables toda la información descriptiva relevante del activo, y que está disponible actualmente en otros sistemas de las compañías.

Otra información de especial utilidad es la referente a la localización geográfica de los activos. El uso de sistemas compatibles con la mayoría de las aplicaciones GIS permite el cruce de información catastral de Open Data.

Este cruce de información y el uso de otras APIS que proporcionan acceso a información de geolocalización se considera muy útil para enriquecer la información de los activos y se considera básico en el proceso de ubicación de los activos y su coordinación con herramientas de trabajo colaborativo, Gobierno de España (2018), y sistemas de gestión de activos.

Por lo tanto, se recomienda hacer interoperables las diferentes Bases de Datos a efectos de poder tomar ventaja de las posibilidades que aporta en la actualidad el tratamiento masivo de datos procedentes de diferentes fuentes.

6.3 Homogeneizar criterio al registrar grandes intervenciones de mantenimiento y/o rehabilitación y/o incremento de capacidad

De cara a poder hacer hipótesis sobre el estado de conservación de los bienes se considera conveniente generar en los inventarios contables registros que permitan caracterizar el tiempo transcurrido desde la última intervención de reposición o transformación, como por ejemplo las actuaciones RS/RSI del material rodante u otras inversiones de incremento de capacidad en infraestructura ferroviaria o edificaciones, tan habituales en las compañías ferrovirias.

Como alternativa a estos registros, que se entiende puede ser una información de difícil obtención para los sistemas contables de las compañías, se puede dar alta de estas grandes intervenciones de mantenimiento como mayor valor de cada uno de los activos a los que afecta, y no como unidades de activo independientes, tal y como se suele hacer comúnmente por los equipos de administración y finanzas.

6.4 Desarrollar metodología para el sistema de activación de las bajas de los activos en los registros de las compañías e indicadores de seguimiento de la evolución de la vida útil de los activos

La implantación de un sistema de indicadores de evolución de la vida útil permite documentar un sistema en un entorno de digitalización y transformación de las organizaciones con el apoyo de las tecnologías para optimizar y planificar los costes de mantenimiento de las inversiones de reposición e incremento del ciclo de vida de los activos mediante una gestión activa en base a los datos e índices de seguimiento y monitorización de los mismos.

Se considera que el resultado de la implantación del procedimiento de revisión y actualización periódica del valor de reposición y due diligence de los bienes incluidos en el balance de activos de las compañías genera unas base firmes en su senda hacia un modelo empresarial que integra los objetivos de desarrollo sostenible tanto de los proyectos de inversión como de las actuaciones empresariales operativas.

7. CONCLUSIONES. PRÓXIMOS PASOS EN LA ESTANDARIZACIÓN DE LA GESTIÓN DE ACTIVOS COMO SOPORTE PARA EL DESARROLLO DE POLÍTICAS PÚBLICAS DE MOVILIDAD

Como se ha comentado en este artículo, para los gobiernos y las autoridades de políticas públicas, una buena gestión de activos es un factor clave para quienes buscan equilibrar la inversión en necesidades inmediatas con objetivos a largo plazo para lograr los resultados sociales deseados, incluido el logro de los Objetivos de Desarrollo Sostenible de las Naciones Unidas.

Desarrollar políticas públicas de una manera que promueva una buena gestión de activos es importante para que los gobiernos y sus autoridades de políticas públicas hagan el mejor uso de los recursos públicos mientras maximizan el retorno social y financiero de las inversiones.

Esta ponencia ha presentado acciones y bases de partida que a tenor de lo publicado por otros agentes e instituciones del mercado ferroviario y a tenor de la experiencia de INECO son las claves para implantar un Sistema de Gestión de Activos basado en los Estándares UNE – ISO 55000, AENOR (2015), en Administradores y Gestores Ferroviarios que permitan demostrar y hacer ver que los activos de la compañía se gestionan con criterios de sostenibilidad. De tal forma que las compañías deban certificarse con los estándares que ya existen y para ello deben aportar datos ante un auditor independiente que acredite el cumplimiento de estos requisitos.

El buen gobierno corporativo y el cumplimiento de estos objetivos fijados por las empresas se ha de dotar de sistemas certificados que permita medir y evaluar el cumplimiento de los objetivos establecidos, AENOR (2018).

En paralelo a estas acciones se habla de establecer sistemas de coordinación y cooperación en materia de transporte y movilidad entre las administraciones ferroviarias con competencia en la materia. Uno de sus pilares sería el establecimiento de sistemas de información globales sobre transporte y movilidad, digitalizado y en tiempo real.

Como consecuencia de estos hechos, los administradores de infraestructuras y las empresas ferroviarias aparte de adoptar una actitud más empresarial como consecuencia de la legislación europea, en la actualidad han de adoptar un enfoque de gestión económico, social y medioambiental que supera el enfoque técnico hacia los costes y el rendimiento, por un enfoque integral que soporte el cumplimiento de los objetivos estratégicos de las organizaciones ferroviarias y del cumplimiento de los acuerdos entre estos y los gobiernos nacionales, provinciales o locales que los financian.

UNDERSTANDING TRANSPORTATION PREREQUISITES TO BE INTEGRATED WITH URBAN DEVELOPMENT IN DEVELOPING COUNTRIES: IRAN AS A CASE

Mohammad Hamed Abdi
Universidad Politécnica de Madrid, Spain
Francisco José Lamíquiz Daudén
Universidad Politécnica de Madrid, Spain

ABSTRACT

Transit Oriented Development (TOD), as an integrated transportation and land use policy and practice, was given attention in recent decades to (re)formulate urban areas worldwide. Amongst different TOD planning dimensions at play in, the transportation design and policies tend to basically form the backbone of TODs, since a multimodal sustainable movement — public transportation (PT) for long trips as well as non-motorized transportation (NMT) for short ones — is on the agenda. Although it is agreed that TOD can provide even greater benefits than in wealthier countries in long term, developing countries (DCs) are characterized with specific transport-related issues such as vexing congestion, inadequate PT infrastructure, financial obstacles, etc., that should be dealt with to deliver successful integrated TOD projects. In this regards, the present study sheds further lights on the transportation prerequisites of transit oriented urban planning in DCs.

First, a systematic review of global literature provided a set of transportation dimensions integrated with urban development. Due to the recent national policies on TOD, Iran was selected as a case and a set of semi-structured interviews was conducted with Iranian urban and transport planners along with government officials in April-June 2019. The results showed that although there are some favorable conditions to TOD developments in Iran e.g., amalgamated transportation and urban development ministries, urban transportation is hindered by pro-car policies such as subsidized fuel price and lack of multi-modal infrastructure in comparison with the best practices in such DCs as Curitiba. The findings have also implications for transportation policymakers, city officials, planners, and interested readers and practitioners in Iran and other DCs interested in TOD.

1. INTRODUCTION

Nowadays, TOD is globally known as an integrating strategy of transportation and land use planning. Initiated by *Peter Calthorpe* (1993), the key idea was based on a movement and urban development linkage, in line with *Smart Growth* and *New Urbanism* in nature (Xu et al., 2017; Dunphy & Porter, 2006) in order to fight against the car dependence issue and its hostile impacts (Shibley, 1998; Goetz, 2013). Apart from urban development and land use readjustment, transportation initiatives can play an important role in TOD planning, too.

Ideally, a quality PT for long trips should be connected to NMT infrastructures for local short destinations. By this, TOD calls for an easy and reasonable NMT accessibility to transit infrastructures. In addition, the location (i.e., centrality) and design of transit stations are key, so that it should be well integrated into urban textures to attract a higher ridership number. The realization of such transportation principles relies on a set of supportive policies. There is consensus that transport policies can widely steer urban spatial growth in general, and transit supportive patterns in particular, including urban form pattern, public services accessibility, etc. They refer to a set of consistent policies on both transit actors and transit context by which transit ridership are increased and, walking and cycling are facilitated within urban settings. They usually include (1) demand-oriented incentives policies such as tax credit, subsidy for PT (e.g., fares), and (2) supply-oriented plans like regional transportation plan, visioning and policy reform, design policy (e.g., road capacity), and auto equalizers (Abdi, 2019).

Recognized with low-quality PT and, subsequently, the predominance of informal transport, walking and/or cycling, as the main modes of urban transports (United Nations Human Settlements Programme, 2013), DCs have recently made some efforts to revolutionize their planning system by developing the sustainable paradigms of urban transportation such as the integrated transport land use model. It can be illustrated by the cases of Curitiba, and partly Bogotá, in which bus-based rapid transit (i.e., BRT) has been developed in connection with urban planning (land use) strategies (i.e., articulated density, mixed development, pedestrian oriented design).

However, the sustainable models in developing world have remained unknown or initiated recently. Of which, Iran's car-oriented transportation development and policies, coupled with subsequent inclement traffic-caused damages (e.g., pollutions and traffic fatalities) put some pressures on the central government and policymakers to adopt a sustainable trajectory, including public transit development. More recently, Iranian Ministry of Road and Urban Development (MRUD) approved a national guide of TOD. While multimodal quality PT and NMT are the focus of guide, transportation challenges and opportunities associated with the TOD policy and planning remained unclear. In this regard, major transportation prerequisites and mechanisms required for the integration have not been paid attention, so far.

To fill this gap, this study endeavors to scrutinize transportation aspects of TOD planning process in Iran. Both transportation development and transportation policies are discussed in this way. To this end, the study benefits from urban and transportation professionals' point of view through conducting a set of semi-structured interviews. They are supported by reviewing the realities of urban mobility in the Iranian context as follows:

2. URBAN TRANSPORTATION CONTEXT IN IRAN

The data for vehicle in use in Iran show that the motorization and private car use rate is rapidly growing in Iran (OICA, 2015). The heavy trend of vehicle use is faster than most of the developed countries (Shaygan et al., 2017) with 15 percent of annual growth rate (Soltani, 2017). What makes this a threat is the coincidence of motorization growth with the lack of sufficient PT services (Mirmoghtadaee, 2016). Although subway system and bus rapid transit (BRT) have recently been introduced in large cities (e.g., Tehran, Tabriz, Isfahan, Mashhad, Shiraz), the conventional buses are the most common system of formal PT in Iranian cities with different population, ranging from medium- sized to large cities.

Despite encountering a different situation across Iran, the bus operation generally suffers from several challenges in Iranian urban areas. Inadequate bus fleet, deterioration and limited capacity, dearth of a special dedicated lane, rare fixed-time plan at the stations, poor coverage of urban buses excluding low-income urban areas or newly-built areas like new suburban housing projects (e.g., Maskan-e-mehr) are some vexing challenges recorded for urban buses, to name a few. On the contrary, formal PT fares remained very low under a high level of subsidization since the relative poverty allows just low prices, even in comparison to the other developing countries in Latin America (Allen, 2013). As an opportunity, it can spur PT and correct price distortions of the fuels, especially those subsidized for private cars (World Bank, 2005).

The barriers facing PT, bus circulation in particular, have made taxis reasonable choices. They are much faster than buses on the same corridor with no big gap in fare and consequently, people prefer to ride collective taxis, or recently introduced much affordable app-based services such as SNAP. In Tehran, taxis are responsible for about 22 percent of daily urban trips, the most modal share among the others (Transportation and Traffic Organization, 2015). It rises up to 80 percent in some small and medium-sized cities with lack of coverage by other PT systems (Soltani & Falah Manshadi, 2017). In addition, there are other informal services by private cars, moto taxis and minibuses, transferring passengers citywide as illegal taxis with no work permits. They provide additional services at the times of day and prices that their formal counterparts are not willing to do so.

The increasing traffic congestion has resulted in constructing an extensive road infrastructure at the expense of limited space for walking and cycling in most Iranian cities. As a result, the quality pedestrian zones and sidewalk can rarely be found in many urban areas. They are typically narrow, non-continuous pedestrian paths interrupted at intersections, and occupied by parked or in circulation motorcycles, mailbox, and wares, with broken pavements, and unlit at nights. Inside under-construction areas, they were also left unpaved. Considering all these issues, it can be found that urban transportation in Iran follows a way projecting unsustainability in general, although several recent improvements have been on the agenda in part.

3. METHOD

In this research, two well-known means of the qualitative method were applied to data collection: literature review and interview. They are used based on the general objective of the paper formulating a case-study qualitative research in Iran. The literature was reviewed to derive transportation dimensions in the process. As Abdi (2019) detailed, two set of *transportation design* and *transport-oriented plan and policies* were found through a systematic review of TOD literature. The interviews were conducted with TOD actors, involved/interested in Iran's urban policymaking and planning system. A total of 11 TOD professionals including academic bodies, practitioners, and politicians and government officials were queried during April-June 2019.

More than half of the participants were academic specialists since they were the most aware group of the TOD actors from the TOD proposals in Iran. They were mostly from Tehran, the capital city. The authors made some efforts to interview other TOD activists in other groups such as transportation associations and bus organizations, but they were reluctant or left the invitation unanswered.

To conduct analysis, a directed qualitative content analysis was applied using the framework mentioned above. Although rarely applied in the urban studies, this method fits the present study’s aim, since it can discover the latent concepts (i.e., opportunities and challenges) in the interviews’ texts. In this regard, the codes relevant to each dimension were extracted and the perspectives of attendees were comparatively analyzed to draw a general image of transportation prerequisites for TOD planning in Iran. Moreover, a degree of agreement was calculated for all the categories based on the summative degree of agreement between the interviewees. To do this, first, all items (challenges and opportunities) mentioned in the interviews' transcription were summarized, and then the frequency of cited items were summed as the weighted final scores. In addition, the results for Iran were compared with those of DCs already systematically studied at (Abdi & Lamíquiz-Daudén, 2020).

4. RESULTS AND DISCUSSION

In this section, the result of interviews is presented. They are in addition and complement to those reviewed in the section 2. In terms of the realities of urban transportation development, the interview participants were asked to consider the general situation of Iranian cities and avoid exceptions in specific cities. However, it was thus clear that Tehran's urban transportation is highlighted more than the rest as most of participants were from Tehran. With regard to the transport policies, the centralized, top-down nature of policymaking and dominant government-led initiatives in Iran have resulted in a set of central, national transport policies by MRUD and supreme Traffic Council with very few local exceptions.

4.1 Transportation development

Transportation design is referred to the realities of urban movement with regard to the primary measures of TOD success in terms of transportation: increasing transit ridership and active transportation modes (Lierop et al., 2016). The core idea of TOD relies on a multi-modal transportation network, including an efficient public transit system joined to NMT network. Such a network should be accessible and cover multiple destinations. Integrated non-motorized initiatives were also the center of transit-oriented proposals in pioneer developing cities reviewed like Curitiba (e.g., Plano Director Cicloviario) and Bogotá (e.g., Cicloruta, Ciclovia). With regard to their mechanisms applied for PT development, both cities provided reliable high-quality mass transit services in the form of BRT and feeder conventional buses, aiming at covering most of the built-up areas.

Not surprisingly, a handful of transportation challenges were recorded during the interviews against the scant opportunities of improved quality of public transport services in large cities, outer Park and Rides connected to the subway and bus services for preserving the historical centers, and new practice of developing pedestrianized zones in a number of cities. On the challenges side, two transport planners referred to the weak regional integration of transport and urban development in Iran criticizing inefficient site selection of central train stations, which are often located out of the city boundaries. One of them clarified that railway have been developed far away from the cities (urban settlements) due to the separated railway and urban planning efforts in Iranian cities, which have already caused unplanned, informal settlements around the rail lines (e.g., Arak and Mashhad). In this regard, they added that the lack of integration between inter-city and urban transport means has been an aggravating factor. Even the urban-suburban connections within the construction works in the newly founded towns around the major cities, have not been under focus of attention after many years.

Moreover, what made general consensus among the participants was the dearth of multimodal urban transport network, especially around major transit stations. In this sense, an urban planner depicted PT stations as a set of isolated islands because of lack of integration with the complementary infrastructures (i.e., walking and cycling) so that another participant, as a walkability specialist, also believed that lack of efficient non-motorized networks thwarts all other policies and practices concerning sustainable mobility in Iran. There were complaints on the inefficient non-motorized transport infrastructures by other participants as well. The chair of national TOD project cited that “walking and cycling are still not recognized as transport modes in formal transport engineering literature”. Accordingly, one transport planner expressed concern on decreasing rate of bicycling in those cities that it had already been the principal transport mode, such as Yazd and Isfahan.

More importantly, more than half of the participants directly criticized the general low-quality of PT services in Iranian cities. An academic body with expertise in sustainable transport planning noted that the quality of public transport is not yet acceptable and there is a long way to establish a high-quality system in place. Accordingly, he suggested that instead of performing a trial-and-error process, the experiences of other pioneer countries be adopted for restarting such systems with higher efficiency and lower operation and maintenance costs, rather than the current systems. Although the status quo might be subject to changes, the city-by-city, bus fleet deterioration, lacking scheduled services, and limited vehicle capacity were some cited issues among the relevant challenges for the general situation of Iranian urban settings.

Similar to the findings presented in the interviews, the literature affirmed that the improvement in PT services has not been paid sufficient attention since the results revealed that despite some improvements, the system still suffers from the lack of quality services. In response, Taxi and informal transport could provide services as a paratransit mode, but not essentially connected to the PT. This would be another positive environment for car movement, in the absence of quality PT and NMT infrastructures, which is in clear contrast to the TOD policy. Hence, the result is high fuel consumption and an increase of the externalities (i.e., pollutions) as well as traffic injuries across Iranian cities.

The table below lists all major opportunities and challenges associated with Transportation Development. It also displays the degree of agreement on the issues (as relative importance) and consider their similarity to the other DCs' experiences. Accordingly, it is clear that there is a convergence of the challenges cited for TOD transportation design in Iran and other DCs. Reviewing developing world studies, the global evidence revealed that the regional transit issue in coordination with the land use planning was underestimated in other studied developing-country cities, where urban transit networks are incomplete in terms of connecting to other public and active transport infrastructures. In addition, the inadequate public transit services and low capacity of vehicles, informal transport and poor coverage were criticized, which were similar to what was claimed for Iran in the above discussion.

Item		Frequency	Similarity to other DCs
Opportunities	Recent improvements in PT services	5	*
	Park and Ride strategy	1	
	New practice of developing pedestrianised zones (NMT infrastructures)	3	*
Challenges	Weak regional integration of transport and urban development	2	*
	Dearth of multimodal urban transport network	4	*
	Lack of integration between inter-city and urban transport means	2	

Table 1 – Major opportunities and challenges associated with TOD transportation development in Iran, their frequency of citation by the interviewees and their similarity to other DCs

4.2 Transportation policy

Several TOD professionals believed that while the recent provision of national TOD guideline, the new guideline of urban street deign, and (re)planning to multi-modal, connected regional rail infrastructures would be opportunities for TOD planning, there are rare assistive transportation policies in line with TOD. One of the urban planning experts pinpointed the fact that there have been some short-term transport plans and decisions to alleviate current urban challenges in Iran but with no forward-looking strategies in Iran. He exemplified the BRT project in Tehran and other large cities in which inter-modal connection, land use integration and similar issues have not been yet adjusted. There was a common consensus on the challenge of subsidized, cheap fuel price in Iran by which car ownership is encouraged (Many opposing views, however, claim that in comparison to the indicator of minimum wage for a worker in Iran, purchasing power for the fuel is quite limited in Iran and thus, the price is still not low. Compared to the cases of Saudi Arabia, Venezuela, Canada and France, Iranian workers can purchase less gasoline per month (Hassannia, 2019) . A municipal official desperately noted that this is a problematic national economic and a political issue which cannot be easily dealt with. The data here shows that the average daily gasoline consumption has been 94 million liters during mid-2018 to mid-2019 in Iran (NIOPDC, 2018) of which a share of 58 percent of final oil products consumption goes to the transport sector (IEA, 2018).

Another major challenge was lack of coordination among transportation policies as well as among responsible bodies. The chief of national TOD project cited that a variety of the corresponding entities, laws and regulations handle the urban transport policy and planning in Iran, which has partly caused a kind of discordance in the planning process. Reviewing the structure and responsibilities of the actors we found that Ministry of Interior (MOI), as the main actor, is responsible for urban transportation policymaking and planning along with city councils at local levels. Meanwhile, MRUD handles the whole transportation sectors excluding the urban transport, while prepares urban development plans.

At local scale, even though municipalities under MOI are in charge for almost all the transportation planning and executive plans, parallel sectoral sub-institutions based on the different transport modes (e.g., metro, bus and taxi) do not play the integrated roles (Mirmoghtadaee, 2016). While Urban Transport Plans are mandated to be coordinated with the city comprehensive and detailed plans, there are typically discordances between the strategies.

The table below lists all major items related to transport and built-environment policies and plans and reveal the similarities between Iran and other DCs. As with the short-term policy adopted for developing PT in Iran, what followed in DCs has been development of BRTs with the hope of directing such cities into a trajectory of sustainable development. Together with Iran, pro-road policies and unsupportive national policies and propositions for PT in the transport planning process were associated with barriers to the integrated transport and land use practices in a number of case studies (see Abdi & Lamíquiz-Daudén, 2020). However, the opportunity of setting TOD policy at national level makes Iran a different country among others.

Item		**Frequency**	**Similarity to other DCs**
Opportunities	National TOD policy	2	
	urban street deign guideline	1	*
	(re)planning to multi-modal, connected regional rail infrastructures	3	*
Challenges	Subsidised (low) fuel price	4	
	Short-term transport vision and policy	1	*
	Inattention to potentials of NMT in transport policies	2	*
	Less attention given to affordable transport alternatives	1	*
	Lack of supportive transportation policy for TOD planning	4	*
	Uncoordinated transport policies and policymakers	2	*

Table 2 – Major opportunities and challenges associated with TOD transport policies in Iran, their frequency of citation by the interviewees and their similarity to other DCs

All in all, the content analysis of modern Iranian urban policies could confirm that except for little evidence of recent transit-based urban policies, urban development policies generally tend to facilitate car mobility, something that is contradictory to TOD principles, through encouraging sprawled developments (i.e., car-oriented new towns and far-reaching constructions) which lack in PT connections and placing priority on pedestrians. In the same vein, some transportation policies also facilitate car use (e.g., fuel subsidy, minimum parking, car purchase loans, etc.).

5. CONCLUSION

The present study tried to find urban transportation prerequisites, to be integrated with urban development in TOD planning process. To this end, the study went through the the context of urban transportation development in Iranian cities as well as ruling policies and regulations. The interview conduction helped to better understand the latent aspects of urban transportation in Iran, going beyond explicit affecting factors. In reality, the car-oriented urban transportation is recognized with the poor quality of PT, disconnected transportation modes at urban and regional scales, and hindered walking and cycling.

These can be stumbling blocks for successful TOD implementation in Iranian cities. Such environment has been the result of the car-oriented policy design over the past decades of transportation policymaking and planning. In fact, the TOD policies are in its very infancy stage and the problematic nature of unsustainable transportation policies still exists.

However, there have been several TOD-supportive transport policies at national tier in recent years, including PT development with a look towards the integration with urban development. They mainly portray a trend towards more sustainable choices for urban and inter-city mobility including rail development, inter-modal connection, etc.

In spite of the fact that TOD is a highly context-sensitive planning instrument (De Vos et al., 2014; Tan et al., 2014), it is important to confirm that there have been some common challenges in DCs as transnational challenges, such as disparate land-use and transport policy-making, uncoordinated transport governance, financial barriers, and technical and planning capacity, as cited in previous relevant studies (e.g. Cervero, 2013; Cervero and Dai, 2014; Suzuki et al., 2013; Pojani & Stead, 2018; Abdi & Lamíquiz-Daudén, 2020). In this regard, most scholars agree that the TOD practices in DCs are usually hindered by weak regional and multimodal connections. Consequently, PT systems do not have sufficient access to the destinations in metropolitan areas. In a study on DCs' transit and land use integration, Cervero (2013) criticised the lack of perpendicular connectors to transit stops and feeder systems. This has been the case in the specific cases of TOD in Hanoi and Bangkok, for instance, where urban transit networks are incomplete (Christine Bae & Suthiranart, 2003; Nguyen et al., 2019).

Similar to the items found in the content analysis of the interviews, the existing body of literature highlights an inter-national set of transportation physical and policy prerequisites is to be dealt with when TODs are under planning and constructions. In this respect, Iranian policymakers and government officials are highly recommended to give their attention to the provision of quality, interconnected PT systems in parallel with urban development readjustments, such as policies for density and zoning regulation, and parking during TOD policy design and planning. In fact, two spheres of the quality transport (i.e., *Node*) and the quality urban spaces (i.e., *Place*) should meet each other to have successful transportation environments built upon the sustainable movements: high ridership, and high walkers and cyclists. In addition, besides direct transport policies, other transport-related policy domains like fuel consumption, travel cost by car, financial mechanisms and social attitudes (education) should be more given weight for policymakers.

ABSTRACT

The sustainable development of freight transport has received much attention in recent years. The new regulations for sustainable transport activities established by the European Commission and the United Nations have created the need for road freight transport companies to develop methodologies to measure the social and environmental impact of their activities. This work aims to develop a model based on supervised machine learning methods with intelligent classification algorithms and key performance indicators for each dimension of sustainability as input data. This model allows establishing the level of sustainability (high, medium or low). Several classification algorithms were trained, finding that the support vector machines algorithm is the most accurate, with 98% accuracy for the data set used. The model is tested by establishing the level of sustainability of a European company in the road freight sector, thus allowing the establishment of green strategies for its sustainable development.

1. INTRODUCCIÓN

Concerning the current environmental situation regarding climate changes has impacted people and businesses, making sustainability a trend in all economic activities around the world. The constant design of strategies to mitigate the damage generated by humans' activities on the planet is more than a trend. In the business world, it is becoming a requirement. Integrating technologies to measure the impact of their activities leads to control over them and supports the strategies established to alleviate the generated impact.

Freight transport in the European Union has been growing significantly in the last decade. In 2017, it registered a total increase of 2.4 %, compared to 2016, being road freight transport (RFT) the main contributor with +4.7% (EEA, 2019). This means an increase of the demand for services in freight transport caused by the development of the global trade and influenced by the consumerism of the society (Nowakowska-Grunt and Strzelczyk, 2019; Nowicka-Skowron and Mesjasz-Lech, 2013). RFT is the main source of greenhouse gas (GHG) emissions because of the growth of its activities, which is offering important business opportunities to this sector but also challenges in the emissions reduction (Diemer and Dittrich, 2018). To achieve the proposed objectives, both governments and entrepreneurs have set out to develop sustainable strategies. Currently, there are different frameworks for sustainable freight transport (SFT) with several key performance indicators (KPIs) but with a limited agreement about the general logic and even the basic terminology to use in sustainability status of RFT providers. The common factor in assessing sustainability is that the three pillars of sustainability have to be considered and ensured that they are managed in a holistic way (Gudmundsson et al., 2016).

SFT aims to balance the economic, social and environmental dimensions of the sector in an integrated way to ensure synergy, complementarity and coherence (Zeimpekis et al., 2018; Kumar et al., 2019). From all regulations on the environmental, social and economic impacts left by RFT activities arises the need for businesses and governments to have methodologies to measure that impact. There is an exhaustive list of what SFT entails (Kumar et al., 2019). Among the characteristics, we can highlight the ability to provide safe, socially inclusive, accessible, reliable, affordable, fuel-efficient, environmentally friendly, low-carbon transport that is resistant to shocks and disruptions, including those caused by climate change and natural disasters (Youssef et al., 2017). The European Commission’s 2018-2020 work programme for “the smart, green and integrated transport” called for the development and validation of new solutions that can be rapidly deployed.

These solutions should address, systematically, modes of transport, infrastructure and operating patterns, apart from integrating them into a user-friendly European transport system. This must be characterized by connectivity and intelligence, evolving according to the needs of customers and allowing the assessment of the impact of transport solutions on society and the economy, while contributing to the competitiveness of the European transport industry (European-Commission, 2017).

Currently, there is no widespread and structured way to integrate traditional and sustainable objectives of the RFT sector, creating a gap between theory and practice in the development of sustainable strategies. This leads to the question of how to integrate and evaluate the sustainability of enterprises in this sector in order to identify and mitigate negative environmental and social impacts. Recent studies have proposed machine learning techniques to analyze real-world data for decision- making problems (Kaab et al., 2019; Nilashi et al., 2018; Molina-Gómez et al., 2020; Kartal et al., 2016; Nilashi et al., 2019).

Therefore, this paper presents the development of a supervised machine learning model based on classification algorithms, for monitoring the RFT activities and determining the level of sustainability on each of its dimensions. As consequence, it allows companies to define and achieve sustainability strategies in the short, medium and long term. This paper is organized as follows: in section 2, a brief literature review on related topics is presented; section 3 details the proposed methodology; section 4 provides the experimental results in the design and development of the sustainability assessment model; section 5 contains the results of the model implementation in a RFT company; section 6 presents some managerial insights; and finally, Section 7 highlights the main conclusions of this work with future research recommendation.

2. LITERATURE REVIEW

The transport sector is essential for the productive development of any economic and social system. This indispensable sector distributes goods throughout the world and transports people to their homes, work, and schools (Crafts et al., 2005). In Europe, the transport sector represents approximately 5% of the gross domestic product, that jointly with storage, represents between 10% and 15% of the total costs of finished products (Kallas, 2011). As a result, maintaining SFT has gained growing interest within the transportation sector. According to Gatto (1995), SFT is “sustained economic development, without compromising the existing resources for future generations”. In addition, Salas-Zapata and Ortiz-Muñoz (2019) point out that sustainability itself is based on four points: (i) sustainability as a set of socio-ecological criteria that guides human action; (ii) sustainability as a vision of humanity realized through the convergence of social and ecological objectives of a given reference system; (iii) sustainability as an object, thing, or phenomenon which occurs in certain socio-ecological systems; and (iv) sustainability as an approach that involves the incorporation of social and ecological variables in the study of a human activity, process, or product. On the other hand, freight Transport “supports production, trade, and consumption activities by ensuring the efficient movement of raw materials and finished goods and their on-time delivery” (Rajabi, 2011).

According to Centobelli et al. (2020), an effective sustainability program adopted by freight transport providers must include long-term environmental strategies, management execution, and information technologies (ITs) support. Its environmental strategies must focus on prior assessment of opportunities and impacted areas. In addition, SFT involves a balance between the effectiveness and efficiency of the planning and provision of transport services, and the environmental effects resulting from both economic and social circumstances. Similarly, the United Nations conference on trade and development (UNCTAD) established an ecological and socially measurable framework approach for SFT by incorporating the triple bottom line (TBL) framework (Youssef et al., 2017), which addresses the economic, environmental, and social dimensions applying indicators for defining and evaluating sustainability policies. The gathered information from the evaluation provides a broader insight for establishing sustainability guidelines, provided that these dimensions are aligned with the corresponding goals, or United Nations sustainable development goals (UN, 2015). In addition to the TBL, the global reporting initiative is put into place. According to Zhang et al. (2019), this framework that captures economic, environmental and social performance is used as an assessment of sustainability through the reliability of indicators. Additionally, UNCTAD devised a series of framework steps to achieve RFT sustainability. Furthermore, Mostert and Limbourg (2016) substantiate the growing interest in environmental sustainability research in their literature review which identifies various researchers who investigate five environmental challenges: air pollution, climate change, noise, accidents, and congestion. Correspondingly, the RFT sector's environmental sustainability program is aligned itself with measures for reducing carbon dioxide (CO_2) emissions. This alignment includes a framework of four critical points established by the evaluative and logical approach to sustainable transport indicator compilation: measurability, ease of availability, speed of availability, and interpretability.

Also, this framework is required for identifying and selecting sustainable transport indicators (Castillo and Pitfield, 2010). Altogether, research developed for assessing and measuring both logistics and transport sustainability consists of conceptual articles or empirical studies (Marchet et al., 2014).

Reaching and maintaining SFT requires more than just complying with environmental regulations and ordinances. As a result, the transportation sector must devise and incorporate green strategies into its transport operations. A strategic approach proposed by Seroka-Stolka (2014) indicates that green strategies for implementing sustainable development comprises three perspectives: the public or private (stakeholders), the operational and strategic (sustainable performance), and the local or global (geographical location). It should be noted that operational and strategic perspectives are complemented with the adoption of operational changes and the incorporation of environmental principles for strategic planning. In addition, alternative green concepts are devised for reducing the impact of road transport operations. Kadzinski et al. (2017) develop various multi objective application methods for optimizing environmentally compliant supply chains. Measuring environmental sustainability requires an extensive assessment of economic, social, and environmental principles. Although there is no definite model for measuring environmental sustainability, these three principles are fundamental for an effective and efficient sustainable project. From this perspective, additional methods supporting environmental sustainability are considered. For example, when the RFT sector adopts multi-actor and multi-criteria decision-making methodologies (Bandeira et al., 2018; Awasthi et al., 2018), and combined them with fuzzy models (Rai et al., 2017). These methodologies and models collectively allow the assessment of transport sustainability while taking into account the economic, social, and environmental principles. In addition, other factors affecting the sustainability frameworks are defined by the overall goal of the sustainability strategies, whether they be economic, social, or environmental. Moreover, measuring environmental sustainability requires aligning sustainable strategies and the three TBL dimensions mentioned in the early stages of this literature review. Today, many environmental sustainability investigations are limited to one or two TBL dimensions. As a result, not adopting the three TBL dimensions reveals that these three factors are not always attainable for measuring or evaluating environmental sustainability. With the adoption of sustainability measures, the reduction of emissions becomes an evident measurable equation. Therefore, measurable equations can lead not only to minimizing costs and GHG emissions, but also to generating green benefits (Arseculeratne and Yazdanifard, 2014). Consequently, the literature for assessing the sustainability of transportation remains limited and provides only valuable ecological methodologies and strategies and no evaluative framework that measures sustainability itself.

3. METHODOLOGY

The methodology of this research is based on supervised machine learning techniques for the assessment of sustainability through a set of sustainability KPIs. Figure 1 presents the proposed methodology in a schematic way, which consists of four main steps -the selection of the KPIs, the data preparation and training, the evaluation, and the selection of the classification algorithms- and several sub-steps.

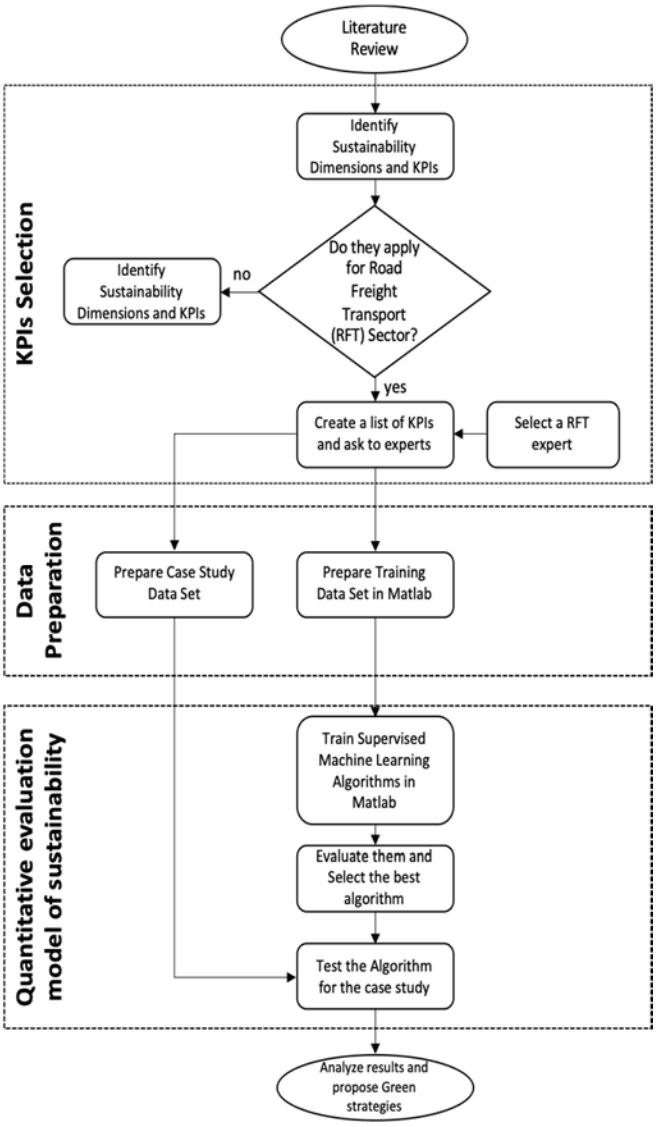

Fig. 1 – Methodology

3.1 Data selection and preparation

Sustainability comprises the TBL, economic development, environmental preservation and social development (Mihyeon Jeon and Amekudzi, 2005). Each of these is made up of a group of KPIs that allow to determine the level of sustainability in that dimension, and also serve as a reference for the quantitative evaluation of sustainability. This case study is based on the European RFT sector and the data was prepared as described in figure 2.

The methodology developed is constructed on the analysis of the KPIs included in different frameworks previously developed by governmental entities, such as the UNCTAD's framework and other scientific proposals, such as the complex performance indicators proposed by Dočekalová and Kocmanová (2016), and the assessment structures of sustainability transport networks (de Campos et al., 2019; Dobranskyte-Niskota et al., 2007; Prause and Schröder, 2015). Once the RFT expert defines the KPIs to be included in the model, the results for the evaluated company are calculated to obtain a total rate for the performance in each of the dimensions. Based on these results, its level of sustainability is measured.

In machine learning techniques, it is important to develop a correct and appropriate training data set, since the algorithms use that information to learn. Because there is no pre-defined data set for measuring sustainability for any of its dimensions, a data set is generated in Matlab with a structure similar to the well-known iris data set from Fisher and Marshall (1936). The values that represent the performance in each of the dimensions are generated as random values with a uniform distribution.

Fig. 2 – Data preparation for the case study

The methodology for the calculation is based on the weighted average. This method is also known as a weighted linear combination or scoring method. It is commonly used in multi-criteria decision-making (Chen, 2012). Generally, the weights of the relative importance may directly be assigned by decision-makers (Afshari et al., 2010). In this case, apart from selecting the most accurate KPIs to the study context, the RFT experts are responsible to assign the corresponding weights, too.

3.2 Development of the Quantitative Evaluation Model

The creation of the model to evaluate sustainability begins with the generation of the training data as aforementioned. For doing that, a series of algorithms available in “Statistics and machine learning toolboxTM” in Matlab which provides functions and apps to describe, analyze, and model data structures is employed. It includes the application called “classification learner” which allows us to train, develop, test, and evaluate several classification algorithms simultaneously. According to the results obtained in the training, the best algorithm is selected for the model development, which is determined according to the classification error (the smaller the error, the greater its accuracy in making predictions) and the metrics for performance evaluation, i.e., the predictive capability of the model (e.g., confusion matrix, cost matrix, ROC curve, etc.). The aim of training several algorithms simultaneously is to find the one that is most accurate for the type of data to be predicted. Figure 3 summarizes the workflow in Matlab for the development of the model. Within the trained algorithms, are included decision trees (Kotsiantis, 2013), discriminant analysis (DA) (Tharwat, 2016), the nearest neighbor (KNN) (Kataria and Singh, 2013; Dhanabal and Chandramathi, 2011), naive bayes (Tripathy and Rath, 2017; Al-Aidaroos et al., 2010), and support vector machines (SVM) (Kotsiantis et al., 2006; Platt, 1998).

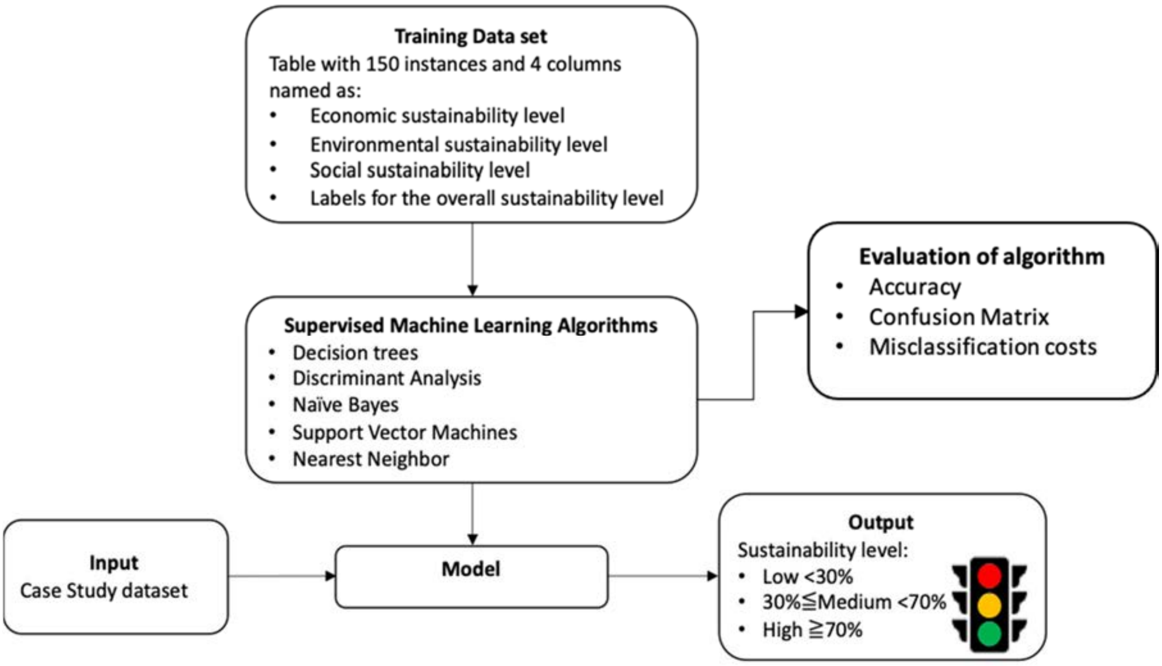

Fig. 3 – Workflow in Matlab

The validation and evaluation of the results of these algorithms are performed in terms of accuracy and classification errors. The estimation of their performance on the predictions for new data compared to the training data is determined by the cross-validation process.

The evaluation of the predictive accuracy of the fitted models is based on the performance in the automated training and the confusion matrix analysis to understand how the model has performed in each class (Amin and Ali, 2018). In addition to these metrics, the performance of the model is also evaluated through a sensitivity analysis to observe how the accuracy of the model changes according to the weights assigned to the dimensions of sustainability.

4. RESULTS AND DISCUSSION OF THE MODEL DEVELOPMENT

For testing our approach, a training data set of 150 instances was randomly generated with a uniform distribution from 0 to 1. As mentioned, these values represent the overall performance in each of the dimensions of sustainability. The data set consists of four columns, each of the first three representing a dimension of sustainability and the fourth the level of sustainability. This level measures the overall level of sustainability, being represented as one of the three following categorical values: “low”, “medium”, or “high”.

For each instance, the RFT expert has defined that its sustainability level is: *(i)* “low” when the weighted sum of the total performance in each dimension of sustainability is greater than 0% and less than or equal to 30%; *(ii)* “medium” when these results are greater than or equal to 30% and less than 70%; and *(iii)* “high” when the values are greater than or equal to 70%. The initial model was trained with the level of impact (weight) on sustainability defined by the expert which was 70% for the economic dimension, 20% for the environmental dimension, and 10% for the social dimension. For each classifier class, Table 1 presents the trained algorithms and their respective results, described by their overall accuracy, the misclassification cost, the prediction speed (in observations per second), and training time (in seconds).

Classifier class	Algorithm	Overall Accuracy	Misclassification cost	Prediction Speed (obs./s.)	Training Time (s.)
Decision trees	Fine tree	89.3%	16	1600	7.7
	Medium tree	89.3%	16	1700	7.0
	Coarse tree	86.7%	20	1500	6.4
	Boosted trees	56.7%	65	4000	11.5
	Bagged trees	88.0%	18	420	14.7
	RUSBoosted trees	89.3%	20	1500	6.4
Discriminant Analysis (DA)	Linear DA	97.3%	4	1300	9.2
	Quadratic DA	95.3%	7	2700	8.8
	Subspace DA	96.0%	6	320	14.6
Naive Bayes (NB)	Gaussian NB	88.7%	17	2700	8.2

Table 1 – Results for all trained algorithms

According to the accuracy obtained, the best algorithm is the linear DA with an accuracy of 97.3% to define the sustainability level and the lowest misclassification costs of 4.

Although its training time of 9.2 s. is not among the lowest, it is close to the mean of all times obtained, which is equal to 9.6 s., and a prediction speed of approximately 1300 obs./s. The quadratic SVM, cubic SVM, and linear DA algorithms obtained the highest accuracy. For each of them, Figure 4 presents the obtained confusion matrix, where the number of correctly and incorrectly classified instances is observed.

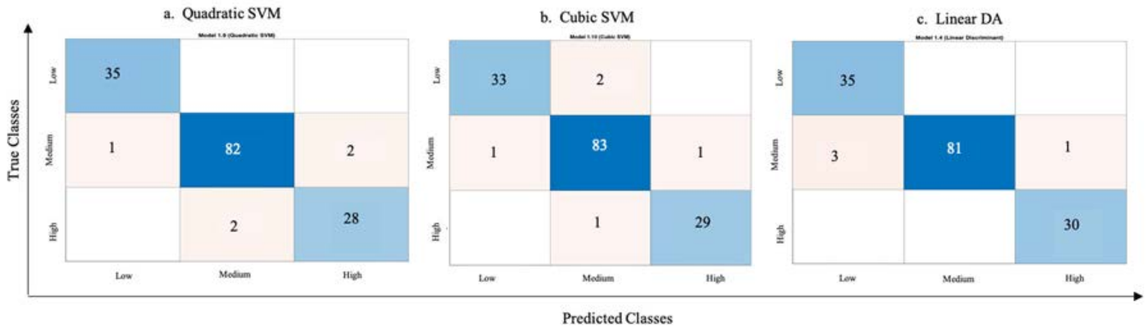

Fig. 4 – Confusion matrix [No obs.] of quadratic SVM, cubic SVM and linear DA

For the Linear DA, a total of 4 misclassifications are observed, being 2 instances as false negatives (FN) for the low and high level of sustainability and 4 false positives (FP) values for the medium level of sustainability. The results obtained show that, in general, the model can be quite accurate, with an F1-Score of 97%. The SVM algorithms have 5 misclassifications. The Cubic has, at least, one FN and one TN for each class, while the Quadratic has no TN for the low class. According to this analysis, both algorithms have a good fit to the data, even though the DA algorithm is more accurate. Comparing the number of misclassified instances, they differ only by one, being 4 for the DA and 5 for SVM. It is possible that by optimizing the hyperparameters of both algorithms, a clearer solution can be obtained as to which one of them fits better to the data used to measure the level of sustainability. When optimizing the hyperparameters of the algorithms with the Bayesian optimizer the SVM algorithm shows accuracy of 98% for measuring the level of sustainability, with 3 misclassified instances. Finally, this model is selected and exported as a code to evaluate the sustainability level of the case study which is a European RFT company.

A sensitivity analysis is performed for the model based on the SVM algorithm. 18 different scenarios were evaluated changing the weights assigned to the dimensions of sustainability. Table 2 presents the accuracy results obtained for each of them after the retraining. The results show that the accuracy of the model can change by approximately 2%, either positively or negatively from the initial 98% accuracy according to the percentage distribution given to the sustainability dimensions to define their impact on the level of sustainability. In particular, the model accuracy is more sensitive to variations where the environmental dimension has the greatest impact on the level of sustainability.

Scenario	Dimension weight			Accuracy
	Economic	Environmental	Economic	
1	0%	100%	0%	99%
2	100%	0%	0%	100%
3	0%	0%	100%	99%
4	33%	33%	33%	97%
5	50%	50%	0%	99%
6	0%	50%	50%	99%
7	50%	0%	50%	99%
8	10%	70%	20%	97%
9	20%	70%	10%	97%
10	10%	20%	70%	99%

14	25%	25%	50%	99%
15	70%	10%	20%	97%
16	60%	20%	20%	99%
17	20%	60%	20%	99%
18	20%	20%	60%	99%

Table 2 – Sensitivity analysis scenarios

5. MODEL IMPLEMENTATION RESULTS IN A CASE STUDY

As a case study, a European company in the freight transport sector with a global transport network is used to evaluate our methodology. This logistics service provider offers not only RFT but also other modes of transport such as rail freight, air freight, shipping, and more services. Since one of its characteristics is the decentralization in the decision-making processes, the sustainability assessment was done only for the region of southern Europe (Iberian countries). From the literature review, the UNCTAD's framework for Sustainable Freight Transport (Youssef et al., 2017) was identified as the most comprehensive framework for the freight transport sector. As KPIs are defined according to the particular circumstances of each case, table 3 presents the KPIs defined for this company with the corresponding definition and formulas according to the experts' criteria.

Dimension	KPI	Definition	Formula
Environmental	Shipments with reported CO_2 emissions	Rate of shipments with monitored CO_2 emissions in relation to total shipments in 1 year (between 0 and 1, the higher the better)	(Shipments with CO_2 emissions reported / Total shipments) * 100%
Economic	Engine Standards	The share of available Euro 6 standards-compliant vehicles (between 0 and 1, the higher the better)	% of vehicles that meet Euro 6 standards
	Transportation cost	Transportation costs as % of turnover (between 0% and 100%, the lower the better)	(Transportation costs / Total turnover) * 100%
	On-time shipments	Rate of on-time shipments in relation to total shipments (between 0 and 1, the higher the better).	[(Total shipments - Shipment delays) / Total shipments] * 100%
Social	Gender equality	Gender equality index among hired employees in the company (between 0 and 1, the higher the better. 1: very good gender equality 0: extreme gender inequality)	(Total number of women employees / Total number of men employees) * 100%
	Workforce Stability	Total workforce Stability index in the company (between 0 and 1, the higher the better. 1: very good workforce stability 0: extreme workforce instability)	(Total number of female employees / total number of employees) * 100%

Table 3 – Case Study KPI definitions and formulas

For the assessment of the level of sustainability, the company provided the data of each KPI for 2019. The weighted average methodology is applied to the company's performance values according to the impact of each of the KPIs determined by the RFT expert for each dimension. As environmental sustainability is given only by one KPI, the company presents a level of environmental sustainability of 77%. The economic dimension is defined as the one with the greatest influence on overall sustainability, and its performance is the lowest of the three with 58%. Transport costs are the most important KPI according to the weight assigned, followed by the other two. For the social dimension, both KPIs present the same level of importance, obtaining a performance of 63%. Based on these values, the input data is calculated to evaluate the sustainability level of the company.

Numerically, the company scored 62% for overall sustainability. Categorically, a high level of sustainability is achieved from a performance of 70%, the company is 8% away from reaching a high level of sustainability, so it has a medium level of sustainability. The greatest weight of the economic dimension on the overall sustainability, and transport costs representing more than 70% of the total turnover, influence negatively the overall performance of this dimension. The results for the other two KPIs of this dimension are good, as on-time deliveries are at 88% and engine standards (Euro VI) are at 90%. These results only represent 40% of overall sustainability. As the environmental dimension is only 20% relevant, its performance only contributes to the overall sustainability by 15%.

The social dimension only represents 10% of the total, contributing 6.3% to the total. With an equitable distribution of the weights, an overall return of 68% is obtained, which only represents a difference of 6% concerning the real value obtained, being also an average level of sustainability. This result means that the company must improve the performance of its sustainability indicators, especially transport costs.

The sustainable strategies are proposed based on the previous results obtained for overall sustainability and each of its dimensions. The selected KPIs reveal the strategies currently proposed by the company for its sustainable development. It can be seen that the company has as its strategy to implement concepts such as the use of IT systems to monitor and control CO_2 emissions, to use environmentally friendly vehicles, to monitor and control the costs and efficiency of transport, and to ensure the equality and well-being of both its employees and the society in general. Understanding the current strategies and performance of the company leads to a medium level of sustainability that allows for the identification of which strategies and which dimension of sustainability should be focused on in the future. Within the company’s results, it is noted that all its KPIs are defined on the basis of European regulations for the RFT. Currently, the company does not have any environmental sustainability indicators that actually show the impact of its activities. The integration of a system for measuring and monitoring GHG and CO_2 emissions as well as fuel consumption is a starting point and a valid strategy for the near future.

The evaluated company needs a more solid long-term strategy to continue its sustainable development. Promoting sustainable transport and involving all stakeholders in the development of the strategy is the best way to promote sustainability among customers and employees and to increase business. The proposed methodology for a sustainable strategy consists of establishing KPIs with a clear objective for each of the dimensions. In this case, for each of the dimensions, different KPIs are proposed based on the available frameworks for sustainable RFT. It is also proposed to include as many externalities caused by activities such as accidents, air pollution, climate change, noise, and management as possible. In addition, maintain the commitment to the continuous improvement of its performance for the KPIs that have been initially established for each of the three dimensions of sustainability. This allows for the evaluation of their level of sustainability and to maintain a historical record of the evolution of their sustainable development.

6. MANAGERIAL INSIGHTS

The growing awareness of sustainability in society is putting pressure on companies to integrate the principles of sustainable responsibility into their strategies and policies. Beyond the development of quantitative criteria for evaluating the sustainability of companies based on automatic learning techniques, such as the methodology developed in this work, companies in the RFT sector need to define and adopt sustainable strategies that integrate their three pillars. In the methodology developed, it can be observed that in order to apply these methods, a whole subsequent administrative process at the strategic level is also necessary, which initiates with the definition of sustainability objectives that integrate the three dimensions. Within the objectives, the key performance indicators for each dimension must be integrated and the performance in each dimension, and the general sustainability must be evaluated, as it has been done for the case study. As a final and starting point of a new strategic sustainable cycle, it is required the commitment of the stakeholders supported by ongoing monitoring, reporting, and communications among stakeholders that, at the same time, promote awareness and engagement. This becomes a cycle that must be constantly updated to continue the sustainable development of the company.

Today's customers are concerned about sustainable development (León et al., 2014). The development and integration of these quantitative models that integrate the three dimensions of sustainability support the decision-making process that integrates sustainability criteria. These methodologies teach companies that they can establish guidelines for their sustainable development that guide them in setting objectives and at the same time evaluate the company's performance in relation to them. Besides, they are adapted to the particular situation of each company or context of the study. This can be seen in that the input data can vary, i.e., the KPIs, and yet these tools fulfill their purpose. In general, the adoption of this type of strategy shows the social and environmental responsibility that companies in the RFT sector have and how they contribute to sustainable development.

7. CONCLUSIONS AND FUTURE RESEARCH

Nowadays, people and many businesses around the world are trying to develop strategies to mitigate the damage generated by humans' activities on the planet, and therefore, reducing the environmental impacts caused by climate changes. With the increase of road freight transport in Europe, the demand for related services in freight transport has been increased and, consequently, greenhouse gas emissions have been potentialized. To overcome this problem, in this paper, we developed a model based on supervised machine learning methods based on classification algorithms to integrate and evaluate the sustainability of enterprises in the road freight transport sector. This methodology aims to monitor the RFT activities and determining the level of sustainability on each of its sustainability dimensions.

For testing our methodology, a data set was generated in Matlab to represent the overall performance in each of the dimensions of sustainability. Each algorithm has been trained through this data, and that one which presented the best performance was selected to evaluate the sustainability dimensions of a European company in the freight transport sector with a global transport network. According to the results, the optimized SVM classifier obtained using Bayesian optimization has presented the best adaptation to the data and predicted with greater accuracy the level of sustainability. For environmental sustainability, the company presented a level of 77%. For the economic sustainability dimension, the company got 58%, which is mainly represented by transport costs (the most important KPI). Finally, for the social dimension, a performance of 63% was concerned. Numerically, the company got a 62% of sustainability out of the 100% possible, being the company 8% away from reaching a high level of sustainability. Therefore, it implies that the company needs a more solid long-term strategy to continue its sustainable development, where promoting sustainable transport and involving all stakeholders in the development of the strategy is the best way to promote sustainability among customers and employees and to increase business.

Future work could be derived on the basis of this paper. This model could be implemented for other companies and in other economic sectors by modifying the KPIs and adapting them according to the studied context. This would make it possible to verify that the model is not only limited to the RFT sector, but it serves to determine the level of sustainability regardless of the sector being evaluated. This therefore provides an opportunity to explore how accuracy may be affected by the results of the context. On the other hand, the developed SML model is subject to a certain level of subjectivity or bias since the parameters were defined by an expert in the sector. Therefore, the subjectivity could be mitigated by integrating this SML methodology with optimization methods based on heuristics and metaheuristics associated to sustainability criteria such as fuel consumption, external costs, CO_2 emissions, among others. These methodologies are characterized by the use of algorithms that allows for the optimal selection of KPIs that maximizes sustainability based on their impact level. A hybrid model such as this would not only allow a more objective and standardized evaluation of the level of sustainability but would also automatically establish the sustainability strategies.

RESUMEN

Con el fin de mejorar la calidad de vida y la sostenibilidad, a nivel mundial los gobiernos han aplicado múltiples políticas de transporte para reducir el uso y la propiedad del vehículo privado, así como para incentivar y ofrecer alternativas de viaje más sostenibles.

Las características de la ciudad y las políticas de transporte influyen en las decisiones de los individuos de poseer y utilizar su automóvil privado, lo que repercute en la generación de externalidades.

En Madrid se han implementado dos políticas que promueven la movilidad sostenible. En primer lugar, el Servicio de Estacionamiento Regulado (SER) que gestiona, regula y controla el estacionamiento en la vía pública, con el fin de racionalizar y compatibilizar el uso del espacio público y el estacionamiento de automóviles. En segundo lugar, el Plan de Calidad del Aire y Cambio Climático, que tiene como objetivo reducir la contaminación del aire. En este último se definió una Zona de Bajas Emisiones conocida como 'Madrid Central', que establece limitaciones de tráfico y de estacionamiento con la intención de reducir el acceso de los vehículos a la zona, especialmente los más contaminantes.

Esta investigación explora en qué medida la propiedad de automóviles está influida por la implementación de políticas de transporte que reducen el uso del vehículo privado. Para ello, mediante la calibración de un modelo logit ordenado multinivel, la propiedad de automóviles en los hogares se explica en función de las características sociodemográficas, variables del entorno construido de la ciudad, atributos de la red de transporte y variables relacionadas con las políticas de transporte.

Los resultados indican que los factores del entorno construido desempeñan un papel fundamental en la explicación de las tendencias de la propiedad de automóviles. Además, las políticas de transporte destinadas a disuadir el uso de automóviles parecen desalentar a los hogares su adquisición.

1. INTRODUCCIÓN

Los responsables de la política pública son conscientes de que las externalidades del transporte están aumentando considerablemente en muchas ciudades del mundo. Lo anterior, debido al creciente uso de los vehículos privados (Gakenheimer 1999; Moriarty y Honnery 2008). Las externalidades más conocidas relacionadas con la carretera son la congestión del tráfico, accidentes, daños al medio ambiente y el deterioro de las carreteras.

Para hacer frente a este problema, los responsables de la política pública y los profesionales dedican grandes esfuerzos a comprender cómo influyen ciertas características de las ciudades en el uso de los vehículos privados y, en particular, en la decisión de adquirir un vehículo. En este sentido, la propiedad de vehículos en los hogares representa una variable importante para que los planificadores locales puedan prever futuras medidas de política de transporte destinadas a garantizar ciudades sostenibles (Ding et al. 2016).

Como menciona Banister (2008), la mejora de la sostenibilidad del transporte requiere no sólo actuar sobre la capa física de la ciudad (forma urbana y flujos de tráfico), sino también sobre su dimensión social (personas y proximidad). Promover la movilidad sostenible y reducir el efecto de las externalidades negativas requiere, por tanto, crear zonas atractivas en la ciudad y mejorar la calidad de los barrios. Estas políticas pueden ser de mando y control (CAC por sus siglas en inglés) o de incentivos (IB por sus siglas en inglés). Una política de mando y control es esencialmente una regulación que hay que hacer cumplir, mientras que las políticas de IB proporcionan incentivos económicos y actúan para alterar el beneficio privado de una determinada respuesta de comportamiento (Santos et al. 2010). Con el fin de mejorar la habitabilidad urbana y la sostenibilidad, los gobiernos locales de todo el mundo han aplicado múltiples políticas para reducir el uso de vehículos privados y la propiedad de automóviles, así como para incentivar y ofrecer una alternativa atractiva a los coches privados.

El efecto de las políticas de transporte sobre el uso de los coches privados, y en particular sobre la decisión de los individuos de poseer un coche, necesita más estudios. Esto proporcionaría a los responsables políticos nuevas herramientas para mejorar el diseño de las políticas o aumentar las medidas de apoyo (Hanying 2018). Además, el impacto de la política de transporte está en consonancia con la fuerza de la construcción del transporte público urbano o el cambio del modo de desplazamiento de los residentes para mejorar el efecto de la aplicación de la política. Sin embargo, hasta la fecha son escasas las contribuciones de investigación que analizan empíricamente el efecto de las políticas de transporte sobre las decisiones de propiedad de automóviles a nivel internacional, especialmente en lo que respecta a las políticas destinadas a restringir el uso de vehículos privados en las zonas urbanas.

El objetivo principal de este trabajo es explorar hasta qué punto la propiedad de automóviles se ve influida por la aplicación de políticas de transporte destinadas a mejorar la sostenibilidad urbana, en particular las restricciones al uso de vehículos privados. Para ello, nos centramos en la ciudad de Madrid (España), ya que este caso de estudio presenta algunas características interesantes. En primer lugar, es una de las ciudades más grandes de Europa, con una presencia tradicionalmente alta de los modos de transporte sostenibles (transporte público y modos activos) en el reparto modal y una marcada expansión urbana experimentada en las últimas décadas. En segundo lugar, Madrid ha puesto en marcha recientemente políticas de transporte posteriores (aparcamiento de pago en la calle, zona de bajas emisiones, protocolo de NO_2) destinadas a reducir el uso del vehículo privado. Por lo tanto, este trabajo pretende contribuir a la literatura actual explorando cómo la propiedad del coche se ve influenciada tanto por las características de la ciudad como por la implementación de políticas de transporte sostenible. Los resultados obtenidos para la ciudad de Madrid pueden ayudar a los planificadores a implementar políticas dirigidas a promover el transporte sostenible y a mejorar la habitabilidad en las zonas urbanas.

El resto de este trabajo se divide como sigue. La sección 2 revisa la literatura previa relativa a la propiedad del coche en entornos urbanos, con especial atención a las características urbanas y a la aplicación de políticas de transporte para reducir las externalidades relacionadas con la carretera. La sección 3 presenta el caso de estudio analizado en este trabajo, la ciudad de Madrid (España). La sección 4 describe los datos recogidos para esta investigación y la metodología adoptada, mientras que la sección 5 presenta y discute los resultados de la modelización. Por último, la sección 6 expone las principales conclusiones de este análisis y señala las recomendaciones políticas para las zonas pobladas.

2. REVISIÓN LITERARIA

En las últimas décadas se han dedicado muchas investigaciones a estudiar las decisiones de propiedad de automóviles. En el campo de la investigación sobre el transporte, se han adoptado preferentemente métodos cuantitativos para analizar las decisiones de los individuos de poseer un vehículo privado, así como las tendencias generales sobre la propiedad de automóviles a nivel agregado. De acuerdo con Gu et al. (2020), los enfoques de la propiedad de automóviles con una perspectiva cuantitativa pueden dividirse en modelos exógenos y endógenos. Los modelos exógenos consideran que las decisiones de propiedad de automóviles son independientes de las restricciones, como la elección modal. Por otro lado, los modelos endógenos analizan conjuntamente la propiedad del coche y otras elecciones (Giuliano y Dargay 2006). Además, los estudios científicos en la literatura consideran variables más específicas como la demografía de los hogares, el empleo de los individuos, los atributos del tránsito, el entorno construido, los atributos del ciclo de vida y las políticas (Anowar, Eluru y Miranda-Moreno 2014).

Se ha comprobado que muchas características sociodemográficas, tanto a nivel individual como de los hogares, influyen en la propiedad del coche. Varios estudios (Dargay 2001; Dargay y Vythoulkas 1999; Golob 1989) muestran que los ingresos de los hogares tienen una fuerte relación positiva con la propiedad de automóviles, siendo las elasticidades de los ingresos generalmente mayores a largo plazo que a corto plazo (Dargay y Vythoulkas 1999). Además, se ha comprobado que la elasticidad con respecto al aumento de la renta es mayor que con respecto a la disminución de la misma, por lo que, una vez adquirido el coche, dejar de usarlo se hace más difícil aunque la renta del hogar disminuya (Dargay 2001). Con una perspectiva similar, otros autores como Chatterton et al. (2016) se han centrado en cómo influye en la propiedad del coche el coste global del vehículo, que se compone de los costes fijos anuales, los costes esporádicos (reparación y mantenimiento), los costes de combustible y la depreciación. También se ha comprobado que la propiedad de un coche está influenciada por la edad (Klein y Smart 2017), ya que los jóvenes (nacidos en las décadas de 1980 y 1990) tienden a tener menos vehículos que las generaciones anteriores.

Además, algunos acontecimientos del curso de la vida influyen en la decisión de poseer un coche. Gu et al. (2020) estudiaron la trayectoria de vida (eventos educativos, matrimoniales, ocupacionales de la vivienda y de la propiedad del coche) de los ciudadanos holandeses y descubrieron, por ejemplo, que los hogares jóvenes sin coche son más sensibles a los eventos relacionados con la composición del hogar como tener un nuevo hijo. En entornos propensos al uso del coche, como Estados Unidos, existe un fuerte efecto positivo entre la propiedad del coche y la probabilidad de estar empleado (Raphael y Rice 2002). Descubrieron que el empleo a tiempo completo tiene una mayor influencia en la obtención de un coche en comparación con el empleo a tiempo parcial. También se llegó a la conclusión de que el comportamiento es diferente según el género y la raza.

Los hogares de las zonas de alta densidad poseen menos coches que los de las zonas de baja densidad (Ding et al. 2016), dado que las zonas urbanas de baja densidad están mal servidas por alternativas de transporte (Giuliano y Dargay 2006). Además, los barrios del centro de la ciudad tienen mayor densidad y heterogeneidad de usos del suelo que los suburbanos. Se ha comprobado que una mayor mezcla de usos del suelo, así como una mayor proximidad a centros comerciales y restaurantes, están asociados negativamente a la propensión a poseer un coche (Li y Zhao 2017).

Christiansen et al. (2017) para Noruega y Guo (2013) para Estados Unidos mostraron una relación positiva entre la disponibilidad de aparcamiento y la propiedad de un coche.

Según estos autores, los hogares con aparcamiento privado tienen una disposición a poseer un coche tres veces mayor. La disponibilidad de aparcamiento en la calle y fuera de ella también influye en la decisión de poseer un coche, y está fuertemente influenciada por la distancia a pie entre la zona de aparcamiento, el hogar y el aparcamiento gratuito.

La propiedad del coche también está fuertemente asociada al modo de transporte que se utiliza habitualmente (Kitamura 1989). Los gastos en transporte público y en tiempo de viaje en coche influyen positivamente en las decisiones futuras de propiedad del coche. El acceso al transporte público puede ser decisivo para reducir la propiedad del coche en los jóvenes (Klein y Smart 2017). Cervero (2002) descubrió que la accesibilidad al trabajo mediante redes de tránsito reducía el nivel de propiedad de automóviles, mientras que la accesibilidad al trabajo mediante redes de vehículos se asociaba positivamente con la obtención de más automóviles.

En todo el mundo se han aplicado algunas políticas de transporte para restringir el uso de vehículos privados y disminuir la propiedad de automóviles. Las políticas de CAC son las más comunes de este tipo. En Singapur (Smith 1992) y China (Hanying 2018), se aplicó una política eficaz que controla el número de coches nuevos comprados, conocida como "Sistema de cuotas de vehículos", para gestionar los niveles de propiedad de coches. En el caso de Singapur, en los dos primeros años de funcionamiento se redujo a la mitad el crecimiento de la propiedad de automóviles.

Las políticas de transporte destinadas a reducir la congestión de las carreteras también influirían, en teoría, en la propiedad de automóviles. Por ejemplo, Wang et al. (2014) exploraron el efecto de una restricción de matrículas sobre las decisiones de propiedad de automóviles en China. Sorprendentemente, aunque la política tenía como objetivo retirar los coches de la carretera, los autores descubrieron que la política aumentaba la propiedad de coches, en el sentido de que los usuarios con intención de evitar la medida conseguían varios coches con diferentes números de matrícula. Hasta donde sabemos, no se aportan pruebas empíricas de otras medidas políticas destinadas a reducir la congestión, como la tasa de congestión, aplicada en varias ciudades del mundo, como Londres, Estocolmo o Singapur.

El aparcamiento de pago es una política aplicada en todo el mundo que establece algunas normas para el uso del aparcamiento en la calle. Dentro de las regulaciones, el precio y la oferta tienen más influencia en la propiedad del coche. Por ejemplo, en Barcelona (España), Albalate y Gragera (2020) llegaron a la conclusión de que un aumento de la densidad de plazas de aparcamiento reguladas incrementa la posesión de coches a nivel de barrio en 0,26 coches por cada 1.000 habitantes.

También se han aplicado algunas políticas de IB, como el "Plan de coches de fin de semana". Esta política permite matricular los coches para utilizarlos únicamente durante las horas de menor afluencia y obtener un importante ahorro económico para los propietarios (Olszewski y Turner 1993). En San Francisco, se ha puesto en marcha el programa City CarShare para promover el uso compartido del coche. Alrededor de 9 de cada 10 miembros del programa pertenecían a hogares con cero o un coche (Cervero y Tsai 2004). La reducción de la propiedad de automóviles se consiguió al facilitar el acceso a los hogares con vehículo, que a menudo evitaron adquirir un segundo o tercer vehículo.

Como puede observarse, existe una amplia literatura que analiza la propiedad de automóviles y sus factores explicativos, con múltiples estudios que explican el comportamiento de la propiedad de automóviles. La mayoría de las contribuciones anteriores se centran en la relación entre la propiedad del coche y la sociodemografía de los hogares y, en menor medida, en los parámetros relativos al entorno construido de la ciudad. Sin embargo, por lo que saben los autores, es necesario investigar más a fondo el efecto de las políticas de transporte urbano en las decisiones de propiedad de automóviles, en particular las políticas de restricción de automóviles. Esto es especialmente interesante en contextos como el de las ciudades europeas, que suelen presentar altas densidades de población y cuentan generalmente con servicios de tránsito de calidad.

3. CASO DE ESTUDIO: MADRID CIUDAD

Esta sección ofrece una breve descripción del estudio de caso seleccionado para explorar hasta qué punto la propiedad de automóviles se ve influida por la aplicación de políticas de transporte destinadas a mejorar la sostenibilidad urbana y reducir el uso de vehículos privados.

Madrid es la capital de España y su ciudad más poblada, con un total de 3,3 millones de habitantes (Ayuntamiento de Madrid 2020a). Madrid sigue la tendencia general europea de mayor densidad, con un valor de 8.832 habitantes/km^2. La concentración de población es especialmente densa en la zona central dentro del primer anillo vial (24.326 habitantes/km2).

Tradicionalmente, la ciudad se divide en dos zonas principales (véase la Figura 1): el centro de la ciudad, dentro del primer anillo vial (M-30), y la periferia, que comprende los distritos fuera de la M-30. En las últimas décadas, la ciudad de Madrid ha experimentado un rápido crecimiento y un proceso de suburbanización, por lo que muchos residentes y puestos de trabajo se están desplazando del centro de la ciudad a la periferia (Díaz-Pacheco y García-Palomares 2014; Gallo Rivera y Garrido Yserte 2012). En la actualidad, alrededor del 30% de los habitantes viven en el centro de la ciudad y el otro 70% en la periferia (CRTM 2020b). El empleo se distribuye por igual entre el centro de la ciudad de Madrid y su periferia (ambos representan el 60% de los empleos), pero la evolución de la localización del empleo en los últimos años muestra un aumento hacia los municipios exteriores del área metropolitana de Madrid (Tobarra Gómez et al. 2016).

El tamaño de los hogares es menor para Madrid Centro en comparación con la periferia, 2,13 y 2,41, respectivamente. En consonancia con el CRTM (CRTM 2020b), Madrid muestra una reducción progresiva del tamaño del hogar.

La movilidad en Madrid se caracteriza por la gran oferta de alternativas de transporte público. Su red de metro es especialmente extensa. Tiene 288 km de longitud y un total de 302 estaciones. La oferta de servicios de autobús de cercanías también es elevada, ya que Madrid cuenta con 209 líneas que recorren 10.877 paradas. Esta red principal de transporte se complementa con servicios adicionales que conectan la ciudad de Madrid con su área metropolitana, como 444 líneas de autobús de cercanías, 8 líneas de ferrocarril de cercanías y 4 líneas de tranvía/ferrocarril ligero (Monzón, A., Cascajo, R., Romero, C., Calzado, R. Lopez 2019). Los modos de transporte público se integran de forma física y financiera para fomentar la intermodalidad. El sistema de bicicletas públicas, conocido como BiciMAD, ofrece una alternativa limpia y saludable a los ciudadanos. El sistema cuenta con una oferta de 2.964 bicicletas eléctricas, 4.116 anclajes y 258 estaciones (Ayuntamiento de Madrid 2020b). Los servicios privados de movilidad compartida han florecido en la ciudad de Madrid en los últimos años. Estas nuevas formas de movilidad incluyen el coche compartido, el ciclomotor compartido, la bicicleta y el patinete compartidos.

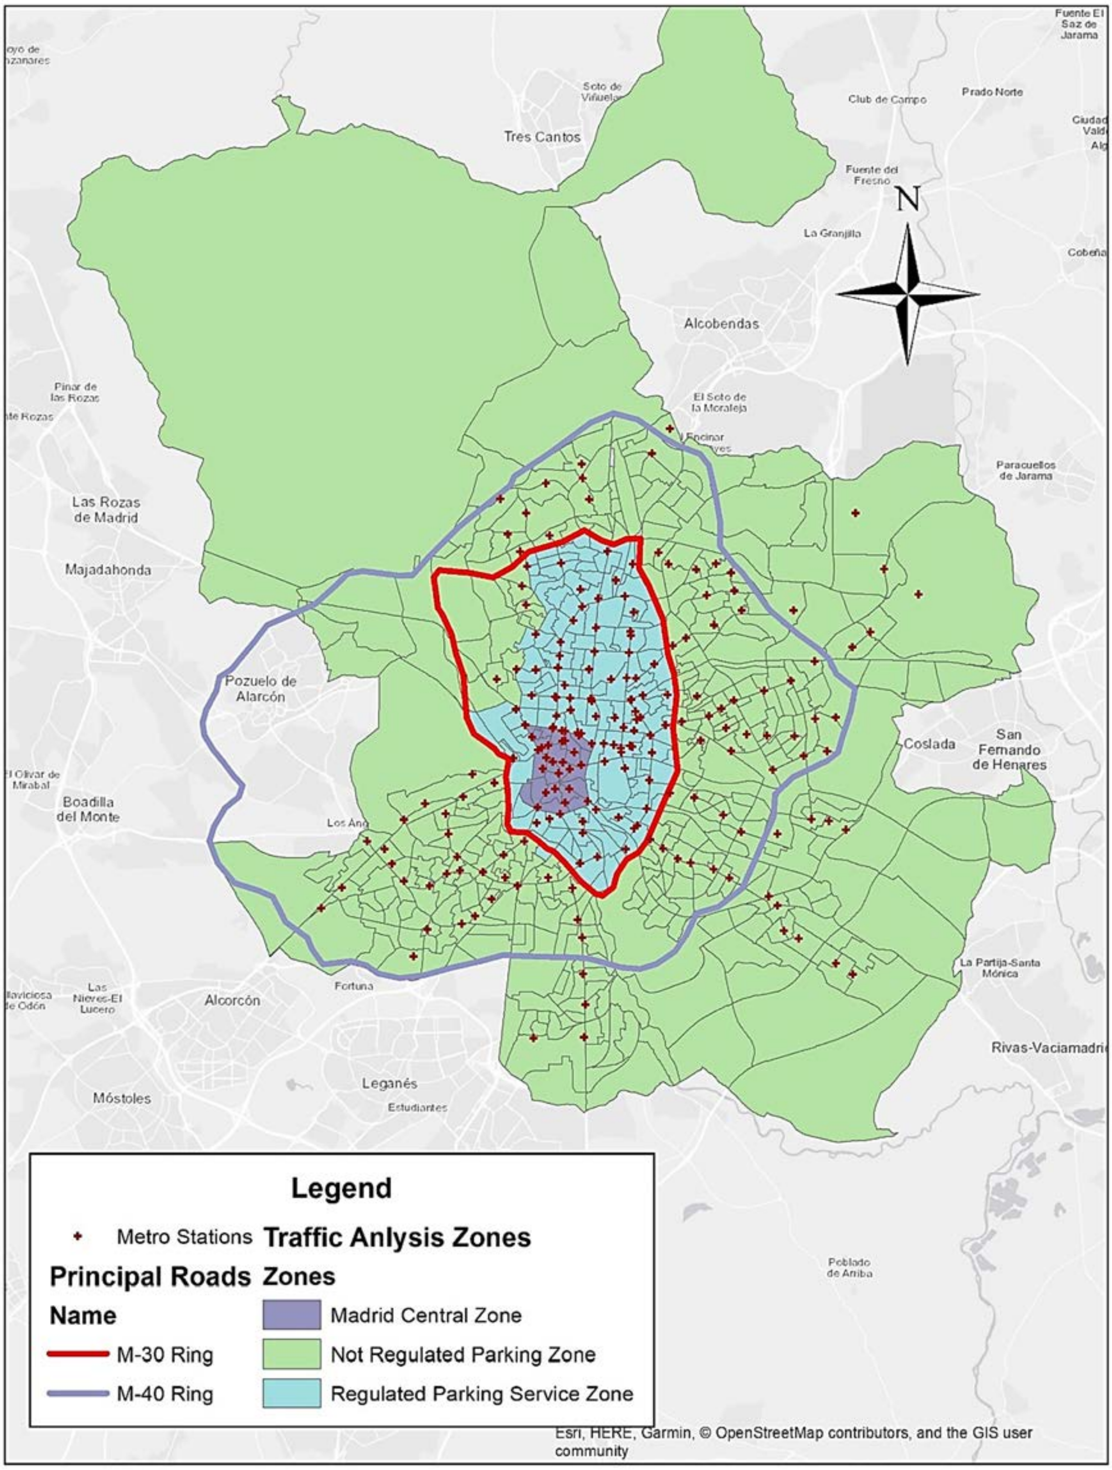

Figura 1 Madrid Ciudad

En los últimos años se han desarrollado dos políticas de transporte fundamentales: El Servicio de Estacionamiento Regulado (SER) y el Plan de Calidad del Aire y Cambio Climático de la Ciudad de Madrid, comúnmente conocido como PLAN A.

El SER se encarga de gestionar, regular y controlar el estacionamiento de vehículos en superficie en los distritos centrales de la ciudad, con la intención de racionalizar y compatibilizar el uso del espacio público y el estacionamiento de vehículos privados (Ayuntamiento de Madrid 2018). Madrid cuenta con más de 150.000 plazas de aparcamiento regulado de pago, divididas en cuatro tipos: i) 26.481 plazas en "Zona Azul" disponibles para todo tipo de usuarios; ii) 124.822 plazas en "Zona Verde" con prioridad para los residentes, aunque los no residentes también pueden utilizarlas a un precio superior al de la "Zona Azul"; iii) 1.397 plazas en "Zona Naranja" para larga estancia disponibles para todo tipo de usuarios, y iv) 382 plazas en la "Zona Roja" para el servicio sanitario. El área cubierta por la política SER puede observarse en la Figura 1.

El PLAN A tiene como objetivo reducir la contaminación atmosférica y contribuir a la mitigación del cambio climático (Ayuntamiento de Madrid 2017). Una de las acciones más importantes de este Plan fue la definición de una Zona de Bajas Emisiones (ZBE) conocida como "Madrid Central" (MC), véase la Figura 1. Esta ZBE se implementó con un conjunto de medidas específicas con el fin de promover un estilo de vida de movilidad de bajas emisiones y promover un centro de la ciudad más amigable para los peatones, ciclistas, vecinos y visitantes MC establece limitaciones de tráfico y estacionamiento con la intención de reducir el acceso de vehículos en la zona, especialmente los más contaminantes. Las condiciones de aparcamiento y las restricciones de tráfico para los vehículos privados se basan en una clasificación armonizada a nivel nacional (Cero, Eco, C, B o A) que tiene en cuenta tanto el motor como la antigüedad del vehículo. Además, el MC incluye otras estrategias para liberar espacio vial para los peatones y las bicicletas.

4. DATOS Y METODOLOGÍA

4.1 Recolección de datos

Esta sección presenta los datos recogidos para esta investigación. Las variables explicativas consideradas en el análisis de las tendencias de propiedad de automóviles en la ciudad de Madrid incluyen las características sociodemográficas de los hogares, las variables del entorno urbano, los atributos de la red de transporte y las variables relacionadas con la política. Los datos se han recogido en dos niveles principales de información: hogares y Zonas de Análisis de Tráfico, ZAT, dependiendo de la disponibilidad de los datos necesarios. Para realizar el análisis se han consultado múltiples fuentes de datos e información a nivel local, regional y nacional

Las características sociodemográficas de los hogares se han recogido principalmente de la Encuesta de Movilidad de Madrid, EM (CRTM 2020b), que proporciona información detallada de un total de 58.492 hogares del Área Metropolitana de Madrid. La muestra utilizada para esta investigación se compone finalmente de 28.794 hogares.

Las variables sociodemográficas de los hogares proporcionadas por la EM incluyen: número de miembros del hogar por edad, miembros del hogar con movilidad reducida, propiedad de aparcamiento privado, número de permisos de conducir y abonos de transporte público adquiridos, por hogar, y número de viajes diarios realizados por hogar. Para describir mejor la estructura familiar, se definieron variables categóricas adicionales, como la presencia de niños en el hogar (entre 0 y 4 años), el número de personas que trabajan y el número de personas con titulación universitaria. Esta fuente también proporcionó información sobre el número de vehículos privados por hogar, que es la variable modelada en esta investigación.

La EM no recogía datos sobre los ingresos. Para hacer frente a este problema, los autores de este trabajo incluyeron la información proporcionada por el Instituto Nacional de Estadística, INE (INE 2016) a nivel espacial de sección censal. A efectos de modelización, esta información debe trasladarse a un nivel espacial de ZAT, por lo que se ha aplicado una media ponderada espacialmente.

El análisis también incluyó variables explicativas relativas al entorno construido de la ciudad. La información sobre la densidad de población se recogió a nivel de ZAT para 2018 (Ayuntamiento de Madrid 2020a). Los atributos de uso del suelo se recogieron del Departamento de Catastro del Ayuntamiento (2020), en particular: áreas residenciales, comerciales, industriales y de oficinas (medidas en metros cuadrados) por ZAT. Un primer análisis exploratorio mostró una alta correlación entre las diferentes áreas de uso del suelo.

La investigación también incluyó información sobre la red de transporte, en particular la accesibilidad del transporte público. Para ello, se recopilaron datos de tránsito de las bases de datos abiertas de la Autoridad Regional de Transporte de Madrid (CRTM 2020a). Se eligió el número de paradas de autobús y de estaciones de metro por ZAT como proxies de la accesibilidad geográfica al transporte.

Finalmente, se incluyeron dos variables ficticias para controlar si el Servicio de Estacionamiento Regulado (SER) y la Zona Central de Madrid (MC) se aplican en cada ZAT. Estas variables permiten explorar si las tendencias de propiedad de automóviles de los hogares difieren entre los barrios en los que se aplican estas políticas o no.

4.2 Metodología: un modelo logit ordenado multinivel

Este trabajo realiza un modelo logit ordenado multinivel para explorar las tendencias de la propiedad de automóviles en la ciudad de Madrid (España). La variable que modelar es el número de coches por hogar, que puede representarse como una variable categórica.

Debido a la naturaleza ordinal y discreta de la variable dependiente, se ha adoptado un marco logit ordenado (Hanushek y Jackson 1977).

Los modelos logit ordenados se basan en los modelos logit tradicionales derivados de la teoría de maximización de la utilidad, es decir, la teoría de la utilidad aleatoria (estocástica). Según Ortúzar y Willumsen (2011), la teoría de la elección discreta supone que cada individuo asigna los recursos de forma que maximiza su utilidad o satisfacción personal (teoría de la utilidad aleatoria). Uno de los principales supuestos de los modelos logit ordenados es el de las probabilidades proporcionales (Wang et al. 2018), por lo que se supone que la relación entre cualquier par de categorías de resultados es igual.

Para explorar las decisiones de propiedad de un coche, adoptamos un modelo logit ordenado multinivel. Los modelos multinivel también se conocen como modelos de efectos aleatorios, mixtos o jerárquicos. En comparación con los modelos clásicos, los modelos multinivel tienen en cuenta la posible correlación entre las observaciones de los datos debido a las estructuras jerárquicas/anidadas de los datos. En este sentido, podemos esperar, por ejemplo, una alta correlación de las tendencias de propiedad de automóviles entre los hogares situados en el mismo barrio/distrito. Ignorar este efecto puede llevar a violar el supuesto de observaciones independientes, con importantes consecuencias negativas en los resultados.

Como se ha señalado anteriormente, los modelos logit ordenados estiman la relación entre un conjunto de variables independientes y la variable de resultado ordinal en una escala del logit (Agresti 2010). Además, la modelización multinivel para las variables de respuesta ordinales permite estimar la relación entre las variables predictoras en diferentes niveles y la variable de respuesta ordinal (Liu 2016). Para este marco de modelización, adoptamos una estructura de dos niveles, en la que el nivel 1 está relacionado con los individuos, y el nivel 2 se refiere a las zonas TAZ. Las especificaciones multinivel consideran un modelo diferente para cada nivel de datos y permiten explorar la variabilidad entre los distintos grupos en los diferentes niveles (Gomez, Papanikolaou y Vassallo 2016). En este caso, el modelo capta la heterogeneidad espacial a través de la TAZ (Giuliano y Dargay 2006).

La especificación del modelo logit ordenado multinivel para el nivel 1 se muestra en la ecuación 1

$$\text{Level 1: } Y_{ijk} = logit\,[\pi_{kl}(Y \leq k)] = \ln\left(\frac{\pi\,(Y_I \leq k)}{\pi\,(Y_I > k)}\right) = \alpha_k - (\beta_{1j}X_{1ij} - \beta_{2j}X_{2ij} - \ldots - \beta_{pj}X_{pij}) \quad (1)$$

Donde α_k son los puntos de corte con $k = 1, 2, 3, \ldots, K-1$; $X_{1ij}, X_{2ij}, \ldots, X_{pij}$ son las variables predictoras para el individuo ith y jth clúster; $\beta_{1j}, \beta_{2j}, \ldots, \beta_{pj}$ son los coeficientes del modelo en el j^{th} clúster a estimar.

La especificación del Nivel 2 se presenta en la ecuación 2.

$$\text{Level 2: } \beta_{0j} = \gamma_{00} + \gamma_{01} + \ldots + \gamma_{0p} + u_{0j} \quad (2)$$

Donde γ_{00} es el intercepto; $\gamma_{01}, \ldots, \gamma_{0p}$ son los coeficientes del Nivel 2 (efectos fijos); u_{0j} es el término del error o el efecto aleatorio relacionado a los puntos de corte.

La variable dependiente Y_k es un parámetro ordenado que capta la posesión de coches, con cuatro atributos categóricos: 0 coches, 1 coche, 2 coches y 3 o más coches. En nuestro caso, el conjunto de variables predictoras X_ij se refiere a las características sociodemográficas, el entorno construido de la ciudad, los atributos del sistema de transporte y las medidas de política de transporte aplicadas en la ciudad de Madrid.

Ocho de las variables explicativas utilizadas en el modelo son categóricas, por lo que es necesario elegir una referencia base para explicar adecuadamente los resultados del modelo. Para CHILD, SER, MC y PRIVATE, el caso de no ocurrencia es la referencia (No = 0). El nivel de referencia para las variables WORKER y PROFESSIONAL es 0 miembros. La referencia base para TRIPS es 0. El nivel de referencia de RENT es el grupo de ingresos anuales de 20 - 40 mil euros.

5. RESULTADOS DE LA MODELIZACIÓN Y DISCUSIÓN

A continuación, en primer lugar, se muestran los resultados de la modelización y, por último, se presenta el efecto sobre la propiedad de automóviles de las actuales políticas de transporte aplicadas en la ciudad de Madrid.

5.1 Modelo de propiedad del coche

Antes de calibrar el modelo de elección discreta, realizamos pruebas de multicolinealidad para comprobar la presencia de una fuerte correlación entre las variables explicativas, según Gujarati y Porter (2009). El análisis mostró dos problemas principales de multicolinealidad en nuestros datos. El número de permisos de conducir por hogar está muy correlacionado con el número de miembros del hogar, por lo que el primero se eliminó del análisis; por lo tanto, la densidad residencial fue la única variable de este tipo que se mantuvo en la modelización.

Los resultados del modelo que explica la propiedad de automóviles en la ciudad de Madrid se presentan en la Tabla 1. Como puede observarse, la mayoría de las variables explicativas que resultaron no estadísticamente significativas fueron finalmente eliminadas de la última versión del modelo. Para ello, realizamos múltiples pruebas de razón de verosimilitud (LR) durante el proceso de calibración, para comprobar que ciertas variables explicativas podían ser omitidas sin impacto en el ajuste global o en el poder explicativo del modelo. Los signos de los coeficientes del modelo se ajustan principalmente a los resultados esperados y a las contribuciones anteriores de la bibliografía. Como puede observarse, las variables sociodemográficas, del entorno construido de la ciudad, relacionadas con el sistema de transporte y de la política de transporte son estadísticamente significativas a la hora de explicar la propiedad del coche en el caso de estudio analizado.

Muchas variables sociodemográficas resultaron estadísticamente significativas a la hora de explicar las tendencias de la propiedad de automóviles. Como cabía esperar en un principio, el coeficiente de MEMBER (número de miembros del hogar) es positivo y estadísticamente significativo, lo que indica que cuantos más individuos viven en un hogar, mayor es la probabilidad de tener más coches. Según los resultados de la modelización, la probabilidad aumenta en torno al 10% por cada miembro adicional en el hogar. Además, como se ha señalado anteriormente, la presencia de niños en el hogar tiene un efecto positivo, pero este coeficiente sólo es estadísticamente significativo al 90%. Como se puede observar en la Tabla 1, el número de miembros del hogar con movilidad reducida aumenta la probabilidad de tener más coches. En particular, el número de coches por hogar aumenta en un 50% por cada persona adicional con movilidad reducida en el hogar.

Tabla 1 Resultados de la modelización

El número de miembros que trabajan y que tienen un título universitario tiene una influencia positiva y significativa en el número de coches por hogar. Lo mismo ocurre con el nivel de ingresos. Como puede observarse, la variable que controla los ingresos medios del hogar (medidos en miles de euros) tiene coeficientes positivos y estadísticamente significativos y coincide con los resultados preliminares mencionados. Cuando el hogar se encuentra dentro de una ZT cuyo nivel de renta media anual se sitúa entre 40 y 50, entre 50 y 60, entre 60 y 70, entre 70 y 80 y por encima de 80 mil euros, el número de coches aumenta en un 19%, 28%, 42%, 79% y 95% respectivamente, en comparación con el caso base (renta de 20 a 40). Estos resultados están en consonancia con múltiples análisis realizados por diferentes autores (véase, por ejemplo, Dargay (2001), Zegras (2010) y Guerra (2015)).

Las variables del entorno de la ciudad también explicaron, de forma estadísticamente significativa, las tendencias de posesión de coches en los hogares. Tanto la densidad de población como la densidad residencial tienen una influencia negativa y estadísticamente significativa en la obtención de más coches. Según los resultados de la modelización, la probabilidad de poseer un coche disminuye un 11% por cada unidad de densidad residencial adicional (m2/hectárea) en el barrio donde se encuentra el hogar. En otras palabras, las zonas de alta densidad residencial reducen la probabilidad de tener un coche, probablemente porque hay menos espacio para aparcarlo. Este resultado está en consonancia con el meta-análisis realizado por Bassolas et al. (2019). Llegaron a la conclusión de que las zonas urbanas densas presentan una organización más jerárquica de la movilidad, lo que conduce a un uso más amplio del transporte público y de los modos activos y a un menor uso del vehículo privado, lo que afecta a las decisiones de propiedad del coche.

Los atributos relacionados con el transporte también tienen importantes implicaciones en las decisiones sobre la propiedad del coche. El número de abonos de transporte público adquiridos en un hogar tiene una influencia negativa y estadísticamente significativa (coeficiente = -0,552, valor p = 0,000) en el número de coches. Según los resultados de la modelización, por cada pase de viaje adicional en el hogar, la probabilidad de poseer un coche disminuye en un 43%. Además, los resultados de la modelización muestran una fuerte influencia del aparcamiento privado en la propiedad del coche, como ya se ha señalado en los resultados preliminares. Los atributos del sistema de transporte, especialmente la accesibilidad a la red de transporte público, también ofrecen resultados estadísticamente significativos. El número de estaciones de metro en el barrio donde se encuentra el hogar influye negativamente en la propiedad del coche (coeficiente = -0,053; valor p = 0,016). La buena accesibilidad a las estaciones de metro en Madrid hace más atractivo el uso del transporte público y proporciona un modo alternativo al coche privado para los desplazamientos urbanos, reduciendo así la propiedad del coche. Este resultado debe interpretarse teniendo en cuenta que Madrid cuenta con una extensa y densa red de metro que cubre razonablemente toda la ciudad. Los resultados relativos a la accesibilidad del autobús público están cerca de ser significativos (valor p = 0,077) e indicarían que cuanto mayor es el número de paradas de autobús en el barrio en el que se encuentra el hogar, mayor es el número de coches en los hogares. En este sentido, las paradas de autobús y los servicios de autobús también cubren razonablemente toda la ciudad, pero comparten las carreteras con otros modos motorizados y generan retrasos en los viajes y pueden disuadir a los usuarios de utilizarlo.

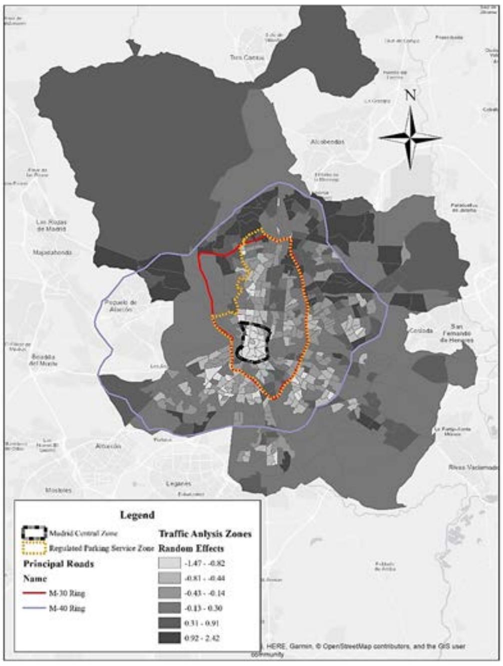
5.2 Impacto de las políticas de promoción de la movilidad sostenible

Ambas políticas de transporte sostenible (SER y MC) evidencian tener un impacto negativo en las tendencias de propiedad de automóviles en la ciudad de Madrid, tal y como muestran los resultados de la modelización (Ver Tabla 1). Este efecto es estadísticamente significativo (valor p = 0,000) incluso después de controlar las características de los hogares y los atributos de la ciudad, como la densidad urbana o la accesibilidad del transporte público. Las políticas del SER y de Madrid Central reducen en un 33% y un 35%, respectivamente, la probabilidad de poseer un coche, en comparación con las zonas donde no se aplican estas medidas. Este resultado parece razonable ya que estas políticas cobran o reducen las plazas de aparcamiento en la calle. En resumen, estas políticas parecen ser herramientas eficaces para desincentivar el uso del vehículo privado (impactando así en las decisiones de propiedad del coche) y para mejorar la sostenibilidad urbana.

Estimamos la heterogeneidad espacial de las tendencias de la propiedad de automóviles en los distintos barrios. Para ello, calculamos los efectos aleatorios para cada ZAT para el modelo nulo obteniendo un efecto aleatorio significativo (coeficiente = 0,4930 y valor p = 0,000). El Figura 2a muestra el efecto aleatorio estimado para cada ZAT. Como se puede observar, existe una gran variabilidad entre las distintas Zonas de Reparto. Por ejemplo, podemos observar los valores más bajos de los coeficientes aleatorios (que indican un menor número de coches por hogar) para casi todas las ZAT dentro de la ZBE Madrid Central, en comparación con otras ZAT fuera de Madrid Central. Del mismo modo, se observan los menores valores del efecto aleatorio obtenidos para los barrios situados dentro de la zona SER, en comparación con las ZAT de fuera de esta zona.

Además, analizamos el impacto de las dos medidas políticas sobre las tendencias de propiedad de automóviles controlando por los niveles de renta. El Figura 2b muestra el valor de los efectos aleatorios respecto a los coeficientes de pendiente de la variable de renta. Estos efectos aleatorios son estadísticamente significativos para el caso de Madrid, lo que implica que el efecto de la renta media anual sobre la propiedad de automóviles varía entre las zonas ZAT. Como se puede observar, los valores de estos efectos aleatorios cambian desde el centro a la periferia de la ciudad.

a. Efectos aleatorios en las ZAT



b. Efectos aleatorios generados por ZAT y renta media anual

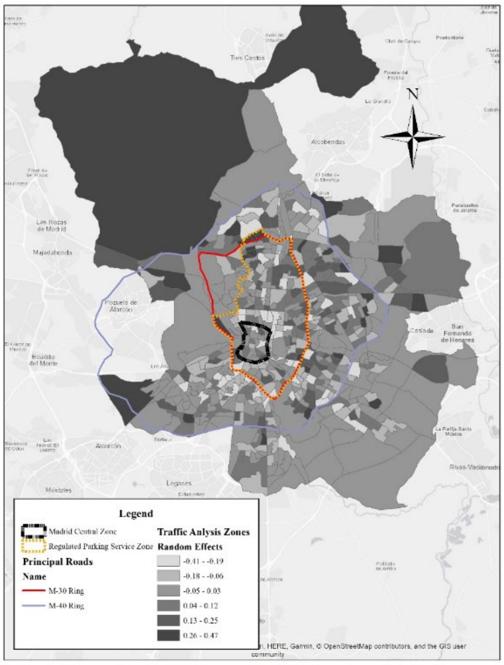


Figura 2 Efectos aleatorios

Hemos estimado los efectos marginales del modelo y hemos incluido estos valores en la Figura 3. Todos los efectos marginales resultaron estadísticamente significativos. La mayor diferencia se identifica en las probabilidades de tener las opciones "Sin coche" y "2 coches". Como puede observarse en la Figura 3a, tanto para las políticas SER como para las de "Madrid Central", la probabilidad de tener "Ningún coche" es en cierto modo mayor si el hogar está situado dentro de las zonas donde se aplican estas políticas. Esto parece razonable porque el control de la oferta de aparcamientos o las restricciones a la circulación de vehículos hacen menos atractivo el uso del coche privado, lo que repercute negativamente en la decisión de los residentes de comprar o poseer un coche (véase la Figura 3a y la Figura 3b).

Además, exploramos con más detalle la relación entre las políticas de transporte y el nivel de ingresos. Por ejemplo, en lo que respecta a la política del Servicio de Estacionamiento Regulado (SER), los mayores ingresos de los hogares reducen la probabilidad de no poseer ningún coche, mientras que aumenta la probabilidad de poseer uno o varios coches", en particular de poseer 2 coches. Un análisis comparativo muestra tendencias similares para las zonas TAZ situadas dentro y fuera de la zona SER. No obstante, las tasas de cambio son mayores para aquellos hogares situados en barrios en los que no se aplica la política cuando no está disponible (ver Figura 3c y Figura 3d). Los resultados son bastante similares para la política "Madrid Central LEZ"; sin embargo, la probabilidad de conseguir un coche dentro de esta zona es menor debido a sus fuertes restricciones (véase la Figura 3e y la Figura 3f).

6. CONCLUSIONES Y RECOMENDACIONES POLÍTICAS

Este estudio explora la propiedad de automóviles y cómo influye en ella la aplicación de políticas de transporte destinadas a mejorar la sostenibilidad urbana. Mediante la estimación de un Modelo Logit Ordenado Multinivel, se analizó el comportamiento del número de coches de los hogares, según las características sociodemográficas de los mismos, las variables del entorno construido de la ciudad, los atributos de la red de transporte y las variables relacionadas con las políticas.

La promoción de modos de transporte alternativos puede generar una reducción de la propiedad de automóviles. Esto es evidente en los resultados encontrados para variables como el número de abonos de transporte y las estaciones de metro. Para fomentar una ciudad sostenible, se han aplicado políticas que mejoran el transporte público y consiguen un modo de transporte alternativo para los ciudadanos con el fin de reducir la propiedad del coche. El uso de políticas de ordenación del territorio para reducir la propiedad de automóviles mediante la creación de ciudades compactas y la construcción de barrios de alta densidad puede desalentar la propiedad de automóviles y la dependencia del automóvil (Oakil, Manting y Nijland 2016). Los resultados demuestran que la alta densidad de población y la densidad residencial tienen un efecto positivo en la reducción de la propiedad de automóviles. Sin embargo, según Van Acker y Witlox (2010), las políticas de planificación urbana no deberían centrarse únicamente en medidas de aumento de la densidad y la diversidad, sino también en medidas indirectas a través de la propiedad del coche.

Nuestras conclusiones tienen varias implicaciones políticas. Las políticas actuales desarrolladas en Madrid han tenido un fuerte efecto en desalentar la propiedad del coche.

El cobro de las plazas de aparcamiento en la calle caracteriza al SER, y ha tenido un efecto positivo en la mitigación de las externalidades del transporte. La política se hizo a través de un marco regulatorio local en una cobertura específica. Como mejora, el SER puede ampliarse para aumentar los beneficios de la política. Además, la política puede explotar las oportunidades de aprovechar las tecnologías emergentes para mejorar la eficiencia. Las estrategias de MC pretenden reducir el acceso de vehículos en la zona mediante limitaciones de tráfico y aparcamiento. Estas estrategias han tenido un efecto positivo en la reducción del número de coches propios, por lo que puede considerarse un éxito.

Los resultados pueden utilizarse para fomentar algunas tendencias que son relevantes para la definición, mejora o aplicación de futuras políticas. La mejora de la sostenibilidad del transporte sigue siendo el objetivo de los responsables políticos, y hay que medir su impacto. Hay que seguir investigando para abordar algunas de las limitaciones de este documento. En primer lugar, las políticas de transporte no sólo tienen un impacto en la propiedad del coche, sino que también debe hacerse un análisis conjunto con otras opciones como el reparto modal, el horario de viaje y la ubicación residencial. En segundo lugar, las políticas evaluadas en el presente estudio se aplicaron durante un corto periodo de tiempo, por lo que el análisis de la propiedad de automóviles podría realizarse en el futuro con una perspectiva a largo plazo. Por último, en todo el mundo se han aplicado políticas de transporte más maduras, por lo que debe estudiarse su influencia.

AGRADECIMIENTOS

Los autores desean agradecer al Ministerio de Ciencia e Innovación (MCIU), a la Agencia Estatal de Investigación (AEI) y al Fondo Europeo de Desarrollo Regional (FEDER), que han financiado el proyecto RTI2018-095501-B-I00.

ABSTRACT

Many cities around the world encourage the transition to battery-powered vehicles to minimize the emissions of greenhouse gases. The standard plug-in electric vehicles have a limited amount of power stored in the battery resulting in frequent stops to refill the power. Wireless charging is an innovation of transmitting power through electromagnetic induction to portable electrical devices for energy renewal.

Online Electric Vehicle (OLEV) is a new technology that allows the vehicle to be charged while it is in motion, thus removing the need to stop at a charging station. Developed by the Korea Advanced Institute of Science and Technology (KAIST), OLEV picks up electricity from power transmitters buried underground.

This paper investigating bus routes to determine the optimum study area for planning out the costs of deploying a pilot service network by comparing the cost of initial investment for the three types of wireless charging: Stationary Wireless Charging (SWC), Quasi-Dynamic Wireless Charging (QWC), and Dynamic Wireless Charging (DWC), using OLEV technology for a bus service transit in the borough of Manhattan (MN) in New York City (NYC).

1. INTRODUCTION

In recent years, an expanding need to develop alternative solutions to traditional energy sources from fossil fuels becomes an imperative needed for sustainable cities. Thus, electric buses reduce fossil fuels uses and, therefore, provide a better living environment. Since transit is significant fuel consumption, the development of electric vehicles (EVs), especially electrical buses provided by effective wireless charging technologies, has become even a priority. Studies have shown the benefits and advantages of pure electric vehicles (EVs) compared to internal combustion (IC)-based cars or hybrid EVs in terms of their environmental effects (Jang et al., 2016). Nevertheless, these benefits may be offset by the limited amounts of energy stored in their batteries.

To make EVs even worse, charging with the fastest charger requires at least 30 minutes (Ulrich, 2012). To fill this gap, the use of Remote Charging Technology, also known as wireless charging (Costanzo et al., 2014), (Garnica et al., 2013), has been testing and implemented. Wireless charging is an innovation of transmitting power through electromagnetic induction to portable electrical devices to ensure optimized energy renewal.

In public transportation systems operation, exist three different types of wireless charging systems, to be specific, (a) Stationary Wireless Charging (SWC), the charging only happens when the vehicle is parked or idle, (b) Quasi-Dynamic Wireless Charging (QWC), when a vehicle is moving slowly or in stop-and-go mode the power is transferred, and (c) Dynamic Wireless Charging (DWC), the charging can be provided even when the vehicle is moving (Ulrich, 2012).

This paper compares the cost of initial investment for the three types of wireless charging (SWC, QWC, and DWC) using OLEV technology for a bus service transit in the borough of Manhattan (MN) (Figure 4), in New York City (NYC), the most populous city in the United States (U.S. Census Bureau 2010).

2. LITERATURE REVIEW

The public bus system helps to reduce traffic congestion and exhaust emissions (Song, 2013). Due to vehicle technology limitations, diesel-powered buses still dominate today's bus fleet. Various regulations related to the problem of battery size, cost, and life and onboard batteries have restricted the popularity of electric buses (Liu and Song, 2017).
Wireless charging technology is changing the form of energy transfer and utilization. Since its initial concept suggested by (Bolger et al., 1978), significant technological achievements have been made in developing wireless charging.

The development of wireless charging technology is surveyed (Esser, 1995; Wang et al., 2005; and Covic et al., 2007). To eliminate cables and dangerous sparking, wireless charging has been actively investigated in transit applications, such as charging for electric vehicles (Jang et al., 2016). Other focuses the charging strategy interacting with the power grid (Paul and Yamada, 2014), on e-buses were based on charging infrastructure comparison (Chen et al., 2018; Bi et al., 2015), and the Battery Management Systems (Ding et al., 2015; Hu et al., 2013; Liu and Song, 2017). (Ke et al., 2016) proposed a model for simulating the operation and battery charging schedule of plug-in e-buses and determined the minimum construction cost of an all plug-in electric bus transportation system.

The OLEV system is the first successfully commercialized EV wireless charging system (Jang et al., 2015; Lee et al., 2010; Shin et al., 2013).

Developed by the Korea Advanced Institute of Science and Technology (KAIST), OLEV picks up electricity from power transmitters buried underground. OLEV technology (KAIST, 2009) has its sights set on economizing and sustaining industrial and commercial electric vehicles' performance, with its current focus being bus transits. This is achieved by reducing the number of batteries required to operate the bus service, reducing the vehicle's cost and weight while always staying in service with its efficient, wireless charging technology.

The OLEV consists of shuttles (similar to conventional EVs) and a charging infrastructure containing a set of energy transmitters that can charge the bus's battery remotely utilizing an ingenious non-contact charging component while the buses are moving over the charging infrastructure.

3. MATERIALS AND METHODS

3.1 Characteristics of EV Types

The OLEV technology currently operates in several bus transits worldwide, including Seoul Grand Park and Gumi City transit lines in South Korea. There are three different categories of wireless charging systems (Figure 1) that OLEV can be used:

a) Stationary wireless charging (SWC),
b) Quasi-dynamic charging (QWC), and
c) Dynamic wireless charging (DWC).

SWC is only parked or idle charging, QWC is when a vehicle moving slowly or in stop-and-go mode, and DWC is supplied even when the vehicle is in motion. Each system's cost and benefit depend on various factors such as route and fleet size, service range, battery prices, and installation cost (Jang et al., 2016; Garnica et al., 2013).

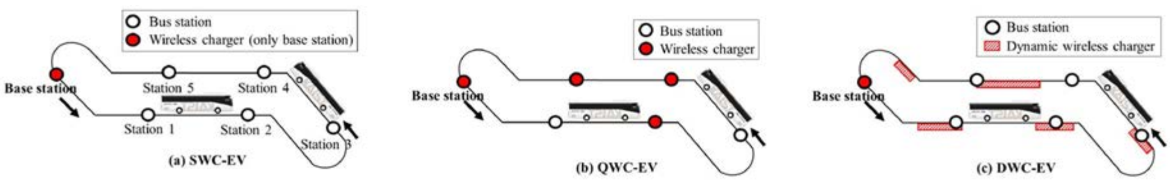

Figure 1. Charging allocation properties for each type of EV (Jang et al., 2016).

Figure 2. shows the OLEV serving as a campus shuttle on the KAIST campus, and the power track installed under the road.

(a) (b)

Figure 2. KAIST OLEV: one of the dynamic wireless charging EVs (DWC-EVs) (Jang et al., 2016). (a) under construction; (b) in operation.

3.2. Dataset Description

Two different datasets were used for the analysis. The first one is the drive-type network data taken from the Open Street Map (OSM) using the OSMnx (Boeing, 2017). The second one consists of General Transit Feed Specification (GTFS), which defines a standard format for public transportation schedules and associated geographic information from the Metropolitan Transportation Authority (MTA, 2020, March 18).

3.3. GTFS Data

The information was collected from the MTA data feeds for the NYC Manhattan Transit Bus transportation services. The downloaded data package contains eight text files: trips, stops, stop_times, shapes, routes, calendar_dates, calendar, and agency.

Open-source Python 2.7.13, an interpreted object-oriented, high-level programming language, was used to visualize GTFS data focusing on MN bus transit into Static Data Feeds (GTFS Schedule Data). Please refer to Correa et al. (2017) for more details on GTFS transit data. Additionally, Matlab programming is used to simulate a battery's state of charge (SoC) throughout a route to determine how well the allocation of charging units fits the model. Figure 3 shows the number of buses from bus lines M1, M2, M3, M4, and M72 arriving at bus stop # 400124 5 AV/E 72 ST, by each hour.

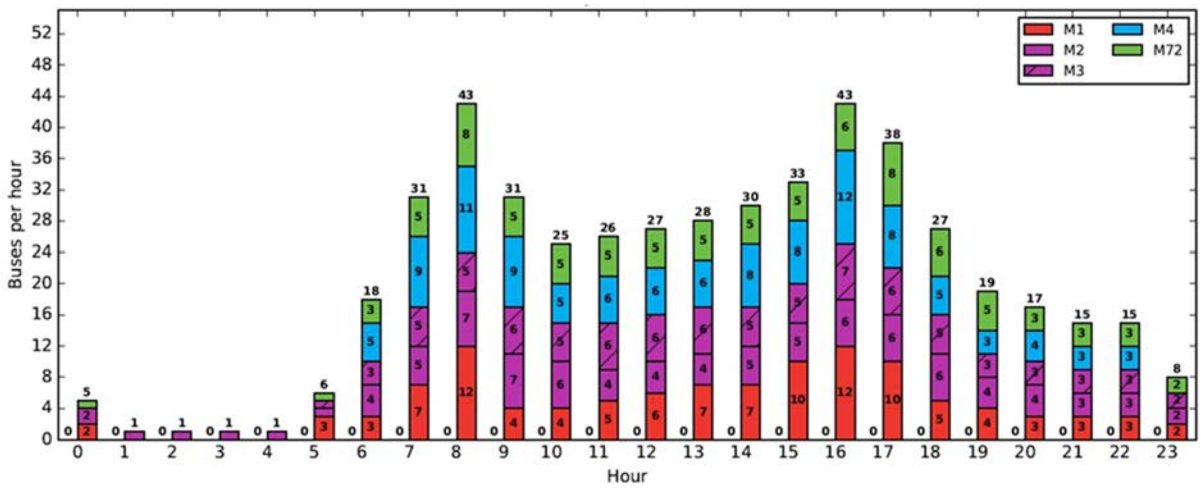

Figure 3. Visualization of GTFZ (Number of arriving buses to bus stop # 400124 at 5 AV/E 72 ST)

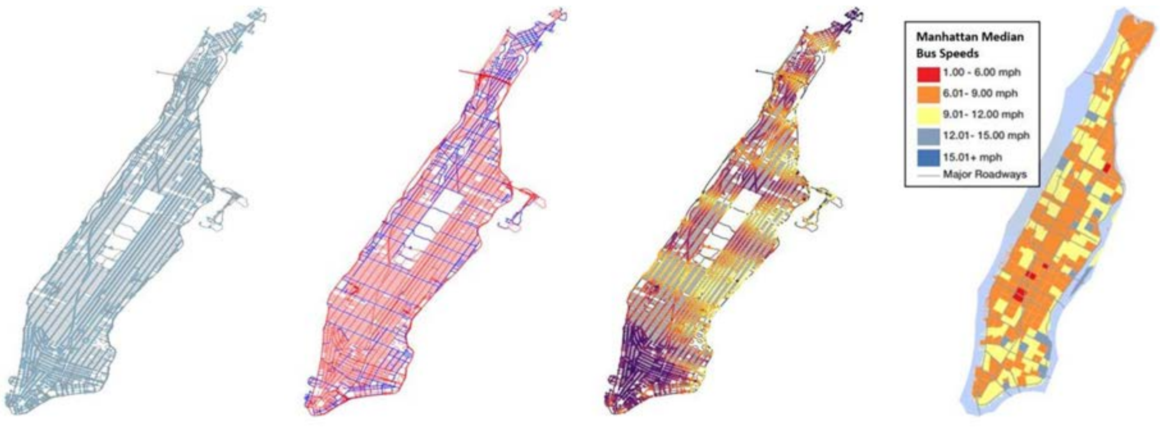
3.4 Network Data

Drive-type network data from MN was taken from OSM using the OSMnx (Boeing, 2017) to extract and clear the network. The network contains nodes for road intersections and joints, as shown in Figure 4. OSMnx downloads street network data that performs topological correction and simplification automatically to calculate accurate edges and nodes. The selected network types are "drive" to get drivable public streets and excluding service roads. (Figure 4a).

OSMnx analyzes networks and calculates network statistics, including spatial metrics based on geographic area or weighted by distance.

OSMnx allows classifying one-way and bidirectional streets (Figure 4b). For oneway streets, directed edges are added from the origin node to the destination node. For two-way streets, reciprocal directed edges are counted in both directions between nodes. This ensures that intersections are not considered dead ends. OSMnx also allows identifying the busiest nodes through the network, as is shown in Figure 4c.



(a) (b) (c) (d)

Figure 4. Study area: Manhattan Borough in New York City. Network Data

Visualization, (a) Network contains nodes for road intersections and joints.; (b) Network provides the single way in red and double way in blue; ((c) M22 bus) Network busiest nodes visualized from low (dark-violet) to high (light yellow); (d) Median bus Speeds of Manhattan.

4. DATA ANALYTICS: TOOLS AND METHODS

The quantity of charging on each power track required for a DWC system is a function of vehicle speed and the elapsed time spent on that power track. In the conventional station allocation problem, the vehicle speed is not related to the allocation.

Therefore, for optimum results, the system implementation should be in places where bus speeds are very low (bus stops, streets historically known for slow traffic). The median speed data shown in Figure 4d is established on GPS bus data time, which indicates the location of individual buses over time on their routes. Data was collected between 4 p.m. and 6 p.m. every typical weekday in 2017 (NYCDOT, 2018).

Based on the network and median bus speed information, we select three MN bus routes located within the low busiest node's area in MN in Figure 4c (dark-violet colored) as the best option for actual potential implementation because it will produce less disruption in the city than the other zones such as midtown.

In this project, information was collected from the Metropolitan Transportation Authority (MTA) data feeds for the NYC Manhattan Transit Bus transportation services. Initially, only three Manhattan bus routes: M8, M9, M22 (colored in green), were examined as the first analysis in the energy logistics (battery and charging infrastructure) cost for each system Figure 5).

(a) (b) (c)

Figure 5. Selected Routes. (a) M8 bus; (b) M9 bus; (c) M22 bus

After data processing, we tested the accuracy of the data obtained from GTFZ feeds, comparing bus stops of each selected route to the real bus stops in the city, using google street view, as is shown in Figure 6. This method allows us to eliminate potential bias in the data collected.

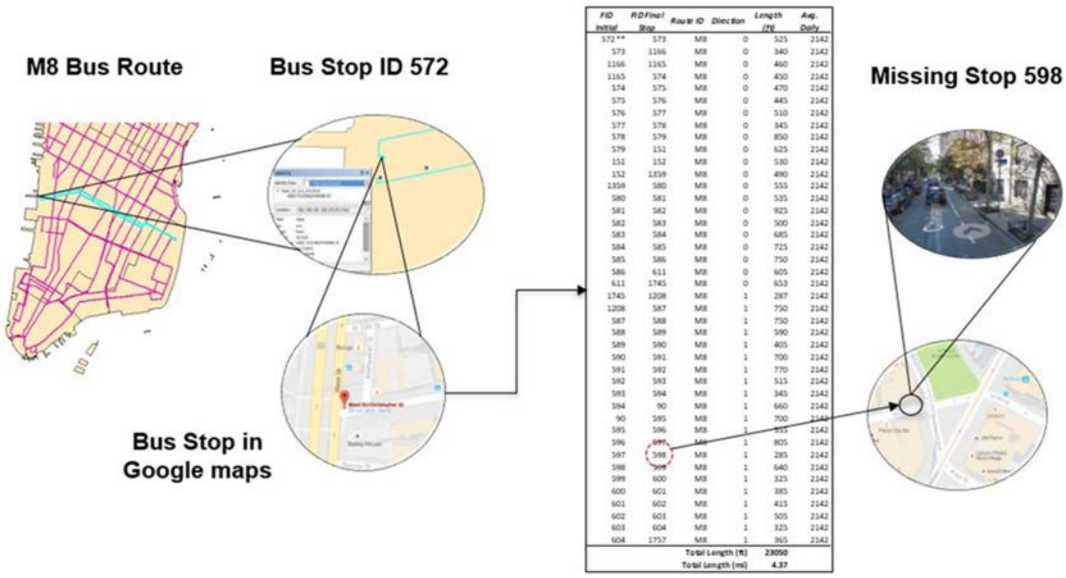


Figure 6. Comparison with real site data

5. COST ANALYSIS

For an EV-based transit system, the initial investment cost is fundamentally composed of two main components: the cost of the charging infrastructure and the cost of a fleet of vehicles.

The cost is divided into the batteries' costs, the vehicle units, and the other charging components. The energy logistics cost accounts for the majority of the total cost of an EV-based transit system.

Therefore, understanding the cost structure of energy logistics is critical for deciding on investments in EV-based transit systems.

In (Jang et al., 2016), there is a qualitative cost-benefit analysis for each wireless system, depending on the battery price and infrastructure cost, as seen in Figure 7. However, investment in the OLEV cannot only be made based on such analysis. Therefore, reports from current OLEV and EV bus transit operations, MTA data feeds, and tools from GIS software were utilized to develop a method for comparing the energy logistics costs for these different types of charging systems on a chosen Manhattan bus route.

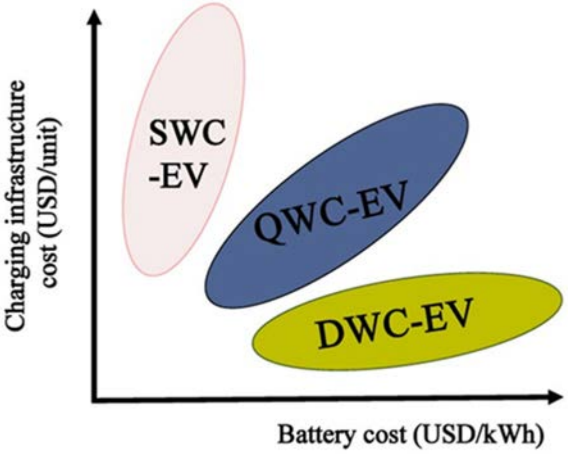

Figure 7. Qualitative analysis of the economic benefits of different EV charging systems (KAIST, 2009)

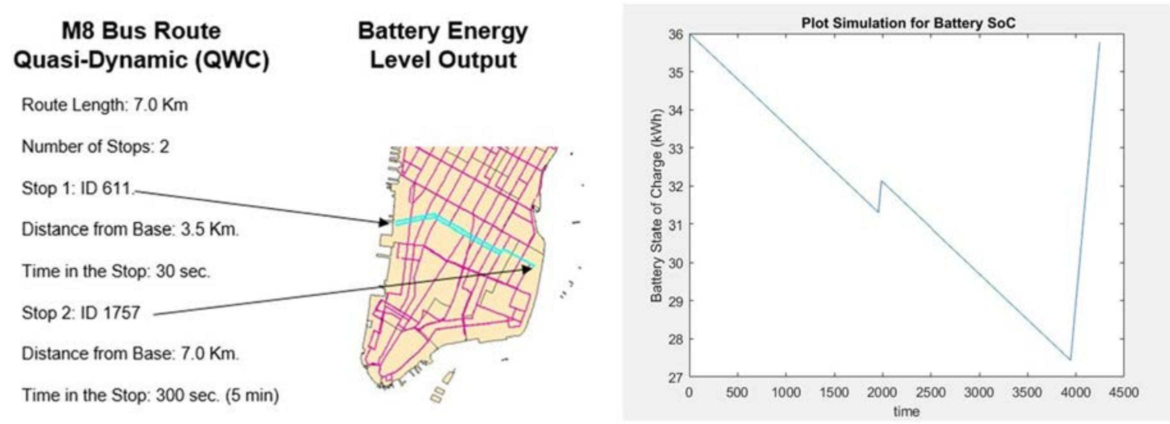
Allocation of chargers for each system is that SWC should be installed only at the station (base) where the vehicles rest between services; QWC - identify where to install the wireless chargers at minimum cost based on energy consumption and depletion between stops in a route; DWC - as the charging can be done while the vehicle is in motion, the vehicle speed should be considered determining the allocation of chargers along the route.

$$\text{SWC \& QWC: min } [(No.\ Buses) * (Cost\ of\ KWh) * (Service\ Batery\ Size)] + [(Cost\ of\ Charger) * (No.\ Chargers)] \quad (1)$$

$$\text{DWC: min } [(No.\ buses) * (Cost\ of\ KWh) * (Service\ Batery\ Size)] + [(Power\ track\ cost\ per\ meter) * (Power\ track\ lenght) + (Cost\ of\ Charger) * (No.\ Power\ track\ units)] \quad (2)$$

Once we determine the charging infrastructure's location and length, we can use equations (1) and (2) to optimize the minimum energy logistics cost for SWC, QWC, and DWC systems. The cost of battery per energy unit, charging unit, and power track per unit length can be found (KAIST, 2009).



(a) (b)

Figure 8. Simulation for Battery. (a) M8 bus details; (b) Battery energy level

Battery simulation for the M8 bus route Figure 8a is shown in Figure 8b. The energy level is within the upper and lower limits. We assume that the energy capacity of the battery is linearly proportional to the cost of the battery. This assumption is realistic, as an EV battery pack contains multiple battery cells, so the capacity is defined by the number of cells included in the battery pack. This method of linear cost calculation is also widely used in the industry.

6. RESULTS AND DISCUSSION

As shown in Table 1 and Figure 9, the data analysis conducted in this study evaluates the commercial fleet size with the cost structure for each system. Axis x and y represent the number of vehicles and the total investment cost, respectively, for the M8 bus route. The entire cost of the system is proportional to the battery's full size (cost of SWC increases linearly).

Beneath this assumption, the charger is installed only at the station base and is fixed just as if the number of Electric Vehicles grows. Thus, the energy logistics cost is linearly proportional to the fleet. In practice, more charging capacity would need to be added to the base station for the SWC system to avoid delays as busses wait to be charged, producing some non-linear discrepancies in the model.

For the DWC case, the increment rate of cost is less significant than that for the case of SWC. Therefore, if the smaller batteries are more economical, it produces a growing number of EVs that increase optimization.

Stationary (SWC)

Route:	M8 (42 stops)	M9 (64 stops)	M22 (44 stops)
Total Dist. in km	7.0	15.7	8.9

Table 1. Cost Analysis of Wireless Network

The cost lines for SWC-QWC and QWC-DWC cross when the number of vehicles is three and seven, respectively, that means if less than three cars, SWC is the most economical; if the number of cars is between three and seven, QWC is competitive. If the number of vehicles is more significant than seven, DWC is the most efficient and economical. The lines with lower costs SWC for fleet <3, QWC for 3 < fleet < 7, and DWC for fleet > 7, regardless of the charging type, should be considered the lower bound for the wireless charging EV.

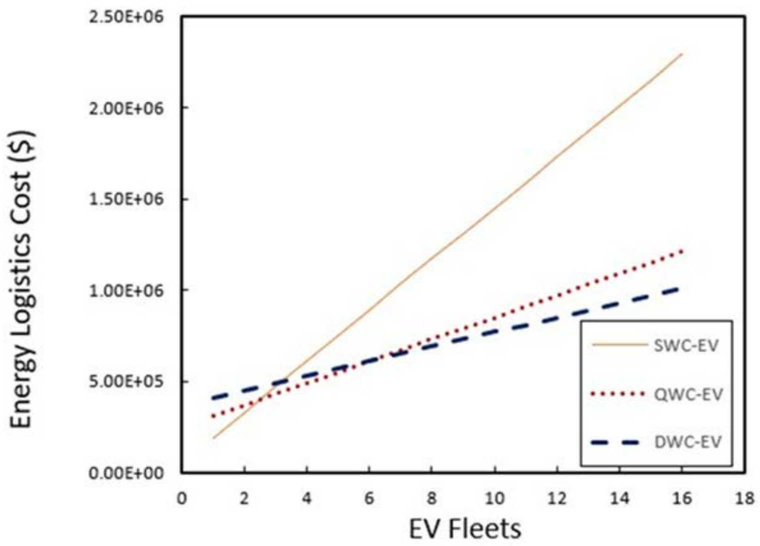

Figure 9. M8 Route Fleet-Scale Plot Analysis.

7. CONCLUSIONS AND FUTURE WORK

Wireless charging technology offers the possibility of eliminating the last remaining cord connections required to replace portable electronic devices. This technology has significantly improved during the past decades and leads to a vast number of applications.

In this article, we have investigated the implementation of wireless charging on bus routes and developed a cost analysis of initial investment for the three types of wireless charging: Stationary Wireless Charging (SWC), Quasi-Dynamic Wireless Charging (QWC), and Dynamic Wireless Charging (DWC), using OLEV technology. They are followed by a cost analysis of existing bus service transit, applying OLEV technology to deploying a pilot study in Manhattan, NYC.

The integration of wireless charging with existing transportation networks creates new opportunities as well as challenges for the development of sustainable cities. This study has shown the analysis of the potential implementation of wireless power charging to an actual bus route, reducing emissions, and improving traffic operations and planning.

This research would provide new possibilities of using OLEV technology, network, and bus route data to determine the optimum study area for planning out the costs of deploying a new electric bus service network. However, the implementation of power charging in networks is less explored and requires further investigation. Additionally, practical challenges in performing similar analyses of several NYC bus routes based on the route's EV history, ridership, and location can be considered the main directions for future research.

NUEVAS FORMAS DE SEMAFORIZACIÓN EN LAS CIUDADES

RESUMEN

Las ciudades aumentan, las formas de vida están cambiando y la población está en constante movimiento. Todo ello hace que para que una localidad desarrolle una mejora completa de su movilidad, se debe aplicar la Inter movilidad considerando todos los factores posibles como son las bicicletas, patinetes, car sharing, coches eléctricos, obras civiles, semáforos inteligentes, etc. que vayan a favorecer la movilidad en su conjunto.

Sin embargo, parece que, a día de hoy el cuello de botella parte del problema de los atascos que se producen en el centro de las grandes ciudades por los vehículos a motor, cuya cantidad diaria no sólo es difícil de disminuir, sino que sigue aumentando. Aun incluso cuando otros sistemas que se implanten logren reducir el número de vehículos en las calles de las ciudades, especialmente de las grandes, como por ejemplo la peatonalización o restricciones a los vehículos en las zonas más céntricas de las mismas, también seguirá siendo necesario minimizar los tiempos "improductivos" de los transportes que seguirán ocasionando acumulación no útil de los mismos en las calles.

Una forma de desbloqueo de los atascos, pasa por los sistemas de control de tráfico urbano (UTC) que permitirán el paso seguro y eficiente de los flujos de tráfico en intersecciones. Es decir, se trata de una comunicación en tiempo real entre el vehículo y la infraestructura bajo tres puntos de vigilancia: la densidad de tráfico, los espacios de aparcamientos y los llamados aparcamientos disuasorios, y el control de semáforos. Precisamente en este último punto, el control de semáforos, es en el que se pone el foco en esta ponencia. Se plantea y estudia en la misma un funcionamiento de semáforos, o bien sin semáforos físicos, o bien con semáforos inteligentes.

1. ANTECEDENTES Y DATOS ACTUALES DE LOS SEMÁFOROS

Se tienen los primeros registros del primer semáforo, el que fue instalado en la ciudad de Londres en 1868 utilizando un sistema de ruidos-alarma, parecido a lo que hoy en día serían los sistemas de comunicación de los barcos. Sin embargo, fue hacia 1920 cuando se instalaron en EEUU los primeros semáforos parecidos a los que hoy tenemos en las ciudades, utilizando el método de los tres colores (verdes, rojo y ámbar). Éstos aparecieron con la llegada de los vehículos motorizados pues hasta entonces ni las bicicletas, ni los carros tirados por caballos, ni los peatones necesitaban la señalización con semáforos para regular su paso en los cruces (SICE, 2019).

Por tanto, en la mayoría de los países desarrollados, la instalación del primer semáforo o ya ha cumplido o está a punto de cumplir el primer siglo de vida, y llevamos por tanto alrededor de cien años incrementando el número de semáforos en las ciudades proporcionalmente al mayor número de vehículos que hay cada día ocupando las calles.

Es el momento de empezar a disminuir su número hasta su desaparición y dejar sólo su imagen residual y simbólica, con la vista puesta en volver a disfrutar de ciudades del siglo XXI, pero sin semáforos.

Como ejemplos, se puede citar:

1. En la ciudad de Madrid, existen actualmente unas 130.000 Uds. de semáforos que regulan unas 2.200 intersecciones (Velloso, 2016).
2. Valencia es la ciudad de Europa con más semáforos por unidad de habitantes, con 1 Ud. por cada 750 ciudadanos (Landete, 2016).

2. CARACTERÍSTICAS ESTRUCTURALES DE LOS SEMÁFOROS

La instalación de semáforos supone una serie de características estructurales a tener en cuenta. En las ciudades, hoy en día no sobra precisamente espacio libre en las aceras y la visualización para los conductores resulta en muchas ocasiones demasiado densa. Mirando hacia el horizonte de muchas calles alargadas de las grandes ciudades, la vista alcanza en demasiadas ocasiones a una hilera continuada de semáforos.

La estructura de los semáforos debe cumplir la normativa vigente que exige una armadura para las partes luminosas y un soporte de tipo columna o forma de báculo. En general, hay que tener en cuenta que la distancia entre el suelo y la cabeza del semáforo suele ser de 450 cm, mientras que el brazo saliente sobre la vertical puede medir desde 350 a 550 cm dependiendo de la ubicación y del tipo de información que transmita. (software SABRE [Best Center, 2012]. En el Reporte NCHRP 796 (TRB, 2014), pág. 29 del documento)

Es decir, que cada semáforo ocupa un área visual aproximada de unos 16 m². Por tanto, si nos fijamos en una ciudad como Madrid, con más de 2.200 intersecciones reguladas por unos 130.000 semáforos, estaremos ocupando un área visual de 2.080.000 m² = 2 km².

Sin la presencia de semáforos, las ciudades quedarían más despejadas, con más espacios libres para peatones y también con una mayor visibilidad para los transportes. Además del ahorro que supondría su fabricación, mantenimiento y sustitución.

3. PROPUESTAS DE SUSTITUCIÓN DE LOS SEMÁFOROS

Dispuestos a eliminar los semáforos de las ciudades, ¿cómo los sustituimos? Aquí entrarían en juego los Sistemas de Control de tránsito Urbano que en cualquier caso deberán asegurar su funcionamiento ante fallos de la red eléctrica, cámaras, detectores-sensores, contadores, sistemas de bluetooth que conecten las vías con los propios vehículos en tiempo real, priorización de los transportes públicos de gran capacidad, y la implantación de leds sobre el asfalto, despejando así las infraestructuras.

El objetivo de las medidas a adoptar deberá consistir en sustituir el funcionamiento de los semáforos actuales consiguiendo los mismos objetivos funcionales de éstos, pero teniendo como finalidad que los flujos de tránsito sean más productivos y favorables.

La parada de los vehículos en las intersecciones incrementa además el gasto de combustible de los mismos al tener que arrancarlo desde parado, y esto produce una contaminación del lugar donde se encuentra, y además puede producir en algunos casos molestia a los vecinos con los ruidos ocasionados por los continuos movimientos de parada y arranque.

En el control de las señales de tránsito en las zonas urbanas, especialmente en las de mayor densidad de población, se debe tener en cuenta a todos los usuarios de la red, incluidos los peatones, los vehículos de motor de dos ruedas, el transporte público, los vehículos privados, bicis, patinetes, etc. Hoy día es cada vez mayor el número de dispositivos de movilidad que forman parte de la red viaria y que son por tanto susceptibles de coincidir en las distintas intersecciones. Es por ello que no sólo se puede configurar el sistema de circulación y de sustitución de los semáforos pensando en los vehículos de motor, sino que es absolutamente necesario contar con todos y cada uno de los usuarios, ya sean peatones o medios de transporte.

3.1 Procedimiento de sustitución

El procedimiento consiste en:

1. Se recogen los datos de flujos de tránsito en las intersecciones que estén interrelacionadas entre sí y que se quieran direccionar.
2. Se analizan los datos de estos flujos de tránsito por franjas horarias y días de la semana y del año. De modo que se pueda proceder a extrapolar sus datos.

3. Se recopilan los datos direccionales en las intersecciones, es decir, hacia dónde se producen en mayor y menor medida los movimientos de giro, cambios de dirección, etc.
4. Teniendo en cuenta los datos recopilados y analizados, se elaboran los planes de sustitución de semáforos mediante las propuestas que se indican en este documento más adelante.
5. Se elabora un plan de viabilidad medioambiental y también de viabilidad económica.
6. Se elabora también un plan de sensibilización con las propuestas tanto de los conductores como de los peatones, es decir, el grado de necesidad y satisfacción que puede proporcionar a los usuarios de la vía, sea cual sea su condición, en el caso de implantar estos nuevos métodos de gestión de la movilidad urbana.
7. Si los planes anteriormente citados, tanto los medioambientales, como los económicos y de satisfacción de los usuarios, son positivos, se hace uso de los modelos de simulación de los planes de sustitución de semáforos en programas informáticos y en vehículos modelo en tiempo real.
8. Se visualizan y se estudian los impactos y estrategias que hayan surgido de las simulaciones efectuadas.
9. Se corrigen los errores que hayan dado lugar y se vuelve a simular una vez corregidos.
10. Se implementan en la vía algunos de los sistemas propuestos de sustitución de los semáforos.
11. Pasado un tiempo de su instalación, se evalúa de nuevo su efectividad, el grado de satisfacción de los usuarios, y la forma en la que se han adaptado los usuarios al nuevo sistema implantado.

3.2 Instalación de semáforos en los vehículos.

En cuanto a los sistemas de sustitución de semáforos, por un lado, se propone que los vehículos lleven incorporados en sus sistemas de control de velocidad o también llamados velocímetros, un propio semáforo en sí, el cual, indique al conductor, que, en función de la dirección que lleven o hacia la que se vayan a dirigir, controlada por sistemas de GPS que ya se utilizan en la actualidad, les vaya informando previamente si su velocidad es la adecuada para que cuando lleguen al cruce en cuestión, éste lo puedan pasar en verde o por el contrario, que su velocímetro marque un color rojo si la velocidad que llevan no es la adecuada para llegar a la intersección con posibilidad de paso en verde.

De este modo se evita que los vehículos tengan que quedarse parados en una intersección, y, por el contrario, se proporciona la regularización de la velocidad en los metros previos a alcanzar dicho semáforo. Así, existirá una circulación en movimiento continuo sin paradas de vehículos proporcionando una mayor inter movilidad y flujo de tráfico.

Aquí hay que tener claro que, en la mayoría de los casos, el tiempo que los automóviles ganan circulando a alta velocidad, lo pierden cuando se detienen en los semáforos. Llegarían por tanto antes a su destino circulando de forma continua a una menor velocidad, no necesariamente siempre baja, sino la adecuada, y utilizando la comunicación que les transmitan los sistemas incorporados en su vehículo y en la red de calles y carreteras.

¿Cuántas veces se ve un semáforo verde y/o amarillo a lo lejos y se pisa el acelerador para evitar llegar a la altura del semáforo en rojo y de esta forma se pone en peligro la seguridad del propio conductor y del resto de usuarios? Con este sistema se evitaría precisamente que los vehículos acelerasen en los metros previos al paso por el semáforo y regulasen su velocidad durante todo su trayecto. Si se diera el caso de que no existe la posibilidad de llegar a la intersección con paso en verde, se podría mostrar una cuenta atrás de los segundos restantes para la siguiente fase en verde, de tal modo, que el conductor pueda regular el ritmo de circulación y evitar igualmente tener que detenerse antes del semáforo.

Para ello, es necesario, no solo que todos los vehículos, cualquiera que sea su formato y sus características, incorporen un pack de GPS + cámara de reconocimiento de señales de tráfico, sino que también, todos los semáforos estén conectados y que dispongan cada uno de ellos de un dispositivo sensor que reaccione en función del tráfico real en cada momento. De este modo, la comunicación de los vehículos con los semáforos y viceversa, facilitará el flujo de la movilidad urbana. Que los semáforos de una ciudad dispongan de dichos sensores, podría decirse que es decisión de un solo organismo. Sin embargo, esta propuesta no funcionará si no incorporan el pack todos los vehículos sin excepción y ello requiere de un compromiso y acuerdo de más partes y por tanto más tedioso.

Recordemos, además, que en la mejora de la movilidad y en todos los sistemas que se quieran implantar, no sólo tenemos que tener en cuenta a los automóviles, sino que también hay que contar con el resto de vehículos. ¿Cómo incorporamos este sistema a las bicis, patinetes, etc. que también forman parte de la movilidad urbana y cada vez con mayor intensidad? Este mismo pack de GPS + cámara deberá también ser incorporado a estos otros medios de transporte.

En este aspecto hay que apuntar que dos marcas tan destacadas del automóvil como Audi y Ford ya trabajan en proyectos que eliminarían de las ciudades los semáforos. Audi prueba en la ciudad alemana de Ingolstadt donde tiene su sede, un servicio de información de semáforos con tecnología V2I (vehículo a infraestructura). Los coches que formen parte del ensayo verán en la instrumentación la velocidad a la que deberían circular para llegar al siguiente semáforo estando abierto, lo que favorecerá incorporarse a lo que han llamado ola verde de la ciudad o Time To Green. Por su lado, Ford trabaja en su proyecto llamado Intersection Priority Management (IPM), se ha probado hace unos meses en las calles de Milton Keynes, en Reino Unido. Funciona básicamente así: conociendo la ubicación, dirección de viaje y velocidad de los coches, cada IPM de a bordo identifica un cruce próximo y la trayectoria de cada vehículo que se acerca a él; a continuación, sugiere la velocidad óptima para cada uno de modo que todos puedan atravesarlo con seguridad (Pedro Urteaga, 2019).

3.3 Semáforos sobre el asfalto

Si una de las propuestas de esta ponencia es precisamente eliminar los semáforos físicos de las vías, es decir, quitar sus estructuras metálicas en favor del espacio y la mayor visibilidad despejada en las ciudades, el sistema propuesto en el punto anterior, el 3.2., quedaría incompleto. Por eso es necesario ampliarlo con la siguiente propuesta.

Ésta consiste en trasladar la estructura del semáforo al asfalto. Se propone que la misma área de visibilidad del alcance de un semáforo actual, se traslade al suelo. De este modo, será el propio asfalto el que se ilumine en los colores que corresponda de verde, rojo y ámbar. El mismo sistema de control de semáforos se lleva al asfalto y se instalan tiras de luminarias led que estén permanentemente encendidas en cada uno de los tres colores con la misma base de funcionamiento actual. El conductor de cualquiera de los medios de transporte, divisará desde bastantes metros de antelación a su intersección, el color en el que está iluminada la vía por la que esté circulando. Por su parte, los peatones, identificarán directamente el color rojo de la vía, como el de permiso de paso para ellos. La alimentación de estas tiras led puede seguir siendo gestionada por las mismas tomas que ya alimentan a los semáforos actuales.

Esta propuesta del punto 3.3. es perfectamente compatible con la propuesta explicada en el punto 3.2. de modo que, con este nuevo formato de semáforos igualmente éstos estén conectados y dispongan cada uno de ellos también de un dispositivo sensor en combinación con los leds, que reaccione en función del tráfico real en cada momento.

4. VENTAJAS Y BENEFICIOS DE LOS NUEVOS FORMATOS DE SEMÁFOROS

Como se ha venido indicando en los puntos anteriores, la eliminación de los semáforos convencionales actuales y su sustitución por otros formatos, recoge una serie de beneficios que favorecen al conjunto de la movilidad urbana, y por tanto suponen una ventaja para todos los usuarios de las vías.

Se enumeran a continuación las ventajas identificadas:

1. Visibilidad más despejada para conductores y viandantes.
2. Más espacio físico libre en calles y aceras.
3. Ahorro de fabricación de estructura metálicas.
4. Reducción de los tiempos de trayectos.
5. Reducción y/o eliminación de tiempos de espera es las intersecciones.
6. Reducción del número de accidentes en cruces.

7. Mayor dinamismo del flujo de la movilidad.
8. Mayor información sobre velocidad, tiempos, y en definitiva conducción para los usuarios.
9. GPS mapeado para reducir las pérdidas en los trayectos desconocidos.

5. GRADO DE ACOGIDA DE ESTAS PROPUESTAS POR PARTE DE LOS USUARIOS

Se ha llevado a cabo una encuesta a usuarios de la vía, de cara a proporcionar y estudiar el grado de acogida de estas propuestas por parte de los mismos. La encuesta se ha realizado durante los meses de noviembre y diciembre de 2020, vía online, a través del portal de encuestas https://www.onlineencuesta.com, con el enlace https://www.onlineencuesta.com/s/65bac8c, el cuál ha sido distribuido a su vez por grupos de difusión y redes sociales de alcance variado con rango de visibilidad y acceso a la misma, no sólo en España sino también en varios puntos de Europa, como Alemania, países Balcánicos, Reino Unido y Sudamérica. El rango de alcance de esta encuesta encuadra diferentes franjas de edad, y, aunque no se puede determinar con claridad el perfil del encuestado, dada su distribución online y por lo tanto de alcance final desconocido, se trataría de personas de al menos clase social media con acceso a internet y sistemas informáticos.

1. ¿cuánta cantidad adicional estarías dispuesto a pagar por que tu vehículo incorporase estos sistemas de control?

		cantidad dispuesto a pagar			
nº de encuestados	franja edad	nada	50 € - 150 €	150 € - 350 €	> 350 €
10 personas	< 18	8	2	0	0
20 personas	18-30	6	13	1	0
25 personas	30-45	5	15	4	1
35 personas	45-65	12	16	5	2
20 personas	> 65	10	7	3	0

Tabla 1. Rango de edad encuestados y cantidad adicional dispuesto a pagar

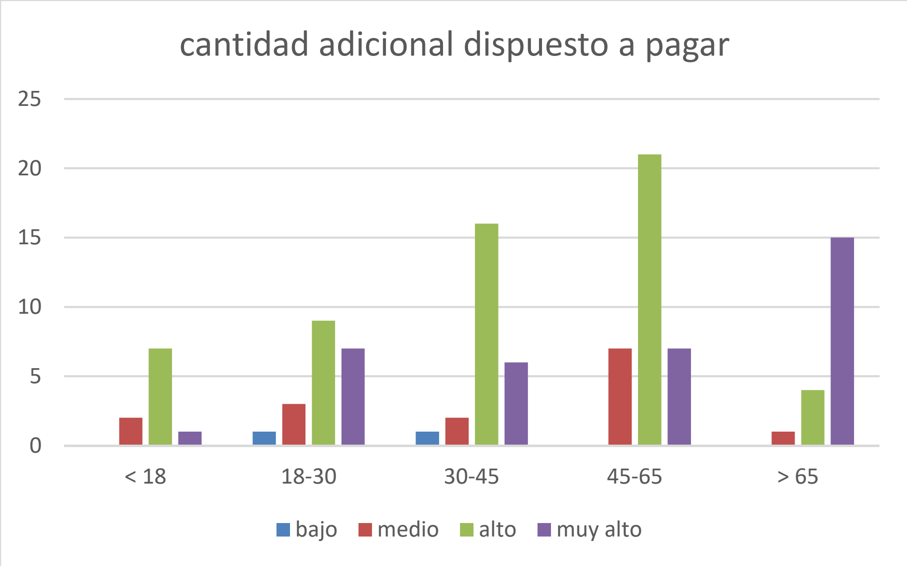

Figura 1. Cantidad adicional dispuesto a pagar porque su vehículo incluya los sistemas de control propuestos

La encuesta y/o gráfica refleja que hay un alto porcentaje de usuarios que no estaría dispuesto a pagar ninguna cantidad adicional al valor del vehículo por el hecho de que éste incorporase sistema de semaforización y sistemas de control de tráfico. Aun así, el porcentaje de los que sí estarían dispuestos a pagar hasta una cantidad máxima de 150 € adicionales es el más representativo.

2. ¿qué grado de dificultad consideras que tiene implantar estas propuestas a medio plazo?

		grado dificultad implantación			
nº de encuestados	franja edad	bajo	medio	alto	muy alto
10 personas	< 18	0	2	7	1
20 personas	18-30	1	3	9	7
25 personas	30-45	1	2	16	6
35 personas	45-65	0	7	21	7
20 personas	> 65	0	1	4	15

Tabla 2. Grado de dificultad que se considera para la implantación de las propuestas

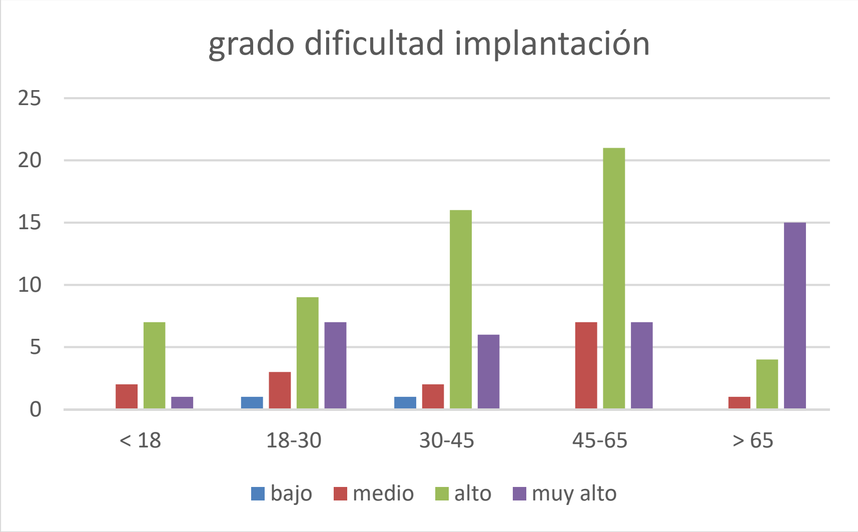

Figura 2. Grado de dificultad que se considera para la implantación de las propuestas

Los resultados de la encuesta reflejan que son los grupos de mayor rango de edad los que encuentran mayores dificultades a la hora de implantar estas nuevas propuestas en los vehículos. Siendo los jóvenes los más favorables a visualizar menos problemas en su puesta en marcha. Aun así, el grado de dificultad alto, es el más representativo en general.

6. CONCLUSIONES

Si la sociedad, en su globalidad, lleva alrededor de cien años incrementando el número de semáforos en las ciudades, resulta fácil entender que un cambio como el propuesto en esta ponencia, es una tarea tediosa. El grado de aceptación de la sociedad a un cambio, y más de este calibre, no suele ser ni fácil ni cómodo. En cualquier caso, la implantación de estos nuevos sistemas de control de tráfico requerirá de largos periodos de tiempo y tendrán que pasar años hasta que, no sólo se vayan implantando algunos de estos métodos en determinadas ciudades puntuales, sino que también los usuarios de la vía se familiaricen por completo con ello.

Como se ha dicho en un punto anterior de la ponencia, la implantación de estas propuestas, requiere de la implicación de variados organismos, como son los fabricantes de vehículos, de bicis, patines, etc. de organismos institucionales, de gobiernos y de los propios usuarios de las vías. Siendo el grupo de mayor aceptación a llevar a cabo estos cambios, el de las personas más jóvenes de la sociedad, tendrán que pasar décadas para que su implantación se convierta en una normalidad.

Sin embargo, está claro que todo cambio precisa de un inicio, y es ese punto de partida el que se debe poner en marcha cuanto antes, para que la cuenta atrás para su desarrollo e implantación, no se demore más en el tiempo.

RESUMEN

Los kilómetros recorridos por los vehículos del parque, son un indicador clave para conocer los patrones de uso y desplazamientos de los vehículos, determinar los niveles de movilidad y emisiones de forma muy desagregada.

En España, una fuente de información de los kilómetros recorridos anualmente por los vehículos, son las lecturas del cuentakilómetros registradas en los centros de inspección técnica vehicular (ITV) y constituyen un recurso valioso para la construcción de indicadores de movilidad.

En este trabajo se presentan los resultados del análisis exploratorio de los datos de una muestra de los registros de kilómetros recorridos anualmente por vehículos tipo turismo, en su paso por las ITV, en España en un período de 5 años.

El análisis permite establecer relaciones entre el kilometraje con atributos del vehículo, tales como la antigüedad, cilindrada, la tara y el número de plazas, además de otros aspectos como la ubicación geográfica y la edad del conductor.

El tratamiento de parte de los datos contenidos en los registros de ITV tienen una aplicación directa en el campo de la investigación científica de accidentes de tránsito.

1. INTRODUCCIÓN

Para el estudio de la seguridad vial, es necesario contar con indicadores de exposición, para poder evaluar los niveles de movilidad de vehículos y personas. Se puede considerar como los indicadores de exposición más idóneos a: vehículos-kilómetros y pasajeros-kilómetros, producidos en un período de tiempo; estos indicadores pueden referirse con otros aspectos, tales como el tipo de vía, la ubicación geográfica, colectivos de usuarios, tipos de vehículos (Direccion General de Tráfico, 2011).

Uno de los parámetros para la estimación de la exposición, es el número de kilómetros recorridos por los vehículos (KV); pero la medición de los KV no resulta sencilla, por lo que se suele estimar en base a los siguientes métodos de recolección de datos: lectura del cuentakilómetros, encuestas de hogares, conteos de tráfico y el consumo de combustible (Transport Division, 2007).

(Góngora, 2012), establece que el método de lectura del cuentakilómetros, presenta la ventaja de ser un registro preciso, aunque demanda un uso muy intensivo de recursos y hay que contemplar la posibilidad de errores de lectura, anotación, transcripción y alteración del cuentakilómetros.

Los centros de Inspección Técnica Vehicular (ITV) registran datos de los vehículos inspeccionados, uno de ellos es la lectura del cuentakilómetros y además información adicional importante, relacionada con el uso, propiedad, prestaciones, averías, entre otras. A partir del 2011, en España, obligatoriamente se realiza la comunicación de los registros de ITV a la Dirección General de Tráfico (DGT), teniendo gran cantidad de información que no está disponible en otros lugares.

En este trabajo se realiza un análisis exploratorio de la movilidad de los vehículos tipo turismo de España, siendo por cantidad de vehículos, el segmento más importante, al conformar el 77% del total de parque de vehículos español. El análisis se lo realiza en base a la información de los registros de ITV, como un aporte al conocimiento de la movilidad de forma desagregada, considerando su importancia para la aplicación de políticas de gestión de tráfico y seguridad vial, enfocadas en colectivos específicos, contribuyendo a conseguir una movilidad segura y sostenible.

2. DATOS

Los datos facilitados por la DGT, constan de alrededor de 6 millones de registros de pruebas de ITV, correspondientes a vehículos de turismo, en un amplio período que incluye inspecciones con fechas del año 1985 hasta julio de 2015. Cada registro contiene 36 variables, con la información referente a los campos: identificación del vehículo, datos técnicos, titularidad, historial de inspección e historial de defectos.

Considerando que desde el 2011 es obligatorio la comunicación de los registros de revisiones técnicas a la DGT, y que a partir de 2013 el registro de vehículos de la DGT se conecta telemáticamente con todas las estaciones de ITV, se tiene que para años anteriores la información no es de buena calidad.

La misma presenta principalmente problemas de datos faltantes, datos registrados con valor de cero y valores incoherentes. En el presente trabajo se han considerado los datos del período 2011-2015, los cuales contienen, por tanto, información de una calidad aceptable.

3. METODOLOGÍA

En este trabajo, la primera actividad ha sido la preparación de los datos, necesaria en vista de los problemas encontrados con los datos suministrados; a continuación, se realiza un análisis exploratorio de la movilidad, utilizando metodología estadística de tipo descriptiva, y finalmente para relacionar la movilidad con la ubicación geográfica, se aplica un análisis clúster.

3.1 Preparación de los datos

Los datos suministrados se han sometido a un proceso de preparación, para lo cual se ha seguido la metodología indicada en la Figura 1. Los criterios de preparación, se han ejecutado mediante la aplicación de algoritmos generados en el lenguaje R (Hastie et al., 2009).

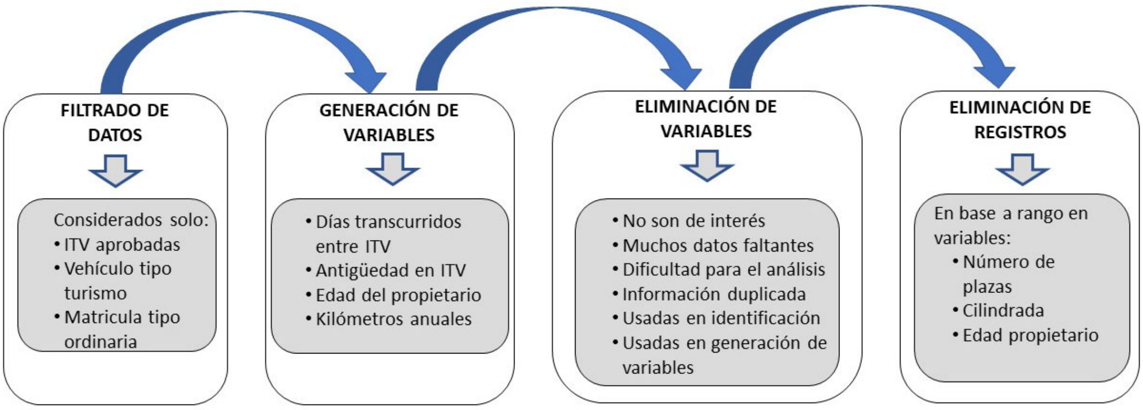

Figura 1: Metodología de preparación de los datos

3.2 Generación de variables

En este estudio se consideran cuatro variables de interés: días transcurridos entre ITV, la antigüedad del vehículo, los KV anuales y la edad del propietario, teniendo claro que el propietario registrado no será el conductor del vehículo en el 100% de los casos, pero se realiza la suposición razonable de que conductor y propietario coinciden en la mayoría de los casos. Las variables consideradas no se encuentran de manera directa en la base de datos, pero pueden ser estimadas partiendo de variables existentes.

Los días transcurridos entre ITV consecutivas, se establecen por la diferencia entre las fechas de revisión ITV y de la revisión ITV anterior, según Ecuación (1).

$$\textit{Días transcurridos entre ITV} = \textit{fecha de ITV} - \textit{fecha de ITV anterior} \qquad (1)$$

La antigüedad que tiene el vehículo, en el momento de pasar por ITV, se determinan por la diferencia entre las fechas de revisión ITV y de la primera matrícula registrada del vehículo, según Ecuación (2).

$$Antigüedad\ del\ vehículo = fecha\ de\ ITV - fecha\ de\ primera\ matrícula \quad (2)$$

La edad del propietario, en el momento de pasar por ITV, se establece por la diferencia entre las fechas de revisión ITV y de nacimiento del propietario, según Ecuación (3).

$$Edad\ del\ propietario = fecha\ de\ ITV\text{-}fecha\ de\ nacimiento \quad (3)$$

Para la determinación de los KV anuales que recorren los vehículos, se realiza la diferencia entre las lecturas de kilómetros registrada en la revisión ITV y en la revisión ITV anterior, este valor se lo divide entre los días transcurridos entre ITV, con lo que se tiene un valor de KV diario, que se lo multiplica por 365, para obtener los KV en términos anuales. Ver ecuación (4).

$$KV\ anuales = (kilómetros\ en\ ITV - kilometros\ en\ ITV\ anterior)/Días\ transcurridos\ ente\ ITV \cdot 365 \quad (4)$$

3.3 Análisis exploratorio de la movilidad

A partir de la base de datos preparada (BD_tur11-15), se hace el seguimiento de los KV a través de los registros consecutivos de inspecciones ITV, que permitirá varios análisis (cumplimiento de normativa, estimación y/o predicción de kilómetros anuales por tipos de vehículos, caracterización de vehículos de uso intensivo, etc.) siendo el objetivo de este trabajo la caracterización de los kilómetros anuales de vehículos turismos según variables de interés.

Como señala (Wilson et al., 2013), no es factible un análisis a nivel de vehículos individuales, pero si es posible un estudio de la distribución del KV a nivel de población de vehículos y establecer relaciones con atributos del vehículo. En este trabajo se consideran datos de un período de tiempo relativamente corto (5 años).

Con base a la información disponible, se han establecido relaciones entre los KV anuales con atributos como la cilindrada, la tara, el número de plazas y la antigüedad, además de otros aspectos como la ubicación geográfica y la edad del conductor y además se han comparado la evolución temporal en los diferentes años del período 2011 – 2015.

3.4 Análisis Clúster

Siendo uno de los objetivos la obtención de la relación entre el KV anual de turismos con aspectos geográficos, se ha formulado la hipótesis que la movilidad sigue unos patrones espaciales además de los temporales. Para obtener los patrones espaciales se recurrió al análisis clúster con el objetivo de encontrar grupos similares, pero que sean diferentes con las observaciones de otros grupos. El enunciado de la hipótesis es: hay diferencias entre las regiones del territorio español que se traducen en los KV anuales, caracterizados por los atributos de cilindrada, tara, antigüedad del vehículo y edad del conductor.

Para este propósito se utilizan algoritmos de minería de datos, que combina el método K-medias (K-means) con el método de agrupamiento jerárquico (hierarchical clustering), que evita especificar anticipadamente el número de agrupamientos (clústers).

4. RESULTADOS

La base de datos conformada ITV-Tur11-15 contiene ocho variables cuyos valores descriptivos se muestran en la Tabla 1.

Variable	Min	Max	Mean	S.D.
Cilindrada del motor (en cm^3)	852	6292	1765	384,12
Capacidad de ocupantes (variable discreta)	4	9	NA	NA
Edad del propietario (en años)	18	80	50,29	13,51
Días transcurridos entre ITV	201	3360	502,1	183,92
Provincia de matriculación (variable categórica)	NA	NA	NA	NA
Antigüedad del vehículo (en años)	1	39,96	12,37	4,20
Tara del vehículo (en kg)	620	2960	1219	224,85
Kilómetros recorridos anualmente	2000	39998	9754	5174,22

Tabla 1: Variables base de datos ITV-Tur11-15. Elaboración propia.

El análisis de la relación entre los KV anuales con la antigüedad de los vehículos, muestra un comportamiento similar al comparar los datos de los 5 años en estudio. Se observa que los vehículos recorren menos KV anuales con la antigüedad del vehículo, con un punto de inflexión en el rango de 4 a 6 años.

En la Figura 1 se puede apreciar que el punto de inflexión define dos comportamientos distintos en la movilidad de turismos: hasta 6 años de antigüedad y los de más de 6 años de antigüedad. La tasa de disminución de kilómetros medios anuales es mayor en los vehículos turismos más jóvenes que la que muestran los más antiguos. Además, los vehículos con antigüedad inferior a los 4 años, presentan aproximadamente el doble de KV en comparación a los que se encuentran el rango de 10 a 12 años, y aproximadamente el triple de KV que los vehículos con antigüedad superior a los 20 años.

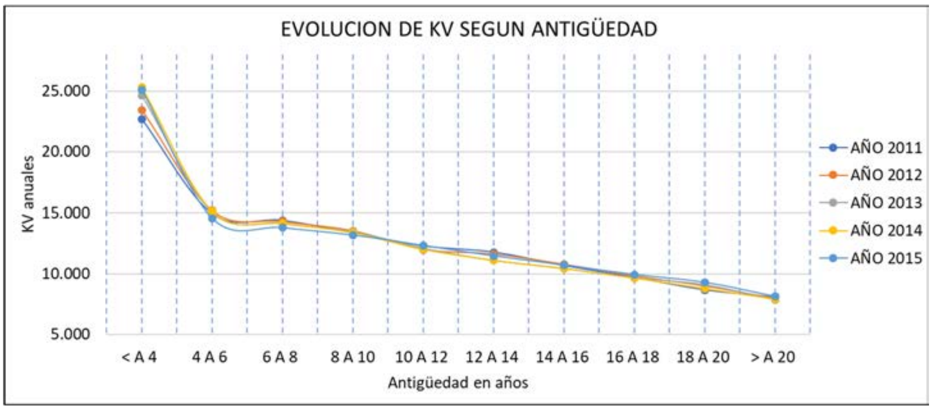

Figura 1: Evolución de los KV anuales según antigüedad del vehículo. Elaboración propia. Fuente: BD_tur11-15.

En la Figura 2, se muestra la relación entre la cilindrada de los vehículos y KV anuales y se observa que los vehículos con cilindrada superior a los 1600 cm^3, son los que mayor KV presentan, siendo aproximadamente un 30% superior a los vehículos de cilindrada inferior a 1200 cm3, que muestran el menor valor medio de KV. Esta información es relevante y muestra un patrón de movilidad diferente según la composición del parque de turismo en los que a cilindrada se refiere. Según las estadísticas de matriculaciones publicadas (Direccion General de Tráfico, 2015), los vehículos de mayor cilindrada constituyen aproximadamente el 27% del parque de turismos y los vehículos de cilindrada en el rango de 1200 a 1600 cm3 representan aproximadamente el 54%.

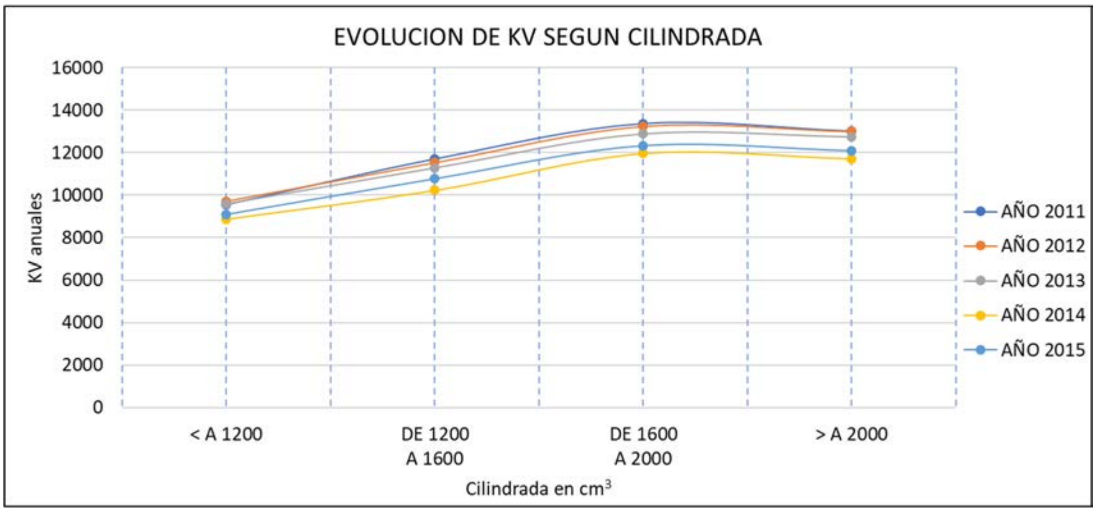

Figura 2: Evolución de los KV anuales según cilindrada del vehículo. Elaboración propia. Fuente: BD_tur11-15.

En la serie histórica han crecido más las matriculaciones de los vehículos más grandes, aunque en los últimos años se observa un repunte de los más pequeños cuyos cambios tecnológicos permiten obtener de éstos unas prestaciones notables. Ver Figura 3.

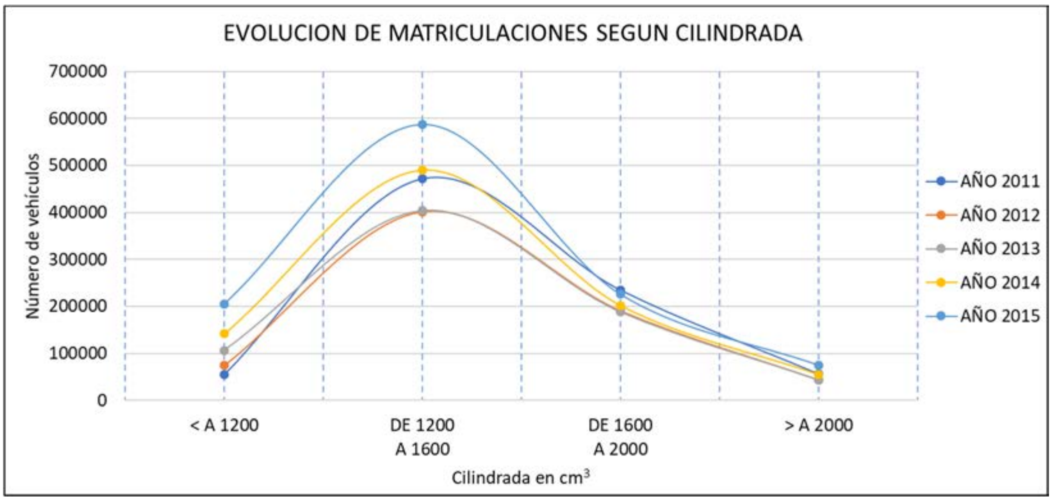

Figura 3: Evolución de matriculaciones según cilindrada. Elaboración propia. Fuente: DGT.

En la Figura 4 se muestra el resultado para la relación entre los KV anuales y la tara de los vehículos en los 5 años del estudio y se puede apreciar que los vehículos de tara más alta, son lo que más KV presentan. Este resultado es lógico, considerando que los vehículos de tara más alta, presentan motores de mayor cilindrada y de mayor uso en grandes recorridos.

Se observa un comportamiento distinto entre los turismos según los intervalos definidos a partir de 2000 kg, en donde los registros de los vehículos de los años 2011 y 2012 indican una disminución de los KV con el aumento de la tara, en cambio los registros de los años 2013 y 2015 muestran un pequeño incremento que refleja de otra manera que la movilidad los vehículos decrece con el factor edad del vehículo y requiere profundizar en el análisis de las relaciones subyacentes.

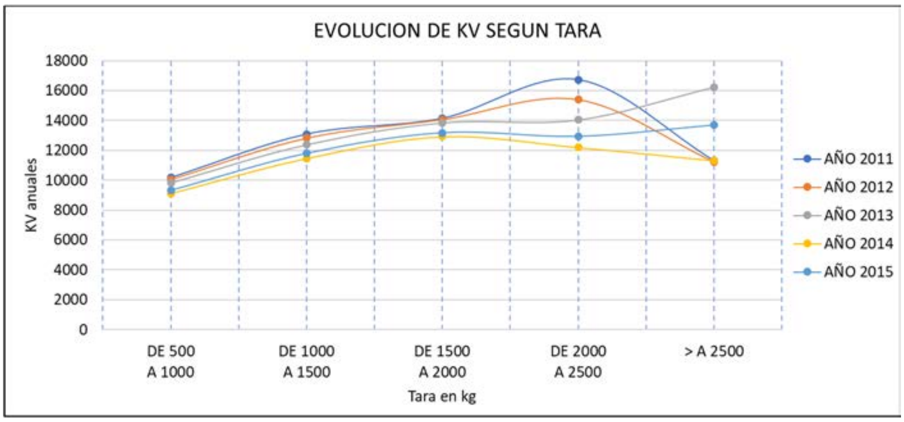

Figura 4: Evolución de KV anuales según tara del vehículo. Elaboración propia. Fuente: BD_tur11-15.

La relación de los KV anuales con la edad de los conductores, se muestra en la Figura 5. El patrón general que se puede extraer es que la movilidad de los conductores se reduce con la edad y este patrón tiene una tasa de cambio mayor a partir del rango de 55 a 60 años: los conductores realizan alrededor de 1000 KV anuales menos, por cada incremento de 5 años. Los conductores en el rango de los 25 y 30 años muestran valores de KV ligeramente superiores a los demás y el resto hasta 60 años tienen patrones de movilidad similares.

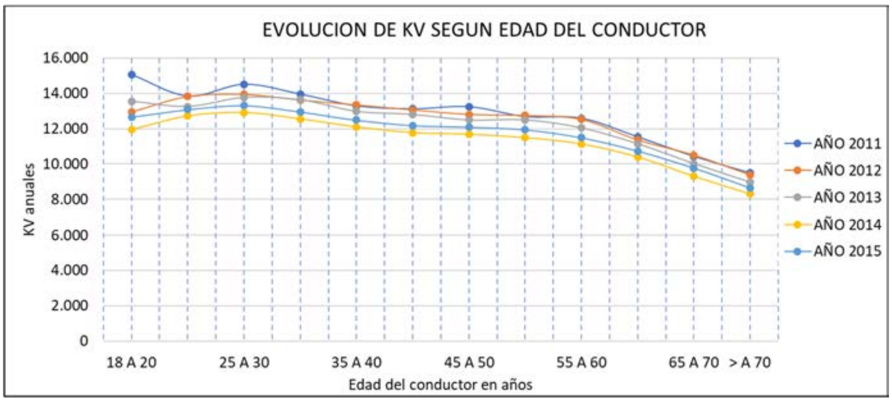

Figura 5: Evolución de KV anuales según edad del conductor. Elaboración propia. Fuente: BD_tur11-15.

En relación con la evolución de la obtención de permisos de conductores con la edad, el segmento más relevante es el que se encuentra en el rango de 35 a 40 años, que son aproximadamente 5 veces más que los conductores en las franjas más jóvenes y las de mayor edad y se corresponde con el grupo de conductores que tienen un comportamiento de movilidad muy parecido al resto de grupos de hasta 60 años de edad. Ver Figura 6.

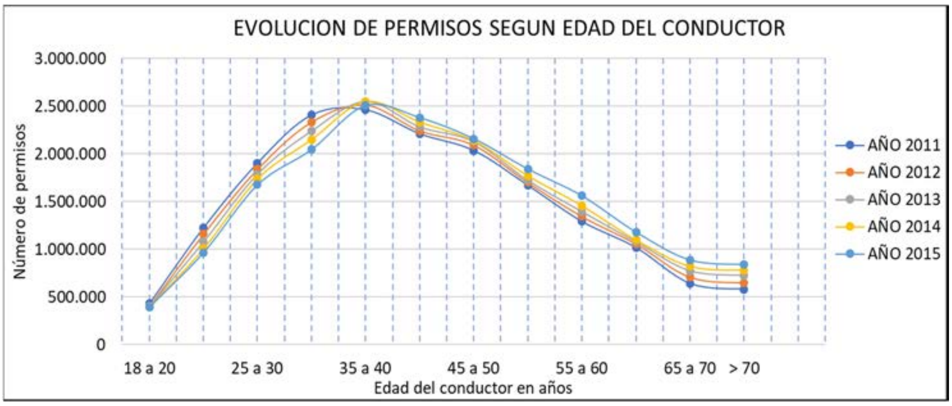

Figura 6: Evolución de conductores con permiso clase B. Elaboración propia. Fuente: Censo de conductores. DGT.

En lo que concierne al número de plazas, la Figura 7 permite observar que a medida que el vehículo tiene más plazas, más KV anuales presentan, es así que los vehículos de 9 plazas recorren alrededor de un 35% más de KV anuales, en comparación con los vehículos de 4 plazas, y un 20% más que los vehículos de 5 plazas.

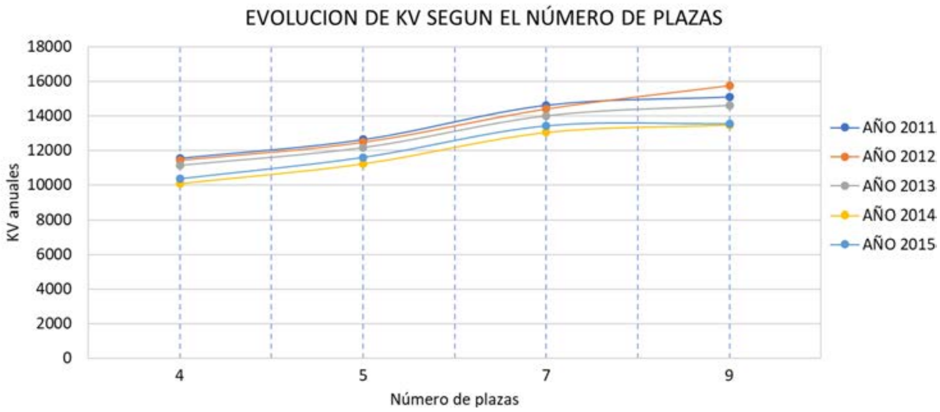

Figura 7: Evolución de KV según el número de plazas. Elaboración propia. Fuente: BD_tur11-15.

Si se asume que los vehículos de mayor número de plazas se utilizan en desplazamientos fuera de los centros urbanos, se puede justificar este resultado. Los vehículos de 5 plazas, representan el 90% del parque de turismos, pero son los vehículos que tienen más de 5 plazas los recorren más KV anuales, según los registros de ITV.

Para el estudio de la movilidad por regiones, a través del análisis clúster, en primer lugar, se aplica el agrupamiento jerárquico para generar un árbol, utilizando el método de “euclidean distance” para medir de similitud entre las observaciones.

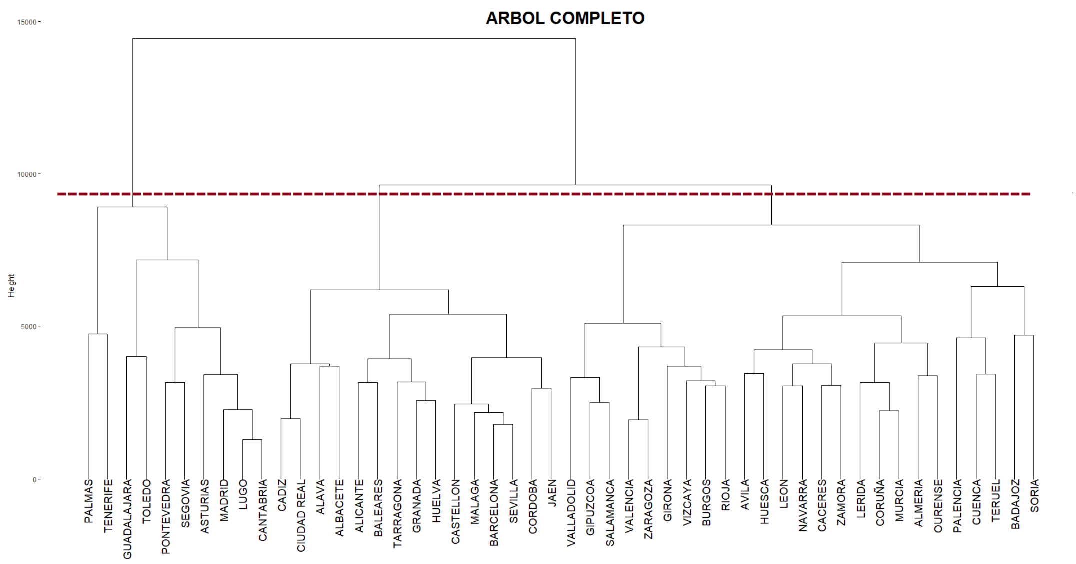

Figura 8: Árbol jerárquico generado con datos de KV de las provincias de España. Fuente: BD_tur11-15.

Para medir la diferencia entre grupos de observaciones, se utiliza el método “complete linkage clustering”, el cual calcula todas las diferencias en pares, entre los elementos del grupo 1 y los elementos del grupo 2, y toma en cuenta el máximo valor de estas diferencias, como la distancia entre los grupos, tendiendo a producir grupos más compactos. El árbol generado, se corta en un número de agrupamientos que se elige de forma visual del árbol generado (Figura 8), estableciéndose 3 agrupamientos.

Los grupos encontrados, se ilustran en la Figura 9, en la cual, al existir varias variables involucradas en la generación del clúster, ha trazado los puntos de acuerdo con las dos componentes principales, de las variables usadas en la generación, es decir las que explican la mayor varianza.

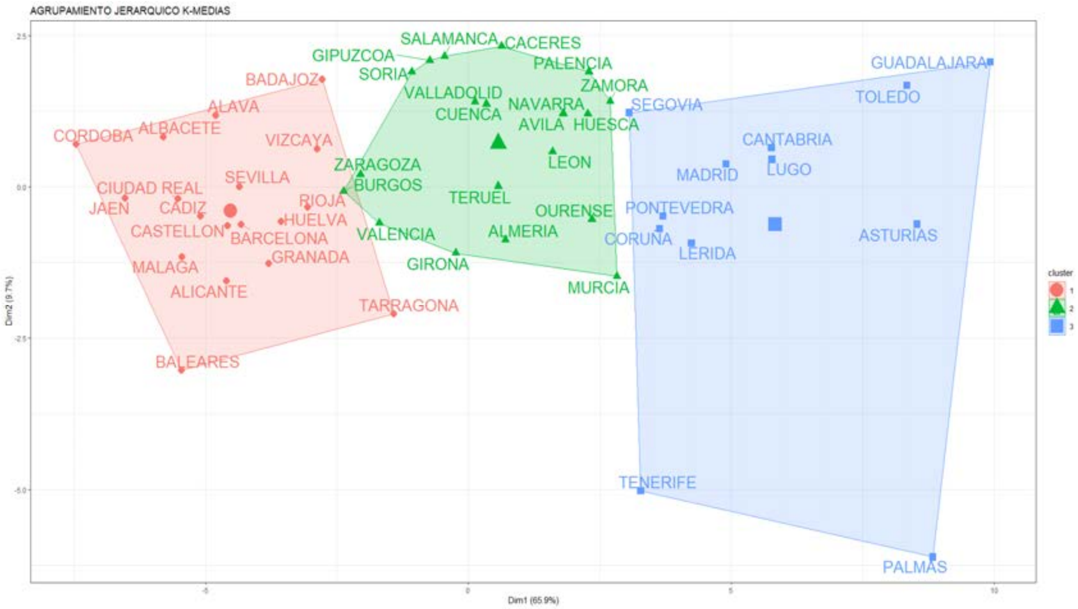

Figura 9: Agrupamientos por método Jerárquico K-medias. Elaboración propia. Fuente: BD_tur11-15.

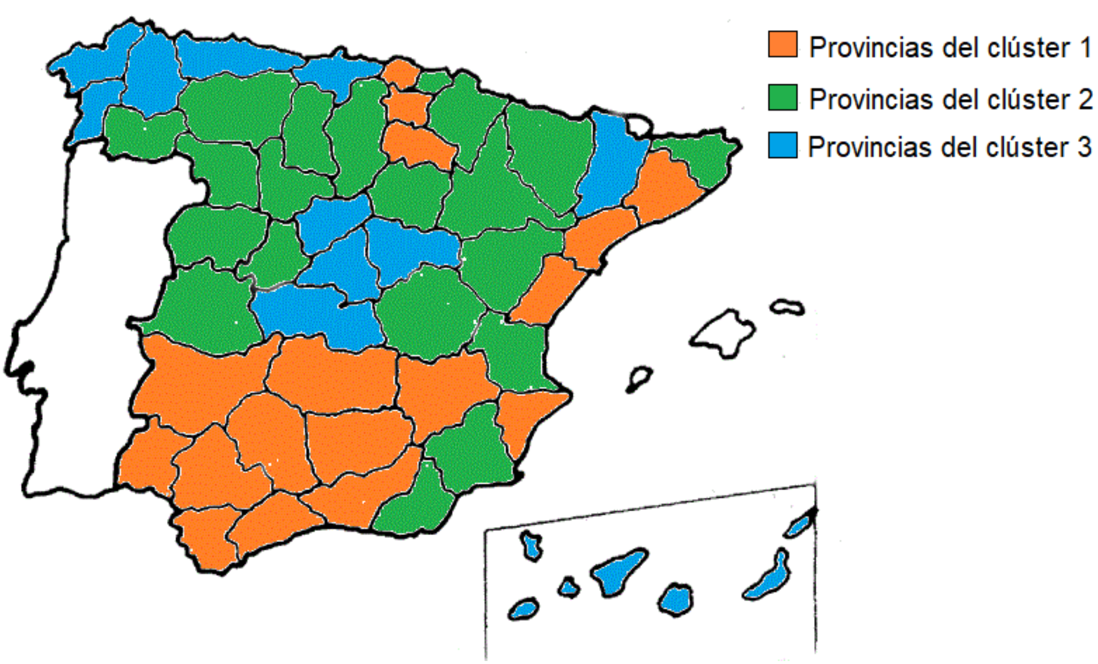

Figura 10: Correspondencia geográfica de los clústeres de provincias. Elaboración propia. Fuente: BD_tur11-15.

Para una mejor comprensión de estos resultados, la Figura 10 muestra la correspondencia geográfica de los agrupamientos de provincias obtenidos en los clústeres, pudiendo observar lo que se detalla a continuación:

- Las provincias incluidas en el clúster 1, geográficamente se encuentran formando tres agrupamientos de provincias colindantes, un grupo formado por las provincias de Vizcaya, Álava y La Rioja; un segundo grupo formado por las provincias de Castellón, Tarragona y Barcelona; y un tercer grupo formado por las provincias de Badajoz, Ciudad Real, Albacete, Alicante, más las provincias de la Comunidad Autónoma de Andalucía, con la excepción de Almería.
- En el segundo clúster se sitúan las provincias de Cáceres, Valencia, Ourense, Guipúzcoa, Navarra, Cuenca, más las provincias pertenecientes a las Comunidades Autónomas de Aragón y de Castilla y León, con la excepción de la provincia de Segovia.
- Las provincias incluidas en el tercer clúster, muestran dos agrupamientos de provincias colindantes, un primer grupo formado por las provincias de Pontevedra, La Coruña, Asturias y Cantabria, que son provincias de la costa norte del país; y un segundo grupo, formado por las provincias Segovia, Guadalajara, Madrid y Toledo, en el centro del país. Además, se puede observar que las islas de Palmas y Tenerife, también se incluyen es este clúster.

Considerando que los niveles de movilidad que presenta una región, está relacionada con la riqueza de la misma, se ha relacionado los agrupamientos obtenidos, con el PIB per cápita de las diferentes zonas del país (Instituto Nacional de Estadística, 2015), encontrando las siguientes relaciones relevantes:

- Las provincias pertenecientes al clúster 1, de la zona sur del país, pertenecen a las comunidades autónomas de Andalucía, Extremadura, Valenciana y Castilla La Mancha, teniendo un PIB per cápita inferior a 18.500 Euros/habitante, con excepción de la provincia de Alicante que pertenece a la comunidad Valenciana, con un PIB superior a 20.500 Euros/habitante y las pertenecientes a Cataluña con un PIB superior a los 27.500 Euros/habitante.
- Las provincias que forman parte del segundo clúster, en su mayoría forman parte de comunidades autónomas que tienen un PIB superior a 18.000 Euros/habitante, con excepción de Cáceres y Almería, las cuales pertenecen a comunidades autónomas con PIB de 16.000 Euros/habitante y 17.000 Euros/habitante, respectivamente.
- Las provincias incluidas en el clúster 3, ubicadas al norte del país, se distribuyen entre las comunidades autónomas de Galicia, Cantabria y Asturias, las mismas que tiene un PIB per cápita similar, alrededor de 20.500 Euros/habitante. Las provincias del centro del país constan de Madrid (PIB superior a los 31.000 Euros/habitante) y de las provincias de Guadalajara, Toledo y Segovia, pertenecientes a comunidades autónomas con PIB inferior a los 21.000 Euros/habitante.

Los niveles de movilidad de los clústeres establecidos, se representan por el valor de la media de los KV anuales; en la Tabla 2 se muestra la relación con la cilindrada del motor, en la Tabla 3 se muestra la relación con la tara del vehículo, y en la Tabla 3 y Tabla 4, se muestra la relación con la edad del propietario y la edad del vehículo, respectivamente.

CLUSTER	RANGOS DE CILINDRADA EN cm^3			
	MENOR_A1200	DE1200_A1600	DE1600_A2000	MAYOR_A2000
1	8135	9655	11569	11449
2	8247	10170	12272	12221

2	8709	11753	13330	13175
3	10094	12772	13824	14367

Tabla 3: Media de KV anuales de los clústeres con relación a la tara. Elaboración propia.

CLUSTER	EDAD DEL PROPIETARIO EN AÑOS								
	18 a 20	20 a 25	25 a 30	30 a 35	35 a 40	40 a 45	45 a 50	50 a 55	55 a 60
1	8363	12441	12422	11984	11457	11126	11016	11081	10675
2	8931	13518	13657	13254	12353	12097	11929	11740	11342
3	9731	14240	14103	13891	13349	13138	12983	12815	12256

Tabla 4: Media de KV anuales de los clústeres con relación a la edad del propietario. Elaboración propia.

CLUSTER	ANTIGÜEDAD DEL VEHÍCULO EN AÑOS								
	< 6	6 a 8	8 a 10	10 a 12	12 a 14	14 a 16	16 a 18	18 a 20	>20
1	15391	13369	12656	11465	10669	9999	9129	8363	7449
2	15644	14470	13783	12381	11582	10817	9839	8931	7847
3	16174	14861	14047	13015	12120	11392	10676	9731	8427

Tabla 5: Media de KV anuales de los clústeres con relación a la antigüedad del vehículo. Elaboración propia.

Al examinar los valores de KV anuales presentados, se observa en el clúster 1, los valores más bajos de KV y en el clúster 3 los valores más altos de KV, lo cual va en concordancia con los valores del PIB per cápita, indicados anteriormente.

4. CONCLUSIONES

La aplicación de la metodología de preparación de los datos, ha permitiendo contar con una base (BD_tur11-15) apropiada para aplicación en los análisis de movilidad, así como establecer variables de interés que no se encontraban registradas de manera directa.

A través de un análisis exploratorio de la movilidad, utilizando estadística descriptiva, se ha establecido la existencia de patrones de movilidad (representada por los KV anuales) con la edad del conductor y con los atributos del vehículo: antigüedad, cilindrada, tara, número de plazas.

El uso de minería de datos, a través del método de agrupamiento jerárquico combinado con K-medias, y considerando la forma en la que se reparten los KV anuales por los atributos del vehículo, en las diferentes provincias de España, ha permitido establecer 3 grupos de provincias, estos grupos además se encuentran distribuidos geográficamente en bloques de provincias colindantes y se observa coincidencia con los valores de PIB per cápita de las diferentes regiones.

Los resultados muestran información relevante, de interés en estudios de movilidad, con una metodología de análisis, que puede ser aplicada a otros tipos de vehículos.

AGRADECIMIENTOS

Este trabajo se ha realizado en el marco del programa de doctorado de la UPM en el Instituto Universitario de Investigación del Automóvil Francisco Aparicio Izquierdo (INSIA-UPM) adscripto a la Escuela Técnica Superior de Ingenieros Industriales. El primer autor agradece a la Universidad Politécnica Salesiana de Cuenca (Ecuador), que brinda el marco para la realización de estancias para el desarrollo de su tesis doctoral en la UPM. Los autores agradecen a la Dirección General de Tráfico el acceso a los datos del paso de los vehículos por las Inspecciones Técnica de Vehículos y a la Comunidad de Madrid por la financiación parcial a través del programa SEGVAUTO 4.0-CM (P2018/EMT-4362), para la difusión de los resultados.

EVALUATION OF THE EFFICIENCY OF TRAFFIC LIGHTS TURNING RED IN CASE OF EXCEEDING SPEED LIMIT WITH PREVIOUS PANELS INDICATING THE SPEED

ABSTRACT

A usual traffic calming measure (TCM) to reduce vehicle speed in urban areas is the traffic lights that turn red when a vehicle exceeds the speed limit. These traffic lights can detect if an approaching vehicle exceeds the speed limit and, if so, stop it by means of a red light. It is generally employed in interurban roads rather than in big cities, where the presence of traffic lights is common. In a rural road crossing a small village, they are deployed to reduce the risk of accidents to vulnerable road used when vehicles arriving at high speeds tend to conflict with pedestrians attempting to cross the road.

The aim of this paper is to analyze the efficiency of this TCM, preceded by panels indicating the vehicles' speed, by controlling the vehicles' speed in the A-132 road that crosses through the village of Azazeta in the province of Álava/Araba (Spain). Different sequence of the TCMs can be found in each direction approaching the village; in A direction, warning traffic lights, the panel indicating the speed and the traffic light turning red; and in B direction, the panel, the warning traffic lights and the traffic lights turning red.

However, similar results were obtained in both directions for average speeds and percentile 85 of the speed distribution at the traffic lights, and speed was reduced as motorists faced the TCMs. However, although average speed was below speed limit (50 km/h), the percentile 85 was over it, implying that more than 26% of drivers did not respect the red light. Moreover, after the traffic lights turning red, motorist speed up and higher values were measured at the midpoint of the urban segment, the place where pedestrians use to cross from one side of the village to the other one, although no pedestrian crosswalk is available.

1. INTRODUCTION

Traffic calming measures (TCMs) are a usual solution for reducing vehicles' speed in urban areas. TCMs are defined as the combination of mainly physical measures that reduce the negative effect of motor vehicle use, alter driver behaviour and improve conditions for non-motorized street users (Lockwood, 1997). Their main aim is the reduction of vehicles' speed and volumes in an area because speed is directly related to the probability of death for pedestrians involved in a crash, as shown in Table 1 (TRB, 2010; Tefft, 2011) despite the multiple factors that are involved in a highway crash (Llopis-Castelló et al. 2019; Ziolkowski, 2019).

Collision speed (km/h)	80	65	50	32
Chance of pedestrian death (%)	100	80	40	5

Table 1: Chance of pedestrian death if hit by a motor vehicle.

There are a wide variety of possibilities for TCMs but they are generally classified in the following groups (Kveladze and Agerholm, 2018; Gonzalo-Orden et al. 2016; Ziolkowski, 2018; Pérez-Acebo et al. 2020a):

- Vertical deflection: Speed hump, speed bump, speed cushion, rumble strip, raised intersection, raised crosswalk, road lump and table.
- Horizontal deflection: Curb-extension, chicane, gateway, traffic circle, raised median island.
- Physical obstruction: Semi and diagonal diverter, right-in and right-out island, raised median through intersections, street closure
- Signs and pavement markings.

In urban areas, calmed road segments are achieved due to the succession of traffic calming measures in the area. Nevertheless, an important problem is observed in the transition from and interurban area to an urban area, i.e. at the beginning of the urban area (Gonzalo-Orden et al. 2018; Pérez-Acebo et al. 2021a). The problem is increased in rural roads crossing small villages that are not bypassed. When drivers arrive to a short urban area, as the ones that can be found in rural roads crossing small villages, they do not usually reduce their speed conveniently, maintaining high speeds allowed in the interurban area and, hence, increasing the risk for pedestrians in the village (Table 1).With the aim of reducing the speed of the vehicles during the short segments of these villages, traffic calming measures are placed at the entrance to indicate that drivers are entering an urban area, even for a short period of time, and, to force them to speed down. Typical solutions at the border between non-urban and urban areas are raised crosswalks, signs with speed limits, panels displaying vehicle speed, radars (which could fine if drivers exceed speed limit), etc., and their efficiency is being analyzed (Gonzalo-Orden et al. 2018; Daniels et al. 2019).

A common solution in Spain is traffic lights turning red if the speed limit is exceeded. The traffic lights detect an approaching vehicle, measure its speed and, if it is higher than the speed limit, they try to stop it by turning red immediately. Consequently, in theory, drivers speed down in front of a red light and, when speed is reduced below the limit, the lights turn yellow again. Few studies can be found in the literature about this type of TCM. Generally, papers are focused on traffic offenses involving red lights and how red light cameras can be efficient on crashes (Llau et al. 2015; Baratian-Ghorghi et al. 2016). Pérez-Acebo et al. (2021a) analyzed the efficiency of traffic lights turning red in case of exceeding speed limit and they showed that better results were obtained if the traffic lights were combined with a crosswalk.

The aim of this paper is to measure the efficiency of traffic lights turning red in rural roads crossing villages with a short urban segment, preceded by panels indicating the speed. The case study took place at the A-132 road and at the village of Azazeta, in the province of Álava/Araba (Spain). The traffic lights were placed at the entrance of the village on both directions and before them panels indicating the instantaneous speed of each vehicle were also posted. It was aimed to observe the speed reduction achieved combining both TCMs (the traffic lights and the panels) at the centre of the village.

2. METHODOLOGY AND CASE STUDY

As explained before, the village of Azazeta and the A-132 running trough it were selected as a case study for analyzing the efficiency of traffic lights turning red in case of exceeding speed with previous panels indicating the drivers' speed. The A-132 road belongs to the Regional Government of Álava/Araba, one of the 3 provinces of the Basque Country. Due to the special legal status of the Basque Country, all the roads in each of the provinces belong to the regional government of the province, even those connecting to other regions and countries. Consequently, the Spanish Government does not manage any road in the Basque Country (Pérez-Acebo et al. 2020b; 2021b).

The A-132 road is included in the Basic Network (orange network), which is the second level of importance in the province. Table 2 shows all the road network categories in which the road network of the province is divided (DFA/AFA, 1990; Hernández et al. 2021). The A-132 road goes from Vitoria-Gasteiz (the capital of the province of Álava/Araba) to Estella, in the Region of Navarre.

When entering in the Region of Navarre, as that stretch from the border to Estella belongs to the Regional Government of Navarre, the road changes its name to NA-132-A. In the segment in the province of Álava/Araba, there is the mountain pass of Azazeta, and at the bottom of it, after crossing it coming from Vitoria-Gasteiz, the village of Azazeta is located.

Road Network level	Lenght (km)
Preferential interest network (red)	145.7
Basic network (orange)	146.42
Provincial network (green)	200.91
Local network (yellow)	534.23
Neighborhood network (grey)	373.02

Table 2: Length (km) of the road network in the province of Álava/Araba.

At the mountain pass, there is a permanent counting station, measuring passing vehicles continuously and, hence, provided values are real. The obtained values, shown in Table 3, represent the traffic flow for a 17.5 km-long segment, including the entire mountain pass and the village of Azazeta.

Table 3 shows the values of the Average Annual Daily Traffic (AADT), the percentage of heavy vehicles and the Average Annual Daily Traffic of Heavy Vehicles (AADTHV), in both directions. In Spain, a vehicle needs to weight more than 3,500 kg to be considered as a heavy vehicle (MFOM, 2003; Pérez-Acebo et al. 2020b). As seen, the total traffic volume and the percentage of heavy vehicles increase each year.

Years	AADT (vehicle/day)	% of heavy vehicles	AADTHV (heavy vehicle/day)
2019	3510	8.6	302
2018	3453	5.1	280
2017	3411	6.2	213
2016	3352	6.0	221
2015	3239	5.9	192
2014	3202	5.8	187

Table 3: Traffic volume values at the permanent counting station of Azazeta (190) for the last years.

The A-124 crosses the village of Azazeta, in a segment of approximately 240 m, dividing the urban area in two approximately similar parts (Figure 1).

There is not any pedestrian crosswalk between the two parts. Nevertheless, the Regional Government of Álava/Araba wanted to reduce the speed of vehicles crossing the village because inhabitants cross the road to access the other part of the village.

With this aim, various traffic calming were introduced to speed down the traffic. Moreover, in the direction from Vitoria-Gasteiz to Estella, vehicles have just gone down the mountain pass and their speed tends to be high. Consequently, the TCMs were necessary to calm down the urban area of this short road segment.

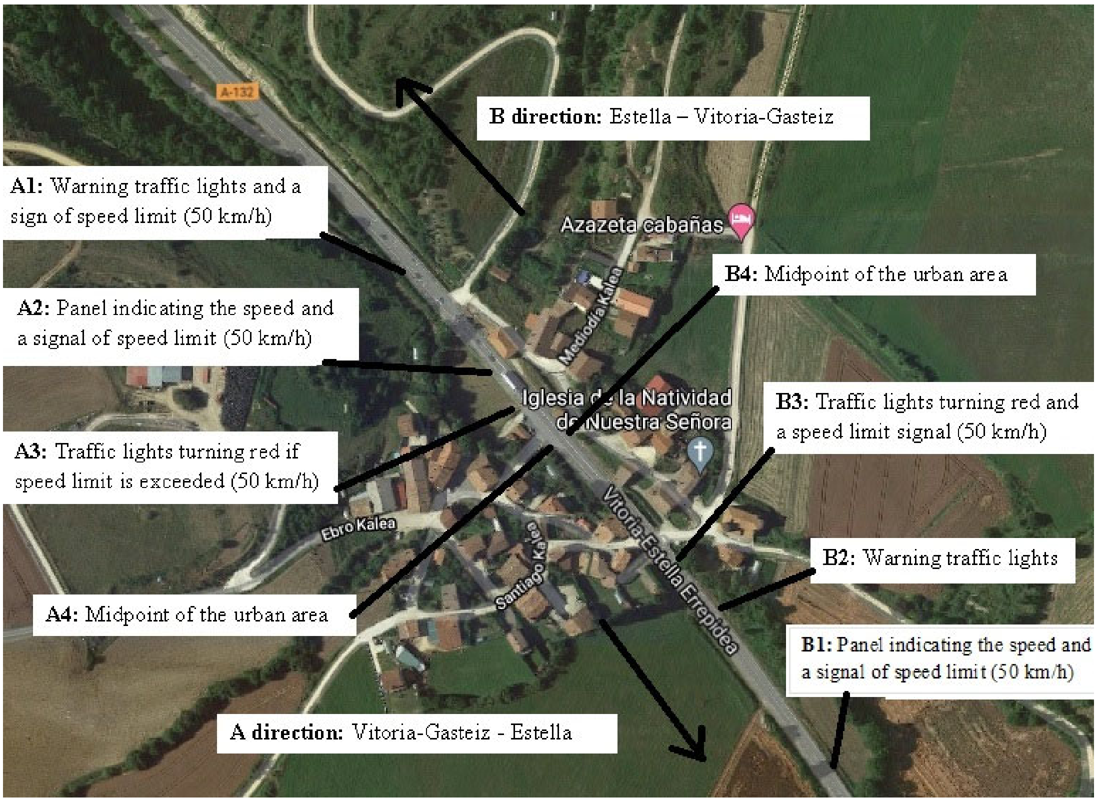

Figure 1: Aerial photo of the village of Azazeta and locations of the TCMs.

Traffic lights turning red if speed is exceeded and some previous panels indicating the speed of each vehicle were placed in both directions. In each direction, the sequence of the TCMs is as follows:

Vitoria-Gasteiz – Estella direction (north – south) (Figure 2):

- Point A1: Traffic lights warning about the presence of traffic lights and a signal with a speed limit of 50 km/h.
- Point A2: A panel indicating the speed of each vehicle (with a speed limit of 50 km/h).
- Point A3: Traffic lights turning red if speed limit is exceeded.
- Point A4: Mid-point of the urban segment, where pedestrian cross the road.

Estella - Vitoria-Gasteiz (south - north) (Figure 2):

- Point B1: A panel indicating the speed of each vehicle (with a speed limit of 50 km/h)..
- Point B2: Traffic lights warning about the presence of traffic lights.
- Point B3: Traffic light turning red if speed limit is exceeded and a signal reminding the speed limit (50 km/h) some meters before.
- Point B4: Mid-point of the urban segment, where pedestrian cross the road.

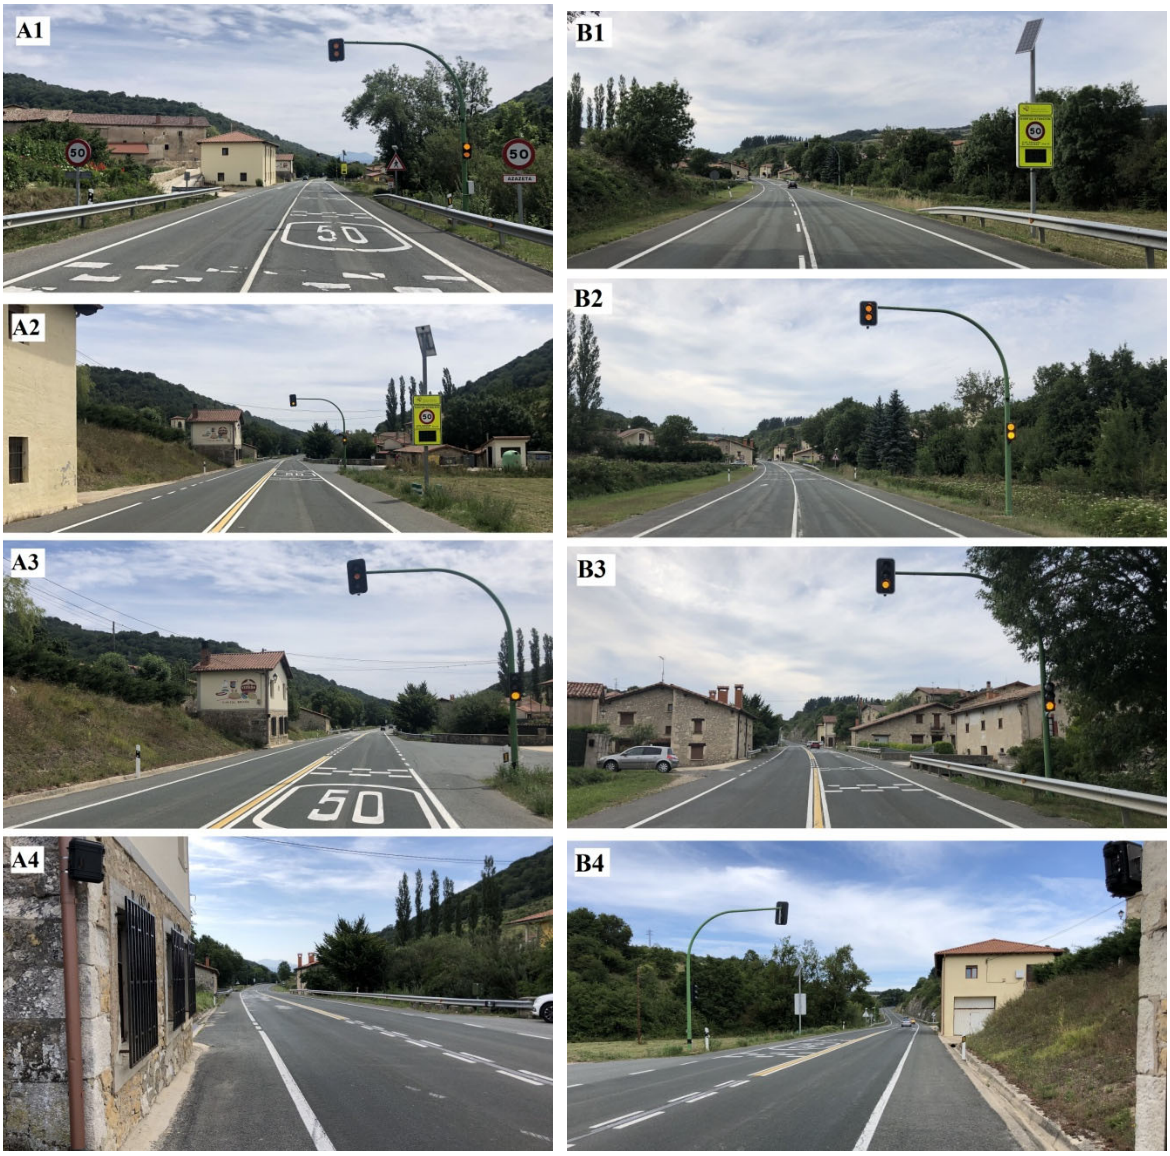

Figure 2: Traffic calming measures in direction A (points A1, A2, A3, and A4) and in direction B (points B1, B2, B3, and B4).

As seen, the sequence is not identical in both directions. While in north-south direction, there are traffic lights warning about the presence of more traffic lights and then the panel indicating the speed appears, in the other direction the panel is placed before the warning traffic lights. Additionally, Point A4 and B4 represents the same point, the midpoint of the urban area and the different name for it means the direction of the measured traffic volume.

Speed measurements were taken on August 6, in 2019. This type of small villages has a higher population in summer because many people spend their holidays in these small villages, leaving the big cities. A fixed radar was placed in point A4/B4 to measure the speed at the midpoint of the urban area, where inhabitants tend to use to cross the road in spite of the lack of an adequate pedestrian crosswalk. Moreover, warning signals (triangular) indicating that pedestrian could eventually cross the road are placed between A1 and A2 and between B2 and B3.

Therefore, this point represents the place where the effect of the traffic calming measures must take place in case pedestrians want to cross the road. Furthermore, at this place, vehicles coming from any of the two urban areas access to the main road, the A-132.

Additionally, from 11:00 am to 2:00 pm, a gun radar was employed to measure the speed of vehicles in points A1 and A3 from a hidden place, not to disturb vehicles' speed. Speeds shown to the vehicles in the panel of point A2 were also recorded and, hence, a complete speed profile of the vehicle was possible to obtain. Similarly, from 3:30 p.m. to 6:30 p.m., the same gun radar was used to measure the speed of vehicles in point B2 and B3 from a hidden place and the speed indicated in the panel in B1 was also registered.

The aim of this study was to show how the speed is reduced at the traffic lights turning red in the case of exceeding speed limit in two different configurations (with the panel indicating the speed nearer or further from the traffic light), know the speed profile of the vehicles approaching the traffic lights and how the reduced speed is maintained after the traffic lights, at the place where pedestrian would cross the road.

3. METHODOLOGY AND CASE STUDY

More than 1700 vehicles were controlled at the midpoint of the urban area (A4/B4) in both directions, and 334 vehicles in direction A and 257 in direction B. Table 4 presents the average speed of the vehicles, V_{ave}, the percentile 85th of the speed, V_{85} (which is the speed not reached by 85% of vehicles or, from another point of view, the speed achieved or exceeded by 15% of the vehicles), the maximum speed V_{max}; and the minimum speed, V_{min}. Moreover, Table 4 also includes the number of vehicles exceeding the speed limit (50 km/h), and the percentage of vehicles exceeding this limit from the total of measured vehicles.

Direction	Vitoria-Gasteiz – Estella				Estella – Vitoria-Gasteiz			
Points	A1	A2	A3	A4	B1	B2	B3	B4
V_{min} (km/h)	27	27	19	7	35	26	10	4
V_{ave} (km/h)	56.33	49.9	46.2	53.4	68.7	59.0	46.5	55.0
V_{85} (km/h)	67	59	55	65	83	72	56	66
V_{max} (km/h)	105	92	79	99	103	95	84	103
Total number	334	334	334	361	257	257	257	807
Vehicles V>50 km/h (units)	216	122	88	588	231	180	79	569
Vehicles V>50 km/h (%)	64.7	36.5	26.3	61.2	89.9	70.0	30.7	70.5

Table 4: Measured values of selected variables at control points in both directions.

As observed, in the Vitoria-Gasteiz – Estella direction, the average speed at A3 (the point of the traffic light turning red) was 46.2 km/h, and the V_{85} is 55 km/h, implying that 26.3 % of the vehicles did not respect the speed limit and the red light, and continued their way. Fortunately, a decrease on the speed can be seen from point A1 to point A3 (Figure 3a).

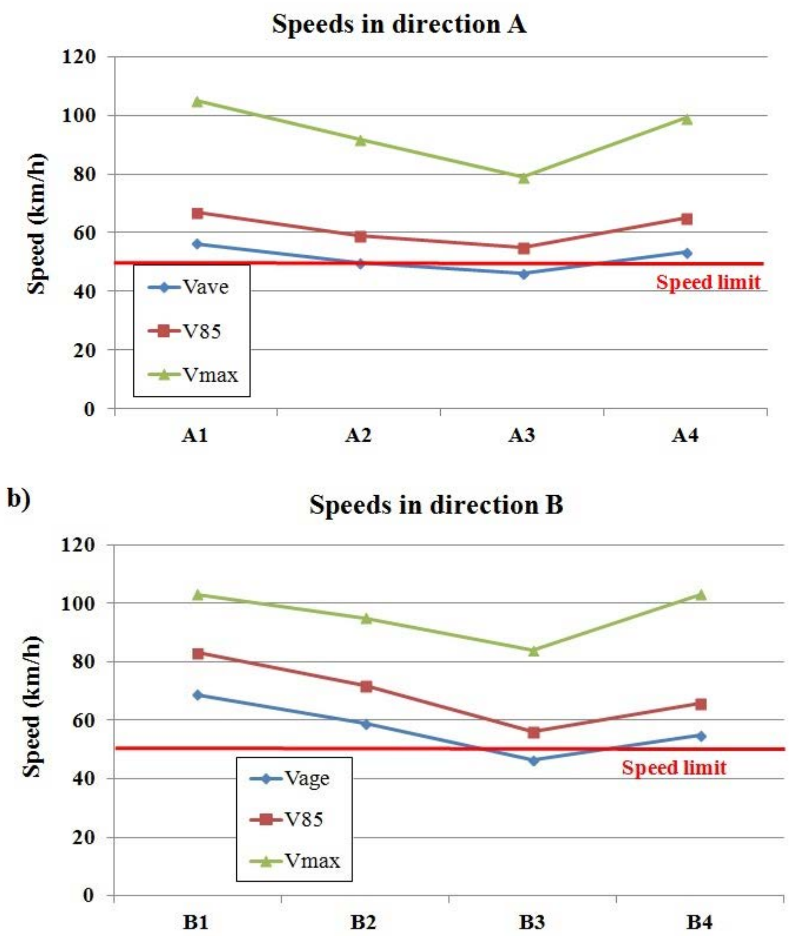

Figure 3: Speeds at each controlled point, a) in direction A; b) in direction B.

It shows that the first traffic lights warning about the presence of traffic lights serves as a first warning but even the average speed is over the speed limit at this point. Motorists speed down at the next point, where the panel indicates their speed, and the V_{ave} is below the speed limit, but not the V_{85} (36.5 % of the vehicles did not respect the limit). Finally, as commented, the better values are obtained at point A3, with the traffic light turning red, as drivers drive more carefully due to the possibility of a fine. Nonetheless, at point A4, the midpoint of the urban area, the place where pedestrian could appear, motorist speed up as they feel they are not controlled. Even the average point at this point (A4) is over the speed limit, with 61.2 % of vehicles faster than allowed (Figure 3a). In Figure 4a, the cumulated distributions of speeds at each point in A direction are shown.

In the other direction, Estella – Vitoria-Gasteiz, similar results were obtained (Table 4, Figure 3b). Speed is reduced from point B1 to B3, reaching the lowest value at B3, where the traffic light that can turn red if speed is over 50 km/h is placed. At B1, where the panel shows the speed to drivers, high speed values were registered despite the speed limit of 50 km/h: the average speed is over 68 km/h and the V_{85} is 83 km/h. Fortunately, lower values were measured in B2 and in B3, the average speed was below the speed limit, 46.5 km/h, and the V_{85} was 56 km/h.

The percentage of drivers not respecting the red light was 30.7 % in B3. Once again, at point B4 motorist speed up and an average speed of 55 km/h was observed, V_{85} was 66 km/h and 70.5% of vehicles did not respect the speed limit. In Figure 4b, the cumulated distributions of speeds at each point in B direction are shown.

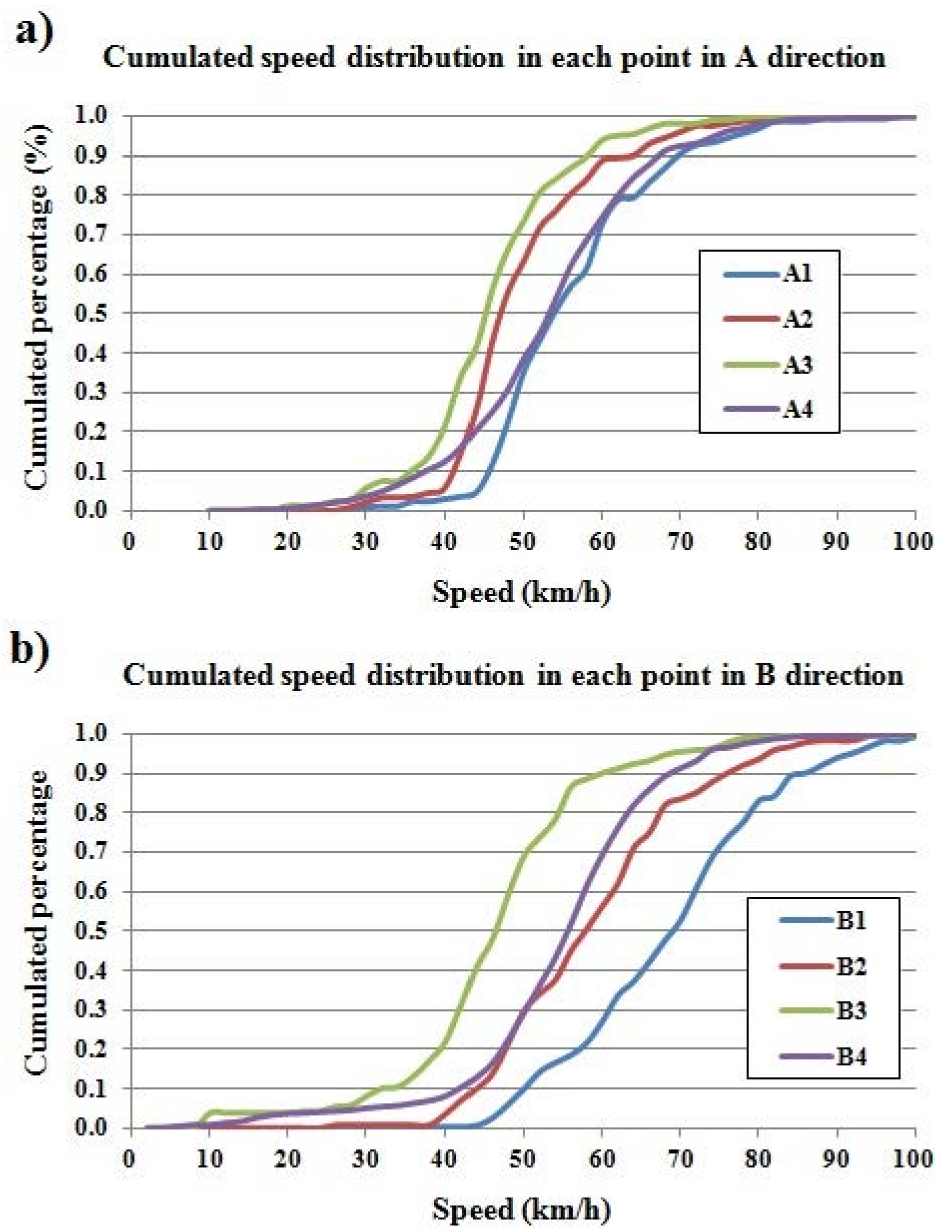

Figure 4: Cumulated speed distribution at each point, a) in A direction, b) in B direction.

If values obtained at the midpoint of the urban area are compared (A4 and B4), similar values are obtained. Average values of 46.2 and 46.5 km/h and V_{85} values of 55 and 56 km/h were measured in direction A and B, respectively. Consequently, the order of the sequence (panel and warning traffic lights or warning traffic lights and panel) obtained similar results at the subsequent traffic light turning red in case of exceeding speed limit and at the midpoint of the urban area.

However, it must be noted that higher values were recorded in B1 than in A1, but it could be due to the fact that B1 is further from the urban area than A1, which is very near from the start of the urban area. Although panels show the driving speed to motorist, they understand that they are still far from the urban area and they may think that they have time to speed down.

Moreover, the fact that values obtained in A4 and B4 are similar and higher than in A3 and B4 indicates that drivers tend to accelerate as they feel that they have passed the traffic light turning red and that, despite being in an urban area, the controlled area (at the traffic lights) is finished. Drivers' experience show them that the traffic lights could be the place where the radar of the police could be located (controlling the speed or not violating a red light), but not after passing them. These values also show that although drivers can respect the speed limits at the TCMs but, after them, they forget their effect.

Finally, if we compared the values obtained at the traffic lights of Azazeta with a similar study in Ábalos (Region of La Rioja, Spain) (Pérez-Acebo et al. 2021a) some conclusions can be deduced. In Ábalos, traffic lights turning red in case of exceeding speed limit were placed after warning traffic lights but without panel indicating the speed. However, in one direction the traffic light included a pedestrian crosswalk, and in the other one without pedestrian crosswalk. Table 5 compares the measured speed values in Azazeta and Ábalos.

Location	Azazeta (Álava/Araba)		Ábalos (La Rioja)	
Point	A3	B3	A2	B3
Placed TCM	Traffic lights turning red	Traffic lights turning red	Traffic lights turning red	Traffic lights turning red and pedestrian crosswalk
V_{ave} (km/h)	46.2	46.5	50.5	30.5
V_{85} (km/h)	55	56	60	42
V_{max} (km/h)	79	84	85	80
Total number	334	257	261	1411
Vehicles V>50 km/h (units)	88	79	224	255
Vehicles V>50 km/h (%)	26.3	30.7	58.8	18.1

Table 5: Speed values in traffic lights turning red in Azazeta and in Ábalos (from Pérez-Acebo et al. 2021a).

As seen, the presence of a crosswalk help reducing the vehicles' speed, reinforcing the effect of the traffic light turning red in case of exceeding the speed limit. As seen, the introduction of a panel indicating the speed helps also improving the efficiency of the traffic lights, better if it is located just before the traffic light (as in A3 in Azazeta) and not at the beginning of the sequence as in B3 in Azazeta. Nonetheless, the best effect is achieved if the pedestrian crosswalk is placed with the traffic lights, because drivers would respect more the speed limit.

Apart from the possible fine if the limit is not respected, a pedestrian could appear, wanting to cross the road and that possibility contributes to a higher speed reduction (or a higher percentage of drivers respecting the speed limit).

4. CONCLUSIONS

The study analyzes the efficiency of traffic lights turning red if the speed limit is exceeded preceded by panels indicating the vehicles’ speed. Traffic lights that turn red if the approaching vehicle exceed speed limit are a usual traffic calming measure in rural roads crossing short urban segments. The selected village, Azazeta, is crossed by the A-132 road (Vitoria-Gasteiz – Estella), managed by the Regional Government of Álava/Araba, and traffic lights turning red, panels indicating the speed and warning traffic lights in a different sequence. While in A direction (Vitoria-Gasteiz – Estella), the sequence is warning traffic lights, the panel, and the traffic lights turning red, in B direction (Estella – Vitoria-Gasteiz), the sequence is the panel, warning traffic lights and traffic lights turning red. In both directions a speed reduction is observed as drivers pass each traffic calming measure, achieving the lowest speed at the traffic lights turning red, with a similar average speed (slightly over 46 km/h), below the speed limit (50 km/h), but the percentile 85 of the speed distribution is over the speed limit (55 and 56 km/h in A and B direction, respectively), indicating that 26.3% and 30.7% of drivers did not respect the red light. Moreover, after the traffic lights turning red, drivers speed up and higher speeds are measured at the midpoint of the urban segment in both direction. Additionally, obtained results were compared to other traffic lights turning red in Ábalos (La Rioja) and the lowest speeds were obtained when combining the traffic lights with a pedestrian crosswalk.

RESUMEN

El uso de la bicicleta en España es aún reducido, pero se ha incrementado de manera significativa, como medio de vida saludable por la práctica deportiva entre los ciudadanos y también como modo de transporte en las ciudades en las que se ofrecen infraestructuras específicas o adaptadas, lo que se extiende también a áreas periurbanas para ir al centro de estudios o al trabajo, es un hecho constatado por diversos estudios. Se desconoce el tamaño y evolución del parque de bicicletas y la venta de unidades y que ha experimentado un gran crecimiento en los últimos años.

En el año 2018, se produjeron 102.299 accidentes en España, de los que 37.892 se produjeron en carretera y 64.407 en ámbito urbano. De este total, en 7.598 accidentes estuvieron implicados ciclistas, de los que 2.143 fueron accidentes en carretera mientras que 5.465 fueron en urbano. Entre 2003 (año de referencia de la importante mejora de la mortalidad general en accidentes de tráfico y a partir del cual se invierte la tendencia de accidentes con ciclistas) y 2018, el número de accidentes con bicicletas aumentó el 236%, mientras los accidentes totales lo hicieron el 2%.

Los datos relacionados con la accidentalidad de ciclistas ponen de relieve la necesidad de estudios rigurosos para la comprensión del fenómeno y los factores de influencia que motiven la aplicación de medidas de intervención adecuadas. En este trabajo se presenta el análisis de la evolución de los accidentes con lesionados ciclistas y la identificación de patrones accidentológicos de ciclistas con técnicas estadísticas de análisis clúster, de los microdatos de las Bases Generales de Accidentes (BGAs) de los años 2000 – 2015.

Entre los patrones identificados se destaca el bajo uso del casco entre ciclistas en ámbito urbano y sobre todo entre mujeres y jóvenes, lo que puede motivar acciones especialmente dirigidas para campañas de concienciación y control entre los colectivos identificados.

1. JUSTIFICACION DEL TRABAJO

El uso de la bicicleta en España es aún reducido, se viene incrementando de manera significativa en los últimos años, como medio muy atractivo para incrementar el ejercicio físico de muchos ciudadanos y como modo de transporte, especialmente en ciudad. Los poderes públicos están fomentando el uso de este medio, ofreciendo infraestructuras especiales o mejor adaptadas, tanto en entornos urbanos como en áreas periurbanas. Se desconoce el tamaño del parque de bicicletas y su evolución, aunque las ventas de este tipo de vehículos reflejan un gran crecimiento. En el año 2018, se produjo un notable incremento de las ventas si se consideran como referencia las 800.000 unidades del año 2011, y el mercado muestra una gran estabilidad, por encima del 1.000.000 de unidades. En la Unión Europea, las ventas oscilan entre 20 y 21 millones de bicicletas en los últimos años.

En la medida que se incrementa el uso de la bicicleta, el riesgo de accidentes con implicación de estos vehículos y el correspondiente balance de víctimas, tiende a crecer, y, si bien su número sigue siendo muy reducido en relación con los accidentes y víctimas totales, la proporción entre ellos crece especialmente desde el año 2004, con mayor tasa de incremento en zona urbana, debido a la evolución del número de heridos leves y graves en estos accidentes.

Entre 2010 y 2018, el número de víctimas mortales entre lesionados ciclistas, pasó de 67 a 58 que representa una reducción del 13%; mientras que el número de heridos graves se incrementó en un 124% (de 467 a 620) y el número de heridos leves en un 124% aumentando de 2.962 a 6.633, correspondiendo las mayores tasas de variación de heridos graves y leves al ámbito urbano.

En términos relativos, en 2010 el número de víctimas mortales en accidentes con ciclistas representó un 2,7% de las totales por accidente de tráfico mientras que en el año 2018 este porcentaje fue del 3,2%.

En los países de la UE este fenómeno es análogo, aunque el mayor uso de la bicicleta en algunos países hace que los valores sean distintos a los españoles. En función de los datos europeos disponibles en el periodo 2005-2016; el porcentaje de víctimas mortales de ciclistas en relación a los totales pasó de un 7% a un 8% en el conjunto de la UE; el cambio para España fue del 1,8 al 3,2%, en Holanda fue de 20 a 19%, en Dinamarca del 12 al 15% y en el Reino Unido de 5 a 6%. República Checa y Noruega experimentaron incrementos de 6 puntos porcentuales y representan los valores más altos de la UE.

Los anteriores datos nos indican que la contribución de los accidentes con ciclistas implicados al balance general de accidentes y víctimas de tráfico puede seguir creciendo en España y, por tanto, se trata de un colectivo que debe ser estudiado en profundidad.

Este estudio, realizado por un equipo investigador del INSIA de la UPM, en el marco de la Cátedra Universidad-Empresa Eduardo Barreiros y financiado por la Fundación Eduardo Barreiros, tiene como finalidad contribuir al conocimiento de los factores de mayor influencia en los accidentes con ciclistas implicados y de ofrecer conclusiones de interés para la adopción de medidas orientadas a reducirlos. Aparicio et al. (2020).

2. DATOS ESTADISTICOS DE ACCIDENTES Y VÍCTIMAS CICLISTAS.

2.1 Evolución de los accidentes con implicación de ciclistas

En el año 2018, se produjeron 102.299 accidentes en España, de los que 37.892 se produjeron en carretera y 64.407 en ámbito urbano. De este total, en 7.598 accidentes estuvieron implicados ciclistas de los que 2.143 fueron accidentes en carretera mientras que 5.465 fueron en urbano.

En el periodo de 1993 a 2018 los accidentes de tráfico con implicación de bicicletas presentan un comportamiento de ascenso notable hasta los casi 7.600 del último año y ha sido espectacular desde 2004. Figura 1.

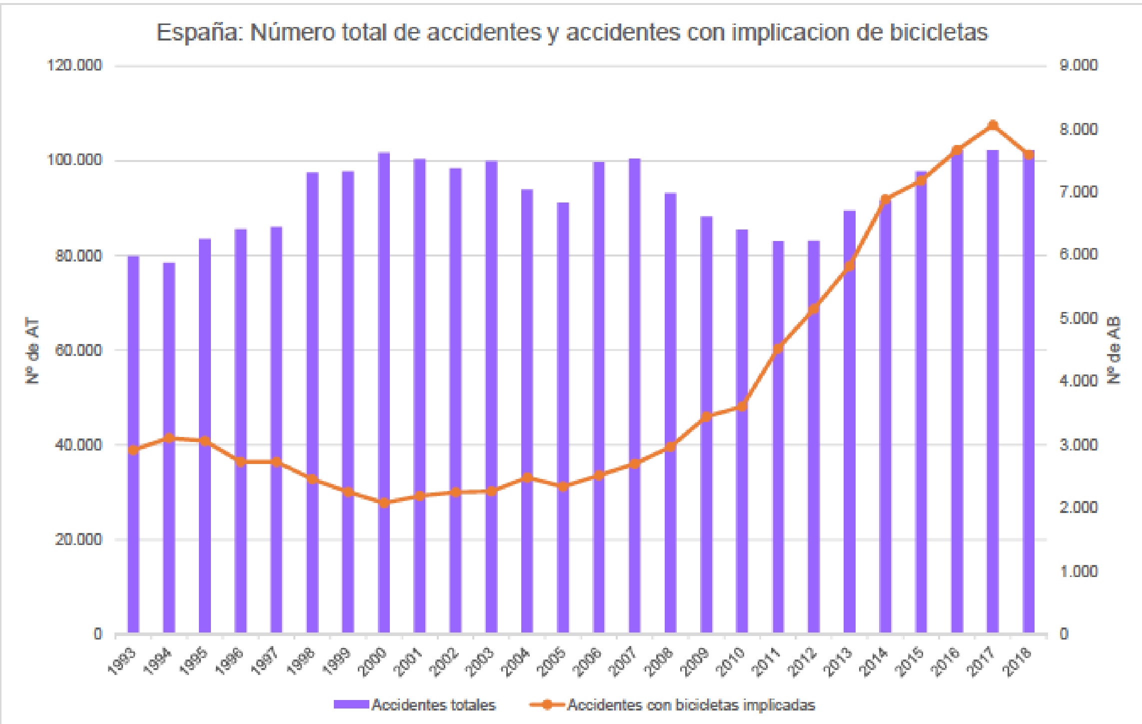

Figura 1: España: accidentes totales y con bicicletas implicadas. 1993-2018. (Fuente: DGT)

Entre 2003 (año de referencia de la importante mejora de la mortalidad en carretera y a partir del cual se invierte la tendencia de accidentes con ciclistas) y 2018, el número de accidentes con bicicletas aumentó el 236%, mientras los accidentes totales lo hicieron el 2%.

El mayor aumento de accidentes con bicicletas se observó en zona urbana que alcanzó el 272% frente al aumento del 23 % de los accidentes totales en la misma zona. Los accidentes con bicicletas en zona interurbana aumentaron: en 168% frente al descenso del 20% que experimentó el conjunto de la accidentalidad cuando se consideran todos los vehículos.

En formato de número Índice (Año 1993=100) los accidentes con bicicletas se han multiplicado por 3 en ciudad y prácticamente por 2 en carretera. Desde 2010, la evolución de este índice referido al total de accidentes muestra el ascenso de los accidentes en ciudad y un comportamiento muy estable en torno al índice 100 en carretera.

La implicación de bicicletas en accidentes de tráfico (en % del total de vehículos implicados) tiene tendencia creciente tanto en carretera como en ámbito urbano desde el año 2000 hasta 2014, a partir del cual se produce un estancamiento.

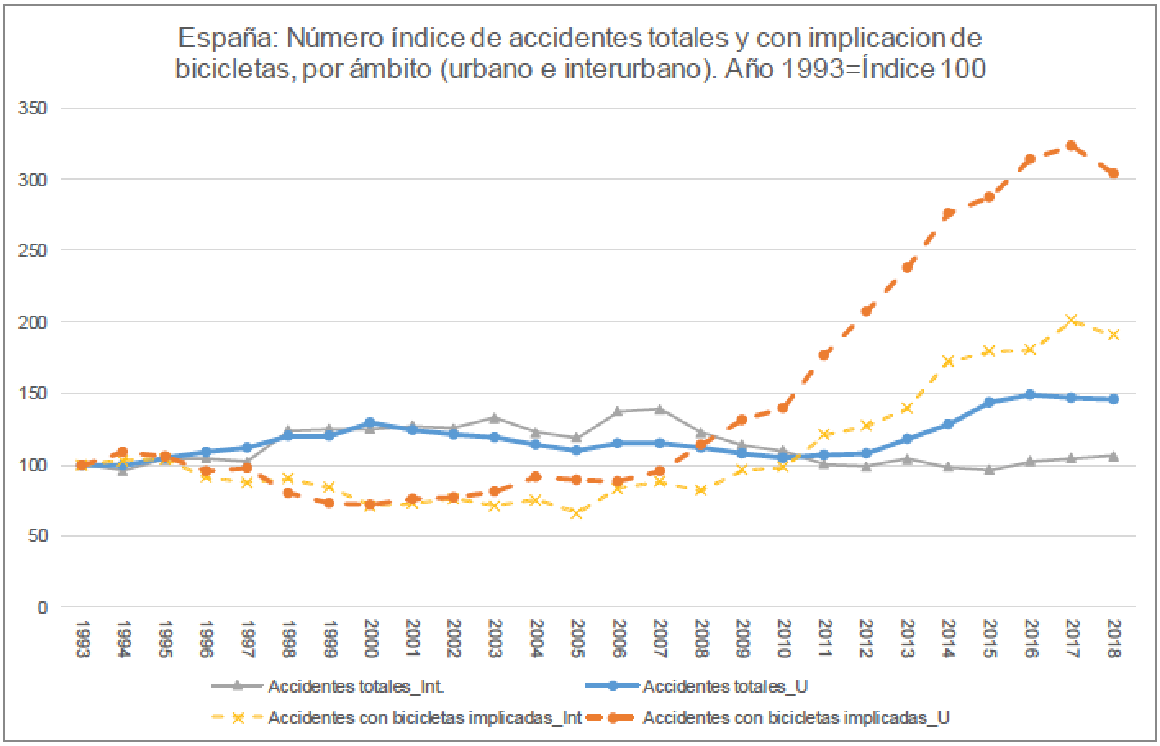

Figura 2: España: Número índice de accidentes totales y con implicación de bicicletas. Año 1993=Índice 100. (Fuente: DGT).

Desde el año 2000, la implicación de bicicletas en accidentes de tráfico en carretera pasó del 1,1% al 3,6% y en vías urbanas del 1,3% al 5,0 % en 2018. La implicación de bicicletas en accidentes en vías urbanas fue superior al de carretera en la serie completa de años y su tasa de crecimiento es más acelerada que la de vías interurbanas.

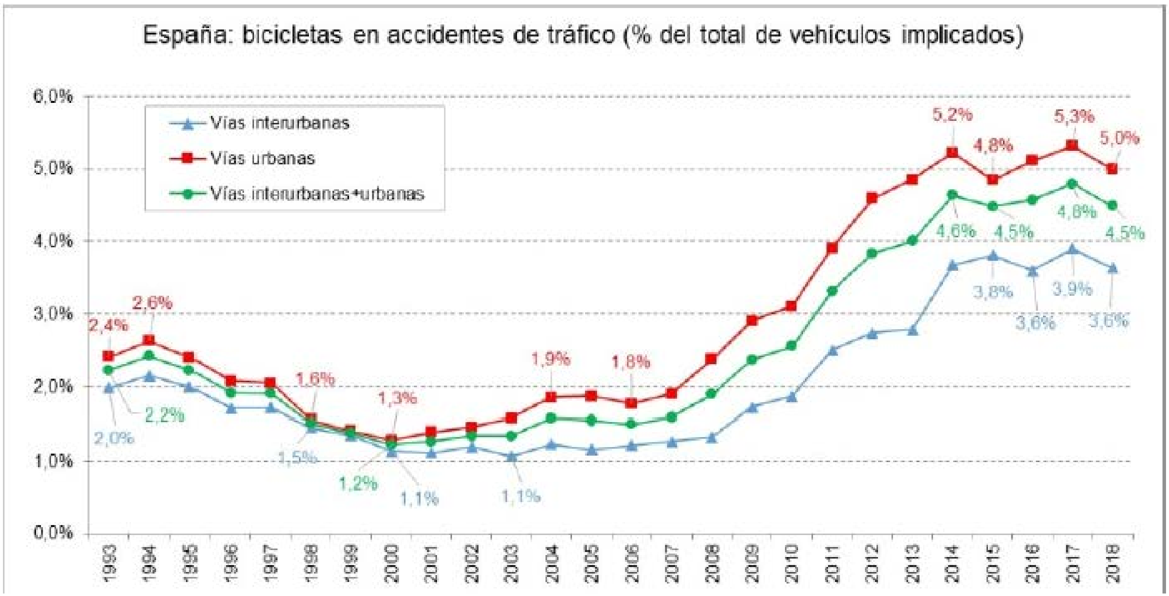

Figura 3: España. Bicicletas implicadas, en accidentes de tráfico en % del total de vehículos implicados. Según ámbito de ocurrencia. 1993-2018. (Fuente: DGT).

1.2 Evolución de los lesionados ciclistas

En el periodo 1993-2018 el número de conductores de bicicletas muertos en carretera presenta una tendencia decreciente, con fluctuaciones en todo el período. El valor máximo fue de 118 en 1994 y el mínimo de 37 en 2011, a partir del cual los valores fluctúan entre 40 y 50. En zona urbana, se aprecia un estancamiento y los valores fluctúan entre 20 y 40, con valor máximo de 39 en 1993 y el mínimo de 10 en 2015. Sin embargo, en 2016 y 2017 la serie ha recuperado los niveles de 1993.

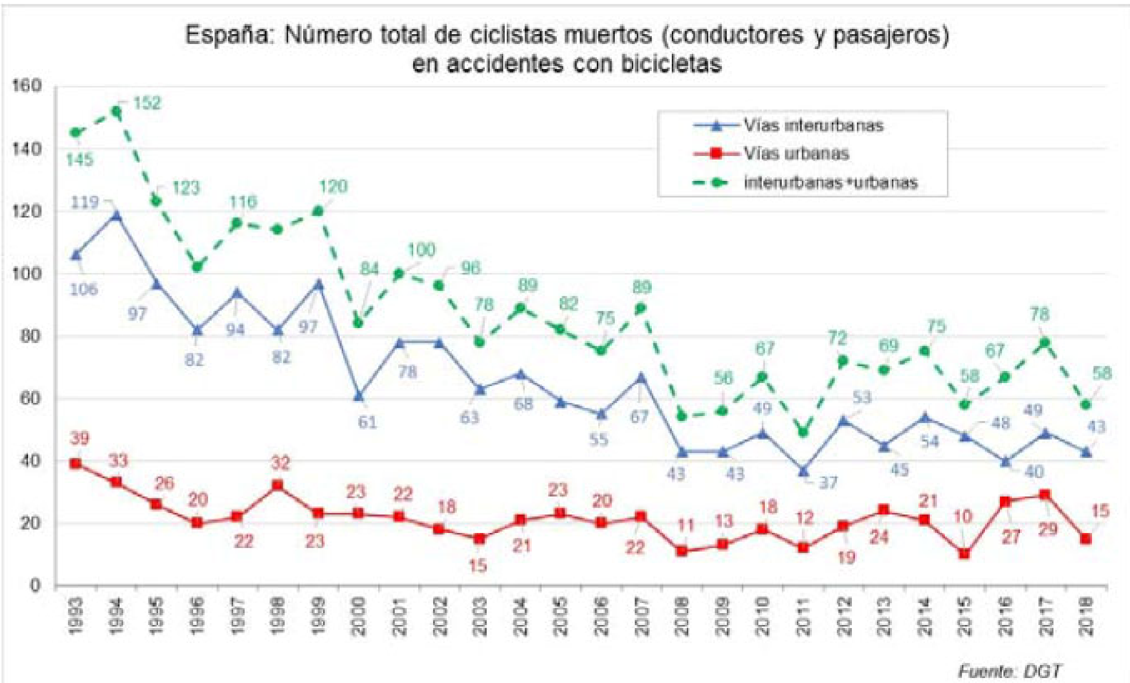

Figura 4: Total de fallecidos en accidentes con bicicletas por zona de ocurrencia España 1993-2018. (Fuente: DGT).

El 99% de las víctimas son conductores de la bicicleta. Las cifras de muertos en carretera son significativamente más elevadas que en zona urbana.

De media, el 75% de víctimas mortales se producen en accidentes en carretera, mientras que el 25% en calles urbanas. El peso porcentual de víctimas mortales en accidentes en carretera con bicicletas relativo al total de víctimas en esos accidentes, ha bajado desde el máximo de 83% en 2015 al 74% en 2018, pero solo ha cambiado en 1 punto porcentual en todo el periodo. En urbano el peso ha cambiado del 27% al 26% en todo el período.

El porcentaje de víctimas mortales en accidentes de tráfico con implicación de bicicletas en el periodo 1993-2018 según zonas (en términos relativos al total de víctimas fatales en accidentes de tráfico), ha aumentado en zona urbana hasta el 5,7% frente al 3,4% en interurbano en el año 2018.

La evolución desde 1993, de ambos números en paralelo en la Figura 5 muestra el descenso claro e importante de las muertes totales, frente al estancamiento de la mortalidad de ciclistas y hasta un repunte en los últimos años, que coloca el último registro al nivel de la década del 2000 y pone de manifiesto la atención que merece este colectivo en particular. Como ya se dijo, el año 2003 marcó un hito para la mejora de la política de seguridad vial española con un descenso acumulado del 67% de la mortalidad hasta el año 2018, por la mejora en ámbito interurbano fundamentalmente con una reducción del 71% y una aportación del ámbito urbano del 47%. En el mismo período la mortalidad en accidentes con ciclistas experimentó sólo el 25,6% de mejora. Las víctimas mortales en urbano en el año 2018 igualaron las de 2003 (15 ciclistas muertos) mientras que las habidas en carretera bajaron el 31,7%.

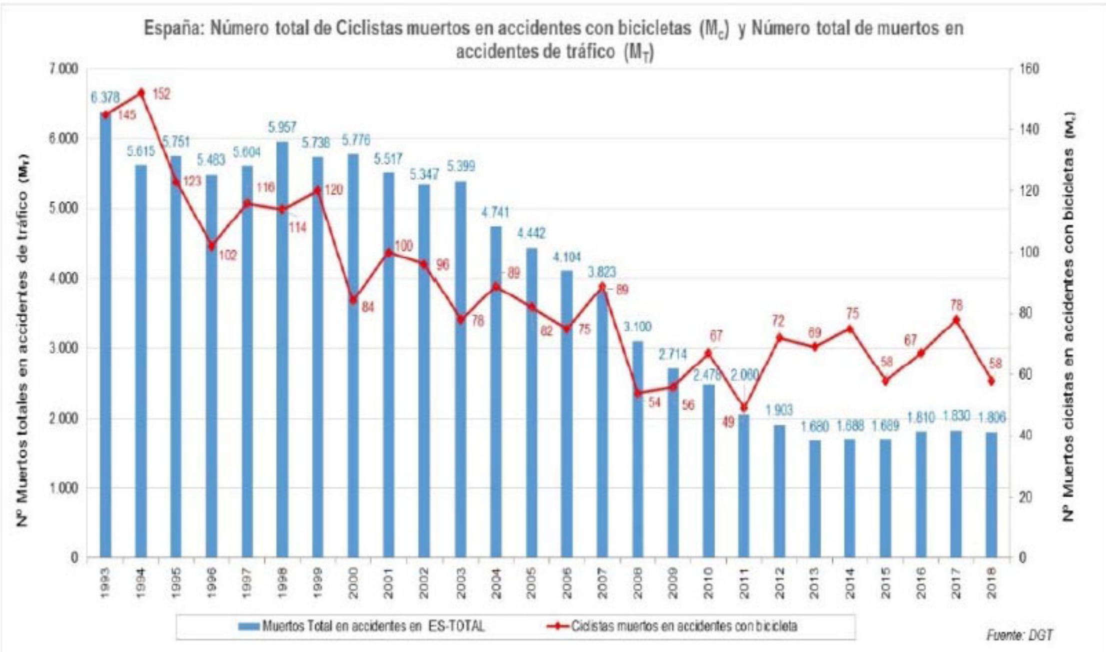

Figura 5: Total de muertos en accidentes de tráfico y en accidentes con bicicletas implicadas. (Carretera+urbano). España 1993-2018. (Fuente: DGT).

En la Figura 6 se muestra la evolución del indicador Muertos por accidente (en los totales (AT) y en los que han estado implicados bicicletas (AB). (Valor índice 100=año 1993) y se aprecia la evolución favorable hasta 2014 en ambos casos, con un estancamiento en ambas series hasta el último año.

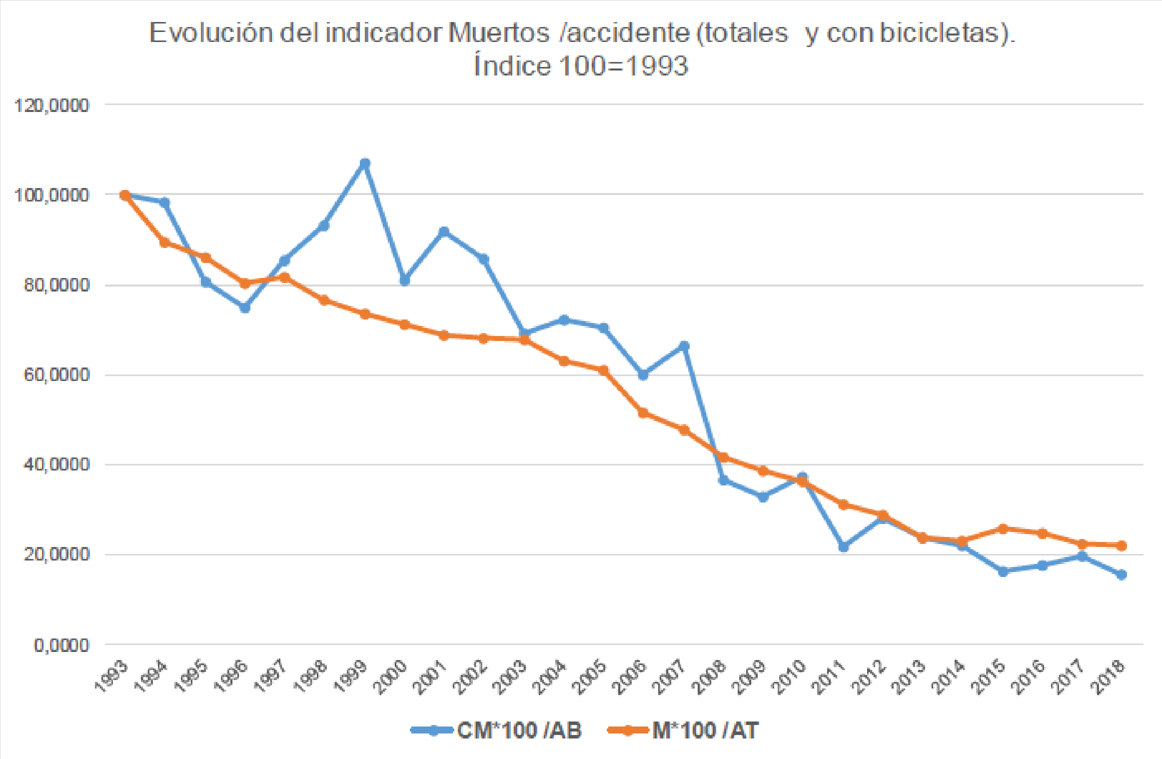

Figura 6: España: Indicador Muertos por accidente (totales y con implicación de bicicletas). 1993-2018. Valor índice 100=año 1993. (Fuente: DGT).

En la Figura 7 se muestran los valores absolutos de los heridos graves en accidentes de tráfico con ciclistas y su peso porcentual de las producidas en accidentes totales. La evolución de ambas es creciente en prácticamente todo el período con un importante aumento de su peso porcentual: la incidencia de ciclistas heridos graves en 2018, ha multiplicado por más de 4 veces el valor de 2001.

En la Figura 8 se muestran los valores absolutos de los heridos leves en accidentes de tráfico con ciclistas y su peso porcentual de las producidas en accidentes totales. La evolución de ambos es creciente desde 2001 en el que se produjo el valor mínimo de 1,3% y no ha parado de crecer: hasta alcanzar el valor máximo de 5,5% en 2017, en el que ha multiplicado por más de 4 veces el valor mínimo indicado. En el año 2018 el peso porcentual ha descendido sólo 4 décimas.

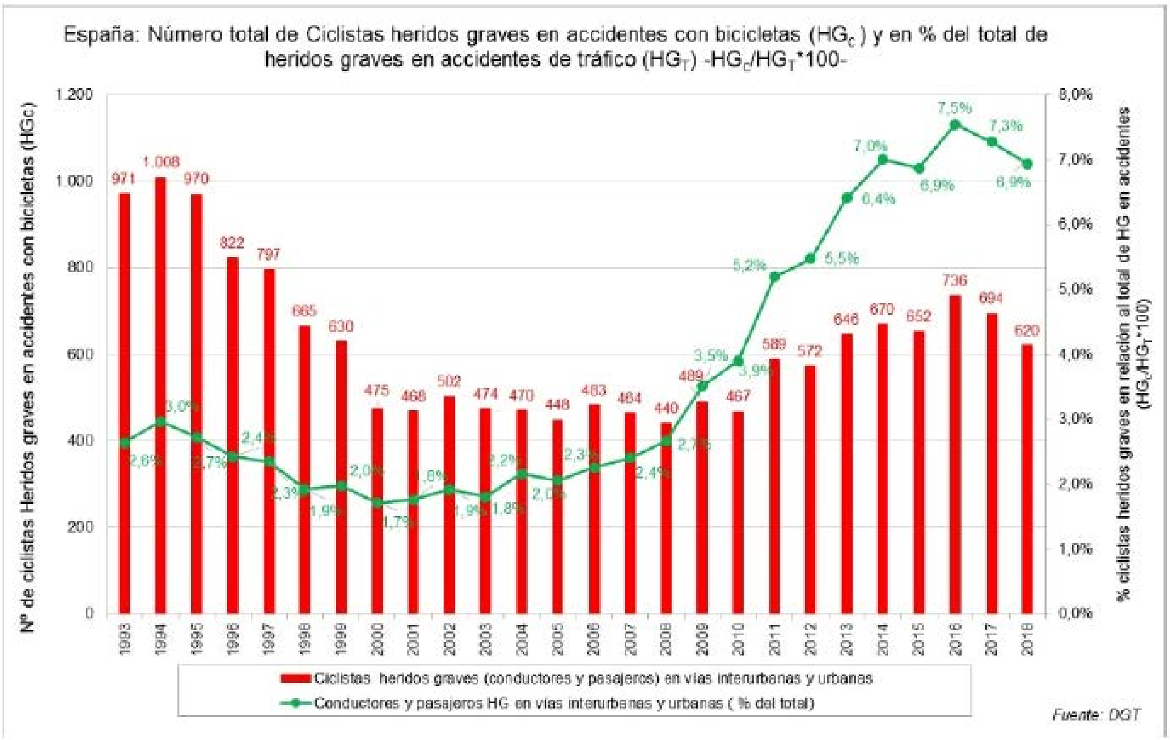

Figura 7: España. Número de ciclistas heridos graves en accidentes con bicicletas (HGC) y su porcentaje en relación al total de heridos graves en accidentes de tráfico (carretera+urbano) (HGT). 1993-2018. (Fuente: DGT).

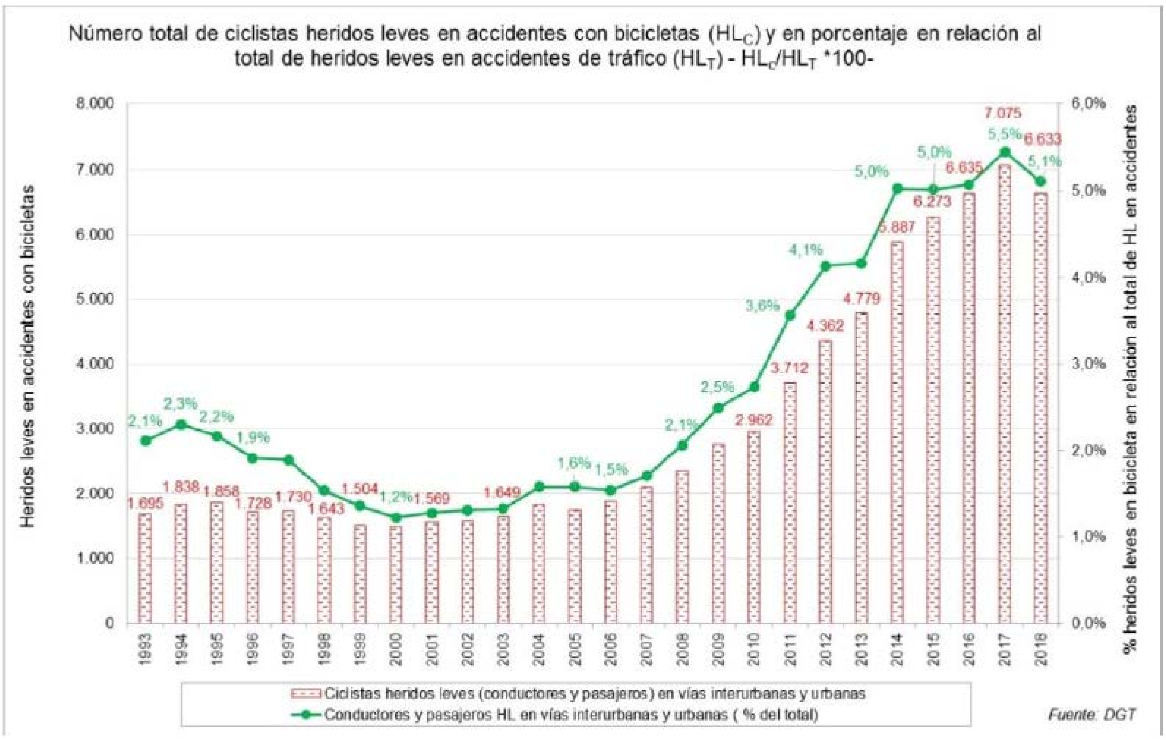

Figura 8: España.Total de ciclistas heridos leves en accidentes con bicicletas (HLC) y su porcentaje en relación al total de heridos leves en accidentes de tráfico (carretera+urbano) (HLT). 1993-2018. (Fuente: DGT).

2. IDENTIFICACIÓN DE PATRONES ACCIDENTOLÓGICOS DE CICLISTAS

Las variables de la base de datos creada para estos modelos fueron: género, edad, grado de lesividad, infracción del conductor/ciclista, infracción de velocidad e infracción administrativa. El periodo analizado corresponde al periodo 2000 a 2015.

2.1 Técnicas estadísticas de análisis clúster

Para la identificación de patrones de accidentalidad de bicicletas se han aplicado técnicas estadísticas de análisis de conglomerados o clúster y dentro de esta categoría, se han seleccionado los mapas autoorganizativos (Self organizing Maps- SOM) por su rapidez de interpretación. Los mapas SOM forman parte del campo de Machine Learning y ponen de manifiesto las asociaciones multivariante más frecuentes que explican la ocurrencia de accidentes. Las primeras referencias al SOM se encuentran en los artículos de Kohonen (1982), Kohonen (1990), Kohonen (1995), Kohonen (1998), y en los trabajos Von der Malsburg (1973), Rumelhart y Zipser (1985) y Willshaw & Von Der Malsburg (1976) sobre aprendizaje competitivo (competitive learning).

La metodología Self-Organizing Maps (SOM) de clúster ha sido aplicada a diferentes campos, siendo su aplicación en el ámbito de los accidentes de tráfico, más limitada. Hu et al. (2004) propusieron un modelo probabilista para predecir los accidentes de tráfico mediante la monitorización 3D de los vehículos. Para ello, se usó un modelo SOM difuso, con el objetivo de aprender patrones de actividad para las rutas de muestra. En el artículo de Chen et al. (2006), se aplicó SOM con el propósito de revelar patrones de tráfico regionales específicos. Por su parte, Liu (2009) desarrolló un modelo analítico para aprender acerca de la asignación de responsabilidad en accidentes de tráfico en Taiwan. Tiwari et al. (2017) aplicaron las técnicas de SOM, así como otras herramientas de Data Mining, para analizar los accidentes de tráfico con el objetivo de analizar los diferentes tipos de atributos que contribuyen a que se produzca el accidente, entre ellos el tipo de vehículo (bicicleta entre otros). Por último, debe mencionarse el trabajo realizado por Giacomo et al. (2012), quienes estudiaron accidentes de peatones aplicando técnicas de clúster, con el fin de identificar patrones que pudiesen ayudar a diseñar medidas preventivas y asignar recursos para los problemas identificados en los accidentes de tráfico mortales de Israel entre 2003 y 2006 y en especial dirigidas a los usuarios más vulnerables de la carretera, entre los que se encuentran los ciclistas.

3. RESULTADOS

El mapa de calor de la implicación de ciclistas en razón de género y en accidentes según la zona de ocurrencia del accidente se muestra en la Figura 9. La variable sexo toma valor 1 cuando el ciclista es varón y 0 cuando es, los nodos aparecen de color rojo y azul respectivamente.

En el mapa de la Figura 9 se observa que predomina el género masculino, solo un 15% de los ciclistas implicados son mujeres ciclistas y requiere estudios que consideren la exposición de cada colectivo.

Las mujeres ciclistas, en general, han estado mayoritariamente implicadas en accidentes ocurridos en vías urbanas (alrededor del 84%).

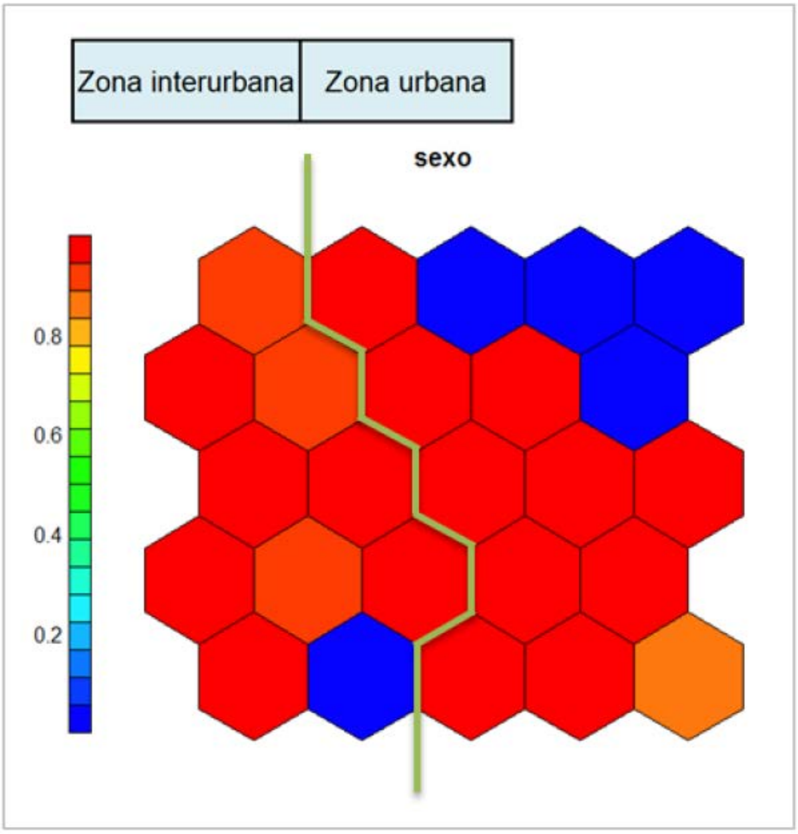

Figura 9: Mapa de calor para "sexo" en el mapa SOM. (Fuente: Elaboración propia a partir de las BGAs).

En el mapa de calor de la variable lesividad (Figura 10), se puede observar cómo en el área derecha, que corresponde a la zona urbana, la lesividad de los ciclistas es, en general, menor en comparación con la que se observa en la zona interurbana. En color azul lesividad baja (valores próximos a 0); en verde cuando la lesividad es media (valores próximos a 0,5); y en color rojo cuando la lesividad es alta (valores próximos a 1).

Dentro de la zona urbana también hay un nodo de alta lesividad, el nodo naranja C53, que alberga en torno a 500 ciclistas. Sin embargo, el nodo de alta lesividad que está incluido en la zona interurbana, nodo rojo C41, contiene más de 1.000 ciclistas.

En los accidentes ocurridos en zona interurbana la lesividad es, en general, mayor con más heridos graves y muertos en relación a los accidentes ocurridos en zona urbana, donde predominan fundamentalmente los heridos leves.

También es importante señalar que los accidentes mortales, a pesar de que predominen en la zona interurbana, son un parte pequeña en comparación con el resto de accidentes que sufren los ciclistas, tal y como se muestra en la escala del mapa de lesividad, donde el nivel 1 (muertos) no llega a estar representado, y el valor máximo del vector de peso es de 0,75 como se muestra en la Figura 10.

En relación a la lesividad, se observa que, en general, las mujeres presentan una lesividad media leve, siendo complicado sacar conclusiones sólidas acerca de la lesividad de los varones, dado que su presencia está muy distribuida a lo largo del mapa, debido a su elevada presencia en el estudio en comparación con su contraparte femenina.

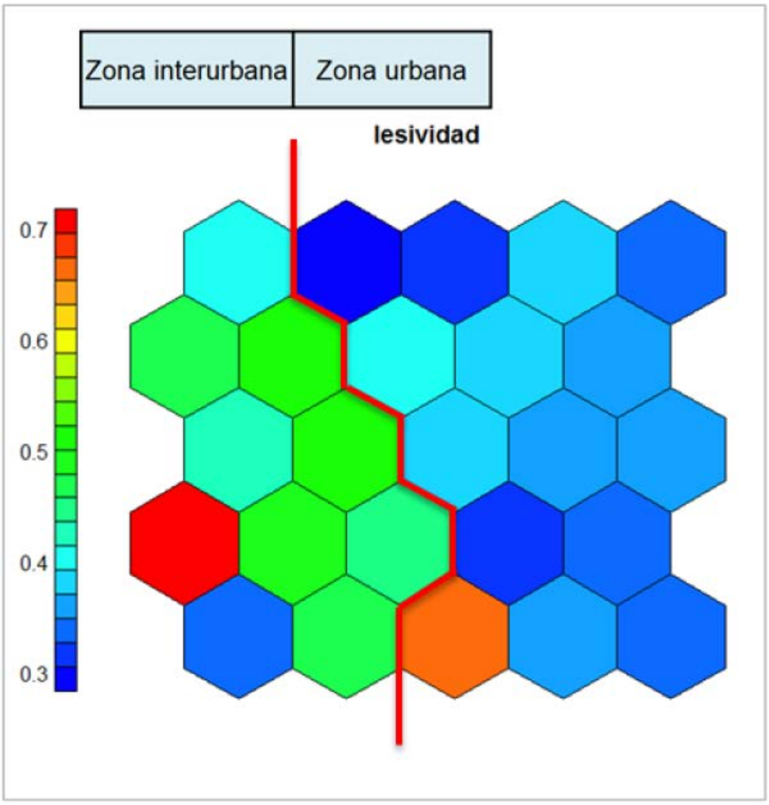

Figura 10: Mapa de calor para “lesividad” en el SOM. (Fuente: Elaboración propia a partir de las BGAs).

Otros mapas SOM con la edad indican que, entre los ciclistas más mayores (50-64 años y mayores de 65), se observa una escasa presencia de mujeres, frente a este colectivo entre los varones. Este patrón está en consonancia con el detectado en la conducción de turismos, donde se observa que la presencia de mujeres disminuye en las edades más avanzadas.

En la Figura 11 aparecen representado en azul los porcentajes de ciclistas de cada nodo que estaban usando el casco. De todos los ciclistas involucrados en accidentes observados en este análisis, de media el 26,5% estaban usando el casco y el resto no. De media el 40% de los ciclistas lo usaba cuando se produjo el accidente en una vía interurbana y sólo el 14% cuando se produjo en vía urbana.

En el nodo C51, se identifican 2.967 ciclistas, con el mayor porcentaje de uso del casco 66% frente al 34% que no usaban casco en el momento de ocurrencia del accidente en una carretera.

A primera vista en el mapa con los porcentajes, se observa que a la izquierda del mapa el porcentaje de ciclistas que usan casco es significativamente mayor. Si lo comparamos con el mapa SOM con la variable "zona", se ve claramente cómo la zona de ciclistas con mayor porcentaje de uso de casco coincide con la parte del mapa en la que predominan los accidentes ocurridos en zona interurbana.

Se resaltan algunos ejemplos de grupos que requieren algún tipo de atención: 1) en el clúster C52 hay 582 accidentes ocurridos con ciclistas mujeres de edad media, que han resultado con severidad media y entre las que el 59% no usaban el casco, 2) en el clúster C41 se clasifican 1.201 accidentes en los que el 48% de los ciclistas (mayoritariamente varones de edad media) no usaban el casco y han resultado con severidad alta, 3) los clústers C22, C32 y C43 presentan los porcentajes más altos de no uso de casco en medio interurbano (86, 83 y 72% respectivamente).

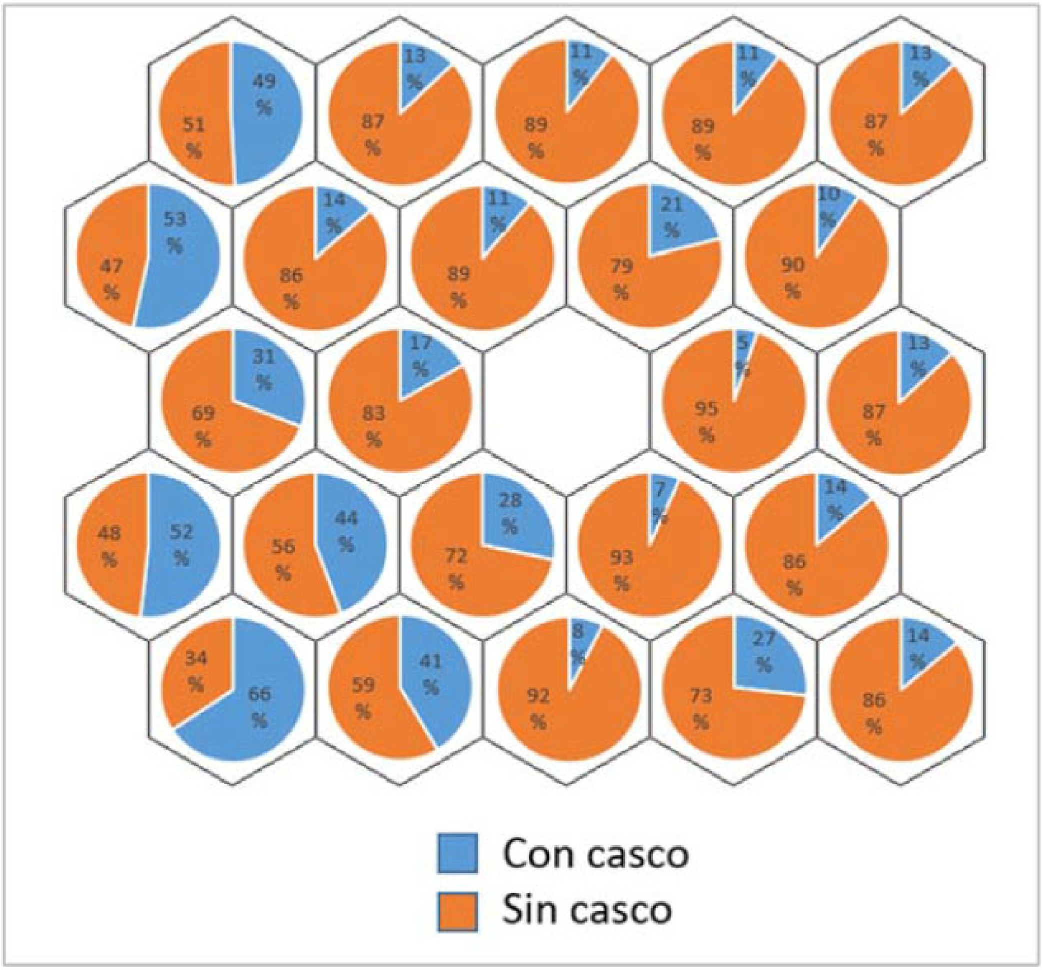

Figura 11: Mapa de uso del casco (en porcentaje) en el mapa SOM. (Fuente: Elaboración propia a partir de las BGAs).

3.1 Aceptación o rechazo de las hipótesis de trabajo

A continuación, se transcriben 3 de las 10 hipótesis formuladas en el proyecto de investigación seleccionadas para el análisis con los mapas SOM en éste trabajo.

- H(a). "Los ámbitos de uso de las bicicletas: urbano e interurbano, así como de diferentes infraestructuras en cada uno de ellos (vías convencionales, vías de alta capacidad, intersecciones, etc.) ejerce influencia en los patrones accidentológicos de los ciclistas".

Para verificar o rechazar la H(a) se han realizado el estudio de la evolución temporal de la accidentalidad por tipo de vía y zona de los datos contenidos en las BGAs, así como el ajuste de mapas SOM para la identificación de los patrones de accidentes según la zona. Hay mayor severidad en accidentes en vías interurbanas.

Los resultados parciales de los resultados mostrados contribuyen a la verificación de la hipótesis H(a). Otros mapas SOM y los patrones multivariantes encontrados permiten concluir que se ha verificado la hipótesis H(a).

- H(b). "Los diferentes colectivos de ciclistas: grupos de edad y género, presentan, también patrones accidentológicos diferentes".

La verificación o rechazo de la hipótesis H(b) se ha abordado mediante el estudio estadístico de las BGAs y la identificación de patrones por sexo y rangos de edad con los mapas SOM. Hay más ciclistas varones y mayores en accidentes interurbanos que mujeres y más mujeres de hasta 50 años en accidentes urbanos.

Los resultados parciales de los resultados mostrados contribuyen a la verificación de la hipótesis H(b). Otros mapas SOM y los patrones multivariante encontrados permitenconcluir que se ha verificado la hipótesis H(b).

- H (c). El uso de medios de protección adecuados, especialmente del casco, ejerce influencia en la severidad de las lesiones en caso de accidente.

Para esta hipótesis (H(c) la variable uso – no uso de casco se abordó en el estudio estadístico de las BGAs y en la identificación de patrones mediante los mapas SOM. Los patrones complejos de SOM indican que el tipo de vía y zona influyen en esta variable de comportamiento de los ciclistas.

Hay diferencias entre entorno urbano-interurbano. Los mapas SOM identifican comportamientos multivariantes y el sexo y la edad son factores relevantes en el patrón de uso-no uso de casco. Su no uso resulta en accidentes más severos. Se considera verificada la hipótesis H(c).

4. CONCLUSIONES

La implicación de bicicletas en accidentes de tráfico (en % del total de vehículos implicados) tiene tendencia creciente tanto en carretera como en ámbito urbano. La implicación de bicicletas en accidentes en vías urbanas fue superior al de carretera en la serie completa de años y su tasa de crecimiento es más acelerada que la de vías interurbanas, lo que es un indicador de su mayor uso en las ciudades por la incorporación de la bicicleta como medio de desplazamiento cotidiano.

Aunque el porcentaje de víctimas mortales en accidentes de tráfico con implicación de bicicletas en el periodo 1993-2018 según zonas (en términos relativos al total de víctimas fatales en accidentes de tráfico), ha aumentado en zona urbana hasta el 5,7% frente al 3,4% en interurbano en el año 2018.

La reducción observada en la mortalidad total (-67% entre 2003 y 2018) es mayor que la de ciclistas (-25,6% en el mismo período) y marca una línea de trabajo enfocada en este colectivo para una mayor contribución a la mejora de la seguridad vial en España.

A través de los mapas SOM se han identificado patrones de accidentes de ciclistas, y se concluye que la zona de ocurrencia y el sexo son factores relevantes en la identificación de patrones en accidentes y severidad de lesiones de ciclistas.

La lesividad de los ciclistas en accidentes urbanos es menor que la que se observa en la zona interurbana.

El porcentaje de mujeres ciclistas es reducido respecto al de hombres tanto en zona interurbana como urbana, siendo esta diferencia mayor en vías interurbanas.

El no uso de casco deviene en mayor lesividad y hay diferencias en el uso en entorno urbano e interurbano que requiere medidas de vigilancia adecuadas.

AGRADECIMIENTOS

Este trabajo ha sido posible gracias a la Fundación Eduardo Barreiros a través de la Cátedra Universidad – Empresa “Eduardo Barreiros Automóvil y Movilidad Sostenible”. Los autores agradecen a la DGT por el acceso a las Bases de datos de accidentes y a la Comunidad de Madrid por su financiación parcial que, a través del programa SEGVAUTO 4.0-CM (P2018 / EMT-4362) ha contribuido a su desarrollo y difusión.

RESUMEN

La gran Pandemia mundial, como consecuencia de la COVID-19, no sólo ha afectado a nuestra salud sino a toda nuestra forma de vivir la vida. El Gobierno ha propuesto distintas medidas con el objetivo de reducir su expansión entre las que se encuentran el mantenimiento de una distancia mínima interpersonal, el uso de mascarilla en espacios cerrados y la higiene constante.

Estas imposiciones, unidas a la posibilidad de teletrabajar ofertada por algunas empresas y a la responsabilidad personal han modificado los patrones de comportamiento en cuanto a la movilidad urbana se refiere.

La población ha tendido a reducir sus viajes, priorizando determinados destinos y, en algunos casos, modificando su elección modal habitual hacia modos individuales en vez de colectivos. Este cambio de tendencia es factible en ciudades de tamaño pequeño y mediano en las que las distancias a recorrer no son relativamente excesivas y los usuarios tienen la opción de desplazarse a pie o en bicicleta en vez de usar el autobús o decantarse por el uso del vehículo privado.

El objetivo de este artículo es analizar la variación en el flujo de tráfico desde un estadio prepandémico al estadio actual en una ciudad de tamaño medio. Para ello, se han tomado mediciones mediante un radar, en la ciudad de Burgos, en una serie de puntos de referencia situados en vías de zonas de alta y baja demanda de tráfico y se han comparado con datos de IMD y velocidad obtenidos en esas mismas secciones respetando la estacionalidad, los días y las horas de la toma de datos para comprobar la variación sufrida.

El análisis de los resultados ha permitido comprobar que las medidas impuestas, como el teletrabajo y las medidas de distanciamiento social, han tenido repercusión en la movilidad, reduciendo la intensidad de tráfico de la ciudad de Burgos y hacen reflexionar sobre si estos resultados obtenidos se mantendrán a lo largo del tiempo o evolucionarán hacia los valores prepandémicos.

1. INTRODUCCIÓN

La pandemia mundial del coronavirus SARS-CoV-2, conocido como COVID-19, ha tenido, y sigue teniendo, un gran impacto en la vida cotidiana a nivel mundial. Ha conseguido alterar los patrones de comportamiento referentes a la vida laboral, vida familiar y al modo de desplazarnos o de hacer compras intentando evitar riesgos en todo momento (Eisenmann et al., 2021; Hörcher et al., 2021; Fischer and Winters, 2021; Cazelles et al., 2021; Barbieri et al., 2021; Aloi et al., 2020).

En la primavera de 2020, con objeto de reducir la propagación del COVID-19, se cerró la educación y el sector del ocio y restauración. El teletrabajo y el comercio on line pasaron a formar parte de nuestro día a día y la mascarilla y el gel hidroalcohólico se alzaron como accesorios indispensables para reducir la propagación del virus (Abboah-Offei et al., 2021).

Las medidas de presión impuestas durante el estado de alarma se fueron suavizando durante los distintos intentos de desescalada lo que derivó en distintos repuntes de los casos que llevaron a sufrir distintas olas de contagios como justifican Cazelles et al. (2021). En el caso particular español, se sufrieron hasta un total de cinco olas de contagio, con picos en los meses de marzo, septiembre y octubre de 2020 así como enero y abril de 2021 (RNVE, 2021).

La posibilidad de teletrabajo ofertada por algunas empresas y la responsabilidad personal han llevado a la población a reducir sus viajes, priorizando determinados destinos y, en algunos casos, modificando su elección modal habitual hacia modos individuales en vez de colectivos.

Este cambio de tendencia es especialmente factible en ciudades de tamaño pequeño y mediano en las que las distancias a recorrer no son relativamente excesivas y los usuarios tienen la opción de desplazarse a pie, en bicicleta o patinete en vez de usar el autobús o decantarse por el uso del vehículo privado.

El miedo de los usuarios a sufrir contagios en el transporte público o la propia percepción de inseguridad ha derivado en una reducción a nivel mundial del transporte público colectivo (Barbieri et al., 2021). Ese traspaso hacia modos de transporte no colectivos ha suscitado muchísimo interés en la comunidad científica.

Desde Bohman et al. (2021) que desarrolló su investigación en Suecia, país que no sufrió medidas de confinamiento estricto hasta múltiples estudios realizados por todo el mundo como los de Basu and Ferreira (2021), Jiao and Azimian (2021), Souch et al. (2021) en Estados Unidos, Fischer and Winters (2021) en Canadá, Dingil and Esztergár-Kiss (2021) y Nikitas et al. (2021) y Dingil and Esztergár-Kiss (2021) en el Reino Unido, Eisenmann et al. (2021) y Anke et al. (2021) en Alemania, Borkowski et al. (2021) y Wielechowski et al. (2020) en Polonia, Cazelles et al. (2021) en Francia, Aloi et al. (2020) y Orro et al. (2020) en España o Campisi et al. (2020) y Barbarossa (2020) en Italia.

Muchos de estos estudios han detectado que la migración hacia otro modo de transporte es dependiente de los grupos socio demográfico y que, por tanto, han presentado como variables destacables el sexo, edad, el poder adquisitivo, el puesto de trabajo, el nivel de estudios y el lugar de residencia contribuyendo a la estigmatización del transporte público (Bohman et al., 2021; Borkowski et al., 2021; Hasselwander et al., 2021; Fischer and Winters, 2021; Barbieri et al., 2021; Campisi et al., 2020; Dingil and Esztergár-Kiss, 2021). En Burgos, por ejemplo, donde la mayor parte de los usuarios del transporte público está compuesto por jóvenes, ancianos y mujeres de edad media, el 41% de los burgaleses reconoció que había reducido su uso de los autobuses urbanos durante los últimos meses (MOOVIT, 2021).

Por tanto, como algunos autores han remarcado, estamos ante una gran oportunidad para modificar la movilidad urbana hacia alternativas más sostenibles e incluso podría ser el momento de evolucionar hacia una ciudad planificada de manera más sostenible (Basu and Ferreira, 2021; Eisenmann et al., 2021; Awad-Núñez et al., 2021; Fischer and Winters, 2021; Campisi et al., 2020; Nikitas et al., 2021).

Algunas ciudades, han aprovechado las desescaladas para promover acciones en favor de una reorganización urbana llegando a restringir el tráfico rodado en determinadas calles para permitir el distanciamiento social (Barbarossa, 2020). Este tipo de iniciativas ha conseguido promover los desplazamientos andando, en bicicleta (también en bicicleta de préstamo) y patinete eléctrico, devolviendo la ciudad a los usuarios más vulnerables. Según MOOVIT (2021), Burgos sería una de las tres ciudades españolas en las que más se usa ha usado la micromovilidad en la primera mitad de 2020.

Parece presumible pensar que no toda la migración del transporte público se haya producido hacia modos de transporte sostenibles en contra de las políticas de sostenibilidad que defienden las ciudades europeas. Toda la inversión, tanto económica como humana, realizada en los últimos años, en favor de la potenciación de soluciones eco-responsables, puede llegar a perderse como consecuencia de la sensación de desprotección e inseguridad sufrida al desplazase en transportes públicos colectivos (Orro et al., 2020; Campisi et al., 2020).

Sin embargo, distintos autores han confirmado que tanto en los periodos de confinamiento estricto como en los periodos posteriores, el uso del automóvil se ha visto reducido en base al descenso de los niveles de contaminación ambiental experimentados (Crowley et al., 2021; Querol et al., 2021; Griffiths et al., 2021; Aloi et al., 2020).

El presente artículo tiene por objeto analizar qué es lo que ha sucedido con el tráfico rodado en la ciudad de Burgos una vez alcanzada la "nueva normalidad" justo antes de levantarse el estado de alarma.

Puesto que la nueva ordenanza municipal de tráfico de Burgos (AYTO BURGOS, 2020) entró en vigor en el 24 de enero de 2020, y comparte con la MPR (2020) las limitaciones de velocidad a 30 km/h en calzadas de una vía para cada sentido de circulación, también se ha aprovechado para comprobar qué es lo que está sucediendo con las velocidades en las vías urbanas burgalesas.

2. METODOLOGÍA Y CASO A ESTUDIO

Como ya se ha argumentado, algunos autores han comprobado que se ha producido en algunas ciudades un traspaso de usuarios del transporte público hacia, principalmente, el vehículo privado. Sin embargo, también se ha detectado que en algunos casos el volumen total de vehículos que circulan por las vías urbanas ha descendido. Por tanto, este artículo se centra en averiguar qué es lo que ha sucedido con el tráfico en la ciudad Burgos, ciudad de tamaño medio de 180.000 habitantes situada en la parte norcentral de la península ibérica.

Para ello, se han tomado mediciones mediante un radar móvil en distintos puntos de referencia de la ciudad en los que Gonzalo-Orden et al. (2018) ya habían tomado medidas antes de la pandemia en 2018 (valores prepandémicos) y así comprobar la variación experimentada tras la vuelta a la nueva normalidad (valores en pandemia). Las mediciones fueron tomadas respetando la estacionalidad y la variabilidad semanal. Es decir, se tomaron medidas en el primer cuatrimestre de 2021 los mismos días de la semana y mes en los que se habían realizado en el estudio anterior para así poder compararlos.

Los puntos de medición se dividieron en cuatro tipologías diferentes:

- Tipo 1: hace referencia a vías urbana de alta capacidad
- Tipo 2: hace referencia a zonas de conexión urbana
- Tipo 3: hace referencia a zonas de carácter residencial y zonas de paso
- Tipo 4: Hace referencia a zonas residenciales principalmente periféricas.

A continuación, se detallan los distintos puntos medidos.

2.1 Tipo 1

Esta zona a estudio comprende la Avenida de Caja Círculo (carretera del cementerio) (Fig.1). Se trata de una vía de alta capacidad de dos carriles para cada sentido de circulación que no ha experimentado reducción en su velocidad como consecuencia de la entrada en vigor de la nueva ordenanza de circulación burgalesa.

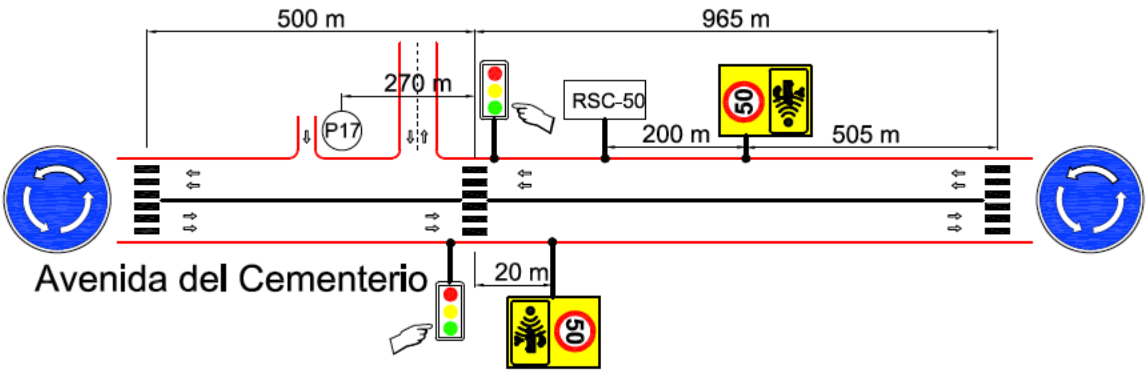

Figura 1: Puntos analizados en zonas tipo 1.

2.2 Tipo 2

La zona a estudio comprende la Av. Arlazón (Fig. 2), Av. Palencia (Fig.3) y la calle Pozanos (Fig.4). Los puntos medidos tanto la Av. Arlanzón (Fig. 2) como la Av. Palencia (Fig. 3) han visto reducida su velocidad a 30 km/h, respecto a la situación de 2018, por tratarse de tramos de un solo carril para cada sentido de circulación.

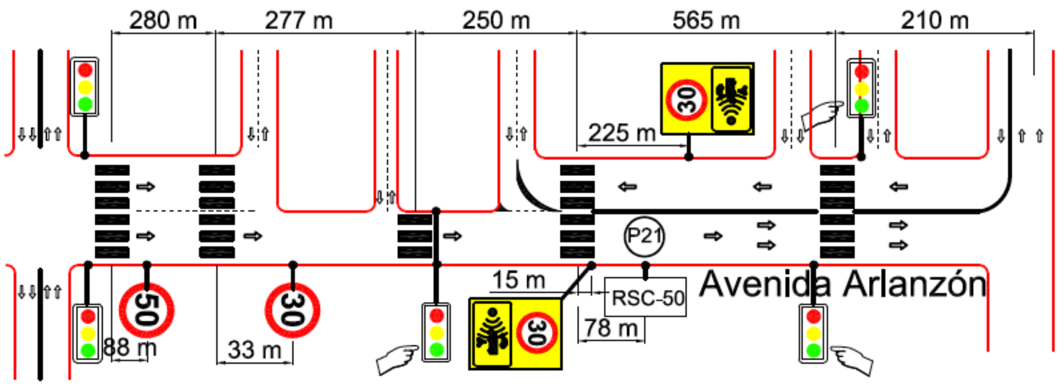

Figura 2: Puntos analizados en Avenida Arlanzón (Zona tipo 2).

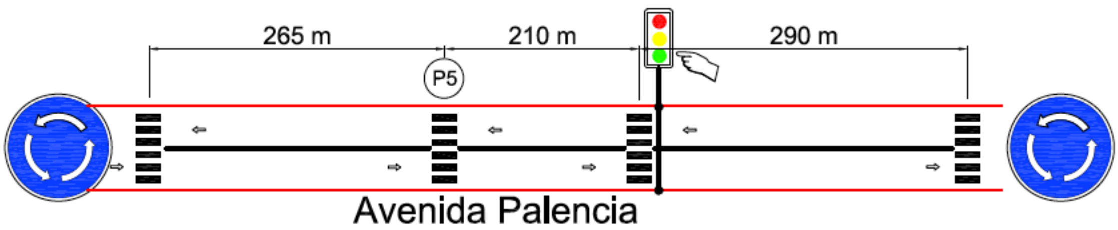

Figura 3: Puntos analizados en Avenida Palencia (Zona tipo 2).

Respecto a la calle Pozanos (Fig. 4), se han realizado modificaciones en su geometría en su primer tramo (Gonzalo-Orden et al., 2016), reduciéndose de dos a un carril para cada sentido. Respecto a la velocidad de esta vía, el tramo a estudio ya estaba reducido a 30 km/h por tratarse de una zona escolar por lo que no ha experimentado ninguna variación.

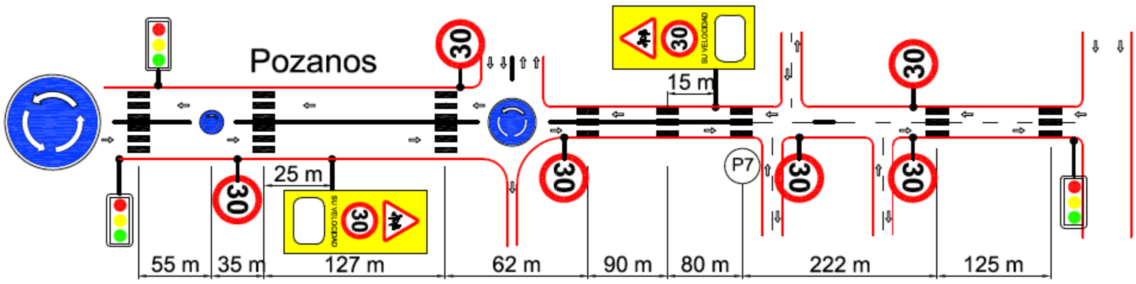

Figura 4: Puntos analizados en Calle Pozanos (Zona tipo 2).

2.3 Tipo 3

Esta zona recoge las vías que pertenecen a zonas residenciales de la zona centro en las que las vías no solo dan servicio a residentes si no que por su carácter central sirven también como vías de paso entre zonas. En esta categoría estarían los puntos pertenecientes a las calles Jose Luis Santamaría y el Carmen (Fig. 5) y el Paseo de la Isla (Fig. 6). Como puede verse en los esquemas, son vías de un solo carril para cada sentido de circulación por lo que su velocidad actualmente está limitada a 30 km/h.

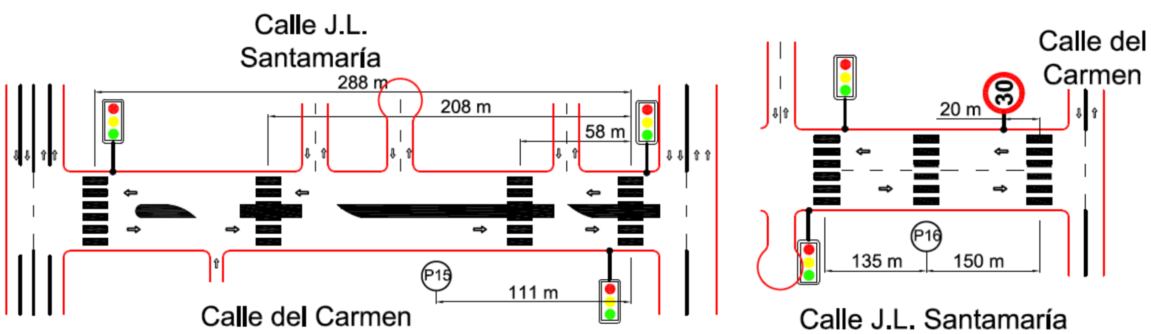

Figura 5: Puntos analizados en las Calles J. L. Santamaría y El Cármen (Zona tipo 3).

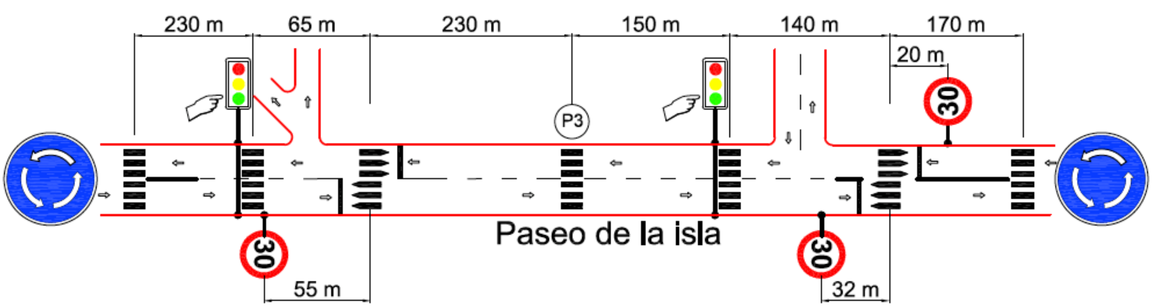

Figura 6: Puntos analizados en Paseo de la Isla (Zona tipo 3).

2.4 Tipo 4

La zona a estudio comprende dos puntos pertenecientes a zonas residenciales periféricas en las que el paso de vehículos es principalmente de residentes (Fig. 7). De igual manera a los casos anteriores, su geometría hace que la velocidad actual en esos puntos se haya reducido a 30 km/h.

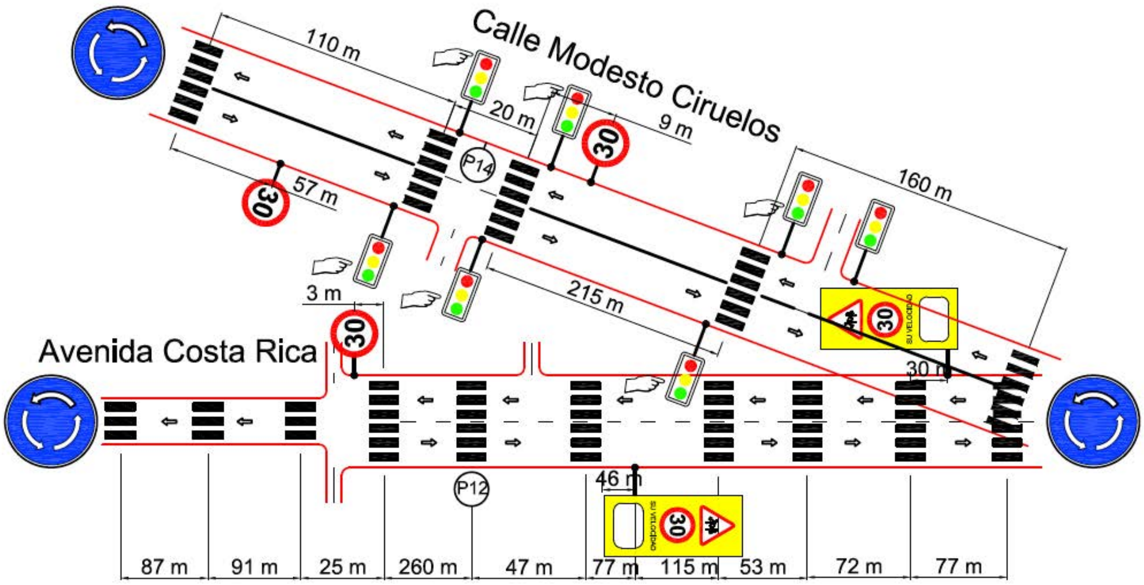

Figura 7: Puntos analizados en Zona tipo 4.

3. RESULTADOS Y DISCUSIÓN

La tabla 1 recoge los valores medidos en los puntos seleccionados en un periodo prepandémico (Gonzalo-Orden et al., 2018) y en el primer cuatrimestre del 2021 cuando todavía no se ha levantado el estado de alarma por la pandemia del COVID-19.

Año	Zona a estudio	1	2			3			4	
	Punto medido	P17	P21	P5	P7	P15	P16	P3	P12	P14
2018	Intensidad de tráfico (Veh/h)	1326	416	604	753	460	251	430	72	240
	Velocidad V_{50} (km/h)	59	44	55	42	29	40	45	44	56
	Velocidad V_{85} (Km/h)	71	50	64	50	39	50	55	55	67
	Velocidad media (Km/h)	60	45	54	41	29	39	45	40	55
	Lím. Velocidad	50	50	50	30	50	50	50	50	50
2021	Intensidad de tráfico (Veh/h)	995	285	553	491	253	236	406	78	106
	Velocidad V_{50} (km/h)	35	34	40	30	31	29	42	41	50
	Velocidad V_{85} (Km/h)	43	42	48	38	40	37	51	50	64
	Velocidad media (Km/h)	36	35	40	31	31	29	42	39	50
	Lím. Velocidad	50	30	30	30	30	30	30	30	30
2018 – 2021	% Reducción Intensidad (Veh/h)	24,96	31,49	8,44	34,79	45,00	5,98	5,58	-8,33	55,83
2018 – 2021	% Reducción velocidad (km/h)	40,00	22,22	25,93	24,39	-6,90	25,64	6,67	2,50	9,09

Tabla 1: Valores de las mediciones para los distintos periodos seleccionados.

En ésta se recogen los valores de Intensidad, V50, V85, Vm y la limitación máxima de velocidad para dichos puntos así como la variación experimentada entre 2018 y 2021.

Como puede verse tanto en la tabla 1 como en la Fig. 8, la intensidad de tráfico ha sufrido una reducción en todos los puntos salvo en el P12 en el que la intensidad prácticamente se ha mantenido.

Como puede verse en la Fig. 8, las zonas 1 a 4 se encuentran ordenadas de mayor a menor volumen medio de tráfico mientras que en la Fig. 9 muestra el % de reducción de intensidad experimentado entre 2018 y 2021.

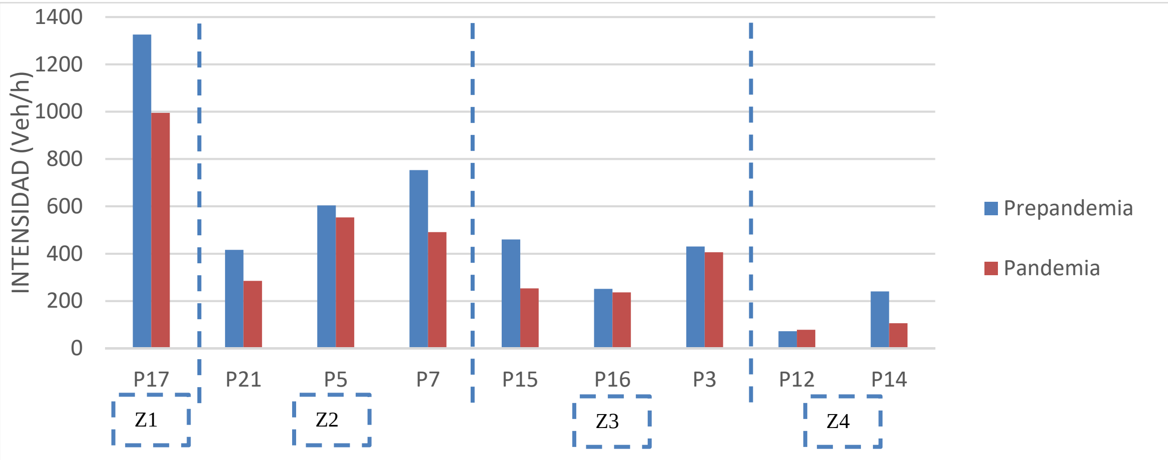

Figura 8: Intensidad horaria para los puntos medidos.

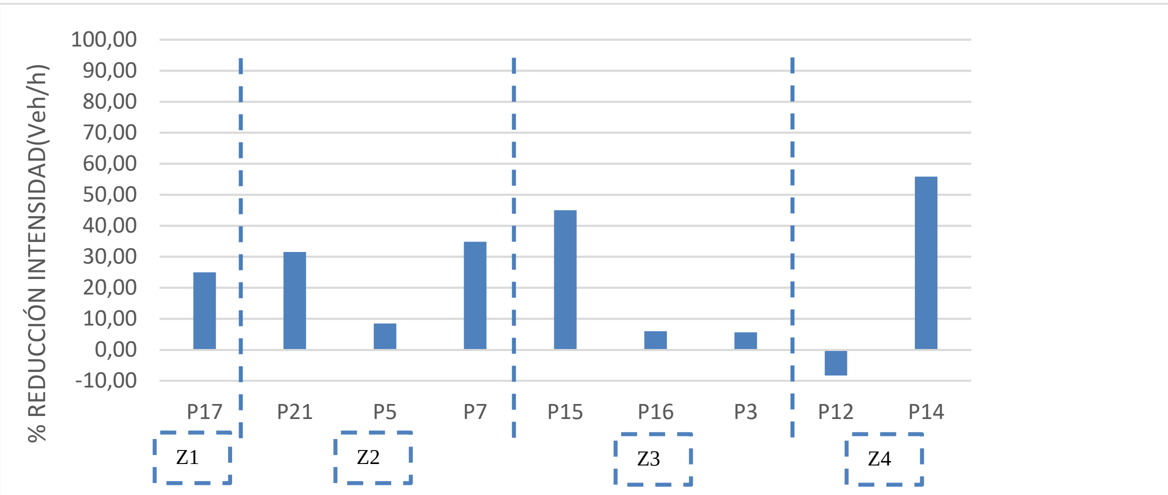

Figura 9: % de reducción de la Intensidad horaria respecto a 2018.

De manera general puede afirmarse que el porcentaje de reducción de la intensidad de tráfico experimentado en la ciudad de Burgos es del 22,64%. Discretizando por la limitación zonal predefinida, se obtiene que la zona 1 ha experimentado un porcentaje de reducción del 24,96%, la zona 2 ha experimentado un porcentaje de reducción del 18,85%, la zona 3 un porcentaje del 18,85% mientras que la zona 4 un 23,75%.

Como ya se ha comentado, la entrada en vigor de la nueva ordenanza de movilidad burgalesa (AYTO BURGOS, 2020) modificó los límites de velocidad impuestos para la mayor parte de las secciones analizadas por lo que es posible comprobar el cumplimiento de dichos límites. Tanto la limitación anterior como la actual quedan recogidas en la tabla 1. La Fig 10 recoge la variación experimentada en km/h tanto para la V_{50} como para la V_{85} mientras que la Fig. 11 recoge la variación porcentual de la velocidad media respecto a 2018.

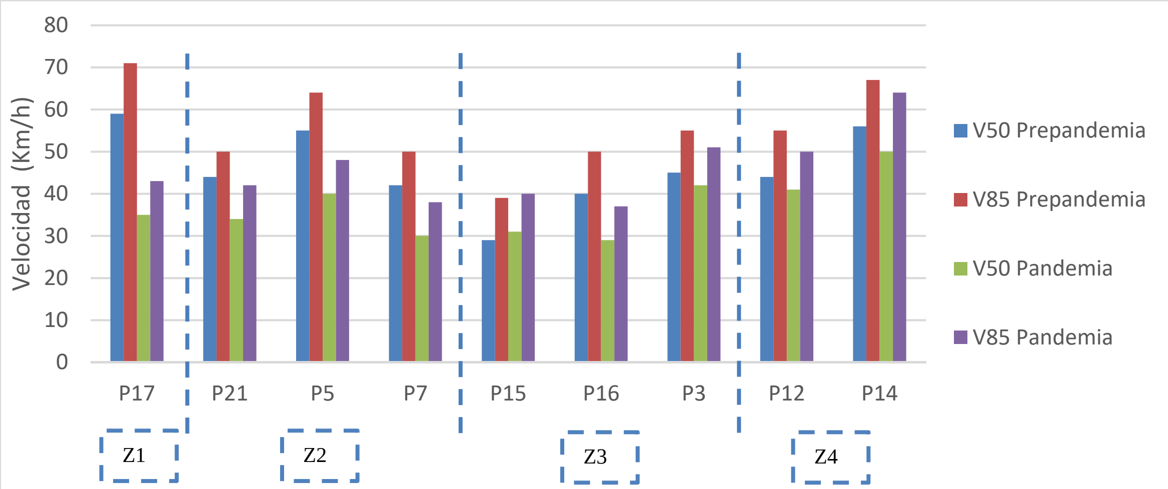

Figura 10: Valores de V50 y V85 para los años 2018 y 2021.

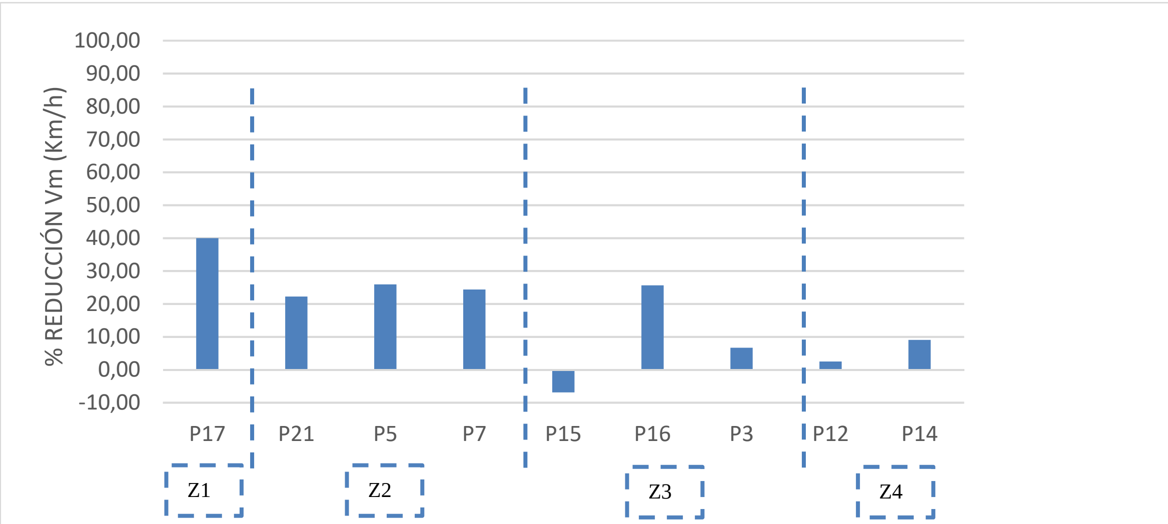

Figura 11: % de reducción de la velocidad media (Vm) para los años 2018 y 2021.

Salvo los P17 y P7, el resto de puntos han visto limitada su velocidad al nuevo valor de 30 km/h. Como puede verse en la figura 10, la V_{50} se encuentra por encima de ese valor en la mayor parte de las secciones analizadas. Según la figura 11, las vías que más han sufrido un descenso en su velocidad serían las catalogadas como vías de conexión urbana (zona 2).

Como anécdota, es necesario destacar que las mediciones en el punto P17 se realizaron con posterioridad a una campaña de radar en la que se impuso un elevado número de sanciones por exceso de velocidad.

Finalmente, puesto que las variables analizadas habían sido Intensidad, velocidad media, porcentaje de reducción de intensidad y porcentaje de reducción de la velocidad media, se trató de encontrar alguna relación entre estas variables para las cuatro zonas propuestas. Sin embargo, y en vase a los gráficos de las figuras 12 a 14 no es posible relacionar las mismas con los valores y el número de secciones analizadas.

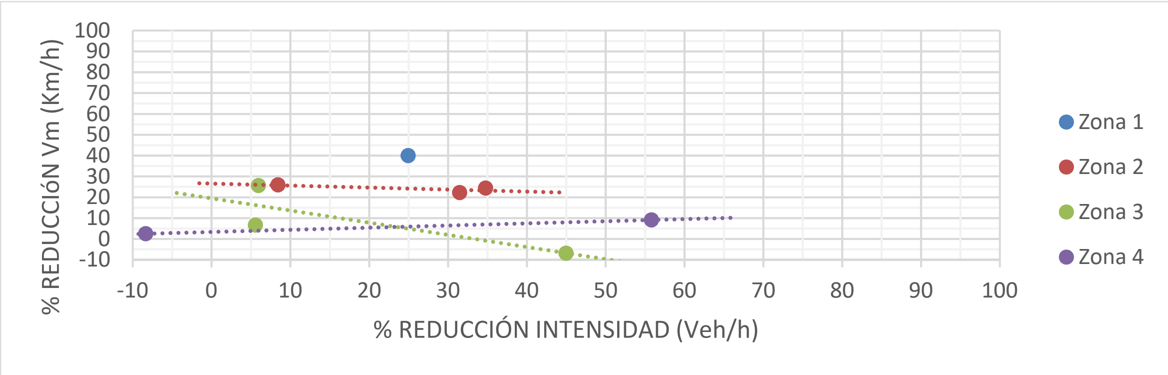

Figura 12: Relación entre el % de reducción de la intensidad y el % de reducción de la Vm para las distintas zonas analizadas.

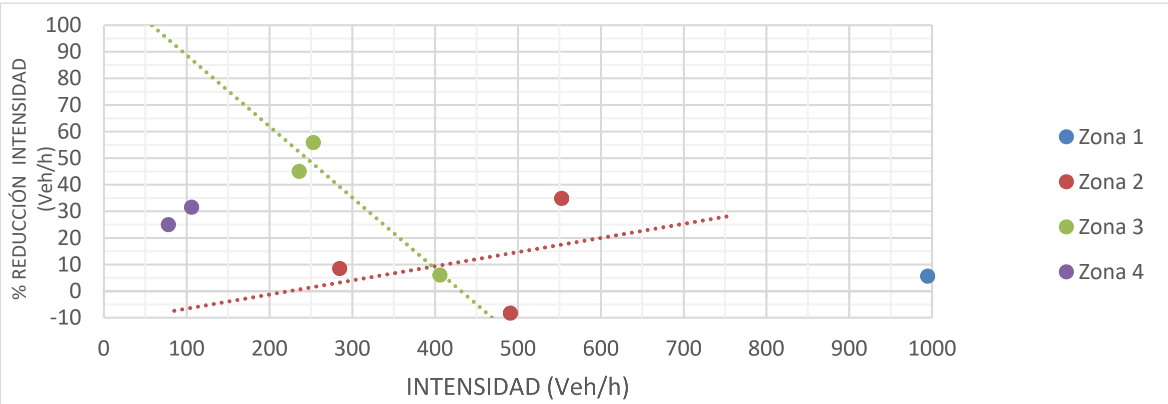

Figura 13: Relación entre la intensidad y el % de reducción de la Intensidad para las distintas zonas analizadas.

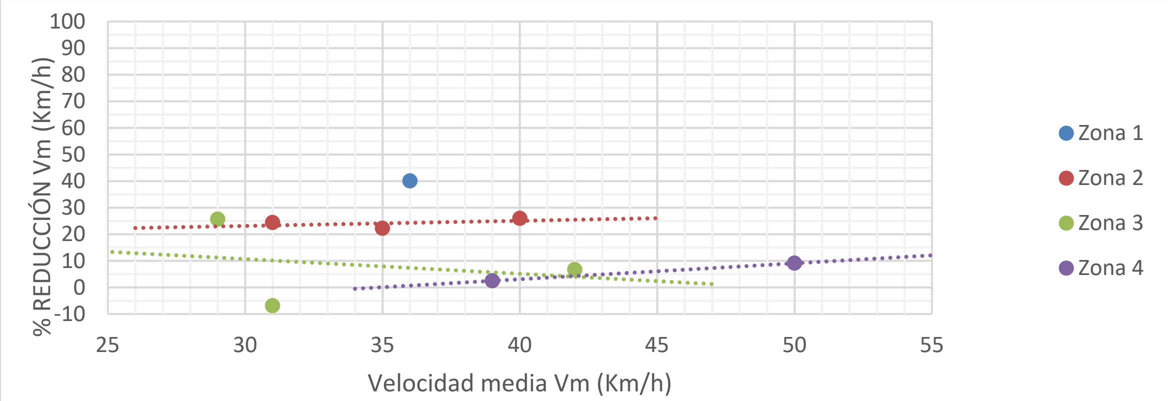

Figura 14: Relación la Vm y el % de reducción de la Vm para las distintas zonas analizadas.

4. CONCLUSIONES

Del análisis de resultados no puede concluirse que existan evidencias de relación entre la intensidad de tráfico y Velocidades medias entre periodos pre y pandémico para las vías de la ciudad de Burgos analizadas que pueden clasificarse como vías urbanas de alta capacidad (zona 1), zonas de conexión urbana (zona 2), zonas de carácter residencial y zonas de paso (zona 3) y zonas residenciales principalmente periféricas (zona 4).

Sin embargo, sí que es posible afirmar que, de manera general, el número de viajes realizados por las vías urbanas analizadas ha descendido en un 22,64% respecto a valores prepandémicos y que la nueva velocidad máxima aplicable a vías de un solo carril y sentido parece no estar respetándose, siendo las vías que más han experimentado una reducción e velocidad las que pueden ser consideradas como vías de conexión urbana.

A diferencia de lo que *a priori* se pudiera esperar, la vuelta a la nueva normalidad no ha supuesto la recuperación de los niveles de desplazamiento por carretera previos a la pandemia. Puesto que los viajes en autobús, el principal transporte público que dispone Burgos, se han visto importantemente reducidos cabe preguntarse ¿qué es lo que ha sucedido?

Está claro que la oportunidad de continuar con el teletrabajo ofertada por algunas empresas, la reducción de viajes autoimpuesta por la propia población como medida racional para evitar la propagación del virus y la floración de bicicletas y patinetes eléctricos en nuestras calles han contribuido en esa reducción de viajes.

A medida que las ciudades avanzan hacia la recuperación con la distribución de las vacunas y una vez olvidado el virus, desconocemos si este cambio en el comportamiento de los ciudadanos tendrá un efecto resiliente. Lo que sí es cierto es que antes de que desaparezca este efecto de nuestras memorias estamos ante una gran oportunidad para aprender de la experiencia y proponer soluciones de una Re-evolución verde de cambio hacia modos más sostenibles.

MITIGACIÓN DEL IMPACTO DE LA IMPLEMENTACIÓN DEL ‘PLATOONING’ DE CAMIONES EN LAS VISIBILIDADES DISPONIBLES EN AUTOPISTAS

Daniel Pastor-Serrano

Alfredo García
Catedrático, GIIC, Universitat Politècnica de València, España

RESUMEN

El ‘*platooning*’ de camiones está cada vez más próximo. Muchos expertos ven en esta tecnología la solución a gran parte de los problemas del transporte de mercancías por carretera. Sin embargo, el ‘*platooning*’ de camiones provocará una reducción de la visibilidad en los adelantamientos en curvas a derechas que deberá ser compensada de alguna manera. En ese sentido, esta ponencia se plantea como una aplicación práctica de la investigación previa sobre la influencia del espaciamiento entre camiones del ‘*Platooning*’ en la visibilidad en curvas a derechas, en la que se demostró la gran afección a la visibilidad causada y se confirmó la necesidad de plantear nuevas soluciones al problema planteado.

Para todo ello, se pretende llevar a cabo un análisis de distintas alternativas que permitan minimizar el efecto de los ‘*platoons*’ de camiones en la seguridad vial. Dichas alternativas van desde las más conservadoras, que pretenden corregir el problema, hasta otras más innovadoras que pretenden evitar el problema. Lo hacen aprovechando al máximo los recursos disponibles en la vía que podrían dejar de ser necesarios gracias al incremento de la conducción autónoma.

Las alternativas planteadas giran en torno a tres ejes: actuaciones sobre la infraestructura, actuaciones centradas en la conectividad y actuaciones centradas en la automatización. Adicionalmente, se ha cuantificado, cuando ha sido posible, el nivel de mitigación del impacto en visibilidad de los ‘*platoons*´ de camiones.

1. INTRODUCCIÓN

Tras años de desarrollo, la conectividad y automatización de los vehículos comienza a ser una realidad. La importancia del transporte de mercancías por carretera y su impacto en la economía europea (Janssen *et al.*, 2015) han llevado a que gran parte de los esfuerzos de modernización se hayan centrado en este ámbito. En ese sentido, la creación de corredores inteligentes que permitan la mejora de la industria logística ha sido uno de los ejes principales del desarrollo de los sistemas inteligentes de transporte (Oonk, 2016; Tavasszy y Janssen, 2016).

En este contexto, se conoce como ‘*platooning’* a la posibilidad de unir virtualmente varios vehículos. Aunque los orígenes se remontan a los años 80 y 90 (Sheikholeslam y Desoer, 1990), ha sido en los últimos años cuando se han planteado diferentes proyectos para desarrollarlo (Robinson *et al.*, 2010; Bergenhem *et al.*, 2012; Willemsen *et al.*, 2018). Estos proyectos incluyen enfoques muy diferentes, que varían desde la consideración de flujos de tráfico mixtos hasta otros que se centran en la unión virtual de vehículos pesados de mercancías (Bergenhem *et al.*, 2010). En este caso, este artículo se centra en el ‘*platooning*’ de camiones entendido como un conjunto de vehículos pesados de transporte de mercancías que circulan unidos virtualmente con poca separación entre ellos (Janssen *et al.*, 2015).

Se contemplan tres niveles claramente diferenciados relativos al ‘*platooning’* de camiones (Janssen *et al.*, 2015). Este hecho lleva a la necesidad de estudiar los efectos del ‘*platooning*’ en cualquiera de sus tres fases de desarrollo. El primer nivel implica que los camiones están conectados y en seguimiento automático entre ellos. Sin embargo, la presencia del conductor sigue siendo necesaria en todos los vehículos que forman el ‘*platoon’* para reaccionar ante cualquier eventualidad. En cuanto al segundo nivel, éste es análogo al anterior pero no requiere atención completa de los conductores que se encuentren en los vehículos en seguimiento. De esa forma, el tiempo de estos conductores podría conmutar como tiempo de descanso. El último nivel implica la no necesidad de conductor en los vehículos que se encuentran en seguimiento.

En cuanto a las ventajas del ‘*platooning’* de camiones, la mayoría se centran en el ámbito económico. En ese sentido, la eficiencia energética es una de sus principales ventajas. La posibilidad de minimizar la separación entre los camiones podría llevar a descensos en los consumos de combustible de hasta el 13% (Robinson *et al.*, 2010; Alam, 2014). Por otra parte, la creciente automatización podría derivar en un incremento de la productividad y, con ello, a la disminución de la necesidad de recursos humanos (Jacob y Arbeit de Chalendar, 2015; Tavasszy y Janssen, 2016).

Los ‘*platoons*’ de camiones podrían circular con separaciones de tan solo 0.3 s (Janssen *et al.*, 2015). Esta capacidad provocará que los ‘*platoons*’ de camiones circulen con separaciones muy inferiores a las de los camiones que viajan en convoy en la actualidad. Con ello, se logra una de las principales ventajas de esta tecnología: el mencionado ahorro de combustible y de emisiones. Sin embargo, el reducido espaciamiento entre los camiones es también el causante de una de sus principales debilidades: la afección a la visibilidad que podría provocar. En ese sentido, la visibilidad durante maniobras de adelantamiento a ‘*platoons’* de camiones en autovías, autopistas y carreteras multicarril podría verse muy limitada dado que la limitación de visibilidad ya no estaría impuesta por un único camión sino por un conjunto de camiones cuya longitud podría superar los 50 m (Janssen *et al.*, 2015). En la Figura 1 se muestra la situación de afectación a la visibilidad tratada.

Figura 1: Efecto de apantallamiento en las maniobras de adelantamiento a un grupo de camiones

Los modelos tradicionales para evaluar la visibilidad (Hassan *et al.*, 1995; Lovell, 1999) no proporcionan resultados satisfactorios para la evaluación de la visibilidad en este caso tan concreto, pues no son capaces de incluir las particularidades del '*platoon*' de camiones. Tampoco permiten considerar las particularidades del tráfico mixto, pues los vehículos que interactúan sobre la calzada podrían estar conectados o incluso automatizados.

Dada la necesidad de estimar el impacto de los '*platoons*' de camiones en la visibilidad de autopistas, autovías y carreteras multicarril, Pastor-Serrano y García (2020) desarrollaron un modelo que proporciona la visibilidad en cada instante del adelantamiento a un '*platoon*' de camiones, tanto para un coche con conducción humana como para un coche automatizado.

El modelo de cálculo de la visibilidad desarrollado permitió confirmar la gran afectación que provocarían los '*platoons*' de camiones en la seguridad vial. En ese sentido, se confirmó la necesidad de adaptar la infraestructura en caso de que no se desease limitar los '*platoons*' de camiones a vías con radios mínimos de 2500 m (Pastor-Serrano y García, 2020). Esto se debe a que la limitación de visibilidad provocada por el 'platoon' de camiones lleva a la necesidad de limitar la velocidad de la curva por visibilidad mucho más allá de lo requerido en la actualidad por su propia geometría.

Por todo ello surge esta ponencia que, de forma aplicada, pretende proponer diferentes soluciones dirigidas a compensar la reducción de visibilidad provocada por los ‘*platoons*’ de camiones. En ese sentido, se desarrollan a lo largo de esta ponencia propuestas centradas en tres aspectos diferentes: la infraestructura, la automatización y la conectividad.

2. ACTUACIONES CENTRADAS EN LA INFRAESTRUCTURA

Ante el problema de visibilidad que, con seguridad, los ‘*platoons*’ de camiones causarán en las carreteras, se plantean diversas soluciones. Las primeras de ellas se centran en actuar sobre la infraestructura. En ese sentido, este tipo de soluciones tienen como objetivo maximizar la separación lateral entre los ‘*platoons*’ de camiones y los vehículos que se encuentran realizando la maniobra de adelantamiento.

Las actuaciones centradas en la infraestructura deben prestar especial atención, en todo caso, a su viabilidad económica. Deben ser soluciones que exploten al máximo las posibilidades que ofrecen las infraestructuras en su condición actual. Por ello, se debe buscar el equilibrio entre la mitigación de la problemática detectada y su viabilidad. En ese sentido, es posible que las actuaciones sobre la infraestructura que no requieran de grandes inversiones se limiten a compensar el problema de forma parcial.

2.1 Separador entre carriles

En la actualidad, la circulación de ‘*platoons’* de camiones se plantea, principalmente, por autovías, autopistas y vías multicarril. Este tipo de vías, sobre todo las dos primeras, presentan con frecuencia secciones trasversales generosas que proporcionan cierto margen de actuación. El objetivo de esta propuesta es aprovechar al máximo la sección de ese tipo de vías para, como se ha mencionado, maximizar la separación lateral entre ‘*platoons’* de camiones y vehículos que se encuentran realizando una maniobra de adelantamiento.

En concreto, se propone la ejecución de un separador entre carriles con forma de huso esférico que maximice dicha distancia. Se plantea la ejecución de dicho huso de forma puntual en las curvas en las que, por sus características, se debería limitar la velocidad más allá de su geometría debido a la limitación de visibilidad causada por los ‘*platoons’* de camiones (Pastor-Serrano y García, 2020). En las Figuras 2 y 3 se puede observar simulaciones de la actuación propuesta, así como el aumento de visibilidad que proporciona respecto a la situación inicial de la infraestructura.

El diseño del huso propuesto se concreta, en vías de al menos dos carriles por sentido, como un espacio de reserva entre los dos carriles exteriores existentes en una curva a derecha (Figura 4). La configuración geométrica se corresponde con un arco circular concéntrico con el correspondiente a la línea de separación de los dos carriles y con una diferencia de radios igual a la anchura del separador. En el inicio y final de la curva, la divergencia y convergencia de las líneas de borde se logra a través de las clotoides de transición.

Dicha separación entre carriles deberá ser, en todo caso, rebasable. Al crear un espacio entre los dos carriles se logra maximizar la separación lateral entre los vehículos, aumentando con ello la visibilidad tangente al ‘platoon’ de camiones por parte del vehículo que se encuentra realizando el adelantamiento.

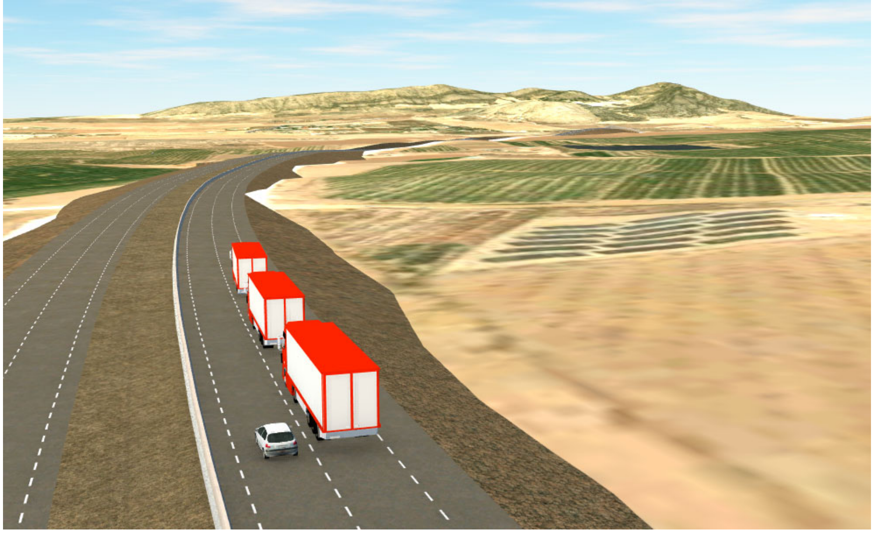

Figura 2: Simulación de un vehículo adelantando a un ‘platoon’ de camiones, antes de la actuación propuesta

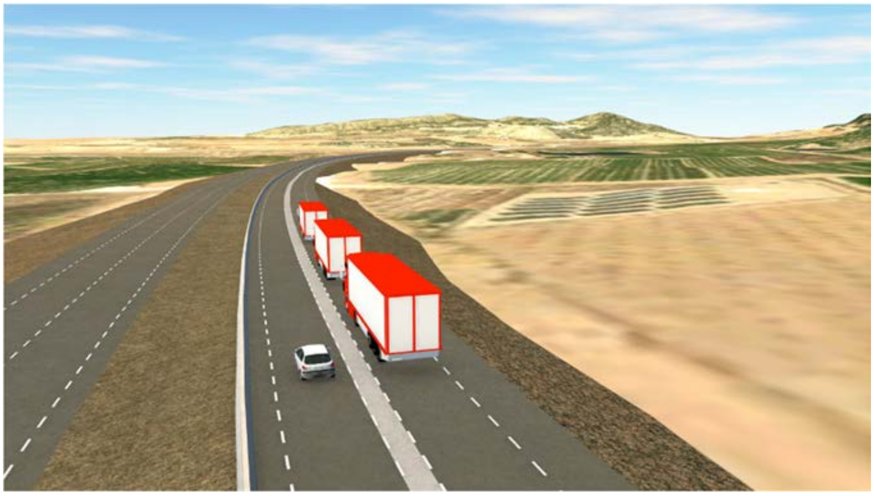

Figura 3: Simulación de un vehículo adelantando a un ‘platoon’ de camiones, tras la actuación propuesta

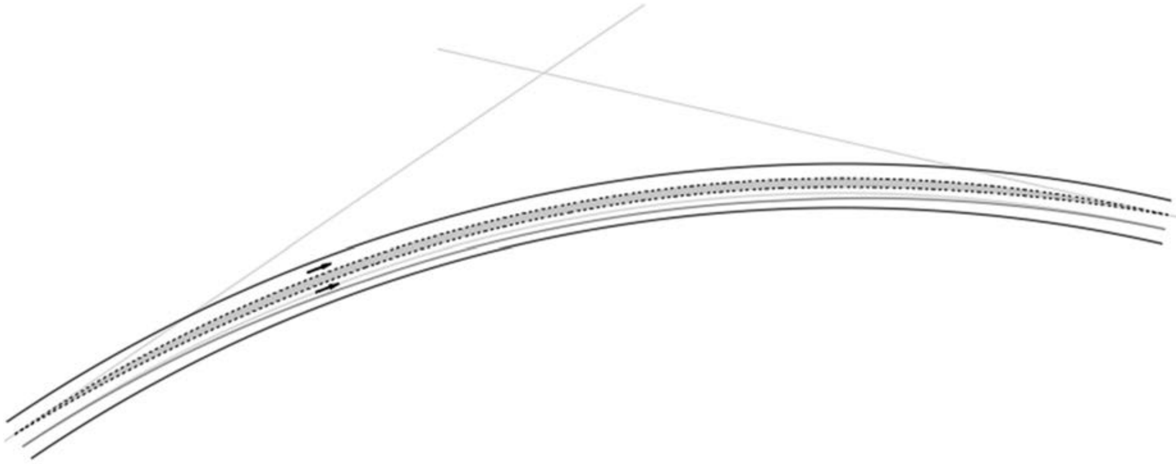

Figura 4: Esquema básico de la actuación propuesta

La señalización del huso debe ser adecuada para que, aun siendo rebasable e incluso permitiendo cambios de carril, se asegure que los conductores lo perciban como un espacio que no pertenece al propio carril. En las Figuras 3 y 4, por ejemplo, el huso propuesto ha sido representado con un color diferente al del resto de la vía.

La nomenclatura de huso se ha tomado como referencia por su similitud a un huso de una esfera. Esto se debe a la necesidad de realizar una transición conforme aumenta la curvatura de la curva, de forma que la aparición del huso intermedio se haga de forma gradual (Figura 4).

En cuanto a sus dimensiones, se ha tomado como referencia una sección transversal habitual formada por dos carriles de 3.5 m de anchura y un arcén exterior de 2.5 m de anchura. De esta forma, y teniendo en cuenta el objetivo de mitigar el problema maximizando el uso de los recursos existentes, se ha considerado una anchura máxima de huso a disponer de 2 m.

Del ancho máximo de huso propuesto, 0.5 metros provendrían del propio carril exterior. Esta decisión se ha tomado porque se considera que un carril de 3 m sigue teniendo una anchura suficiente. A la vez, el hecho de que el propio huso sea rebasable ofrece cierta flexibilidad en caso de emergencia o de necesidad de carriles de mayor anchura.

Por otra parte, se propone la reducción de la anchura del arcén a 1 m. Al tratarse de una reducción puntual y progresiva en la anchura del mismo no se considera que esta actuación penalice en ningún caso la seguridad de la vía.

En la Figura 4 se ha representado la actuación propuesta en los términos anteriormente descritos. En ese sentido, se pueden observar tanto los límites iniciales de los carriles (en gris) como las nuevas delimitaciones de los carriles (en negro) y el huso propuesto (con sombreado gris).

En cualquier caso, se podrían proponer configuraciones diferentes que permitan la creación del citado huso recurriendo a otras partes de la sección de la vía, si bien es probable que dichas alternativas requieran de modificaciones en la infraestructura. Una posibilidad podría ser la ampliación de la plataforma de la vía hacia el interior de la vía. La viabilidad de este tipo de actuaciones dependerá, en todo caso, del nivel de implementación de los '*platoons*' de camiones y la capacidad de paliar el problema con otro tipo de actuaciones.

Como se ha visto en la introducción, Pastor-Serrano y García (2020) desarrollaron un modelo de estimación de la velocidad en la maniobra de adelantamiento a un 'platoon' de camiones en curvas a derechas. Dicho modelo permitió estimar los límites de velocidad impuestos por la visibilidad de parada en dicha maniobra.

Partiendo del modelo previamente desarrollado, se ha evaluado la efectividad de la medida propuesta. Para ello, se ha estimado tanto la visibilidad como la velocidad requerida para garantizar la distancia de parada asociada a la misma. Estas estimaciones se han hecho para radios y anchuras de huso diferentes. Los resultados obtenidos se muestran en la Figura 5, que se comenta a continuación.

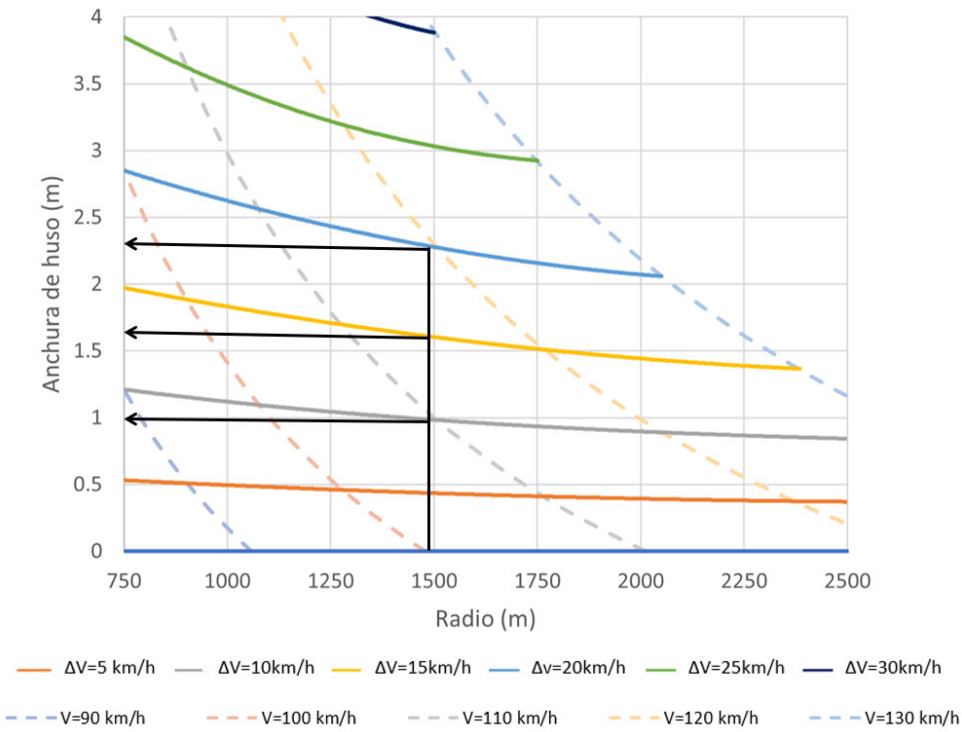

Figura 5: Anchura de huso necesaria para mitigar la limitación de visibilidad, según el radio de la curva

En primer lugar, se puede observar cómo en la Figura 5 se representa la anchura de huso necesaria para cada radio en función de dos tipos de datos. Por una parte, se representan con línea discontinua velocidades predeterminadas. En línea continua, por otra parte, se representan incrementos de velocidad cuya interpretación se detalla a continuación.

Como se ha mencionado, el estudio realizado parte del modelo desarrollado por Pastor-Serrano y García (2020). Por ello, en el caso de disponer de una anchura de huso nula (0 m), lo que se obtiene es la velocidad a la que habría que limitar la circulación para garantizar que existe la distancia de parada necesaria según el radio. Éste era, precisamente, uno de los principales resultados de la investigación inicial.

Respecto a las líneas discontinuas, estas tomas valores fijos de velocidad entre 90 y 130 km/h, con incrementos de 10 km/h. En concreto representan, dado un radio, la anchura de huso que sería necesario disponer para compensar totalmente la limitación de visibilidad provocada por un ‘platoon’ de camiones y, de esa forma, poder permitir la circulación a la velocidad correspondiente en condiciones de seguridad.

En cuanto a las líneas continúas, éstas vienen a completar la figura complementando la información anterior. En ese sentido, dichas líneas representan incrementos de velocidad. Dichos incrementos toman como referencia la velocidad a la que habría que limitar una curva (en función de su radio) debido a la limitación de visibilidad provocada por los ‘*platoons*’ de camiones. La decisión de representar los incrementos de velocidad que representaría cada huso, en comparación con la limitación causada por los ‘*platoons*’, se debe a la imposibilidad de compensar totalmente el efecto para la mayoría de radios, pues se requerirían grandes anchuras de huso.

Por ejemplo, si tomamos una curva con un radio de 1450 m, tendríamos que, si no se dispone el huso, la velocidad se debería limitar a 100 km/h. Para lograr la velocidad máxima se debería alcanzar una velocidad de 120 km/h. O lo que es lo mismo, un incremento de velocidad sobre la limitación causada por los ‘*platoons*’ de 20 km/h. Tomando cualquiera de estas dos referencias (la velocidad objetivo o el incremento de velocidad sobre la limitación provocada por el ‘*platoon*’) se obtiene un ancho necesario de huso de 2.35 m. Dado que se trata de una anchura en todo caso excesiva, se debería plantear la posibilidad de tomar anchuras de huso más reducidas, pese a que con ello solo se compensara el problema parcialmente. Continuando con el ejemplo, si se tomara un huso de 1.6 m de anchura (cercano al límite de lo que podría ser aceptable), se compensaría el efecto en 15 km/h. Si se tomara un huso de 1 m, por otra parte, la compensación sería de 10 km/h, obteniendo una limitación de velocidad a 110 km/h.

A partir de la Figura 5, se puede observar cómo solo para los radios más grandes la creación de un huso entre los dos carriles podría compensar totalmente el problema. Para radios menores a 1,750 m, le necesidad de anchuras de huso excesivas lleva a pensar que la solución propuesta puede ser efectiva para paliar el problema, pero no en su totalidad.

3. ACTUACIONES CENTRADAS EN LA CONECTIVIDAD Y LA AUTOMATIZACIÓN

Las soluciones centradas en la conectividad y la automatización son aquellas que buscan aprovechar al máximo las nuevas posibilidades tanto de los propios '*platoons'* de camiones como del resto de vehículos de la vía, e incluso de la propia vía, para mitigar el efecto de limitación de visibilidad provocado. En ese sentido, se ha decidido agrupar conjuntamente las actuaciones centradas en la conectividad y en la automatización debido a que, aunque podrían tratarse de forma separada, se considera que la conectividad debe entenderse como un paso más en el camino hacia la automatización de niveles superiores.

Aunque las soluciones propuestas se centran en la comunicación entre vehículos (V2V), la comunicación con la propia infraestructura (V2I) mediante elementos como las '*Road Side Units'* podría ser también útil para el objetivo planteado.

3.1 Adaptación y optimización del '*Region Of Interest*' (ROI)

La distancia de parada depende, como bien es sabido, del tiempo de percepción y reacción del conductor. En el caso de los vehículos autónomos, este tiempo es menor que el humano, pero está aún lejos de ser casi nulo. Minimizar el tiempo de percepción y reacción de los vehículos que adelanten a un '*platoon*' de camiones debe ser una prioridad, pues podría mitigar en gran medida el problema de visibilidad existente al minimizar la distancia de parada requerida.

Por todo ello, se plantea que se maximicen los beneficios que podría aportar la conducción autónoma minimizando el tiempo de percepción y reacción. Para ello, se propone que los fabricantes tomen conciencia de la existencia del problema evidenciado y lo compensen en la medida de lo posible. Esta compensación se realizaría mediante lo que se conoce como '*Region of Interest*' (ROI).

El ROI representa el área en el que los sensores que monta un vehículo autónomo se focalizan para reducir el tiempo de procesamiento. En general, el ROI abarca la máxima área posible teniendo en cuenta las posibilidades de los distintos sensores. Sin embargo, podría ser razonable que, en situaciones de especial riesgo, el ROI se limitara a las propias áreas de riesgo.

En este caso, lo que se propone es que un vehículo autónomo que adelante a un '*platoon*' de camiones focalice su atención en la visual tangente al propio tren de camiones. El resultado de esta focalización sería, con toda probabilidad, una disminución de los tiempos de percepción y reacción ante cualquier eventualidad en la vía. El beneficio obtenido, en función del tiempo de percepción y reacción logrado, se puede estimar a partir de los resultados ofrecidos por Pastor-Serrano y García (2020).

Por el contrario, el hecho de focalizar la atención del vehículo en un área tan específica llevaría a perder la atención de otras zonas de la vía o, al menos, hacerlo con tiempos de percepción y reacción mayores. Sin embargo, el hecho de que se trata de una situación puntual con un riesgo relevante podría justificar esta propuesta.

3.2 Soluciones basadas en la sensorización

En caso de existir cierta conectividad o incluso automatización en los vehículos, soluciones similares a la propuesta planteada de creación de un huso podrían llevarse a cabo sin necesidad de actuaciones sobre la infraestructura. Por ello, las soluciones basadas en la sensorización pretenden compensar el problema de limitación de la visibilidad mediante el uso de elementos que permitan aumentar la información disponible durante la maniobra de adelantamiento.

3.2.1 Sensorización trasera y lateral

Esta propuesta consistiría en disponer sensorización lateral y trasera en los diferentes vehículos implicados para aprovechar al máximo su automatización. En ese sentido, el objetivo sería que, en una maniobra de adelantamiento, tanto los camiones que forman parte del '*platoon*' como el vehículo que realiza la maniobra de adelantamiento sean conscientes de la maniobra que están realizando.

De esa forma, la propuesta sería que, al ser conscientes de la situación, los vehículos maximizaran la distancia lateral entre ellos. Así, todos los vehículos implicados se retirarían, en la medida de los posible, hacia los extremos de sus respectivos carriles. La distancia lateral entre ellos se maximizaría y, con ello, la visibilidad.

Al plantearse esta actuación, los fabricantes deberán tener en cuenta su compatibilidad con otras particularidades de los '*platoons*' de camiones. En ese sentido, uno de los problemas que podrían causar los '*platoons*' sería un mayor desgaste del pavimento debido al paso repetido de grandes cargas por áreas muy concretas del firme. Para solucionarlo, diferentes investigaciones han propuesto actuaciones destinadas a variar la posición transversal de los vehículos para distribuir al máximo posible el desgaste y los daños del firme (Chen *et al.*, 2016; Chen, 2020; Gungor y Al-Qadi, 2020). Dichas actuaciones deberían tener en cuenta el problema tratado en esta ponencia.

Por otra parte, esta actuación guarda gran parecido con la propuesta de creación de husos entre los dos carriles existentes, ya que comparten el objetivo de maximizar la separación lateral entre los diferentes vehículos para maximizar con ello la visibilidad. Sin embargo, en este caso no se precisa de actuación alguna en la infraestructura. Pese a ello, esta propuesta requeriría una automatización total del parque móvil, ya que en caso de existir tráfico mixto solo los vehículos autónomos se verían beneficiados.

3.2.2 Sensorización delantera

En este caso, la propuesta se centra en los ‘*platoons*’ de camiones. Dado que el ‘*platooning*’ precisa de cierto nivel de conectividad y automatización, incluso en sus niveles más básicos, parece razonable asumir la viabilidad de incorporar sensorización delantera en todos los ‘*platoons’* de camiones. Si bien dicha sensorización podría tener múltiples funciones, esta propuesta se centra en la capacidad de dicha sensorización para detectar obstáculos en el carril adyacente al del propio ‘*platoon’* de camiones.

La propuesta se centra, por lo tanto, en la posibilidad de que sea el camión delantero del ‘*platoon´* de camiones el que detecte el peligro para los vehículos que lo adelanten. Una vez detectado el peligro, sería el propio ‘*platoon*’ el que advertiría a los vehículos que le adelanten para que reduzcan la velocidad y maximicen su atención.

El principal beneficio de esta propuesta es que no requiere ni de automatización ni de conectividad entre todos los vehículos. En ese sentido, si existiese comunicación V2V el aviso sería directo. La reacción, si el vehículo fuera además autónomo, sería además inmediata. Sin embargo, la propuesta incluye la disposición de varias luces de advertencia en el lateral de los camiones que forman el ‘*platoon*’, de forma que estas se enciendan de forma intermitente al detectar un peligro (Figura 6). Por todo ello, esta solución es compatible y adecuada para casos de tráfico mixto con diferentes niveles de conectividad y automatización.

Figura 6: Propuesta de aviso en caso de peligro.

5. CONCLUSIONES

El '*platooning*' de camiones conllevará grandes ventajas, pero su implantación podría ser conflictiva si no se tienen en cuenta sus efectos sobre la seguridad vial. Por ello, es necesario prever sus efectos con la antelación suficiente, disponiendo así las actuaciones necesarias para mitigar los aspectos más negativos a la vez que se ensalzan los positivos.

Aunque es necesario seguir investigando en la materia, se puede afirmar que los '*platoons*' de camiones provocarán un efecto de apantallamiento que podría generar grandes inseguridades en las maniobras de adelantamiento en curvas a derechas. Por ello, se han propuesto a lo largo de esta ponencia soluciones que pretenden atacar el problema desde diferentes perspectivas.

Debido a la diversidad de soluciones propuestas, cada una de ellas parte de condicionantes muy diferentes. Dado su diferente enfoque y su garantizada pero limitada efectividad, es probable que una combinación de actuaciones sea necesaria para garantizar la mitigación del problema detectado en su totalidad.

En ese sentido, sería necesario ampliar esta investigación en el futuro para cuantificar la efectividad de las diferentes propuestas no solo por separado, sino también como conjunto. Además, se podrían aportar soluciones adicionales que complementen a las ya propuestas. Para todo ello, sería de especial interés la aplicación de estas actuaciones en un caso de estudio que contemple su aplicación en una vía real.

Por último, sería conveniente que el desarrollo de las actuaciones destinadas a compensar el efecto de limitación de visibilidad no colisione con el de otras actuaciones destinadas a compensar otros problemas causados por los '*platoons*' de camiones, como puede ser el del desgaste del pavimento. En ese sentido, se deberían aprovechar las sinergias existentes para generar soluciones globales que integren todas las perspectivas y afronten todas las problemáticas simultáneamente. Solo así se podrá aprovechar al máximo el potencial que estas nuevas tecnologías ofrecen en todos los ámbitos.

ABSTRACT

In Spain, on November 2020, a new law imposed that the generic speed limit on single carriageway two-lane roads is reduced from 50 km/h to 30 km/h.

The changes in the general rules of traffic, proposed by the Spanish government, are a sample of the evolution, in the use of the shared space of the streets, and at the same time shows its sensitivity towards road safety. Traditionally, the objective of the regulation was to attend to the growing increase in the use of motor vehicles (mainly cars), and for this reason, it was the protagonist in most of the articles of the General Traffic Regulations. Today, in many cities, the car is no longer the protagonist and shares the space on the streets, not only with other motor vehicles as buses or motorcycles, but also with pedestrians, bicycles, electric pedal-assisted cycles (EPAC), personal mobility vehicle (PMV), …

Pedestrian mobility is becoming more and more important every day but the number of pedestrians that died inside Spanish urban areas in road accidents is almost 50% of total urban areas road fatalities. In this sense, the mobility and road safety policies developed by local administrations have to focus on the objective of the reduction of accidents and their severity involving pedestrians and other vulnerable users in urban areas.

This article collects studies and experiences in other countries that show the effects of reducing the speed of motor vehicles in urban areas in order to reduce accidents and/or their severity if they occur. It also analyzes other options that reinforce this measure and that could help reduce this problem.

1. INTRODUCTION

Several articles of the General Traffic Regulations were modified in Spain, on November 11, 2020. The changes that affect article 50, which deals with speed limits on urban roads, stand out (BOE, 2020). The generic speed limits on urban roads/streets now are established as follows:

- 20 Km/h on roads with a single-carriageway one-lane road. 30 Km/h on single-carriageway two-lane roads.
- 50 Km/h on carriageways with two or more lanes per direction.

In this paper, we will focus on the new speed limit for urban streets with a unique carriageway and two-lanes, one per direction. Before this change in the regulation, the usual maximum speed of these streets was 50 Km/h.

Speed has been identified as a key risk factor in road traffic injuries, influencing both, the risk of a road crash as well as the severity of the injuries that result from crashes. Therefore, a reduction in the speed would improve road safety (Gonzalo-Orden et al, 2016, 2018).

Over the world, road safety is one of the major problems (Llopis-Castelló and Findley, 2019). In 2013, there were 1.25 million fatalities in collisions. Fatalities among pedestrians, cyclists, and motorcyclists are painfully high and represent more than 48% of the total. If we focus on pedestrians, the average value over the world is 22%, 26% in Europe and as higher as 39% in Africa (WHO, 2015).

In the European Union, during 2019, almost 23,000 people died in crashes, which is 21 hundred less than in 2018, and 135,000 were seriously injured. The yearly cost of road crashes in the EU has been estimated to be around EUR 280 billion, equivalent to about 2% of Gross domestic product (GDP) (EC, 2020a; EC, 2020b).

The road fatalities in Spain have been decreasing in the last decades. The peak number of fatalities reached a maximum of 9,344 in 1989. This situation changed reaching the lowest annual total in 2013 with 1,680 people died in road accidents. The last official data, related to 2019, indicates that there were 1,755 fatalities, 8,613 people seriously injured and 130,745 injured. On interurban roads, 1,236 people died, 4,303 people were seriously injured and 51,407 were injured. On urban roads, 519 people died, 4,310 people were seriously injured and 79,338 were injured. (DGT, 2020).

If we look back 10 years, in 2009, 2130 people died outside urban roads and 584 inside urban areas. As the reduction outside urban areas shows a great improvement (42%), inside urban areas the improvements are smaller (11%) (DGT, 2020).

If we focus on pedestrians in urban roads, 247 pedestrians died during 2019 and 269 during 2009. For these vulnerable users, the reduction was only 8%.

	Non-Urban. Total fatalities	Non-Urban. Pedestrian fatalities	Urban. Total fatalities	Urban. Pedestrian fatalities
2019	1236	134	519	247
2009	2130	201	584	269
% reduction	42%	33%	11%	8%

Table 1: Urban/non-urban total/pedestrian traffic road deaths in Spain 2009-2019.

The reduction achieved outside urban areas has been much higher than the small decrease that has been accomplished within them.

In urban areas, apart from the 247 pedestrians who died, we find other users who, in the event of an accident with a motor vehicle with 4 or more wheels, have a high probability of suffering serious injuries or death. We can highlight that, in 2019, in Spain in urban areas, 32 cyclists, 22 moped users, and 126 motorcyclists also died in traffic accidents.

In the following sections of the article, we will see the effects of speed on urban road safety.

2. THE REDUCTION OF SPEED AND ITS EFFECT ON VISIBILITY AND IN THE STOPPING DISTANCE

One of the most important aspects to reduce the probability of an accident when the trajectory of two street users intersect is to increase the visibility distance at which they begin to see each other. For example, if the driver of a car sees a pedestrian approaching a crosswalk from further away than another driver, he/she will have more time to react and adapt his/her speed or even stop than the driver who sees the pedestrian later.

In this section, we will see how to calculate the Stopping Sight Distance (SSD) and how it varies depending on the traveling speed of the car at the moment the driver decides to stop. The SSD is necessary to provide the drivers the ability to see far enough in front of them to be able to stop before hitting a hazard that is in their path in the roadway. Also, we will need to define the Sight Distance (SD) as the distance a driver can see ahead at any specific time. To avoid an accident, the Stopping Sight Distance must always be less than the Sight Distance.

As indicated in the Spanish Standard of I.C. 3.1. related to the Design of Roads (BOE, 2016) the Stopping Sight Distances is composed of two distances:

- dpr: Distance traveled during perception and reaction time.
- db: Distance required to physically stop the vehicle.

$$SSD = (V \cdot t_{pr})/3.6 + V^2/(254 \cdot (f_l + i)) \quad (1)$$

where:

- SSD = Stopping Sight Distance (m)
- V = Initial traveling speed of the car at the moment the driver decides to stop (km/h)
- tpr = Brake perception and reaction time (s)
- fl = Longitudinal friction coefficient mobilized wheel-pavement
- i = Longitudinal grade (m/m)

The perception and reaction time assumed in the Spanish standard (2.0 s) is lower than the one assumed in the USA, where the value is 2.5 s (AASHTO, 2018). The braking action is based on the driver's ability to decelerate the vehicle while staying within the travel lane and maintaining steering control during the braking maneuver. For the values of t_{pr} of 2.0 s and 2.5 s and i=0 %, the d_{pr}, d_b, and SSD are calculated and presented in table 2.

V (km/h)	t_{pr} (s)	f_l	d_{pr} (m)	d_b (m)	SSD (m)
50	2,0 - 2,5	0,411	27,78 -34,72	23,95	51,73 - 58,67
40		0,432	22,22-27,78	14,58	36,80 - 42,36
30		0,453	16,67-20,83	7,82	24,49 -28,66

Table 2: Stopping Sight Distance, dpr, and db in a road with i=0.

The values used for the longitudinal friction coefficients (f_l) provide comfortable vehicle decelerations for the user who must stop, in a controlled manner, the vehicle before reaching an obstacle that is in his path in the roadway.

These calculated SSD distances make us see the first problem. In our cities, we find numerous examples where the design of the pedestrian crossings is not adequate. The design does not allow enough sight distance between the pedestrian and the driver of the motorized vehicle.

Figure 1: Example of crosswalk before and after improvement.

The left and center photos in Figure 1 show how the garbage containers do not allow drivers to see, with enough time (or distance), the pedestrians who want to cross.

As a partial improvement, in the right photo, the sidewalk has been widened, narrowing the lane of the street, and improving mutual visibility between the pedestrian and the driver. Other more effective solutions are removing parking spaces (Figure 2 right) or switching parking spaces for bicycle and motorcycle parking. The same problem is reproduced when we have close to the crosswalk provisional works areas (Figure 3 center), rail barriers (Figure 3 left), urban furniture, a bus stop (Figure 3 right), vegetation, etc. In other cases, we find that the difficulties in the design of the crosswalk are related to problems of sun glare or dark-lighted conditions.

In all these cases, we have limitations on the mutual visibility of the driver and the pedestrian.

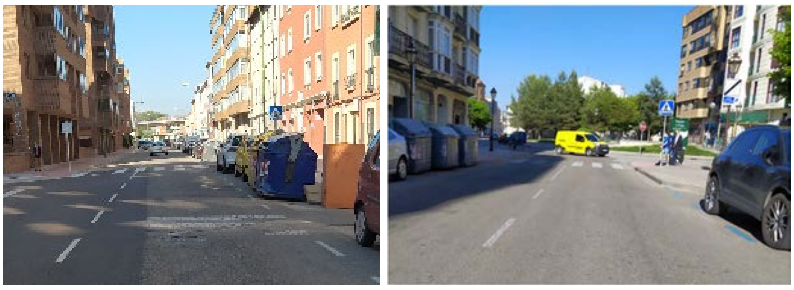

Figure 2: Examples of crosswalks with limited visibility by car parking (left) and improved by sidewalk widening (right).

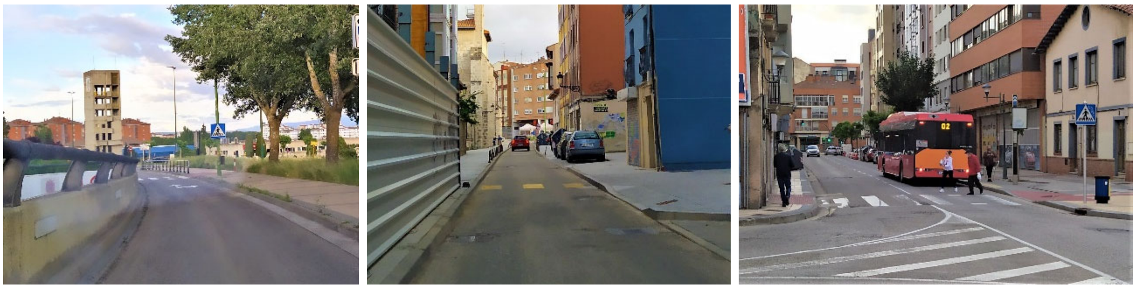

Figure 3: Other examples of crosswalks with limited visibility.

Figure 4: Blinker pedestrian sign with a real-time warning when pedestrians are in or about to enter an approaching crosswalk.

Finally, we can also find traffic signs with presence sensors that turn on a warning light when pedestrians are in or about to enter an approaching crosswalk. (Figure 4) or traffic light that activates the change to red of the traffic light for the driver.

In a few years, it will be normal to find that this information will be sent not only to the traffic lights or signs but also to the approaching vehicles.

We see that a first problem appears in many of the pedestrian crosswalks where the Sight Distance (SD) is less than the Stopping Sight Distance (SSD). In case of need, the driver can perform emergency braking, reducing d_b by more than 34% (DfT, 2007). Even so, of the 61,177 accidents where pedestrians were involved, recorded in Spain during the years 2016, 2017, 2018, and 2019, in more than 42% of the collisions, the pedestrian was crossing properly (Febres et al, 2021).

In addition to increasing the Sight Distance (SD) by changing the street design and reducing the braking distance (d_b) we can try to reduce the distance traveled during the perception and reaction time (d_{pr}). Although this objective has traditionally depended on the driver (attention, reaction time, age, fatigue ...), in the coming years it will also depend on the vehicle. Little by little, the vehicles are incorporating automatic emergency braking systems that will allow us to reduce those almost 17 m traveled at 30 km / h due to d_{pr} or the almost 28 m, traveled while we perceive and react, when we are driving at 50 km/h.

Although new vehicles with advanced emergency braking systems (AEBS) are arriving, the public space should be reorganized. The sidewalk should always be extended over the parking lane and narrowing the roadway. Furthermore, in streets where the maximum speed is 30 km/h, at the pedestrian crossings, at least the two previous parallel parking spaces (10 meters) should be replaced by an obstacle-free zone that facilitates the vision between pedestrians and drivers (or the intelligent vision systems that vehicles have incorporated). If the maximum speed is 50 km / h, it would be necessary to think about clearing a larger area and/or installing a traffic light.

Therefore, we have seen in this section that we should try to increase the SD and reduce the SSD. To increase the SD, we must consider a new design of the crossing areas, eliminating obstacles that reduce visibility or, with the incorporation of sensors in those areas, detect sooner the people approaching these crossings. In order to decrease the SSD we have seen that an instant measure is to reduce the circulation speed. Additionally, as a slower implementation action, it is necessary to accelerate the incorporation of AEBS in all the new vehicles that are sold.

3. THE REDUCTION OF SPEED FROM 50 KM/H TO 30 KM/H AND ITS EFFECT ON THE SEVERITY OF THE ACCIDENTS

Speed has been identified as a key factor in traffic fatalities crashes influencing both the probability of an accident and its severity (Aarts and van Schagen, 2006; Anderson et al, 1997; Davis, 2001; Elvik, 2004; Elvik 2009; Hussain, 2019; Kong and Yang, 2010; Kroyer et al, 2014; Kroyer, 2015; Rosen and Sander 2009; Rosen et al 2010; Telf, 2013).

Analyzing different studies, we realize the difficulty of directly relating the speed of a vehicle with the probability that a pedestrian will die if hit by that vehicle. In Spain, within the dissemination campaign of the General Directorate of Traffic (DGT) about its star measure of reducing the speed from 50 km/h to 30 km/h, it indicates that in the event of being run over at 30 km/h the probability of dying is 15% and 85% when the speed rises to 50 km/h (DGT, 2021). Older studies such as Bonanomi (1990) offer similar values as indicated in the following table.

Speed of collision (km/h)	60	40	20
Probability of death (%)	85	30	10

Table 3: Relationship between the speed of the vehicle and the probability of death of the pedestrian involved in an accident (Bonanomi, 1990).

The probability of survival and the severity of the injuries not only depend on the speed of the vehicle. Other recurrent factors, that we found in the different studies, are the age of the pedestrian, the response time of emergency assistance, or the type of the vehicle (Ballesteros et al 2004; Desapriya et al 2010; Henary et al, 2006; Hussain, 2019; Kröyer, 2015; Lefler and Gabler 2004; Rosén, 2009; Sze, and Wong, 2007). For example, for pedestrian older than 15 years, Rosén (2009), proposed the following pedestrian fatality risk function (P) (Eq. 2) where P is the probability of death of the pedestrian of age “A” in years that is hit by a motorized vehicle that circulated at a speed of “V” Km/h.

$$P(V,A) = 1/(1 - \exp(\,9.1 - 0.095 \cdot V - 0.040 \cdot A)) \qquad (2)$$

In addition to the age of the pedestrian, within the urban environment, other variables have also been analyzed, such as height, weight, sex, or Body mass index (BMI) (Telf, 2013). Basem (et al, 2006) highlighted that the irrespective of impact speed, vehicle body type, and pedestrian weight, height, and gender, senior pedestrian victims are at higher risk of morbidity and mortality than adult victims. Tefft (2013) showed that the average risk of death for a 30-year-old pedestrian struck at a given speed is similar to the risk of death for a 70-year-old pedestrian hit by the same car at a speed 19 km/h slower.

If we focus on the effects of speed reduction on pedestrian fatality risk we see that they are treated in many studies (De Pauw et al., 2014; De Pelsmacker and Janssens, 2007; Elvik, 2009; Fridman, 2020; Heydari et al. al., 2014; Hussain et al, 2019; Rosén, 2009). A reduction in speed limits can help reduce the kinetic energy of the vehicle and therefore, the damage to the pedestrian. Rosen (2009) indicated that the fatality risk at 50 km/h is more than twice higher than the risk at 40 km/h and more than five times higher than the risk at 30 km/h. Analogous values were found by Hussain et al (2019).

Hussain et al (2019), Rosén et al (2009), and Rosén (2011) highlighted that a faster and better emergency assistant and a medical care system will help to reduce the fatality risk.

Finally, it is necessary to indicate that the designs of the new vehicles take into account the damage they can do to the pedestrian in the event of an accident and to underline that Sport Utility Vehicles (SUVs) and Light Truck vehicles (LTVs) have a higher fatality risk than the passenger cars. (Ballesteros et al 2004; Desapriya et al 2010; Henary et al, 2006; Hussain, 2019; Kröyer, 2015; Lefler and Gabler 2004).

Some lessons that we extracted from these studies is that, in general, they cannot be directly extrapolated to other situations different than the cases studied. Some of the problems that we find, when applying them to other cities, are the following:

- Year of the study. Studies carried out many years ago do not consider improvements in vehicle designs or improvement in the assistance of the injured pedestrian. In these cases, these models will deliver death rates higher than the real ones.
- Distribution of the age of the population. Regions or cities in the same country with an older population will have death rates higher than the country's averages.
- Development of the emergency and medical care system. Countries with less-developed emergency and medical care will present a higher fatality risk.
- Average age of vehicles and Typology of vehicles. Cities with higher percentages of SUVs and lower percentages of passenger cars will present a higher fatality risk. Cities with more modern vehicles will have a lower number and severity of pedestrian collisions.

4. DISCUSSIONS AND PROBLEMS OF THE APPROVED REGULATION

The new article 50 of the General Traffic Regulations (BOE, 2020) that establishes the generic speed limits on urban roads/streets is flexible and allows being more restrictive or less:

- "The established generic speeds may be lowered after specific signaling, by the Municipal Authority."
- "Exceptionally, the Municipal Authority may increase the speed on roads with a single lane in each direction up to a maximum speed of 50 km / h, after specific signaling".

These two degrees of freedom make it possible for some municipalities to abuse the "exceptionally" by preserving most of their streets at 50 km/h and leaving, therefore, this standard unused or almost unapplied.

The "exceptionality" should be applied in streets with few buildings, few pedestrians, and long-distance traffic, and when the main reason is to attract long-distance traffic from other streets with a higher density of buildings and with greater pedestrian traffic.

It is necessary to indicate that, in Spain, at present, the fines for speeding up to 20 km/h, in streets limited between 20 to 50 km/h are only 50 euros if paid before 20 days from receipt. If the speeding is between 21-30 km/h the fine rises to € 150 and in case of exceeding by 31 km/h up to 40 km/h the fine would be € 200.

We see, therefore, that fines for speeding in urban streets should be reconsidered as their punishment is not comparable to the damage caused by this increase in speed in the event of a run-over. In case of maintaining this low level of penalty (low effectiveness), it should be compensated with informative campaigns so that drivers and pedestrians better understand the risks of "seeping" in urban areas and their consequences in the case of a pedestrian run over.

Finally, apart from incorporating changes in the fines for speeding, laws should be modified to improve and reduce street design problems. These laws should prevent numerous obstacles limiting visibility at pedestrian crossings and cycle lane crossings between motor car drivers and vulnerable users.

If we leave it on the hands of the specific training and sensitivity towards road safety of those responsible for our cities, it will take longer to win the battle to reduce these accidents. A State or European regulation for the design of these crossings and intersections between streets, bike lanes, and pedestrian routes would strongly help to reduce this type of accident.

5. CONCLUSIONS

The basic rule that we can deduce from this study is that in order to improve the crossing areas of the paths of pedestrians (and other vulnerable users) and motor vehicles, it is necessary to increase the visibility distance between both so that they have more time to react and make decisions that do not end in a pedestrian run over. We have seen how, at daily traffic speeds in our cities, an accident can lead to serious injuries to pedestrians and, in too many cases, their death.

Therefore, it is recommended:

- Inventory and safety audit of all the existing crossings and those areas where there is a high number of pedestrians who cross badly due to lack of enabled crossings.
- Redesign those that are needed and or install new ones that are required.
- Do not extend the reduction of the speed from 50 km/h to 30 km/h to all streets. A higher speed will help to redirect motor traffic to those areas with less pedestrian traffic and less inhabited.
- Increase fines and reduce the first range of 20 km/h of excess in the first level of infraction. The same fine for going at 31 km/h or for going 49 km/h will not help to maintain the speed limit lawbreaker at speeds closer to 30km / h.

- Education and dissemination campaigns for drivers and pedestrians.
- Promote the implementation of advanced emergency braking systems (AEBS) and other safety measures in the design of new vehicles that help reduce the number of accidents and the severity if they occur. Encourage the renewal of the fleet of vehicles not only because they are less polluting but also because they include more measures to improve safety.

ABSTRACT

The world generalized phenomenon of population ageing, caused by an increase in life expectancy, has led to a more elderly being actively part of mobility and road traffic. In developed countries, like Spain, fatalities and severe injuries among elderly pedestrians in the urban context are a matter of concern since, in the last decades, the fatal accident risk for elderly pedestrians is rising. Although there is an extensive literature on the decline of driving and pedestrian skills in the elderly, few research has been devoted to the impact of the street type and socioeconomic factors per urban district on this type of collisions.

The road safety analysis of pedestrians´ collisions is complex due to the diversity of the features, the dispersion of the data and the lack of infrastructure information associated to the accident location at official databases. The main target of this paper is the identification of the basic socioeconomic and infrastructure factors that contribute to elder pedestrian accident at urban level, taking the administrative units (districts) as territorial accident location. Madrid is the capital of one of the most rapidly ageing nations in the world, and was selected as case study because it also has a high proportion of elderly residents (19%). The Spanish General Directorate of Traffic (DGT) provided the database (2006-2018) on accident statistics and the crashes involving an elderly in Madrid were filtered to elaborate and ad-hoc data base. The study methodology was based on a negative binomial model to test the accident occurrence at district level. Results revealed the clear influence of the district population variables (density and total inhabitants) together with the activity centres associated to the elderly mobility, followed by the road length and the ageing rate per district.

1. INTRODUCTION

According to UE statistics (Eurostat, 2015), the 24% of the population in Europe will be aged over 65 years in 2030 and in 2050 this figure will reach the 28%. This fact will be translated, in terms of mobility, into more elderly being actively part of road traffic.

Road safety figures have started to provide evidence of the consequences: at the moment one road traffic fatality out of five is aged 65 or over (European Commission, 2015); but by 2050 (if the risk rates of older people and younger age groups decline at the same pace) it is expected that one road traffic fatality out of three will be an older person (European Commission, 2015).

Elder Pedestrians and cyclists, which concentrate in urban areas, are the weakest users. Statistics reflects that elderly make up 39% of all pedestrian fatalities and 40% of all pedal cyclist fatalities compared to 18 and 19% of all car driver and passenger fatalities (European Commission, 2015). If we check statistics provided by OECD countries, the real fact is that persons 65 years and over 65 years represent 13 to 20% of the population, but they make up more than 50% of pedestrian fatalities (ITF, 2012). Consequently, there is a scientific need to understand the factors that affects the elder pedestrian accidents and prevent them implementing countermeasures on our streets.

Although there is an extensive literature on the decline of driving and pedestrian skills in the elderly, few research has been devoted to the impact of the street type and socioeconomic factors per urban district on this type of collisions. Using a negative binomial model applied to Madrid case study, the main target of this paper is the identification of the basic socioeconomic and infrastructure factors that contribute to elder pedestrian accident at urban district level. The paper is divided into the following sections: Section 1 contains a brief introduction; Section 2, the state of the art on elderly pedestrians; Section 3 gives a detailed description of the case study, model structure and main results; Finally, Section 4 shows the conclusions and future research lines.

2. ROAD SAFETY OF ELDER USERS

An extensive literature (Dunbar et al, 2004; Oxley et al. 2004; Palamara and Broughton, 2013) has been devoted to study the specific physical and mental limitations of the elderly as road users. These physical and mental limitations use to be exacerbated by age-related illnesses and certain chronic medication. Having more than on illness (comorbidity) is also more usual among the elderly population and is also linked to a higher accident´s risk. Due to their physical and mental state, also this age group registers greater fatality rates (Henary et al, 2006). Until now, the higher road collision risk of the elderly has been linked to the reduction in physical and mental faculties with advancing age, which can lead to an inappropriate and unexpected behaviour in elderly pedestrians and drivers compares to the rest of road users (except children).

Elderly drivers have been paid more scientific interest than elderly pedestrians (Charlton et al, 2017; Charlton et al; 2006), although figures reflect that fatal accidents involving elderly drivers are still very few compared to elderly pedestrian fatalities (Langford et al., 2006).

We know that physical and mental limitations of elderly pedestrian are usually related to a lower walking speeds, reduced ability to make head and neck movements, less muscle agility, a poorer vision, poorer hearing, and longer reaction time. The idea of adapting street infrastructure for an ageing society is starting to grow among policymakers and local authorities and institutions like the World Health Organization is promoting the approach of creating “age-friendly” cities (WHO, 2007).

According to this idea of adapting street infrastructure to an ageing society, there is a need to study how the location features of the accident is affecting to the crash occurrence. The location of the accident can be linked to infrastructure features (street crossings, parking lots, signalling, sidewalks width, etc.) and also to socioeconomic factors of the urban district (population density, land use features, ageing rates, etc).

But in most literature studies dealing with elderly users, the analysis of infrastructure and socioeconomic variables is reduced to subjective perceptions declared by the elderly by surveys (Bernhoft and Carstensen, G. 2008, Oxley et al, 2004) and rarely backed by pedestrian collision data and the analysis of the accident location in the city.

In relation to road infrastructure as variable (sidewalks, parking lots and carriageway) some recent studies (Galanis et al, 2017; Corazza et al, 2018; Demasi et al, 2019) have analysed pedestrian road safety in relation to urban road type and traffic flows, but only a few of them have special consideration for elderly pedestrians (Corazza et al, 2018).

The works developed by Galanis et al (2017) are more focused on pedestrian behaviour (legal or illegal walking behaviour) in relation to infrastructure type and traffic flows. Pedestrian walking on the sidewalk for the entire length of the tested street segment was considered a legal behaviour and otherwise was illegally considered.

In a Greek city of 130.000 inhabitants, the legal or illegal walking behaviour in six different types of streets was recorded by video cameras and photos. Results showed that the highest rate of legal behaviour was presented in main arterials (91.8%) and the lowest one in local streets (53.7%). Low motorized traffic flow levels in combination with maintenance and mobility problems in pedestrian infrastructure push pedestrians to walk outside the sidewalk, underestimating road safety issues.

Corazza et al (2018) focused on the pavement state of the sidewalks and its influence on elderly pedestrian accidents. Distressed or too narrow sidewalks may induce pedestrians to walk outside the sidewalks and on the carriageways, providing very unsafe situations, especially for the elderly. Authors classified the pavement state of the sidewalks in a district of Rome (Italy) and studied the relationship with a higher recurrence of accidents involving pedestrians with special attention to elderly pedestrian accidents.

Finally, Demasi et al (2019) focused on all vulnerable users (pedestrians, cyclists and motorcyclists) and designed a methodology to estimate the level of road safety of each section of a street and the hazard index of the overall branch.

Apart from considering traffic flows and speed limitations, authors identified 9 categories of elements of the street infrastructure to evaluate: pavement, geometry (narrow sidewalk, narrow lane width), lighting, intersections, cross-section (missing pedestrian crossing, pedestrian crossing without ramps), private access (lack of visibility, lack of ramps), road signs (traffic lights, roadside signs), urban furniture (safety barriers, urban furniture causes lack of visibility at intersections, urban furniture occupies shoulder or lane) and stopping (illegal parking).

Although the approach of Demasi et al. (2019) is the most interesting and would be linked and applied to elderly pedestrian accidents, it needs a database fed with a very detailed road inventory. Official accident databases use to give poor infrastructure data associated to the location of the accident and sometimes local authorities cannot supply a good inventory of their streets. The quality of the accident database always conditions the research methodology of road safety studies. This database is designed by the national authorities in each country and is compiled from a collection of road traffic accident information. In comparison to other national data bases, the Spanish one is sufficiently consolidated (Casado-Sanz et al, 2019). The pedestrian accident data used in this paper was extracted from the Spanish Accident Statistics database, and includes the accidents on Madrid city streets involving single vehicle and a pedestrian, during a period of 11 years (2006-2018). Three of the weakest points of the Spanish accident database are:

- The absence of traffic exposure data (traffic flow) associated to the accident location.
- The absence of the street road layout (lane width, sidewalk width) and traffic signalling information associated to the accident location.
- The absence GPS coordinates associated to the accident location (as in the US), using instead the kilometric point on the road in interurban roads or the closest street number in urban scenarios, leading to further data processing problems.

The two first points push researchers to collect these variables from other official databases or develop a systematic procedure of ad-hoc measurement. These ad-hoc works are very laborious, but is the only way to obtain a holistic approach for road safety assessments. The third issue is especially important in urban scenarios because working with GPS coordinates eases the process of assignment of other variables (traffic flows, road layout, sidewalk geometry, etc.) to the accident location point. In this preliminary study, a great effort has been devoted to the GPD coordinates procurement process, while basic infrastructure and socioeconomic variables have been obtained directly from official databases.

3. MADRID DATA BASE AND METHODOLOGY

3.1. Madrid case study

Spain is one of the countries in the world (together with Sweden, Finland, Germany, Italy, Greece and Japan) with the largest number of elderly people. In 2019, Spanish people over the age of 65 were approximately 19.3%, and almost 6% were over the age of 80 (INE, 2019); and this amount could reach 40% in 2060 (United Nations, 2019).

Madrid city has been selected as case study in this research because it is the capital of one of the countries in the world that presents the most positive evolution of the ageing of the population. Furthermore, the city has a high overall elderly proportion of 19%. It is a large city with almost 3.5 million of inhabitants and it is divided into 21 districts. This administrative division will be used in the statistical analysis of this research, as information is available and officially provided at this detail level.

The available data for this study consists of a subset of the Spanish Accident Statistics Database during the period 2006-2018, where collisions involving 1 vehicle and 1 elderly pedestrian took place in Madrid city, as it is explained in the next section. The main issue with the database was to geolocate the events, because their location is recorded using the name of the street and not with GPS coordinates.

3.2. Database

In this section it is explained how the database for the statistical operations was constructed. It consists of two separated operation: dependent (number of crashes per district) and independent variables gathering. This last group is comprised of different nature features about each district. It was intended to use only direct data (i.e., already available) as independent variables in this research.

The first step of the data collecting process was to obtain a clean elderly road safety database containing the location and basic characteristics (e.g., date, time, and type) of the accident to perform further processes of filtration. A simplified National Spanish database of accidents for the period 2006-2018 was the starting point.

Accidents with the profile of “vehicle-pedestrian collisions” where kept, summing up a total of 20,236 accidents. Later, a subset of accidents with a configuration of “1 person and 1 vehicle involved” of 18,118 (89 % of total collisions) records were found suitable to be studied for homogeneity purposes. Finally, the database was filtered to obtain events where the involved pedestrian was 65 years or older. This process provided information about 4,663 elderly pedestrian collisions. A preliminary analysis of this database manifests the fragility of the elderly, as this group represents only 25.7% of total collisions but 50.9% and 34.2% of total fatalities and serious injuries, respectively.

One of the most important operations to perform in the proposed study was to geolocate the accidents based on the name of the street and the number or the name of two streets for street crossings. This procedure became more challenging because of the lack or misspelling of this information in some records. The geolocation of the data required the creation of a database containing every possible location of Madrid city. This was accomplished using GIS operations and different databases, mainly the Madrid Council Open Data Portal and Spain National Geographic Institute (IGN). This information was joined to the accidents database using string-searching algorithms and it was possible to geolocate 97 % of the accidents. Later, the district code was added to each observation and this dataset was grouped by district to obtain the dependent variable to study in this analysis: the number of crashes per district. Figure 1 shows the location of the accidents per city district and victim severity.

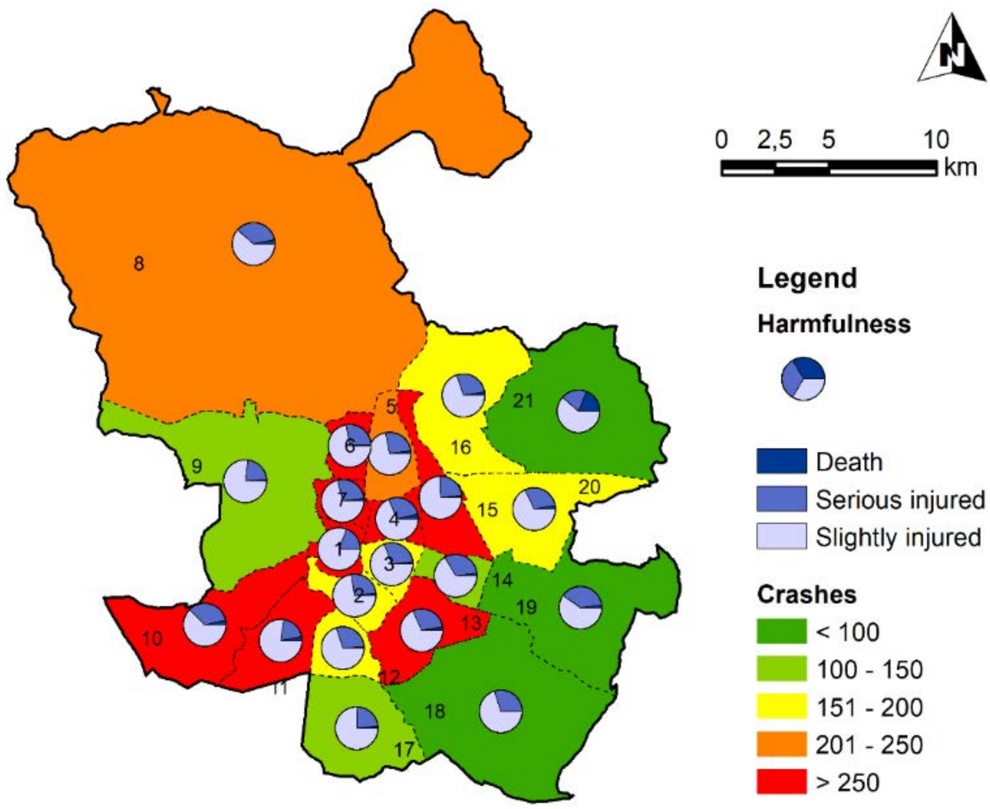

Figure 1: Number of collisions between vehicles and elderly pedestrians and harmfulness in Madrid Districts.

To measure the impact of socio-economic and infrastructure features on elderly road safety in this macroscopic analysis, different variables (see Table 1 and Figure 2) regarding Madrid districts were gathered and processed from various data sources.

Socio-economic variables are inhabitants, population density, ageing rate, average annual income per household and Activity Centres (Point of Interest, POIs). Inhabitants is an indicator of the exposure, in the absence of pedestrian flow data. Population density reflects how crowded a certain district is. Ageing rate captures the population structure.

Average annual income per household states the socioeconomic status of a district. Inhabitants information was available via the Spanish Statistics National Institute (INE) for the period 2006-2014. These data were grouped per year and census section and five-year age group, and via Madrid Council Open Data Portal for the period 2014-2018. These data were grouped per year, district, and age of inhabitants.

It was possible to postprocess both files to construct a single homogenous dataset containing the number of inhabitants living in each district and year, separating them in five-year age groups. Population density was calculated regarding the surface of each district and the information about inhabitants.

Furthermore, ageing rate was obtained as the ratio between inhabitants over the age of 65 and total inhabitants of each district. In the following analysis only last year data will be used for simplicity reasons, because ageing rate has increased slightly in Madrid city. Finally, average annual income per household was obtained for each district directly from the Madrid Council Statistical Portal for the year 2015.

Activity centres were included in this study through the location of Points of Interest (POIs) existing in each district. The number of POIs indicates the possible locations where pedestrians can access to. Hence, it can be associated with a higher pedestrian flow.

This information was obtained directly from the Madrid Council Data Base, when it was possible, and from the Madrid Council Open Data Portal in the form of point-shapefiles that were located on a map and intersected with Madrid districts' geometry. The number of locals per type -restaurants, stores, senior centres, and hospital centres- was calculated in each district. In this study, it was used the total number of these points as a unique variable named POIs.

Infrastructure data group different features about the existing road network. At this point of the research, only direct data will be used. This way, infrastructure variables that require a complex process to be obtained, such as sidewalk widths, are planned to be used in further research. Total length of roads was obtained for each district from the Madrid Council Database.

In consequence, road density considering the surface of each district was computed. Street crossing location was found ad-hoc using the geometry of the street axis and GIS techniques. In addition, signalised street crossing locations is available at Madrid Council Open Data Portal. Hence, it was calculated the proportion of signalised intersections of each district.

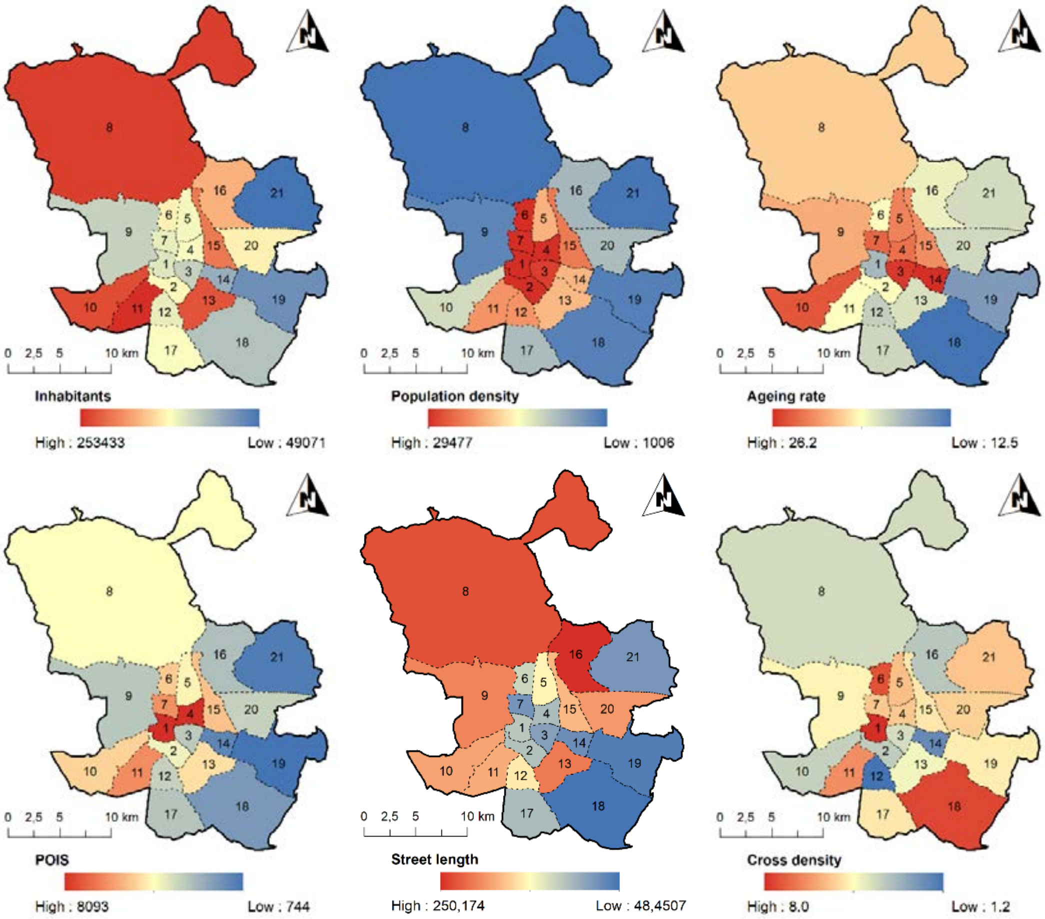

Figure 2: Spatial representation of independent variables.

Group	Variable	Unit	Mean	St. Dev.	Min	Max
Socio-economic	Inhabitants	#	155,834.40	56,436.15	49,071	253,433
	Population Density	#/km2	14,007.85	9,700.58	1,006.00	29,477.78
	Ageing rate	%	20.13	3.78	12.53	26.16
	Average annual income per household	€	39,209.01	11,146.21	24,688.07	60,947.89
	POIS	#	2,844.29	1,637.71	744	8,093
Infrastructure	Road length	km	140.21	62.58	48.45	250.17
	Road density	km/km2	11.67	7.17	0.94	22.74
	Street crossing density	#/km	4.92	1.61	1.18	8.03
	Signalised street crossing	%	18.99	9.69	5.02	43.95

Table 1: Statistical summary of the independent variables.

At this point, the information reunited in this section was ready to construct a statistical model to assess the importance of the independent variables on the number of vehicle-elderly pedestrian collisions per district in Madrid city. These operations are explained in the following sections.

3.3. The Negative Binomial Regression

This study uses a Negative Binomial (NB) Regression, which is widely spread throughout road safety crashes frequency estimation in general and in macroscopic studies (Ziakopoulos and Yannis, 2020). The output of this regression can only have null or positive numbers.

This model is derived from a Poisson-gamma distribution (Hilbe, 2011) and it can handle over dispersed data, on the contrary of the Poisson regression in which the mean and variance of the data are considered to be equal. As overdispersion was present on the crash frequency per district data, a NB was suitable to construct a statistical model. The density function of the NB is as follows (equation 1):

$$\mathrm{P}(Y = y_i) = (\Gamma(y_i + \alpha^{-1}))/(\Gamma(\alpha^{-1}) y_i!) \cdot (\alpha\mu_i)/(1 + \alpha\mu_i))^{y_i} \cdot (1)/(1 + \alpha\mu_i))^{\alpha^{-1}} \quad (1)$$

Where P(Y=yi) is the probability of Y being yi, μi is the expected number of events, α is the dispersion parameter and yi is the number of occurrences at i. The expected number of vehicle-pedestrian collisions is given by the following equation (2):

$$\mu_i = \exp(\beta_0 + \sum_{j=1}^{n} \beta_j' x_{ij}) \quad (2)$$

Where μi is the expected number of events, β0 is the estimated intercept if it is considered, βj are the estimated parameters and xij are the independent or explanatory variables at i.

3.4. Model Assessment

After collecting the proposed variables for every district, the next step is to formulate a Negative Binomial Regression that returns the best goodness of fit in the operation of calculating the total number of crashes in each district. This process involves constructing and comparing every possible combination of the 10 selected variables. Thus, an exhaustive procedure was performed to test every subset of the candidate variables and approximately 1,000 models where constructed and assessed based on their Akaike Information Criterion (AIC). The AIC (equation 3) is an estimator of the goodness of fit based on the likelihood and the number of parameters of the model. This criterion does not report an overall score on the goodness of fit, but a rating to compare a set of models that are employed on the same data. The final model is the one with the lowest AIC value.

$$AIC = 2k - 2\ln(L) \quad (3)$$

Where L is the maximum of the likelihood function and k is the number of parameters of the model.

3.5. Results

In this section it is presented the model that was found to have the lowest AIC value among all the possible ones. This final model is based on inhabitants, population density, ageing rate, road length and number of POIs. All the variables have a positive effect on the total number of collisions between vehicles and pedestrians over the age of 65. The most significative variable is the population density, followed by inhabitants, POIS, ageing rate, and road length. Every variable has a p value smaller than 5%, which means that the null hypothesis of the estimate being null is rejected.

A greater number of inhabitants in a district is found to have direct effect on the number of crashes in that district. This can be explained if it is assumed that a pedestrian that suffers a collision is an inhabitant of that very same district (i.e., pedestrian flow increases with population) or if it is presumed that it is more likely that a person walking in one district is an inhabitant of that district. This way, the variable “inhabitants” could also be understood as an indicator of pedestrians’ traffic. Also, population density is an indicator of how crowded a district is, and even a sign of how tall the buildings are. This way, population density provides an indicator of how many conflicts could happen in an equal area. Ageing rate parameter is found to be positive. It can be understood by the same argumentation about inhabitants and presuming that the elderly usually transits in their own district.

From the infrastructure perspective, as road length increases so does the number of crashes. This is explained because road length is a measure of exposure and as it improves the probability of a crash occurring increases, too.

Finally, from the land use point of view, the number of Points of Interest also has a positive effect on the number of crashes. This fact can be explained because it can be expected that there would be a higher pedestrians and vehicle traffic where there are more of these special locations. In consequence, exposure would be higher in those districts where the number of POIs is elevated. Also, it is important to note that those points act as attractive nodes to people.

Variable	Estimate	Std. Error	z value	p-value	
Intercept	3.103	1.878e-01	16.524	< 2e-16	***
Inhabitants	4.195e-06	8.722e-07	4.810	1.51e-06	***
Population density	2.768e-05	4.775e-06	5.797	6.74e-09	***
Ageing rate	2.354e-02	8.763e-03	2.686	0.00724	**
Road length	2.149e-03	8.456e-04	2.542	0.01103	*
POIs	9.958e-05	2.375e-05	4.192	2.76e-05	***
Significance Codes	0 ‘***’	0.001 ‘**’	0.01 ‘*’		
Log-likelihood	-98.859				
AIC	211.718

4. CONCLUSIONS

In this study, a negative binomial regression model was constructed to evaluate the number of collisions between one vehicle and one elderly pedestrian at a district level in Madrid city, considering socio-economic and infrastructure variables to assess their importance. It can be considered a first approach on the subject by the authors. Because of that, mainly direct data has been used to study the phenomenon. A database containing features about Madrid districts was constructed to be the independent variables in this study.

Crashes that were found to be suitable for this study were geolocated using self-designed algorithms to be placed in a GIS software in order to obtain the number of crash occurrences in each city district, that is the dependent variable in this research. Later, these two objects were joined to form the final dataset to construct the regression model. An exhaustive model search was performed to find the model with the lowest AIC, that was the indicator to assess the goodness of fit.

Variables from all groups have been found to be significant. The final regression model in composed by inhabitants, population density, ageing rate, road length and the number of Points of Interest (POIs), being population density the most significant in the model. The small sample size used in this study (21) is due to the lack of direct information about the proposed variables at a smaller spatial level, such as neighbourhoods. This issue can be solved as it is described in the next paragraph.

Further research is considered to be necessary in various respects due to some reasons:

- There is a remarkable heterogeneity inside the districts in some variables. In consequence, the study of the neighbourhoods or using a homogeneous grid is thought to be the next step to follow. Furthermore, some of the candidate variables have not been found to be significant, but in a further analysis at another scale they will be tested again. Also, sample size will be increased if another spatial unit is used. Finally, one of the most time-consuming tasks carried out was to geolocate the accidents. The data obtained in this respect is understood to be valuable and it will be used in further analysis at a smaller spatial level. Because of these main reasons, a similar study on a smaller spatial unit will be carried out, although it will be necessary to measure some already used variables in a different manner.
- New variables that require to be obtained ad-hoc will be employed in further analysis. For instance, it is the case of not available infrastructure data regarding sidewalks width.
- A change in the methodology is also a way to go. In this sense, a significant number of approaches to study the phenomenon could be used. For instance, a multinomial logistic regression to study the severity level or a study based on street segments.

These proposals imply collecting a bigger amount of data and executing more processes than the option of changing the spatial unit to be studied. Therefore, this option will be implemented after the first one.

The ultimate objective of this research is to develop a set of countermeasures to mitigate road safety issues in view of the present population ageing process. Developing criteria and strategies about how cities should be designed is an important subject to reduce elderly pedestrian road accidents. Further research will explore in more detail possible contributory factors that are not found in this paper.

ABSTRACT

In recent years Spain shows the great reduction in the accident rate that has been achieved and the improvement of the behavior of road users, despite this, there is still a need to improve many areas. In 2016 for the first time since the last 13 years, the number of fatalities increased by 7% concerning to the previous year. In this paper, analysis and prediction of road traffic accidents (RTAs) of high accident locations highways in Spain, were undertaken using Artificial Neural Networks (ANNs), which can be used for policymakers, this paper contributes to the area of transportation safety and researchers. ANN is a powerful technique that has demonstrated considerable success in analyzing historical data to forecast future trends.

There are many ANN models for predicting the number of accidents on highways that were developed using 4 years of data for accident counts on the Spain freeway roads from 2014 to 2017. The best ANN model was selected for this task and the model variables involved highway sections, years, section length ,annual average daily traffic (AADT), the average horizontal curve radius, Slope gradient, traffic accidents with the number of heavy vehicles. In the ANN model development, the sigmoid activation function was employed with the Levenberg-Marquardt algorithm and the different number of neurons.

The model results indicate the estimated traffic accidents, based on appropriate data are close enough to actual traffic accidents and so are dependable to forecast traffic accidents in Spain. However, it demonstrates that ANNs provide a potentially powerful tool in analyzing and predicting traffic accidents. The performance of the model was in comparison to the multivariate regression model developed for the same purpose. The results prove that the ANN model stronger forecasted model which produced estimates fairly close to forecast future highway traffic accidents with Spanish conditions.

1. INTRODUCTION

Traffic accidents in Spain shows the great reduction in the accident rate, that has been achieved in recent years as shown in Figure 1 and the improvement of the behaviour of road users. This reduction is mainly due to the increase in the use of the helmet and the belt, the downward trend in the consumption of alcoholic beverages, better user behaviour, improvement in infrastructure and the updating of the security systems of the vehicle fleet according to (DGT,2011-2017).In spite of this, many areas such as the conservation and signalling of roads, speeding or distractions due to the use of mobile phones are still to be improved.

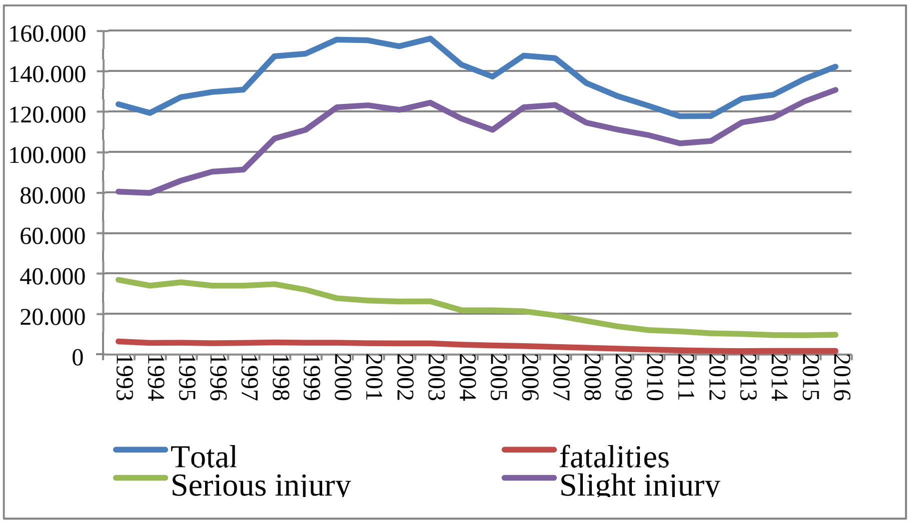

Figure 1: Number of Accidents (interurban and urban roads) in Spain. (DGT, 2017).

However, although the accident rate has been reduced in recent years, in 2016 for the first time since the last 13 years the number of deaths increased by 7% compared to the previous year (Figure 2). The cost in human lives of these traffic accidents requires the implementation of road safety policies as well as studies and methodologies that allow preventing accidents by identifying potential causes and improving infrastructure.

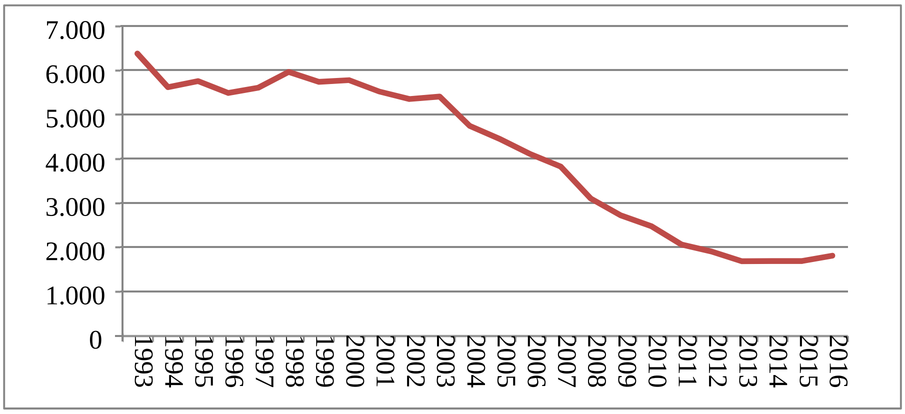

Figure 2: Number of fatalities (interurban and urban roads) in Spain. (DGT, 2017).

Even with relatively low risks, the General Direction of Traffic tries to further increase road safety. From the perspective of road owners and road safety managers, the understanding of the factors that contribute to a higher frequency of traffic accidents is of paramount importance. In addition to the three Es; engineering, enforcement and education used to manage road safety (DFT, 2011), the planning, construction and maintenance of safe roads require in general the consideration of different fields influencing the occurrence of road accidents (e.g. human behaviour, improvements in automotive manufacturing and weather).

Many research has been carried out on the prediction of traffic accidents in countries using various statistical techniques. However, the numerous variables and complex relationships between the characteristics of the various traffic elements require different analytical techniques than traditional ones. A recent approach to analyze these relationships is the artificial neural networks (ANN) that many scientists have proposed and used successfully as an alternative to conventional ones.

Regression method in predicting time series associated to complex atmospheric and environmental phenomena. This paper presents and discusses the development of a prediction model to estimate future traffic accidents in Spain using the ANN method.

2. MULTIVARIATE REGRESSION MODEL

Regression analysis approaches implement ancient accident statistics to relate accidents to the most contributing factors. Multiple linear regression model is planned to have the following form:

$$Y = B0 + B1(X1) + B2(X2) + B3(X3) + B4(X4) + B5(X5) + B6(X6) \quad (1)$$

Where:

- Y: the predicted number of accidents.
- B0: the constant coefficient of the regression line.
- B1, B2, B3, B4, B5, B6: the regression coefficients. Where,
- B1: Segment length
- B2: Slop gradient %
- B3: Horizontal curve.
- B4: Annual Average Daily Traffic (AADT)
- B5: Heavy vehicle percentage .
- B6: Speed.

The analysis was carried out using Statistical Package for Social Science (SPSS) version24 The performance of the model is expected based on the R-Squared (R^2) value of the regression which is presented in the results (Section 5).

3. ARTIFICIAL NEURAL NETWORKS AND APPLICATIONS

Artificial Neural Network is a subdomain of Artificial Intelligence (AI) system which has been used recently to solve many variety of civil engineering problems. A neural network is an information processing prototype and a data-modelling tool that represents complex relationships with similar to the human brain. ANNs are known to be universal function approaches and are capable of exploiting nonlinear relationships between variables. Neural networks are a class of flexible nonlinear regression, data reduction models, and nonlinear dynamical systems. They consist of a large number of neurons, i.e. simple linear or nonlinear computing elements, interconnected in often complex ways and organized into layers according to (Sarle, April 1994).

The fundamental element of this model is the novel structure of the information processing system. It is composed of extremely interconnected processing elements termed neurons. Every neuron has a value, weight and bias (constant) where the neuron’s net input is the value of the neuron multiply by the weight plus the bias.

Layers composed of an input layer which contains the data to be classified by the network (independent variables), one or more hidden layers which do the processing, and an output layer which contains the desired output (dependent variable). Every layer contains of neurons connected to each additional neuron in the preceding layer by a connection that represents the weight. An example of an ANN with its several layers is shown in Figure 3. (S. D. Balkina, et al., 2000).

Activation functions: These are also called transfer functions that define the mappings from inputs to hidden nodes and from hidden nodes to outputs, respectively. (Math Works, 2019) ANNs have been applied effectively in solving in many civil engineering problems related to classification, prediction, and function approximation. In the transportation area, ANN has many applications and when applied to predict speed, for example, (J. McFadden, W. T. Yang, and R. Durrans, 2000) found it to offer predictive power superior to those of regression models. This is mainly because of their ability to model non-linearity, and flexibility with large complex data sets.

Auxiliary applications include the work of (Shoukry ,2005) who used the ANNs in classification of severity levels of accidents and reported several applications of ANN in the transportation field particularly in the traffic safety area.

(Chiou,2006) employed ANN to develop an expert system for the appraisal of two-car accidents (Xiangzheng Xu ,2009) applied the ANNs technique to estimate traffic safety in China, and (Wenhui,2009) researched the evaluation of safety in traffic accident scene based on ANN.

(Alkheder et al., 2017)used data from 5973 traffic accident records that happened in Abu Dhabi (2008 -2013) to develop an ANN model to forecast the degree of injury of road traffic accidents, which model had prediction performance about 74.6 % once using the testing set.

(Borja et al., 2018)was presented an approach for founding an accident risk prediction model, which can be used as a policymaking tool in infrastructure supervision. The method allows for an appropriate handling of the existing data, study show it can be used to develop models using artificial neural networks (ANNs) and creates a systematic optimisation process to determine the optimal architecture of the ANN model. Which was executed using data for accident counts for the Swiss national roads (2009 -2012). It was found that ANNs can be used as a practicable method to predict the frequency of road accidents. As accident rates are quite exceptional events, the data were categorized through a large portion of zero observations.

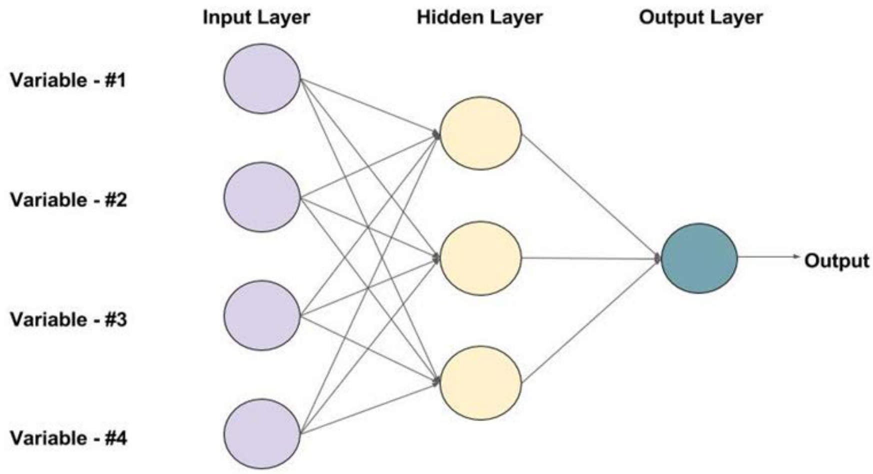

Figure 3: Typical layers in neural networks.

4. METHODOLOGY AND ANALYSIS

4.1 Case study

The collected data of the number of accidents covered a period of four years from 2014 to 2017 and relate to the road network of the many province of Spain as Segovia, Burgos, Madrid, Zaragoza, Soria, Guadalajara, Cuenca, Valencia, Toledo, Sevilla, Cordoba. The traffic accident data were collected from the General Direction of Traffic. Each accident data has several information such as the date, accident location, vehicle type, driver's gender, driver's age, accident type, the day and time, the number of fatalities, the number of injured persons, the number of involved vehicles, and the number of damaged vehicles.

In addition to these data, geometric characteristics of the highway such as 85th percentile speed, Annual Average Daily Traffic (AADT), the degree of horizontal and slope gradient in each section, were collected from ministry of public work and housing of Spain. After removing the absent and incorrect data, these data were categorized with 9 variables as shown in Table 1 (Çodur MY, 2012).

Variable	Variable Name	(Numerical /Binary) code
X1	Year (2014-2017)	Categorical Value (2012-2013-2014-2015-2016-2017)
X2	Segment length (m)	Numerical Value
X3	Slope gradient %	Numerical Value
X4	Radius of horizontal curve	Numerical Value
X5	AADT	Numerical Value
X6	Heavy vehicle %	Numerical Value
X7	85th percentile speed (kph)	Numerical Value
X8	Highway Sections	Categorical Value (A-1, A-2, A-3, A-4)
X9	Freeway Segment	Categorial Value (A-1(Segovia, Burgos, Madrid), A-2(Madrid, Zaragoza, Soria, Guadalajara), A-3(Madrid, Cuenca, Valencia) , A-4(Toledo, Sevilla, Córdoba))
Y	Number of Accidents	Numerical Value

Table 1: Input variables.

In order to analyze the traffic accidents on the highways, one needs to select highways that possess a wide variety of geometric and traffic characteristics. The aim of this data collection is to divide these highways into segments with homogenous characteristics as defined by(Deublein et al., 2015). After reviewing numerous highways around Spain, it was decided that A-1, A-2, A-3, and A-4 median-divided highways were most proper for this task (Çodur MY, 2012).

The highways with total of 655 km of freeway that connect around of Spain. These freeways are long enough to produce a satisfactory number of segments to develop the model. The information on highways includes geometric characteristics such as horizontal curve, slope gradient, and traffic characteristics such as AADT. A-1, A-2, A-3, and A-4 were divided into 3, 4, 3, and 3 highway segments, respectively and defined by any change in the geometric and highway variables. So, each highway segment is uniform with respect to all the possible geometric and traffic features (Figure 4). The freeway routes are as follows:

- (A-1) Segovia, Burgos, Madrid (101 km);
- (A-2) Madrid, Zaragoza, Soria, Guadalajara (231 km);
- (A-3) Madrid, Cuenca, Valencia (163 km); and
- (A-4) Toledo, Sevilla, Córdoba (160 km).

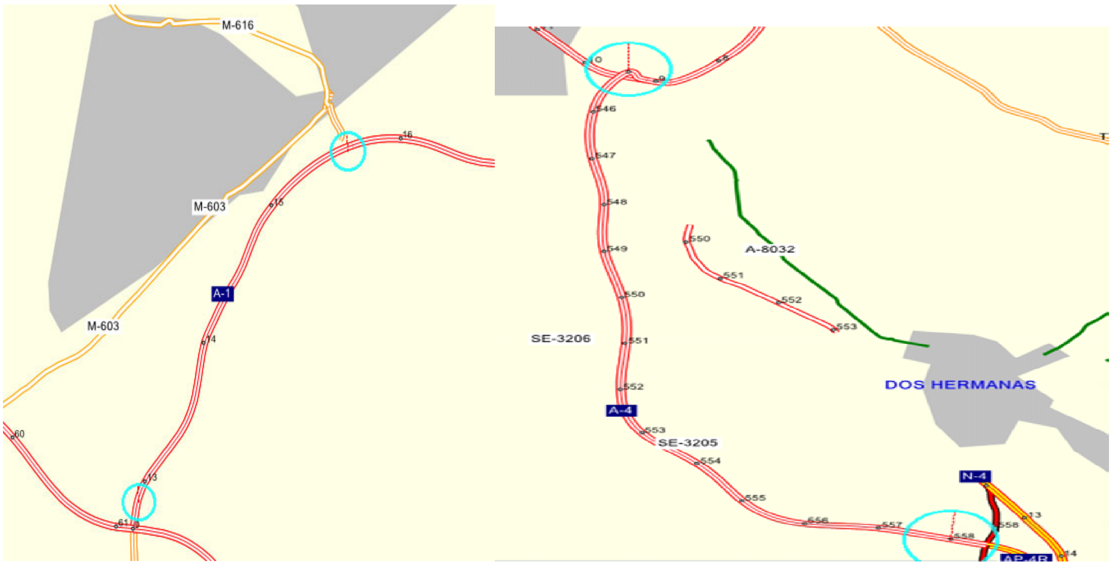

Figure 4: Spain's Freeway (Autovía).

4.2 Development of ANN models

The ANN models are multilayer feed-forward ANNs (i.e. no loops in the network) with between two and ten neurons in a single hidden layer and the equal number of neurons in the output layer as there are output variables. the number of neurons in the hidden layer (h_n) is different from 2 to 10, as advised by (Blum, 1992).

In the ANN model, independent variables are labeled as the input, and dependent variables are labeled as the output. Correlation analysis was performed to access the linear association between the variable. The results of the importance of variables relative to the number of accidents of the correlation analysis is shown in table 2. As of the parameters applied in modelling, eight significant parameters were found based on those criteria. Highlights are years, highway segments, section length (m), annual average daily traffic (AADT), the radius of the horizontal curve, slope gradient (percentage), heavy vehicle (percentage), and 85th percentile speed (km/hr).

The following nonlinear model is proposed to have the following form:

$$y = f\{[\text{years}], [\text{highway segments}], [\text{section length}], [\text{AADT}], [\text{slope gradient}], [\text{heavy vehicle traffic}], [\text{horizontal curve}], [\text{85th percentile speed}]\} \quad (2)$$

Where Y= the number of accidents

Data sets were divided into three sets: the training set (70% of the total data), the validation set (15% of the total data) and the test set (15% of the total data), these phases were performed using MATLAB. Training algorithms don't use the validation or test sets to adjust network weights. The structural design of the ANN was as shown in Figure 5, Personal Communication with(Mosa AL-Akhras, 2019).

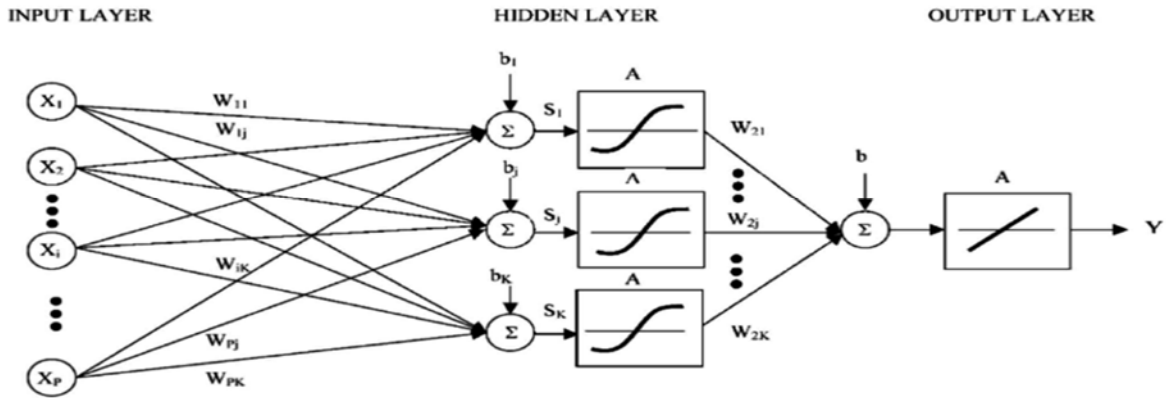

Figure 5: Structural design of the ANN.

The validation set may optionally be used to track the network's error performance, to identify the best network and to stop training if over-learning occurs.

The test set is not used in training at all, and it is designed to give an independent assessment of the network's performance when an entire network design procedure is completed. Selected activation functions were used for input hidden layer; Tan-sigmoid transfer function and for output hidden layer; Linear transfer function.

Variable name	Importance %
AADT	77 %
Segment length	53.4 %
Heavy vehicle percentage	50.3 %
Radius of horizantal curve	41 %
Slope gradiant percnetage	35.5 %
85^{th} percentile speed	22.7 %

Table 2: Importance of traffic accidents variables.

5. RESULTS

The Neural Networks allow the development of different alternatives by changing the number of hidden layers. Nine alternative models, with different number of hidden layers, were considered and Table 3 summarizes the results. Model 8 was found to be the best model with the highest coefficient of determination (R^2 =0.9992).

A comparison between the actual and the predicted values using model 8 produced the results shown in Table 4. The results were found to be very satisfactory with relatively small residuals especially in recent years where more reliable data bases are available through using more advanced data compilation techniques. The ANN model outputs are exhibited in Table 6.

Model No.	Number of hidden neurons (h_n)	Correlation Coefficient (r)
1	2	0.9668
2	3	0.9930
3	4	0.9772
4	5	0.9639
5	6	0.9900
6	7	0.9950
7	8	0.9871
8	**9**	**0.9992**
9	10	0.9927

Table 3: ANN models alternatives with different number of neurons.

R^2 is used to measure the nearness of fit. A perfect fit would result in R^2 approximately equal 1 , a very good fit near 1, and a poor fit would be near 0. In the ANN model R^2 is 0.9992 . This shows that the ANN model is an suitable method for analysing road traffic accidents.

Segment Name	Actual	Forecasted	Residual
Segovia(A-1)	9	40.783	-31.783
Burgos (A-1)	36	28.390	7.609
Madrid(A-1)	735	735	0
Madrid(A-2)	704	704	$-2.27e^{-13}$
Zaragoza(A-2)	325	325	$5.68e^{-14}$
Soria(A-2)	38	38	$-1.27e^{-13}$
Guadalajara(A-2)	183	183	$-5.68e^{-14}$
Madrid(A-3)	543	534.093	8.906
Cuenca(A-3)	42	42	$2.842e^{-14}$
Valencia(A-3)	481	481	0
Toledo(A-4)	209	209	$-8.526e^{-14}$
Sevilla(A-4)	62	53.445	8.554
Córdoba(A-4)	228	228	$-5.68e^{-14}$

Table 4: Actual and forecasted number of accident by ANN during four years (2014-2017) for model No. 8.

A summary of the results obtained from the regression model is shown in table 5. it reported the strength of the relationship between the dependant and independent variables.

R	R^2	Adjusted R Square	Std. Error of the estimate
0.976[a]	0.952	0.903	80.851

a. Predictors: (Constant), Speed, Segment_length, Slop, Heavy_veh, AADT, H.Curve

Table 5: Model Summary.

The multiple–correlation coefficient(R) reflects the linear correlation between the observed value and the expected value, it is large value reflects a strong relationship of how the independent variables can affect the predicted value of accidents.

The high value of R^2 indicates that 0.95 of the variation in accidents is explained by the independent variables in cooperated in the model. Table 6 shows the results obtained from the regression model.

The final regression model developed using the available data as the following form :

$$y = (\mathrm{B1} * 0.004) + (\mathrm{B2} * 7081.988) + (\mathrm{B3} * -11.383) + (\mathrm{B4} * 0.008) + (\mathrm{B5} * 3.07) + (114 * \mathrm{B6}) - 677.128 \quad (3)$$

Segment Name	Actual	Forecasted	Residual
Segovia(A-1)	9	-49.2	58.2
Burgos (A-1)	36	29.1	6.9
Madrid(A-1)	735	573.1	161.9
Madrid(A-2)	704	677.9	26.1
Zaragoza(A-2)	325	339.8	-14.8
Soria(A-2)	38	-58.4	96.4
Guadalajara(A-2)	183	121.6	61.4
Madrid(A-3)	543	605.5	-62.5
Cuenca(A-3)	42	141.8	-99.8
Valencia(A-3)	481	394.2	86.8
Toledo(A-4)	209	191.1	17.9
Sevilla(A-4)	62	28.7	33.3
Córdoba(A-4)	228	119.9	108.1

Table 6: Actual and predicted number of accidents using Regression.

A comparison between multiple linear regression model and the model produced by the ANN is presented in tables above ,it can be seen that the ANN model has better predictive power than regression model.

6. CONCLUSION

In this study, the factors that cause accidents are investigated, for providing road safety, and accident prediction models that include relations between these factors have been established. For the geometrical features of highways sections and traffic accident reports the years from 2014 to 2017 were used to form the database. The obtained data from the database in this study have been investigated with ANN as a tool of forecasting techniques. Since ANN method is a more flexible methodology also, capable of evaluating all of the traffic accident characteristics, it is selected for modelling the traffic accidents data.

The model results show that the traffic volume (AADT) with the high percentage (77%) is the most significant factor affecting the number of accidents on the highways. Heavy vehicle percentage and segment length have almost the same effect as the second important parameter. The degree of horizontal curvature is the third one and Slope gradient %, percentile speed have small influence on the output factor.

These results have suggestions for policy makers, transportation system designers, and researchers. Transportation safety designers cannot easily identify factors, make recommendations for incremental changes in the factor, and hope to achieve major differences in accident levels. The problems have to be evaluated from a multidimensional perception: a wide variety of geometric and traffic characteristics. Researchers similarly may adopt techniques such as neural networks for analysis of such variables. This paper goals to proposal and apply the potential of neural network analysis concluded an pattern of the accident prediction model in the transportation engineering.

ABSTRACT

Few studies have examined whether there is an association between these services and traffic accidents, and virtually all of the existing studies focus in cities of United States. In this study, we analyse the impact of ridehailing services on traffic accidents with at least one young person dead or seriously injured (16-39 years old) in the municipality of Madrid from 2014 to 2018. To do this, a regresion analysis has been carried out using a Random-Effects Negative Binominal Regression (RENB). The results of the model show that Uber and Cabify services are related to a reduction in urban accidents.

1. INTRODUCTION

Traffic accidents are one of the world´s leading causes of death among children and young people between the ages of five and twenty-nine. Around 1.35 million people per year die as a result of a traffic accident. Furthermore, between 20 and 50 million people involved in traffic accidents sustain injuries which, in many cases, result in a disability (World Health Organization, 2018).

In Spain, 1.755 people died in traffic accidents, according to the final balance of the General-Directorate for Traffic (2020). This figure includes people who died on interurban and urban roads during the 30 days following the accident. On urban roads, there were 519 deaths, 6% more than in 2018. Cities accounted for 30% of all deaths, the highest percentage since records have been kept.

The emergence of “ridehailing” platforms, such as Uber, which operates in more than 630 cities in 80 countries around the world (Uber, 2020), or Cabify, which is present in 11 countries and more than 90 cities in the world (Cabify, 2020), can improve the supply in demand segments that previously had difficulties to access taxis, thereby reducing road traffic-related deaths and injuries.

Despite the fact that two of Uber's top five markets are located outside of the United States, and that the majority of ridehailing trips worldwide occur beyond US borders, most studies of the relationship between the advent of Uber and road accidents have focused on the United States. Research from the United States has produced mixed findings, with some research observing a decline in at least some types of traffic fatalities following the rollout of Uber, but with other studies finding evidence for either no effect of Uber or even an increase in fatalities (Kirk et al., 2019; Barrios et al., 2019; Greemwood and Wattal, 2017; Martin-Buck, 2017; Peck, 2017; Dills and Mulholland, 2018; Morrison et al., 2018; Brazil and Kirk, 2016).

Most of these studies have analysed the impact of these services on alcohol-related road accidents. For example, A report by MADD (Mothers Against Drunk Driving) shows that this type of services offers positive results in terms of road safety: young people prefer to use this service as a designated driver instead of trying to drive themselves home after they had too much to drink.

The study results are also supported by other data: after UberX launched in cities across California, monthly alcohol-related crashes decreased by 6.5 percent among drivers under thirty (Flor et al., 2020).

Although alcohol consumption is one of the main causes of death in road accidents, this study focuses on Madrid, and ask whether the deployment of ridehailing services, as Uber or Cabify, has been associated with a significant change in the number of traffic accident fatalities and seriously injuries related young people, whether or not they have consumed alcohol.

If ridehailing yields declines in traffic fatalities and seriously injuries in Madrid and beyond, it may be advantageous for cities to partner with ridehailing companies to promote its use. Conversely, if ridehailing actually increases the risk of road accidents and fatalities, it may be advisable for cities to be cautious in their licensing and regulations with respect to ridehailing (Kirk et al., 2020).

2. METHODS

To analyse the impact of ridehailing platforms on traffic accidents in Madrid, the authors had to face two main challenges.

On the one hand, in a big city like Madrid, with more than 3 million inhabitants, there are large geographical contrasts. For this reason it was necessary to analyse performance by districts.

On the other hand, to carry out an indeph study of the traffic accidens, with young victim, ocurred in the period from 2014 to 2018.

It is also necessary to know the impact of Uber and Cabify as well as the evolution of other socio-economic factors on accident rates. To this end, it was decided to carry out a spatio-temporal analysis to establish a comparative analysis between the accident rate in the previous years to the implementation of these services and the years thereafter.

2.1 Sample

We used an observational panel study design to examine within-district changes in traffic accident fatalities and seriously injuries related young people before and after implementation of Uber and Cabify services for the period from 2014 to 2018. The analytic sample contained yearly observations of each of the 21 district of Madrid (Fig.1).

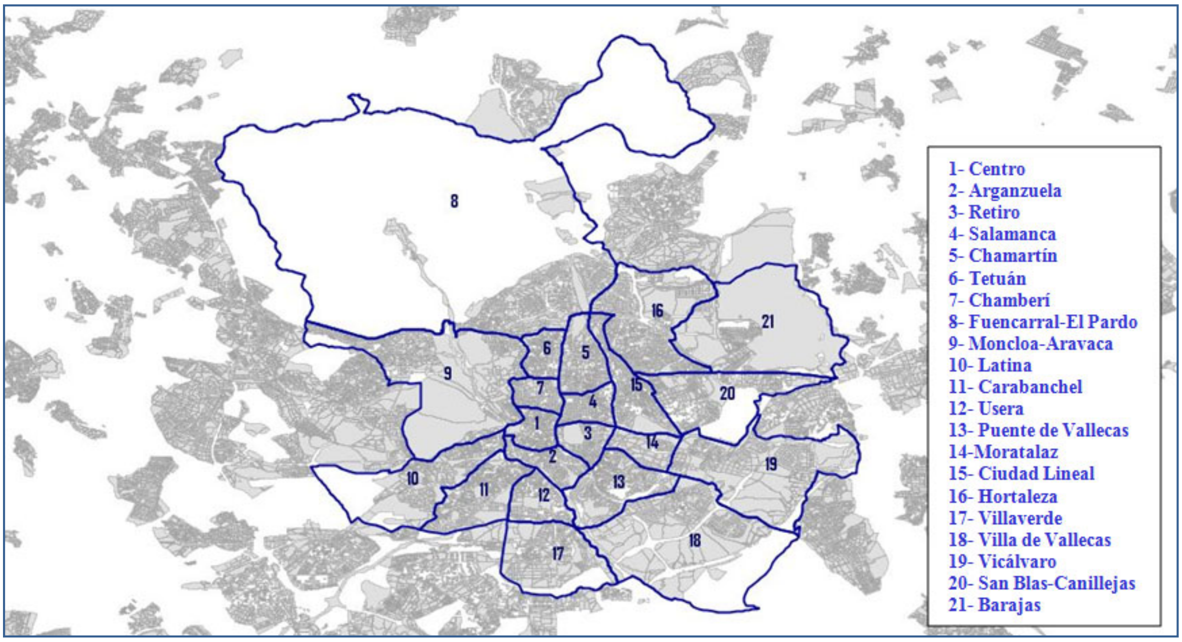

Figure 1: Map of the 21 districts of Madrid. Source: own research.

2.2 Dependent variable

According to the study carried out by Young and Farber (2019) in the city of Toronto, with regard to age, ridehailing users tend to be younger than average, and to be most often aged between 20 and 39 years old. Despite there being slightly more 30-39 than 20-29 years old ridehailing users, raidhailing trips made by 20-29 years old represent 2% of all trips conducted by individuals in this age group, which is more than double the share of raidhailing trip overall, making this age group the most likely to use radehailing service.

For this reason, in this study we wanted to analyse what has happened to accidents with victims in these age groups since the arrival of Uber and Cabify in Madrid. As all kinds of traffic accident variables have been considered, the dependent variables are divided into two separate group. In the first group, the age range for young victims cover from 15 years, in the case of involved moped accidents, up to 29 years.

The second group includes young victims from 30 to 39 years old. The two dependents variables measured for each of the 21 districts of Madrid are:

- total accidents with at least one fatality or serious injury between 15 and 29 years of age
- total accidents with at least one fatality or serious injury between 30 and 39 years of age

During the period from 2014 to 2018, a total of 2.182 accidents, with at least one young people death or seriously injured, were recorded (Fig.2). These data have been obtained from the City Council of Madrid which regularly publishes road accident data of the city and was produced by the Municipal Police. Each file includes a record for each person involved in the accident (drivers, passengers, pedestrians, witnesses, etc.), the type of accident (double collision, multiple collision, pedestrian impact, etc.), the time of the accident, the district, the street, the meteorological factors and the harm caused.

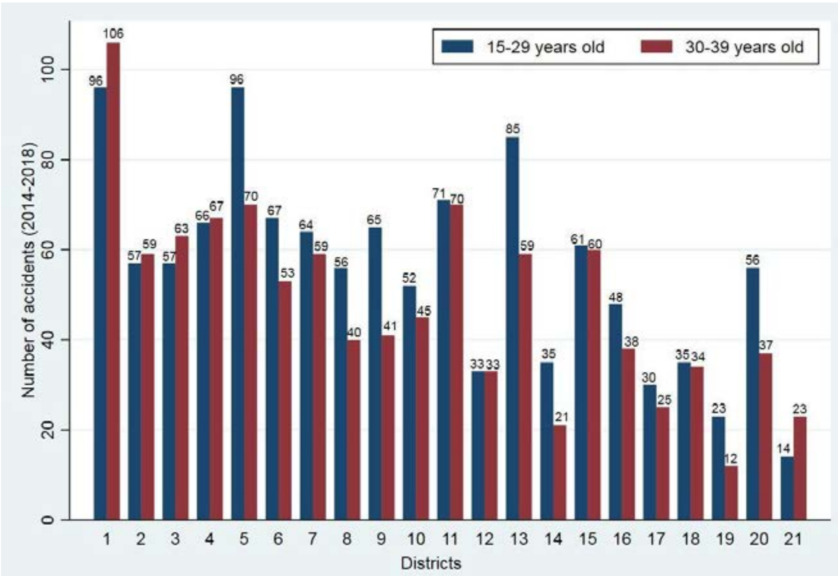

Figure 2: Crash count distribution in each district of Madrid. Source: own research.

2.3 Independent variable

The measure of Uber and Cabify deployment is a binary indicator of whether, in a given year, Uber or Cabify had established services in Madrid.

Cabify arrives in Madrid in 2011. Although it may seem logical to consider years prior to 2014 for this study, 2016 has been considered as the first year in which these services have been operating in the city of Madrid for two main reason:

- Uber arrives in Madrid in 2016
- In the case of Spain, the companies running the ride-hailing platforms Uber and Cabify recorded a considerable increase in revenues from 2015 onwards (Fig. 3).

The revenues of these companies in previous years reflect that the weight of these platforms might not be significant, as they were not yet well known among users.

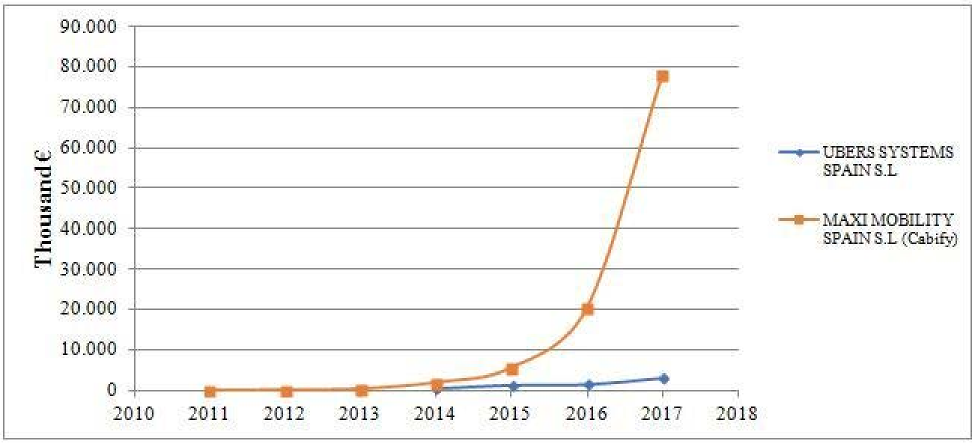

Figure 3: Evolution of Uber and Cabify income in Spain. Source: own research.

It has also been considered relevant to take into account other factors associated with crash risk. In previous studies, investigators found evidence that population influenced the rate of driver fatalities (Kirk et al., 2020). Dumbaugh and Rae (2009) studied how urban form—specifically land use and street network configurations— may influence the incidence of traffic-related crashes injuries and deaths in the City of San Antonio (Texas, USA).

The results showed that specific types of commercial land uses, such as big box stores, are related to a higher risk of accidents. Therefore, for this analysis we have taken into account the number of leisure establishments per district as points of attraction for drivers. We have also taken into account the density metro/cercanias station per district (equation 1), as a if young people do not have their own vehicle or a metro/cercanias station nearby, they may be captive to these services, generally cheaper than taxis. These data have been obtained from the City Council of Madrid publishes in its open data bank.

$$Density\ Urban\ Transport = Population/Number\ of\ metro\ stations \quad (1)$$

Table 1 shows a summary of the variables considered in this analysis.

Variables	Definition
Total accidents (15-29 years old)	Number of total accidents in each district of Madrid with at least one fatality or serious injury between 15 and 29 years of age
Total accidents (30-39 years old)	Number of total accidents in each district of Madrid with at least one fatality or serious injury between 30 and 39 years of age
Population	Number of people registered in each district
Leisure Establishments	Number of premises dedicated to the catering, leisure and entertainment activities
Density Metro/Cercanias Stations	Indicator calculated from the population of each district and the number of metro/cercanias stations.
Ridehailing	Year dummy variables 1: Uber or Cabify presence 0: neither Uber nor Cabify

Table 1. Explanatory variables. Source: own research.

2.4 Modelling urban traffic accidents

Models such as the Poisson regression, the Negative Binomial (NB), the Zero-inflated Negative Binomial (ZINB) or Multivariate analysis are frequently applied for statical analysis at the section level, but limitations in the available methodology should be tested (Lord and Mannering´s, 2010).

Considering the Madrid database of the study, over-dispersion affects the registered data corresponding to road accidents. This is one notable characteristic of crash-frequency data: the variance exceeds the mean of the crash counts, and indicates that the most common count-data modelling approach (the Poisson regression model) cannot be used.

Consequently, the most common models applied with over-dispersion and cross-sectional data are the Negative Binomial model and the Zero-Inflated Negative Binomial or ZINB model. The latter is applied when the database has a large number of zero-crash observations, thus the most appropriate model for this case is Negative Binomial, which can account for overdispersion (Casares et al., 2019).

Moreover, temporal analysis has to be included in the modelling. In other words, information has been gathered from several individuals (districts) in a given moment during various periods of time (series of years) and the best of way of processing this data is by using a cross-sectional panel data structure.

Therefore, the multivariate analysis cannot be used. As a result, the most common models applied with cross-sectional data and in the case of over-dispersion are the Negative Binomial model and the Zero-inflated Negative Binomial or ZINB model. The latter is applied when the database has a large amount of zero shock observations, so the most appropriate model for this case is the Negative Binomial model, which can explain the excessive dispersion.

However, in this case, and as we have previously seen, the accident data have been collected from 21 districts over a period of five years, which means that the data could have specific location effects and it is likely that they are serially correlated.
If there are spatial effects in the data that cannot be considered as such, the estimated standard deviations of the regression coefficients will be underestimated, as each observation actually contributes less information than the real one (Chin and Quddus, 2003). For this reason, it was decided to consider the Random-Effects Negative Binomial Model (RENB).

3. RESULTS

As previously mentioned, the study was conducted using data corresponding to the period between 2014 and 2018. Table 2 provides descriptive statistics of the variables.

	Obs	Maximum	Minimum	Standard Deviation	Mean
Dependent variables					
Total accidents (15-29 years old)	105	27	2	5,67	11,11
Total accidents (30-39 years old)	105	24	0	5,26	9,67
Independent variables					
Population (per 1.000)	105	253,433	45,95	54,11	152,67
Leisure Establishments (per 1.000)	105	3,22	0,058	0,61	0,86
Density Urban Transport	105	29.800,8	6.028,14	7.177,76	14.256,78
Ridehailing	105	1	0	0,49	0,6

Table 2: Descriptive statistics. Source: own research.

Both models are statistically significant as shown in Table 3. The ridehailing services variable is statistically significant with a negative coefficient in model 2, showing that the entry of ridehailing services has reduced young casualty crashes aged 30-39 years old.

	Dependent variables	
	Model 1	**Model 2**
Independent variables	**Total accidents (15-29 years old)**	**Total accidents (30-39 years old)**
Population	0.00379** (3.20)	0.00338** (2.89)
Density Urban Transport	-0.0000158 (-1.71)	-0.0000194* (-2.13)
Leisure Establishments	0.275** (2.80)	0.358*** (3.78)
Ridehailing	-0.0789 (-1.07)	-0.215** (-2.94)
Ln_r	4.407*** (7.50)	5.020*** (6.66)
Ln_s	3.649*** (5.77)	3.676*** (5.11)
Log-likelihood with constant only	-325.5092	-317.26
Log-likelihood at convergence	-297.60511	-281.98443
Ratio of log-likelihood index (ρ^2) and adjusted log-likelihood index (ρ^{-2})	0.091, 0.074	0.111, 0.10
Prob > chisq	0.0000***	0.0000***
LR test vs. pooled: chibar2(01), Prob>=chibar2	7.05, 0.004	4.69, 0.015
Hausman Test: chi2(8), Prob > chi2	4.87, 0.3012>0.05	6.67, 0.1547>0.05
***Significant at 0.001 level **Significant at 0.01 level *Significant at 0.05 level		

Table 3: Results of the estimated model (z-statistics in parentheses). Source: own research.

As for leisure establishments, this variable is significant with a positive coefficient in both models, which means that there is a strong relationship between agglomerations of leisure venues (restaurants, pubs, theatres, cinemas...) and a higher concentration of accidents with young people seriously injured or killed in the municipality of Madrid. With respect to the influence of the population on traffic accidents, this variable is also statistically significant with a positive coefficient in the two models, which shows that a higher level of population generates more traffic and, as a result, gives rise to an increase in traffic accidents, in the same way as in the study carried out by Casares *et al.* (2019). With respect to Density Urban Transport this variable is significant with a negative coefficient in Model 2, indicating that a higher number of metro stops decreases accidents with young people 30 to 39 years old.

4. CONCLUSIONS

The findings presented in this study reveal that the arrival of ride-hailing services in the Madrid municipality is related to the decrease in accidents with seriously injuries or deaths with young people aged between 30 and 39 years. The analysis also shows that metro stations decreases road traffic fatalities and serious injuries in this group of young people. Furthermore, population, as well as the presence of leisure establishment, increase traffic accidents with young people.

Finally, this study has only considered the traffic accidents with at least one person dead or seriously injured with young people aged betweeen 15 and 39 years. But it is very interesting to analyze what happens with other types of accidents. That is why, at present, this line of investigation continues and it is being analyzed how others variables and the presence of Uber and Cabify affect the 21 districts of Madrid, considering other kinds of road accident variables.

RESUMEN

El transporte colectivo de personas en autobús y autocar es muy importante en la mayoría de los países de Iberoamérica, y los accidentes de tráfico con implicación de estos vehículos involucran pérdidas elevadas si se consideran las pérdidas humanas, materiales y de productividad de las empresas del transporte. En cualquier país del mundo en el que éstos eventos ocurren, tienen un alto impacto mediático y avivan la preocupación por la mejora de la seguridad y la protección de los ocupantes. En la región de América del Sur, la mejora de la seguridad vial necesita alcanzar un mayor nivel de desarrollo de los sistemas de información que permitan llevar a cabo una investigación detallada y en profundidad.

Para suplir la escasez de información detallada de los accidentes con implicación de autobuses y autocares del transporte colectivo de personas (AT-TCP), cinco equipos de investigadores de las universidades: UPM de España, UPS de Ecuador y UTN, UNSa y UNTDF de Argentina, participaron en un proyecto cooperativo de investigación de accidentes en transporte colectivo de pasajeros (COOPERAXVII-12) ocurridos en los tres países y desarrollaron una metodología de análisis de datos tomados de publicaciones en medios de comunicación y datos oficiales disponibles, enfocado en el desarrollo de estudios de patrones y aplicación de modelos estadísticos.

En este trabajo se evaluó la severidad de una sub-muestra de 94 accidentes AT-TCP ocurridos en Argentina y España entre los años 2017 y 2018. Los datos fueron analizados con modelos de minería de datos: árboles de clasificación y bosques aleatorios. Los modelos permiten identificar los factores de influencia en la severidad del accidente y algunos patrones según el contexto y concurrencia de diferentes factores. De los resultados, se destaca que los accidentes de mayor severidad han ocurrido en vías interurbanas y son de tipo colisión entre vehículos, vuelco sobre la calzada y salidas de la vía con desbarranco.

1. INTRODUCCIÓN

El transporte colectivo de personas por vía terrestre, tiene una función vital en todos los países y en especial en aquellos en los que los costos del transporte por medios más veloces son elevados para grandes sectores de la población. En los países en los que existe un sistema de transporte de personas de mayor desarrollo, los medios de alta velocidad ferroviario, ofrecen a los ciudadanos una oferta mayor en un sistema competitivo de precios del transporte. Pero en países sin un sistema de transporte con alternativas, el realizado con autobuses y autocares (AyA) cumple un papel vertebrador del territorio y de la economía. Los impactos negativos del transporte como los accidentes de tráfico en todo el mundo superan el número de 1.200.000 víctimas mortales, con las consecuencias graves desde el punto de vista humano y económico dentro de la colectividad. Distintos organismos (World Health Organization (WHO) – UN) coinciden en señalar a los accidentes de tráfico como una de las principales causas en la pérdida de vidas humanas y especialmente en los colectivos de edades más tempranas. Villar Fernández, (2012) señala que los accidentes de tráfico son la segunda causa de muerte, y la primera dentro de la población juvenil comprendida entre 15 a 29 años, siendo uno de los principales problemas de Salud Pública en España.

En referencia a pérdidas humanas en España, durante el año 2017, los diferentes miembros policiales notificaron 102.233 accidentes con víctimas. Estos accidentes ocasionaron 1.830 fallecidos (en el momento del accidente o hasta 30 días después del mismo); además, 9.546 personas fueron ingresadas en un centro hospitalario y 129.616 resultaron heridas no hospitalizadas. Del total de víctimas en accidentes de tráfico con implicación de autobuses, se produjeron 3 muertos, 47 personas fueron ingresadas en un centro hospitalario y 1.171 resultaron heridas no hospitalizadas. La mayoría de ellos (87%) se produjeron en vías urbanas , los restantes (el 13%) en interurbanas, siendo la lesividad de los accidentes, en general, mayor en vías interurbanas. (DGT, 2017).

La Asociación Civil Luchemos por la vida de Argentina en el año 2017, reporta que 5.420 personas fallecieron (en el lapso de los 30 días posteriores al accidente), 6.626 resultaron heridos graves hospitalizados y 51.945 con heridas leves en los accidentes de tráfico ocurridos.

Otra fuente de Argentina (Anuario estadístico de siniestralidad vial) reporta para el mismo año: 5.472 víctimas fatales; 113.805 heridos, de los cuales 8.174 son graves que requerían hospitalización, en un total de 81.592 siniestros ocurridos. Las principales causas de muerte por accidentes de tránsito fueron: la velocidad y el consumo de bebidas alcohólicas. Para los peatones y los conductores, el problema principal es la distracción. De los números expuestos para Argentina, se deduce que existe dispersión entre ellos según las fuentes y no se disponen de datos desagregados para el estudio científico de los accidentes con AyA.

Contrariamente, en España, existe un sistema de información accesible a los investigadores y que posibilita la realización de estudios de investigación de colectivos de interés (vulnerables, transporte de viajeros, trabajadores in itinere, etc.).

El cuestionario aplicado en el proyecto de investigación COOPERA TCP se ha creado teniendo como base el existente en España, que la DGT aplica para la recogida de datos in situ. El cuestionario COOPERA TCP incluye además campos para las variables de infraestructura obtenidas con Google Maps, con las coordenadas del lugar del accidente en el marco del proyecto de investigación de accidentes con implicación de autobuses y autocares, en el que participaron varias universidades de 3 países participantes (Argentina, Ecuador y España).

Este trabajo analiza una muestra de accidentes de tráfico en Argentina y España, donde se han visto implicados autobuses y autocares, con el objetivo principal de identificar las variables que influyen en la severidad de los accidentes.

Para la identificación de los factores de influencia se utilizan modelos estadísticos cuyo análisis que permitirá realizar un diagnóstico más riguroso y completo dentro de los límites que proporcionan los datos disponibles. Con este estudio se pretende profundizar en el conocimiento de la situación accidentológica de AyA en los países participantes, con limitaciones en el acceso a los datos necesarios para tal fin.

El desarrollo de estudios como éste permitirá analizar los fenómenos causales y extraer los patrones y combinaciones de variables de influencia, y así adoptar las mejores decisiones para la mejora de la seguridad del transporte colectivo de personas.

2. MATERIALES Y MÉTODOS

2.1 Metodología de recolección de la información

El estudio toma como base el proyecto COOPERA-TCP que estandarizó una herramienta de recolección de datos de accidentes de tráfico de autocares y autobuses (Arenas et al., 2018), y de otros vehículos TCP como microbús, combi, autocar de un piso, microbús y autocar de dos pisos en los países participantes. La recolección de datos se realizó entre 2017 – 2018, para la cual se utilizó la metodología de búsqueda, localización y análisis de medios de comunicación masivos. Esta información se contrastó con las bases de datos disponibles en el país y la información se recogió en el instrumento destinado para la recopilación de datos en formato digital.

El formulario utilizado para la ejecución del proyecto reúne los datos de accidentes, de la vía en donde ha ocurrido el accidente y del estado en el que han quedado los vehículos de transporte implicados en el accidente de tráfico, por lo cual contiene campos con las variables de interés para abordar estudios científicos en países de Latinoamérica.

En la figura 1 se presentan los factores del formulario del proyecto COOPERA-TCP, basados en la estructura del modelo MIICA.

Número de factor	Factores de influencia y otros	Tipo de factor de acuerdo a MICAA
1	Datos generales	Datos del momento y espacio. Geo-referenciación.

Figura 1: Factores y datos recogidos en el formulario de accidentes del Transporte colectivo de personas – Proyecto COOPERAXVII-12 (TCP). (Arenas et al., 2018).

La base disponible para este trabajo está conformada por una muestra de 94 accidentes ocurridos en España y Argentina y contiene más de 80 variables. El análisis realizado permite resaltar la potencialidad de la metodología de COOPERA-TCP y de las herramientas propuestas para los objetivos planteados.

Se ha realizado una selección de variables con varios criterios (como evitar repetición de la información, valores nulos o vacíos, etc.) y con modelos Random Forest (RF) considerando su error de clasificación. Se seleccionan las 13 variables superiores en la clasificación con las que se elabora un modelo final. Las 13 variables explicativas se han agrupado en 4 grupos: factor infraestructura, vehículo, entorno y factor humano. Con las variables seleccionadas, se desarrollará un modelo de análisis de la severidad del accidente.

2.2 Metodología estadística para el análisis

2.2.1 Modelos de bosques aleatorios (Random Forest (RF))

Es una versión sofisticada del procedimiento bagging, señalada por (Breiman, 2001), que replica subconjuntos de registros y elige al azar un subconjunto de las variables de entrada (Hastie, Tibshirani, & Friedman, 2008). La herramienta indicada se enfoca en la técnica de aprendizaje automático estándar denominada "árbol de decisiones. Esta metodología también se usa para análisis de sensibilidad (Grömping, 2009).

La técnica de conjuntos de árboles tienen enfoque clásico o frecuencista, y el algoritmo utilizado es el RF (Random Forest de R Core, 2016). Este algoritmo optimiza la precisión en la clasificación mediante la incorporación de aleatoriedad en la construcción de cada clasificador individual. Para la selección y optimización se utilizan dos índices: criterio de Gini y de clasificación.

El mecanismo de construcción de RF establece un baremo que prioriza cada variable en la predicción final. Para ello se calcula el error de la muestra. Para cada variable de la muestra, se intercambia un par de elementos y se calcula el error de la muestra permutada. El resultado debería ser peor que para la muestra original. Este procedimiento se realiza para todos los valores de cada variable y se calcula el promedio. El proceso es realizado para todas las variables. Las variables de menor importancia deberían alterar menos la diferencia entre el error y el error permutado que las variables importantes.

2.2.2 Modelos de árboles de clasificación (CART y Rpart)

Los modelos de Árboles de clasificación son una técnica de aprendizaje controlado para modelar relaciones entrada – salida, no paramétrica, de segmentación binaria, esto es, las particiones se hacen de forma permanente hasta alcanzar un criterio de parada, es decir que el árbol se construye dividiendo los datos repetidamente, en cada nueva división los datos son divididos otra vez en dos grupos mutuamente excluyentes.

El enfoque algorítmico más habitual para el CART creado por (Breiman, Friedman, Stone, & Olshen, 1984) produce de manera inicial un árbol muy grande, para consecutivamente podarlo; es decir, recortar ramas que no incrementen su capacidad predictiva. El grado de poda se define en función de un compromiso entre bondad de ajuste y confusión del árbol, o incluyendo también criterios de precisión de una validación cruzada.

La figura 2 muestra un nodo raíz o madre, que se divide después en nodos hijos, y finalmente el procedimiento de partición se aplica a cada nodo hijo por separado. Estas divisiones se seleccionan, de modo que la impureza de los grupos hijos sea menor que la del grupo madre. Este procedimiento tiene por objetivo, discriminar la respuesta en grupos homogéneos, de tal manera que se pueda mantener el árbol relativamente pequeño. (Pillajo et al., 2018).

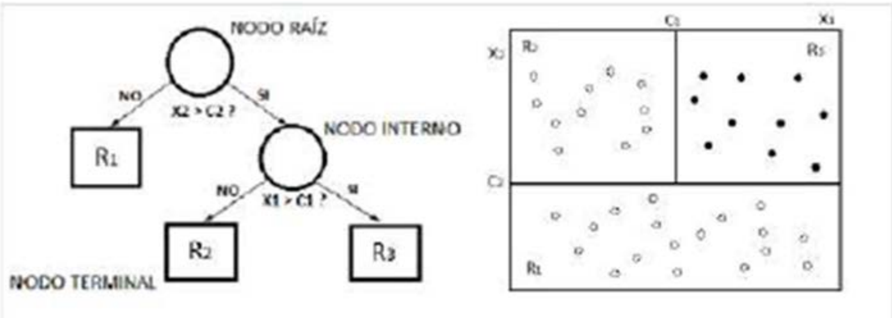

Figura 2: Descripción de objetos de un árbol de clasificación (Zhang / Singer, 2010).

Mediante la función Rpart del programa R, se analiza el modelo de clasificación con las 13 variables seleccionadas previamente con RF y se ejecuta la poda del árbol en función del % de error relativo y del índice de complejidad de división CP óptimo para generar el árbol de clasificación final.

3. RESULTADOS Y DISCUSIÓN

A continuación, se muestra el análisis descriptivo de los datos concernientes a la muestra de 94 accidentes de tráfico de autocares y autobuses ocurridos en las carreteras de Argentina y España implicados entre los años 2017– 2018.

En la Tabla 1 se indica los accidentes según tipo de vehículo de la muestra.

Argentina				Total	España				Total
Autocar/Micro		Colectivo/Autobús			Autocar/Micro		Colectivo/Autobús		
N.º	%	N.º	%		N.º	%	N.º	%	
30*(0.6)*	31.91	20*(0.4)*	21.28	50*(1)*	37*(0.84)*	39.36	7*(0.16)*	7.45	44*(1)*

Tabla 1: Descripción accidentes de TCP en Argentina y España.

El número de accidentes de tráfico con implicación de Autocar/Micro es mayor en España, con un total de 39.36% en comparación con el 31.91% de Argentina. Por otra parte, en lo que concierne a accidentes de tráfico con Colectivo/Autobús, se observa una mayor incidencia en Argentina con el 21.28% en relación a la de España (el 7.45%). Los porcentajes se han tomado en base a los 94 accidentes en los dos países.

Con respecto a Argentina se produjeron más accidentes de tráfico en los que estáninvolucrados Autocar/Micro, el 60% en comparación con la implicación de Colectivo/Autobús que alcanza el 40%. Lo mismo sucede en España con una mayor implicación de Autocar/Micro en accidentes (el 84%).

Se puede identificar que en cualquier relación ya sea en función de los 94 accidentes o por país, en España existe un mayor número de accidentes con tipo de vehículos TCP Autocar/Micro.

Se han generado dos graficas de árbol de clasificación (Fig. 3 y 4) para Argentina y España respectivamente por medio de modelos CART de severidad de los accidentes de tráfico de TCP para las que se ha utilizado el Software R Studio. Dentro de la misma la librería llamada “rpart” que se encarga de realizar los cortes para las ramificaciones, que se han utilizado para el cálculo de Cp (Complexity parameter) y el Error Relativo. La elección de las variables más importante se realizó con RandomForest (RF) de R Studio para la variable respuesta “severidad”. Con respecto a Argentina indica que la variable más importante es el Tipo de arcén, en segundo lugar el tipo de accidente, tercer lugar el tipo de vía, mientras que para España la variable más importante es el Tipo de vía, seguido de Tipo de accidente y en tercer lugar Responsable; con lo cual se aprecia que dentro de los tres primeros lugares están presentes en los dos países las variables Tipo de accidente y Tipo de vía, lo cual indica que estos dos son la factores que más inciden en la severidad de accidentes de tráfico con autocares y autobuses.

Figura 3: Árbol de severidad de Argentina.

En síntesis, en Argentina cuando el tipo de arcén es natural, o cuando está en mal estado, pavimentado u otros, el tipo de accidente es un alcance, y el accidente se ha producido en una intersección resultaría una alta lesividad.

Figura 4: Árbol de severidad de España

En España, cuando el tipo de vía es autopista o carretera de doble sentido y el tipo de accidente es por alcance al autobús, salida de la vía con desbarranco, salida de la vía u vuelco la severidad es alta. De la misma manera , si el tipo de accidentes es por alcance del autobús, choque o vuelco sobre la calzada, y el estado de la vía es mojado y ambos vehículos implicados son responsables, el accidente tiene una alta severidad.

4. CONCLUSIONES

Al existir un incremento de la velocidad en carretera para el tipo de vehículo ‘autocar’, la colisión tiende a ser más grave, por lo que se manifiesta una mortalidad mayor, y no hay diferencias significativas en Argentina con respecto a España.

El factor infraestructura (referente a tipo de vía) es el que resulta con mayor connotación; así como también el factor humano (responsabilidad) en algunos tipos de accidentes.

Los vuelcos de autocares son los accidentes más severos tanto en Argentina como en España, en comparación con autobuses (que se mueven más en ámbitos urbanos o suburbanos).

El método descriptivo estadístico utilizado con BBDD-AyA, es adecuado para identificar y comprender los factores y características que influyen en los accidentes de tráfico con implicación de autocares y autobuses tanto en España como en Argentina. La metodología aplicada en este estudio ha permitido realizar e interpretar clasificaciones claras de variables y combinaciones que determinan la severidad de los accidentes con implicación de AyA.

AGRADECIMIENTOS

Agradezco a la Universidad Politécnica de Madrid por haberme permitido formar parte de este proceso académico, asimismo a los Docentes que han contribuido con sus conocimientos para culminar esta etapa. Los autores agradecen además, a la Comunidad de Madrid por su financiación parcial que, a través del programa SEGVAUTO 4.0-CM (P2018 / EMT-4362) ha contribuido a su desarrollo y difusión.

ABSTRACT

Current road signs confront a fundamental issue: are signs displayed in different devices (posted, on-board, painted or electronic) making the most of the same design rationale? Convergent design principles help drivers enjoy an easier coding, learning and retrieval of the schemes enhancing comprehension. This paper focuses on posted road signs (painted vs electronic) that locate events and how well they complement each other. Fixed signage must be the starting point (*the scheme formed*) to investigate how electronic devices (*the new information*) can functionally locate variable events or situations.

The paper presents preliminary data regarding a sample of 39 participants. The experimental task consisted of 27 blocks of traffic signs. Electronic-adapted traffic signs were shown to all participants; however, only one group was exposed also to fixed (painted) signs. A 3x2 mixed design was used (experimental condition as inter-group factor and event location as intra-group factor), and in addition, the design also included a working memory measure as a covariate. Comprehension rates were high in all formulas of event location. As previous studies, time response showed higher means when the variable event is located 'between' two referents. Moreover, 'working memory (WM) span' showed a marginal significance with time response. This result leads to an interesting question about the consideration of influence of individual differences in WM capacity when designing complex traffic messages. Overall, results highlight the importance of understanding how complex traffic messages are encoded, processed and de-encoded, and the limits human WM may pose.

1. INTRODUCTION

In our interconnected and globalized world it is essential that the main communication routes exhibit effective and functional signage for all drivers (Shinar & Vogelzang, 2013). In consequence an adequate integration of the different road message display devices must be ensured: fixed or electronic panels, on-board systems, etc. At this point considering the characteristics and limitations inherent to the cognitive systems of drivers is essential.

This work addresses the case of electronic signage, specifically, complex traffic signs that inform about the location of circumstantial or variable events (congestion, snow, construction sites).

In this type of signal, the content displayed is specific to each situation. This implies that it is not possible to simply 'recover' or 'remember' the meaning from the previous knowledge, but rather that its understanding requires reasoning processes that must be carried out in real time while driving.

1.1. Traffic signs state of art

Despite the importance of traffic signs messages, its comprehension is not always guaranteed (Ben-Bassat et al. 2019; Arbaiza & Lucas-Alba, 2012). Nowadays, a driver can see and understand similar painted signs in different places (68 countries have ratified the 1968 Convention; UNECE, 1968). However, when it comes to electronic devices, design guidelines are not fully developed. Several aspects regarding traffic configurations are established by national regulations, facing less consistency than painted signage (Ben-Bassat et al., 2019).

In Spain, electronic signals in the national territory are mainly exhibited in Variable Message Signs (VMS) with a hybrid matrix (Fig. 1b). VMSs inform about possible re-routings or variable events on the road (works, congestion, fog, snow; Arbaiza & Lucas, 2012), among others. Focusing on painted signs, the Confirmation Signs in particular (CS, Fig. 1a; S600 / S-699; BOE, 2014) have special relevance because they are frequently displayed on the roads, and are the main way drivers learn to locate places in the road network. The CSs constitute the reference matrix through which drivers understand and anticipate situations and events along the network.

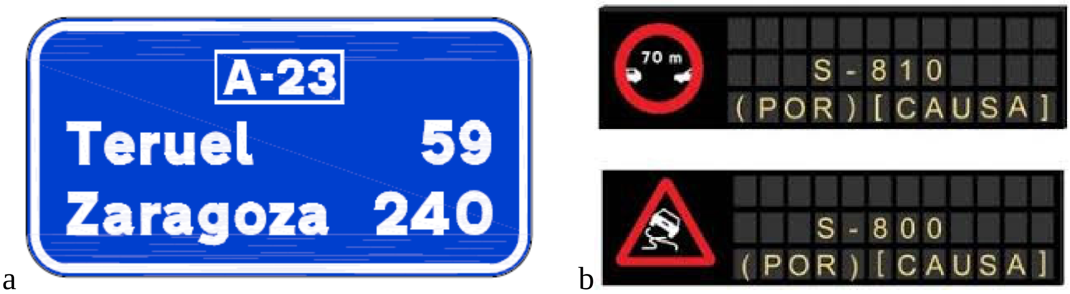

Figure 1: (a) Confirmation Sign (CS); (b) Variable Message Sign (VMS).

This is a key point since the drivers gains in safety and mobility depend on their adequate anticipation of road situations, including their comprehension of complex traffic signs. This research explores if fixed signs facilitate the understanding of new VMS, which electronic format designs are best suited for integration with existing signage, and the cognitive benefits that a better integration of signalling systems could bring to drivers.

1.2. The role of human cognition: schemes and working memory

According to Carroll (2008), a person is able to understand a situation when she is able to activate a memory scheme to assimilate the coming information. Similarly, we propose CS as the starting point (the formed scheme) to investigate the functionality and comprehension of VMS (new information).

One of the VMS functions is to inform about variable events. VMSs display something new when they are presented to the driver. Although some elements can be recovered from the Long-Term Memory (LTM; pictograms, numbers; Arbaiza & Lucas-Alba, 2012), drivers must integrate all the elements (new, known) in real time, and also determine the rules that govern their composition to decode VMSs. Figure 2B shows an example of a circumstantial event (congestion) located at a distance (31 km), before two reference points (Serrada and Alcores).

a b

Fig. 2. (a) Confirmation Sign (CS); (b) Adapted Sign from VMS (AS).

Extracting or decoding the meaning of the traffic message implies that the driver must keep the new (circumstantial) elements of the sign active, as well as those recovered from the LTM in WM (Baddeley and Hitch, 1974). This task must be carried out in real time while driving. However, WM has a limited processing capacity (typically, ±7 units, along roughly 30-60s), so the cognitive load should not exceed these constraints (Baddeley, 2000). At some point, individual differences in people's WM capacity may be important too (Just & Carpenter, 1992), so different tasks have been developed to measure WM capacity (e.g., the Reading Span Test; Daneman & Carpenter, 1980).

1.3. The location of variable events

Previous studies have shown a consistent pattern of results in VMS location formulations concerning a fixed reference point (eg, a city). Drivers understood well (comprehension rates of around 70%) that a variable event (congestion, road works) is located 'before' or 'between' cities, compared to events located 'after' a city (30-40% comprehension rates). (Lucas-Alba et al., 2016). In those cases, the formats tested did not include the numeric distance to events or locations, making the information less determined (Tversky, 2005). Incorporating numeric distance, and approaching the ASs structure to CSs one, could diminish ambiguity promoting higher comprehension rates.

1.4. Objectives and hypotheses

This study intends to determine if the previous exposure of CS affects the subsequent comprehension of the signs adapted to the electronic format of VMS (AS; Fig. 2b) in terms of comprehension rate and response time and if individual differences in WM relate to drivers' performance.

We hypothesize:

- The adapted sign (AS) provides a strong structure obtaining high comprehension rates (higher than previous studies). A ceiling effect on comprehension (no differences between experimental / control) could be observed.
- The previous presentation of a CS facilitates comprehension in terms of response time. Therefore, the experimental condition (presence of CS) will obtain a lower mean response time compared to the control condition (absence of CS).
- Individual differences in WM might be related to performance in the experimental task.

We expect that higher scores in the working memory measure will be related to a shorter response time. Additionally, there will be no significant correlation in the case of comprehension rate, since the cognitive load involved does not exceed the limits of WM.

2. METHOD

2.1. Participants

The sample was made by 39 (30 women), between 18 and 35 years (*M* = 22.36; *DT* = 4.69), mostly university students (87.2%). Participants were required to be in possession of a driving license (82.1%) or having passed the theoretical part of the driving license. Full drivers were asked how frequent their driving on the highway was; 25.6% indicated 'sometimes' and 38.5% 'often' (the rest indicated 'never' or 'not applicable'); their driving experience was relatively short: 84.7% drove for less than 5 years, 15.4% between 5 and 15 years, and 2.6% more than 15 years. Participants were randomly assigned to conditions, 20 to the experimental group -presence of CS- and 19 to control group -absence of CS.

2.2. Stimuli and materials

To prepare the stimuli (CS and AS traffic signs; Figure 2) place names were extracted from the database of the National Institute of Statistics (INE, 2015). This selection was filtered through the ESPAL database (Duchon, Perea, Sebastián-Gallés, Martí & Carreiras, 2013), in order to control for possible strange variables (word length and familiarity).

Thus, 192 place names (outside the region where the study was conducted) remained with a frequency of less than 1 per million words and a length of 3 syllables. One type of sign used as stimuli was based on the CSs mentioned above (Fig. 2a).

The characteristics of the format (typeface, size, box, arrangement of elements) of these signs were consistent with what was published in official documents (BOE, 2014). The elaboration of the second type (AS; Fig. 2b) was based on the structure of the CS, adapting it to the electronic format of the VMS. The study was carried out in the facilities of the Faculty of Social and Human Sciences of the Teruel Campus and in the Faculty of Education of the San Francisco Campus, both centres belonging to the University of Zaragoza. In both cases, the table and chair were arranged in the same way, in rooms with adequate temperature and light conditions for the study. All stimuli were presented through MediaLab software (v. 2014).

2.3. Procedure

Upon arrival, all participants received and signed the Information Consent. The total duration of the study was around 30 minutes.

2.3.1. Experimental task

First, they were asked a series of sociodemographic questions (sex, age, educational level, possession of a driving license, frequency of driving on the highway, approximate number of km per year). Subsequently, they were shown the instructions for the task, performed three test examples, and then performed the experimental task. The experimental phase consisted of 27 blocks with two traffic signs (CS and AS) in the experimental condition, and with only one sign (AS) in the control condition. All stimuli were placed in the centre of the screen. The panels were displayed for 4 seconds, an estimated time that traffic signs can be displayed in real conditions at a standard speed of 120 km/hour. After showing the stimuli, participants were required to answer the question: 'According to the sign displayed, where is the event located?', and two response options were offered. The order and display of responses was controlled through balancing.

2.3.2. Reading span test: measurement of verbal working memory

Once the experimental task was completed, the second part of the study began. The procedure to measure WM capacity was extracted from the study by Elosúa, Gutiérrez, Madruga, Luque & Gárate (1996; Prueba de Amplitud Lectora- PAL). This is a Spanish version adapted from the Reading Span Test elaborated by Daneman & Carpenter (1980).

The person responsible for the administration of the study was located to the side, with access to the mouse that passed the screens, without interfering with the direct vision between the participant and the screen. The responses were recorded in a standardized rubric and the data were subsequently coded according to the descriptive criteria proposed by Elosúa et al. (1996). According to these authors, this test requires the two components of

WM to be activated: processing and storage. This test shows a relationship with reading comprehension, both components being necessary; therefore, it would be expected that if the information processing in complex traffic signs is based on a process similar to the reading of verbal language it could be reflected in the results.

2.4. Statistical design and analysis

A 3x2 design was used: an intra-subject factor (location of the event: before / between / after), an inter-group factor (presence / absence of AS) and a continuous variable such as covariate (score obtained in WM measure; Elosúa et al., 1996). The dependent variables are: the comprehension rate (measured in successes and errors) and the response time (time it takes the subject to answer since the question is displayed).

3. RESULTS

3.1. Descriptive

Table 1 presents the means and standard deviations of the comprehension rate (correct answers) and the response time, divided by the factors: condition and location of the event.

		Comprehension rates		Response times (ms)	
Factors	Levels	*M*	*SD*	*M*	*SD*
Experimental condition	Presence AS	.92	.018	2022	136.133
	Absence AS	.92	.019	2120	139.669
Event location	Before	.96	.010	1660	86.214
	Between	.90	.022	2797	133.067
	After	.90	.020	1755	98.641

Table 1. Descriptive measures of comprehension rate and times response.

3.2. Inferential: performance in the experimental task

The results of the statistical analyses carried out in relation to the comprehension rate and response time are presented below. In both cases, a mixed analysis of co-variance (ANCOVA) was carried out with a 3 x 2 design (event location: before / between / after-intra-subject; presence / absence of CS - inter-group) and a continuous variable included in the design as a covariate (score obtained in the WM measure).

3.2.1. Comprehension rate (correct answers)

The analysis does not show statistically significant differences in the effect of any of the main factors or their interaction. Although the main factor ‘event location’ is not significant, when carrying out simple comparisons it is observed that, in a significant way, locating the event variables 'before' a location (M = .96), obtains greater number of correct answers than when it is based on two locations ('between'; M = 0.90) or 'after' a location (M = .90).

3.2.2. Response time

In relation to reaction time, the main factor ‘event location’ shows statistically significant differences, $F_{(2,72)} = 59.13$; $p <.01$, $\eta_p^2 = 0.62$. The relationship observed between the levels of this factor is quadratic, $F_{(1,36)} = 90.42$; $p <.01$, $\eta_p^2 = 0.72$. Simple comparisons show that the differences are found between the level ‘between’ two localities (*M* = 2797 ms), compared to the other two levels: ‘before’ (*M* = 1660 ms) and ‘after’ (*M* = 1755 ms) a locality.

Furthermore, the main effect of the covariate 'WM score' is marginally significant, $F_{(1,36)} = 2.86$; $p = .099$, so it would be positive to take this influence into account in future studies to see if the trend suggested by these results is confirmed with a larger sample size.

However, the interaction between the covariate ‘WM score' and the intra factor 'event location' is statistically significant, $F_{(2.72)} = 5.67$; $p <.01$, $\eta_p^2 = 0.14$. In order to deepen the relationship between these two variables, this relationship was studied through regression analysis. In this line, it is observed that the variable referring to the scores obtained in the ‘WM score’ correlates significantly with the relative response time only at the level 'between' two locations, of the intra-subject factor 'event location', $r_{xy} = -.379$, $p = .017$. The linear regression hypothesis test, through the ANOVA technique, indicates that the relationship is significant, $F_{(1,37)} = 6.20$, $p = .017$. Knowing that r_{xy} is the same as beta coefficient, the interpretation of these data indicates that the reaction time increases by a factor of 0.379 for each unit decrease in ‘WM score’. The coefficient of determination, $R^2 = .120$ specifies the gain that we can obtain when predicting a variable using this ‘WM score’ variable.

4. DISCUSSION

The comprehension rates achieved in this study exceed 90% of correct answers, which is a first evidence that this format (AS) could be effective in transmitting the location of variable events according to the usual standards (ISO, 2007). The key is knowing why. As we expected, compared to previous studies, higher rates are shown in terms of comprehension rates (Lucas-Alba et al., 2016). One possible explanation is based on the incorporation of numbers (information on the distance between the driver and the reference) improves the comprehension rate with respect to other VMS formats tested so far, which did not have this information. It seems that the structure and elements incorporated provide enough information to correctly extract the meaning of the traffic sign. According to Tversky (2005), determined information (versus indeterminate) contributes to the ability to build a mental model and facilitates the understanding of the message, reflected in the increase in the rate of understanding.

On the other hand, these results are consistent with previous outcomes: locating an event 'before' the reference point is more efficient, compared to 'between' and 'after' in terms of comprehension. The fact that the format of the AS is so structuring could be promoting that the differences between locating an event 'before' and 'after' are diluted in comparison with other studies (ceiling effect).

On the other hand, it has been shown that subjects take longer to respond to the location 'between' two references. This could reflect a greater cognitive load, since the information of one more element must be processed (my situation as a driver, the first reference point, the variable event, the second reference point).

However, it must be taken into account that all the ASs show the same number of elements on the poster and they had the same exposure time. Our explanation is related to reference frames and how these frames can influence our mental representation of spatial information.

Anyway, based on the WM model proposed by Baddeley and Hitch (1974; Baddeley, 2000), we hypothesize that an increase in the number of information elements that the driver must keep active on the WM could be causing a greater consumption of time to evaluate the options and extract the correct meaning; being also not very effective (less success rate than 'before').

This is especially relevant considering the relation showed with the WM measure (PAL, Elosúa et al., 1996). Although further analyses and larger samples are needed, this relation has been especially significant on the 'between' level of the event location. Our explanation arises from WM model. According with these premises, it seems that potential individual differences on WM capacity could be more relevant as the cognitive load they must manage increases.

Moreover, application to the real context would imply a simultaneous driving activity, so the consequences could be more considerable. These data could show initial evidence of the importance of human cognition in comprehension of traffic signs and, obviously, in their design.

One of the most relevant limitations of this study is the size of the sample. As they consist of only preliminary data, they must be completed with a new data collection, thus achieving greater statistical power. Likewise, including participants from other age ranges and driving experience would also mean an improvement in the robustness and generalization of the data.

In conclusion, communications and technology advance all together to improve road safety and mobility services. Specifically, aspects of human cognition also play an important role in understanding traffic signs. Integrating the different signage systems can be a way to take advantage of previous schema of the conductors to facilitate the comprehension of new electronic formats.

In addition, it is essential to understand how the information of these complex signs is encoded, processed and de-encoded; as well as the limits that our information processing systems such as WM may pose. Ultimately, designs consistent with the road environment and drivers' cognition can contribute to prevention and safety in the field of traffic mobility.

ABSTRACT

Road Safety Audit (RSA) has proved to be one of the best road safety management procedures for design, construction, and maintenance of existing and new road infrastructure. At the beginning, the safety review only focused on motor vehicles and the human driver. Later, as well as nowadays, procedures are also applied to the needs for all vulnerable road users, taking into account that each of the groups (pedestrians, cyclists, motorcyclists) has its own specific requirements.

The new and better capabilities of automated vehicles should be in accordance to road technical features, such as geometry, sight distance, signs, and markings. However, the corresponding standards were developed for human driving, and therefore they must be adapted to the new systems without losing compatibility with lower automation levels. While considerable research effort has been carried out for the digital infrastructure, only some studies have been carried out for the physical one with interesting findings that deserve to be incorporated into RSA procedures, such as: new available and required stopping sight distance; new automated speed as the maximum speed that allows the automated system to maintain the longitudinal and lateral control; readable road markings and road signs to facilitate recognition by both human drivers and connected and automated vehicles; etc. The main objective is to achieve the optimal performance of Advanced Driver Assistance Systems (ADAS).

The main result of this study is a first proposal for a new chapter to be included in the checklists to carry out road safety audits for the different stages and road safety inspections.

1. INTRODUCTION

Road Safety Audit (RSA) has proved to be one of the best road safety assessment procedures for design, construction, and maintenance of existing and new road infrastructure. At the beginning, the safety review only focused on motor vehicles and the human driver.

Later, as well as nowadays, procedures are also applied to the needs for all Vulnerable Road Users (VRUs), considering that each of the groups (pedestrians, cyclists, and motorcyclists) has its own specific requirements.

The Directive 2008/96/EC of the European Parliament and of the Council on road infrastructure safety management (European Parliament, 2008) established the implementation of procedures related to Road Safety Audit (RSA) and Road Safety Inspection (RSI), being mandatory in the trans-European road network at the design stage, under construction or in operation.

A RSA should be carried out for all infrastructure projects, forming an integral part of the design process of the infrastructure project at the stages of: preliminary design; detailed design; pre-opening; and, early operation; following certain criteria for every stage. A certified auditor is appointed to carry out an audit of the design characteristics of an infrastructure project.

A RSI is a formal systematic and periodic road safety assessment of an existing road or road scheme, performed by an independent, qualified inspector or team of inspectors, who report on the existing road accident potential for all kinds of road users (VRUs included), identify traffic hazards related to the road environment characteristics (elements and locations to be improved), and propose measures to mitigate the detected hazards, mainly focused or described as maintenance work.

Both RSA and RSI are considered preventive tools because their application to an itinerary or road section does not require researching on their crash record. There are many checklists available for RSA/RSI. These checklists include several families of elements, such as: Road function; Alignment; Junction; Traffic signing, marking, and lighting; Roadside features; Bridge; Tunnel; Pavement; RS; Public and private service; Traffic operation; Cross-town road; Work zone. However, checklists cannot substitute the experience and expertise of road safety auditors, so the checklists should be used just a reminder of which aspects should be reviewed. There are other limitations, such as that most questions are related to a whole road segment, without any specific spatial and/or temporal focus. Another weakness might be due to the accuracy of answers (Yes/No may be for both Safe/Risk indistinctly).

New Amending EU Directive 2008/96/EC on Road Infrastructure Safety Management (European Parliament, 2019a) extends the scope to motorways and other primary roads beyond the trans-European transport network (TEN-T), including a new network-wide road safety assessment and a more targeted road safety inspection. Moreover, there will be new procedures aiming at ensuring the operational use of road markings and signs, common specifications should be established in order to foster the effective readability and detectability of road signs and marking for human drivers and automated driver assistance systems.

However, the new Directive does not include the automated vehicles as a new point of reference for carrying out the procedures for RSA and RSI.

The Society of Automotive Engineers identifies six levels of automated driving:

- 0 – no automation
- 1 – driver assistance
- 2 – partial automation
- 3 – conditional automation
- 4 – high automation
- 5 – full automation (SAE, 2016).

Every level is defined as the minimum capabilities that the system must fulfill, so a vehicle might present different driving automation levels depending on the environment.

There are vehicles in the current market that reach level 2, and even level 3 under very controlled conditions such as a high-end geometric alignments and road markings. A level 2 driving automation system can negotiate speed and lateral position under controlled circumstances. If the system is unable to process certain information (e.g. sharp horizontal curve or crest vertical curve), it transfers control to the driver – often, with a minimal or inexistent warning – in a disengagement event. Conversely, a level 3 driving automation system is able to negotiate more complex situations, so the system is expected to fail on fewer locations. In this case, the system is even expected to predict this failure in advance, transferring control to the driver in a Take Over Request (TOR) event. While level 3 presents a more complex performance, the time required for the driver to resume control is often beyond driver’s abilities, being reported as unsafe by many experts. In fact, there are many international efforts in reaching level 4 as soon as possible. Level 4 ensures performance without any need of human intervention under certain circumstances involving infrastructure, traffic, and environment. The different combinations of these circumstances are called Operational Design Domains (ODDs).

The new and better capabilities of automated vehicles should be in accordance to road technical features, such as geometry, sight distance, signs, and markings. However, the corresponding standards were developed for human driving, and therefore they must be adapted to the new systems without losing compatibility with lower automation levels.

Current semi-autonomous vehicles are equipped with a variety of sensors, including video cameras for environment identification (road markings, signs, vehicles, pedestrians, etc.) and radar for obstacle detection. Cameras are the basis for Lane Keeping Assist (LKA), and radars are the basis for the Adaptative Cruise Control (ACC) and emergency braking.

These devices aim at substituting human sight, but their location differs from driver’s eyes (and also among vehicles), which impacts on how sight distance should be calculated and checked. The new semi-autonomous vehicles should be included for carrying out RSA and RSI as a new point of view for their different sensors (radar, cameras, etc.).

There are other limitations for existing semi-autonomous vehicles. Some studies have recently focused on identifying the limitations of autonomous vehicles regarding line marking and road signs (Austroads, 2019; US TRB, 2018; EuroRAP and EuroNCAP, 2018).

These studies revealed that the quality, position, and consistency of line markings and traffic signs are critical to the performance of automated driving and driver assistance functions. Likewise, it is recommended to use line widths between 100 and 150 mm, a maximum lane width of 4.50 m, and a minimum road marking retroreflection of 150 mcd/lux/m2.

Other studies have explored the limitations of AVs related to road geometry (García, 2017; García et al., 2019; García and Camacho-Torregrosa, 2019; García and Camacho-Torregrosa, 2020). They found that there are still many limitations associated to horizontal and vertical alignment, as well as cross-section and road markings to ensure an adequate performance of semi-autonomous vehicles.

Finally, the coexistence of AVs with non-automated vehicles and other users leads to a complex mixed traffic scenario. The European Parliament resolution of January 15th, 2019 on autonomous driving in European transport (European Parliament, 2019b) highlighted the necessity of incorporating safeguard systems right for this transition phase; stressing the importance of driver assistance systems as a step towards fully automated driving, even now to prevent road crashes by means of active safety systems or reduce the severity of accidents by means of passive safety systems.

2. OBJECTIVES

The main objective of this study is to highlight previous findings on how AVs are constrained by road infrastructure (horizontal and vertical alignment, cross-section, road marking continuity, and pavement condition), by analyzing when AVs might disengage and transfer control to drivers. Based on these findings, new questions will be proposed to be included in Road Safety Audit and Inspection checklists.

However, this paper does not intend to define specific thresholds to be considered in AV-RSA’s, but to stablish a framework on which parts of road infrastructure should be compared to the performance of existing and oncoming vehicles.

3. ROAD INFRASTRUCTURE AND LOW-AUTOMATED VEHICLES

Although each car manufacturer equips different sensors and programs its own Active Cruise Control (ACC) and Lane Keeping Assist (LKA), the technical features of their sensors and CPU are similar because they share parts suppliers.

Therefore, the differences in vehicle performance are minimum. Based on this hypothesis, the authors decided to use a BMW 520d from 2017, equipped with the "Driving Assistant Plus" package, which gives it a level 2 of automation, as the car that can properly represent most of semi-autonomous vehicles on our road networks.

The vehicle was driven by a single driver along a total of 3,000 km in the Region of Valencia (Spain). Once both ACC and LKA systems have been activated, which requires the selection of the cruising speed, the car takes control of the accelerator, brakes, and steering wheel, being able to keep the vehicle within the lane as a result of the detection of road markings through two video cameras located in the interior rear-view mirror.

If the system cannot process the gathered information by the cameras, the system transfers control of the vehicle to the driver showing a warning message on the dashboard, without any acoustic signal. The driver is also asked to be in permanent contact with the steering wheel so as to take over control, if needed.

The vehicle performance was recorded through a Garmin Virb Elite HD video camera, which was placed next to the driver's head. The resulting video recordings included road, navigation system, dashboard, and comments of the driver and passengers. To prevent bias, all tests were carried out in daylight conditions, dry pavement surface, and road markings in good condition.

Traffic volume and operation might influence the performance of the assistance systems. However, a Road Safety Audit aims at detecting safety issues regarding road design, so it should be developed to identify the limitations of autonomous vehicles operating under free flow conditions. To allow reaching a reasonable operating speed, the data used in the following studies were collected during non-peak hours.

The horizontal alignment of the road sections was recreated by means of the procedure proposed by Camacho-Torregrosa et al. (2015), whereas the vertical alignment was extracted through Autodesk Civil 3D using LIDAR data provided by the National Plan for Aerial Orthophotography (PNOA, 2016).

3.1 Horizontal curves

This part of the study aimed at analyzing the capacity of the road infrastructure to host semi-autonomous driving systems on isolated horizontal curves (García, 2017). Particularly, the maximum speed at which a semi-autonomous vehicle can travel along this type of road element was identified for each studied horizontal curve.

A total of 132 isolated horizontal curves were considered in the analysis, which were located in motorways, freeways, multilane highways, and two-lane rural roads. Among different geometric features (radius, deflection angle, length, and Curvature Change Rate), the radius resulted in the most influential variable in the studied phenomenon. Specifically, the radii of the observed horizontal curves varied from 172 m to 3,858 m, with an average of 858.8 m.

The automated speed (Va), which was defined as the maximum speed at which the semi-autonomous vehicle was able to perform automatically, was identified for each horizontal curve by traveling along them at different speeds. This way, if the speed is greater than Va, the system is not able to process the gathered information and transfers the lateral control of the vehicle to the driver. It should be noted that Va could not be determined for those horizontal curves presenting a radius lower than 172 m.

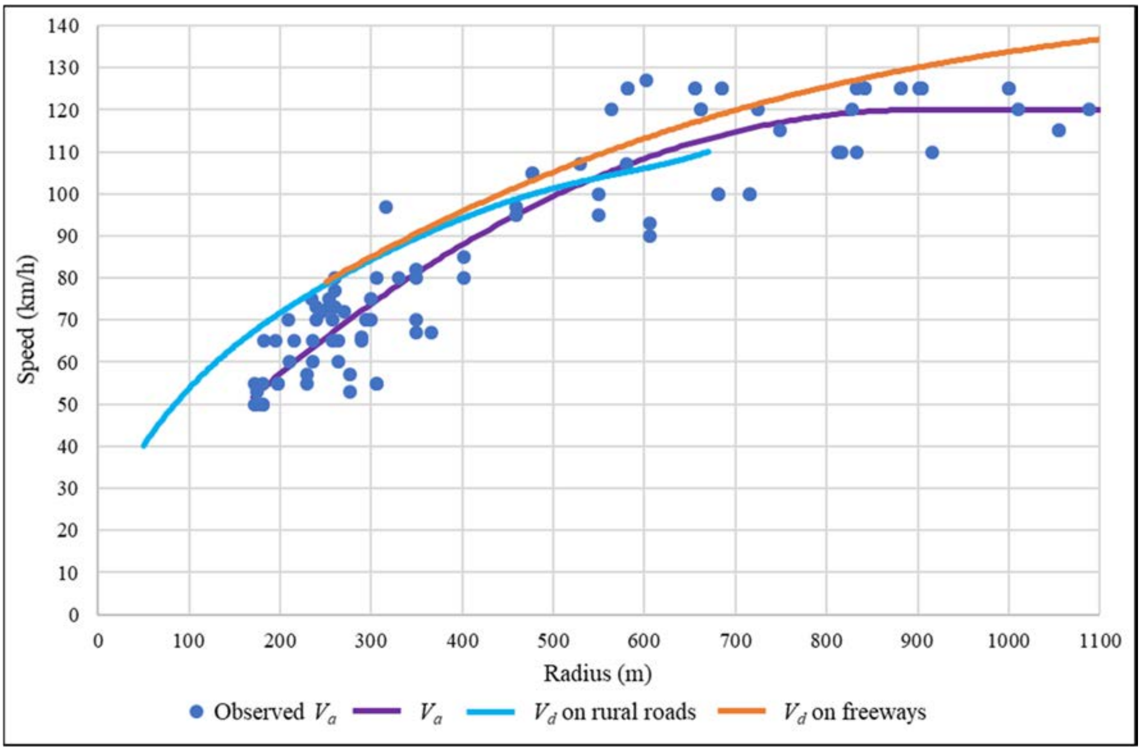

Figure 1: Relationship between the automated speed and the radius of the horizontal curve.

Figure 1 shows the relationship between the radius (R) and the automated (Va) and design (Vd) speeds for each horizontal curve. As expected, the automated speed increases with the radius.

In addition, the automated speed was only greater than the design speed for a few horizontal curves, so an automated driving performance, from the point of view of the road design, is not currently possible mainly along horizontal curves with a radius lower than 500 m.

3.2 Crest vertical curves

Another critical issue related to the automated driving performance of semi-autonomous vehicles is the influence of the vertical alignment. Thus, the objective of this part of the research was to examine the automated driving experience along 42 vertical crest curves overlapped with tangent sections, thus avoiding the influence of the horizontal alignment (García et al., 2019).

It should be noted that the driver tried to go along all studied crest vertical curves at its posted speed limit, but in some cases the operating speed was lower. The K values of these vertical curves ranged between 2.7 m/% and 65.5 m/%, whereas the algebraic difference in grades (A) varied from 0.36% to 11.85%. As a result, 18 of the studied crest vertical curves required the driver to take control of the vehicle. According to the Green Book (AASHTO, 2018), the vertical curve parameter (K) defines its sharpness (Figure 2). It is calculated as the ratio between its length (L) and the algebraic difference in grades (A). Given a parameter K, the stopping sight distance (SSD) can be calculated as follows (Figure 2, top right):

$$SSD = \sqrt{(L/A \cdot 100 \cdot (\sqrt{2 \cdot h_1} + \sqrt{2 \cdot h_2})^2)} \quad (1)$$

where:

- SSD is the Stopping Sight Distance (m); L is the length of the vertical curve (m)
- A is the algebraic difference in grades (%)
- h1 is the height of eye above roadway (1.08 m)
- h2 is the height of object onto the roadway surface (0.60 m).

This expression is only valid when SSD is lower than L.

This SSD can be tagged as available SSD (i.e. SSD_A), since it represents the road length that can be seen for a certain crest vertical curve design.

In addition, a biunivocal correspondence exists between design speed (Vd) and SSD. For a given design speed, SSD can be determined using Equation 2, which is divided into two terms:

- driver perception-reaction distance (dPRT)
- braking distance (dMT) (Figure 2, top left).

$$SSD = d_{PRT} + d_{MT} = 0.278 \cdot V_d \cdot t + 0.039 \cdot V_d^2/a \quad (2)$$

where Vd is the design speed (km/h); t is the perception-reaction time (2.5 s); and a is the deceleration rate (3.4 m/s2).

This is the required SSD (i.e. SSD_R), since it indicates which is the minimum length needed to stop the vehicle, driving at a certain speed. The Green Book assumes that vehicles are performing at the design speed, so $SSD_R \leq SSD_A$ indicates an adequate design, from this perspective.

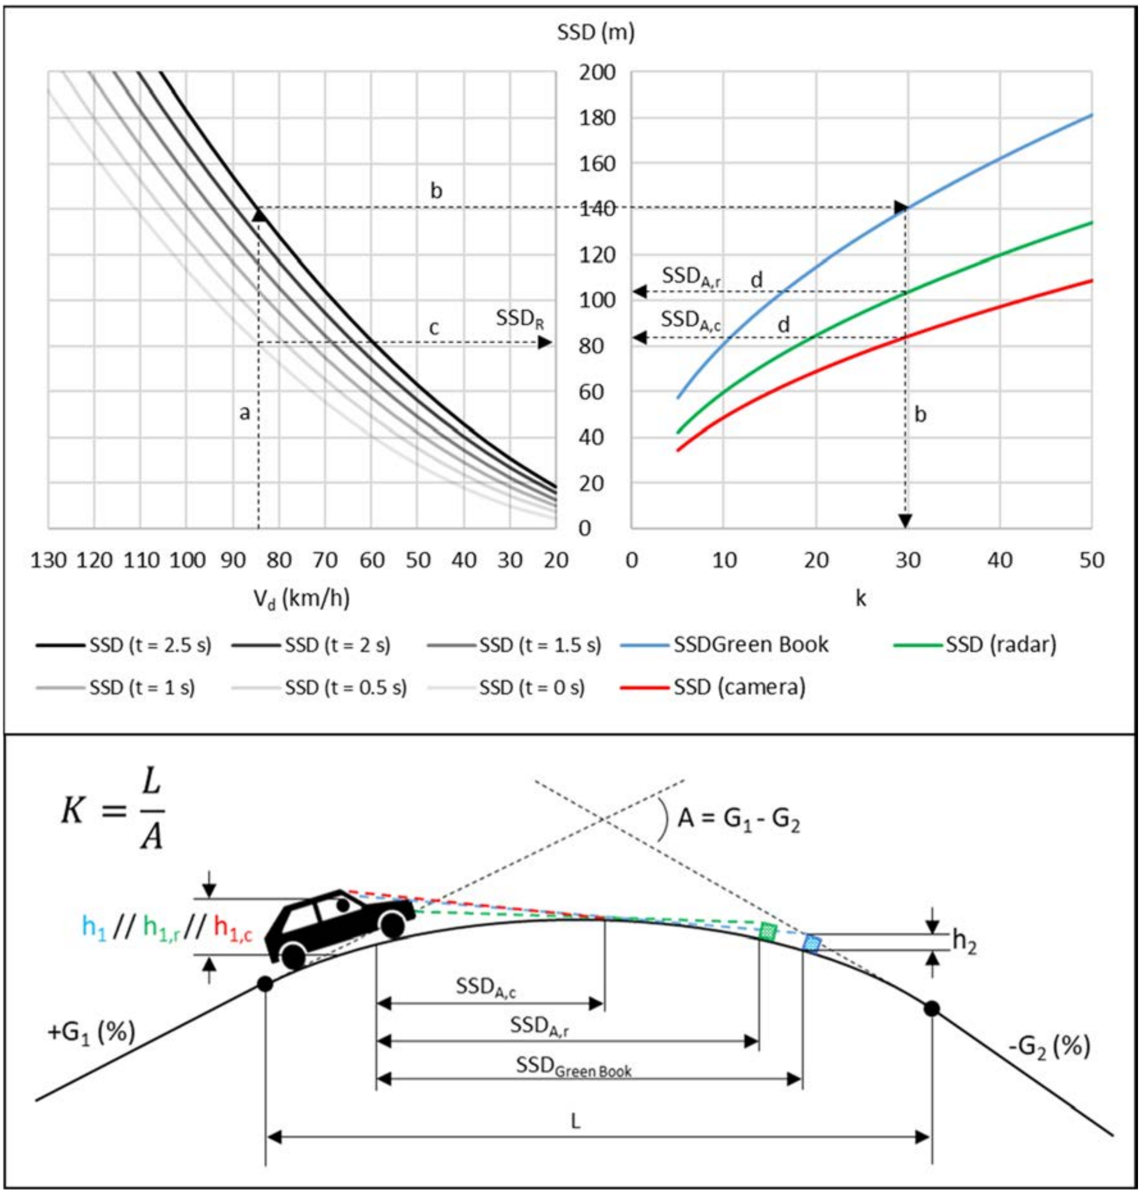

Figure 2: Relationship between SSD, K, and V_d. Left side: relationship between required SSD and design speed (reversed horizontal axis). Right side: relationship between available stopping sight distance and vertical curve parameter K.

The AASHTO Green Book assumes specific values for SSD, but these values must be changed for the devices equipped in the semi-autonomous vehicle: video camera and radar. Therefore, $SSD_{A,r}$ is the available sight distance for the radar, and $SSD_{A,c}$ for the video camera (Figure 2, top right).

The video cameras are usually located in the interior rear-view mirror and are responsible for lane keeping, so h1 can vary from 1 m (passenger cars) to more than 2 m (heavy vehicles), while h2 is 0 m (road markings). On the other hand, the radar is usually placed in the bumper and aims at detecting objects on the carriageway, so h1 ranges from 0.25 to 0.45 m and h2 is 0.60 m according to the Green Book (AASHTO, 2018).

On the other hand, perception and reaction time also changes with these automated systems. This new required distance (SSDR) will be determined considering perception-reaction times ranging from 0 to 2.5 s, since current autonomous vehicle manufactures do not provide the lag that these devices require to process the information and take a decision.

Again, a curve is well designed if the required SSD is lower than the available one for both systems, i.e.: $SSD_R \leq SSD_{A,r}$ and $SSD_R \leq SSD_{A,c}$ (lines c and d in Figure 2). All curves are assumed to be designed according to standards, so $SSD_R \leq SSD_A$ is always true.

As an example, the SSDR for 85 km/h design speed is 140 m (Figure 2: a). According to the Green Book, the minimum parameter K that allows this sight distance is 30 m/% (Figure 2: b). Assuming that the vehicle can perform automatically (i.e., perception-reaction time = 0 s), the SSDR would decrease up to 80 m (Figure 2: c). Likewise, the $SSD_{A,r}$ and $SSD_{A,c}$ would be approximately 105 and 85 m, respectively (Figure 2: d). Therefore, the vertical curve might be travelled in an autonomous way.

However, vehicles need a period of time to gather and process the information, so the success of the system mainly depends on how quick the vehicle system can operate. In the previous example, if the perception-reaction time required by the vehicle is 1.0 s, the driving experience would be manual.

It was hypothesized that the system might shift from automatic to manual in case of having insufficient time to process all information originating from the video camera. Thus, a new parameter called Available Processing Time (APT) was defined as the ratio between the available sight distance for the video cameras (SSDA,c) and the operating speed during the observation.

Figure 3 depicts the relationship between K and APT. First of all, it can be observed that the system tends to transfer the lateral control of the vehicle for K values lower than 20-30 m/%, which is usually associated to a big grade differential.

In addition, those crest vertical curves which required human intervention presented APT values lower than 3 s, whereas the minimum APT associated to an automated driving experience was 2.5 s.

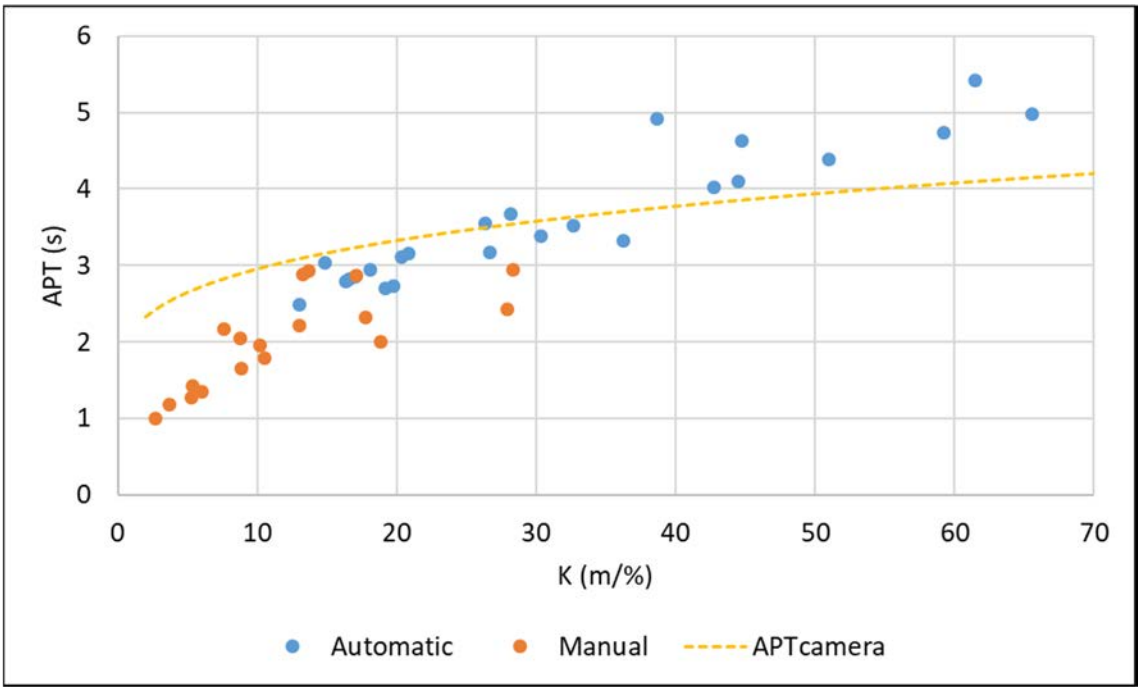

Figure 3: Relationship between *K* and *APT* depending on driving experience.

Therefore, the system needs more than 2.5 s to process the gathered information and take a decision. This processing time includes video recording, algorithms processing, and the time needed to control the vehicle. This *APT* was determined driving at the speed limit (or slightly lower, if posted speed could not be reached).

Figure 3 also shows the theoretical available processing time if the driver travelled at the design speed (dashed yellow line). As can be seen in Figure 4, operating/posted speeds are normally higher than the design speed on sharp crest vertical curves (thus leading to lower APT). Conversely, operating/posted speeds are generally lower than the design speed for smooth crest vertical curves, hence producing higher *APT* than the design-based and enabling more time to process the information and take a decision.

In this case, the automated speed (Va) is estimated as the ratio between the available stopping sight distance for the cameras (SSDA,c) and the minimum available processing time (APTmin). Figure 4 depicts the relationship between the operating speed and the vertical curve parameter (K) for the studied crest vertical curves. Likewise, thresholds for an automated speed considering APTmin equal to 2.5 and 3.0 s (dashed red lines) as well as the curve associated to the design speed (blue line) have been plotted. Additionally, the dashed green lines represent the automated speed for lower APTmin. Therefore, the automatic speed model will be located between both dashed red lines.

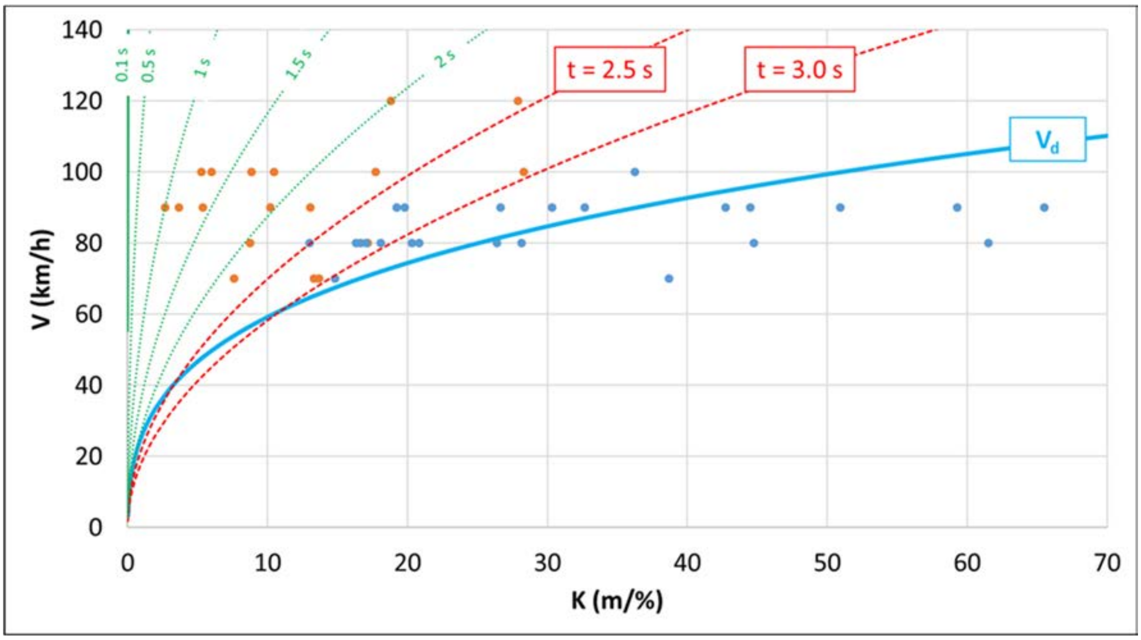

Figure 4: Relationship between the automated speed and the vertical crest curve parameter.

3.3 Lane width

In addition to the horizontal and vertical alignment, the characteristics of the cross-section, mainly lane width, have a great impact on the automated driving performance of semi-autonomous vehicles. To study the influence of this geometric feature on the automatic lane keeping system, an experimental field data collection was performed in an urban environment using the semi-autonomous vehicle described above (García and Camacho-Torregrosa, 2020).

Given that most narrow lane widths are associated with low-speed and urban roads, the data collection was carried out travelling at 50 km/h which is the usual speed limit along these roads. In addition, the use of a constant speed avoided introducing the influence of the speed on the phenomenon.

A total of 12 arterial tangent sections, belonging to a 5.4 km long urban arterial ring road in Valencia (Spain), were selected to be analyzed. This urban road is bi-directional, with several lanes with diverse lane widths, ranging between 2.28 and 3.80 m, with an average value of 2.70 m. The total number of studied lanes was 81 and the minimum number of passes along each lane was 10.

To study the influence of lane width on the automated driving performance, two parameters were defined: the automatic lateral control rate and the manual lateral control rate. The first one was calculated as the ratio between the observed number of passes in an automatic way and the total number of passes, whereas the second one was the number of passes in a manual way divided by the total number of passes.

Figure 5 clusters these rates in 5 cm intervals. As expected, the automatic lateral control rate increases with lane width and, on the contrary, the manual lateral control rate decreases as the lane width is greater. Specifically, the system was always able to perform in an automatic way for lanes wider than 2.75 m, whereas a lane width lower than 2.5 m always led to a manual driving. Additionally, a critical lane width can be estimated as the intersection of both driving performances, determining the same probability for manual and automatic lateral control at a width of 2.72 m.

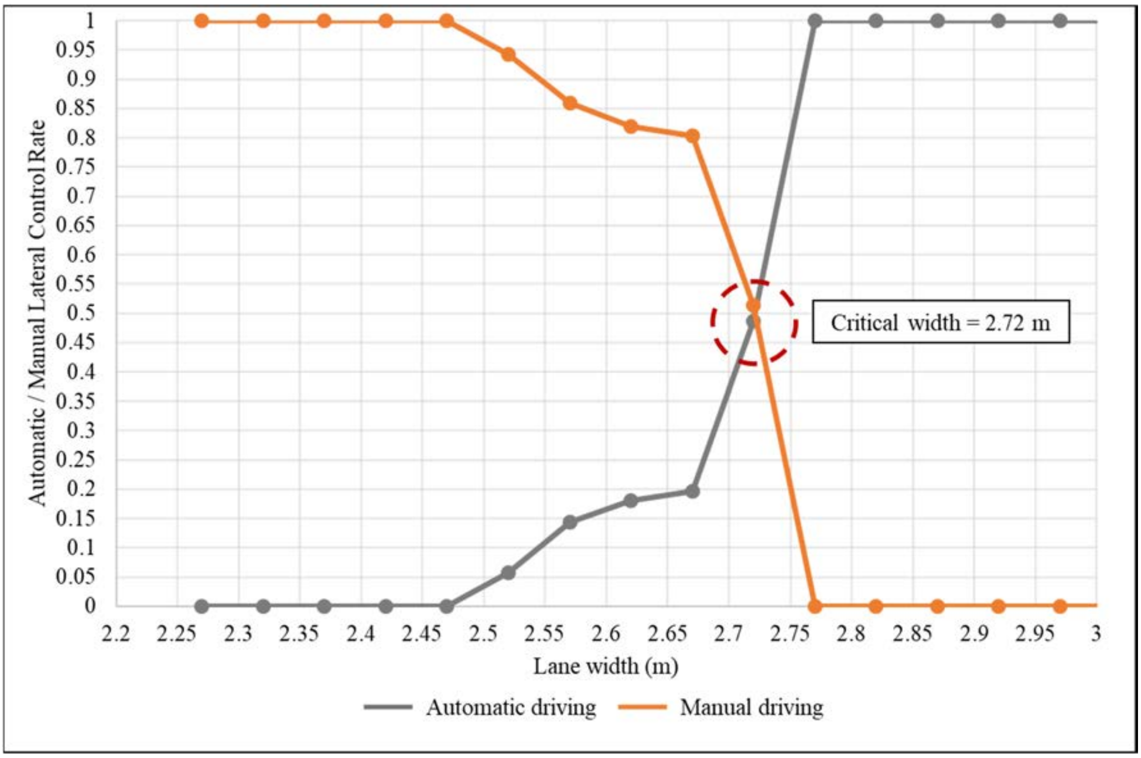

Figure 5: Influence of lane width on driving experience.

Taking into account the observed automatic lane width and the width of the experimental vehicle, the tested vehicle needs a free lateral space of 0.44 m. Since the study only focused on the observed disengagement events and not on the underlying causes, more insight is needed to determine the potential consequences on driving safety and performance. If this limitation arises from the capability of the system to process the visual information, similar limitations for other vehicle types are expected

Conversely, if the remaining lateral space is needed for vehicle maneuvering, it might imply a serious limitation to heavy vehicles, since the minimum width to support automation with current technology is inferred to 3.43-3.48 m. Moreover, these findings clearly define 2.50 m to 2.75 m as an Operational Design Domain threshold, which is not compatible with most low volume roads and some urban environments.

These findings can be complemented with those obtained by Austroads (2019). To this regard, the maximum lane width that allows an automated driving is 4.50 m.

This threshold was established by analyzing autonomous vehicle performance on 25,000 km of different road types in Australia and New Zealand.

3.4 Road marking

When comparing technical capabilities of autonomous vehicles with road infrastructure, a common thought is that signals in good condition establishes an adequate operational domain for semi-autonomous vehicles. Special mention deserves road markings, which are expected to have a good visibility and contrast. However, there might be some cases in which a good infrastructure with good road markings is not enough for semi-autonomous driving (García and Camacho-Torregrosa, 2019).

Thus, this research examines the system capability of the above mentioned semi-autonomous vehicle along different road marking configurations in 25 km of freeway. Particularly, the driving experience was studied on 25 exit ramps and 27 entrance ramps so as to determine the impact of the marking gap, i.e., the absence of the edge road marking at the beginning of the exit ramp and at the end of the entrance ramp. To this regard, Spanish regulations for road markings establish that the broken extension line must begin or finish when the acceleration or deceleration lane becomes 1.5 m wide. This results in a zone with a gap or edge line discontinuity. Its length depends on the cotangent of the corresponding taper. These assumptions are correct as long as the road marking was adequately set up.

At the studied locations, information on the station, ramp type (entrance/exit), existing gap (yes/no), width of the acceleration and deceleration lane (m), horizontal alignment (left curve/right curve/tangent), vertical alignment (upgrade/downgrade/crest curve/sag curve), and driving experience (manual/automatic) was collected. It should be noted that the semi-autonomous vehicle travelled at the speed limit, which was 120 km/h at most locations, and always located on the right lane.

Then, the automatic and manual lateral control rates were calculated for both exit and entrance ramps (Figure 6). As a result, 32% of the exit ramps and 19% of the entrance ramps led to a transference of the lateral control of the vehicle to the driver. In this way, it seems that the analyzed semi-autonomous system is more sensitive to exit ramps, since the lateral control is transferred at a greater frequency.

Similarly, most lane-reductions or additions also caused the system to fail. As said above, this is mainly due to the gap with no channelizing lines that the Spanish guidelines set for these sections. For these configurations, a longer discontinuity of the edge line exists.

Another observed issue was related to road-splits and road merging sections. If the sum of the lanes at the separated sections differ from the merged one, a large zone without any road marking appears, thus impeding any guidance by the semi-autonomous system.

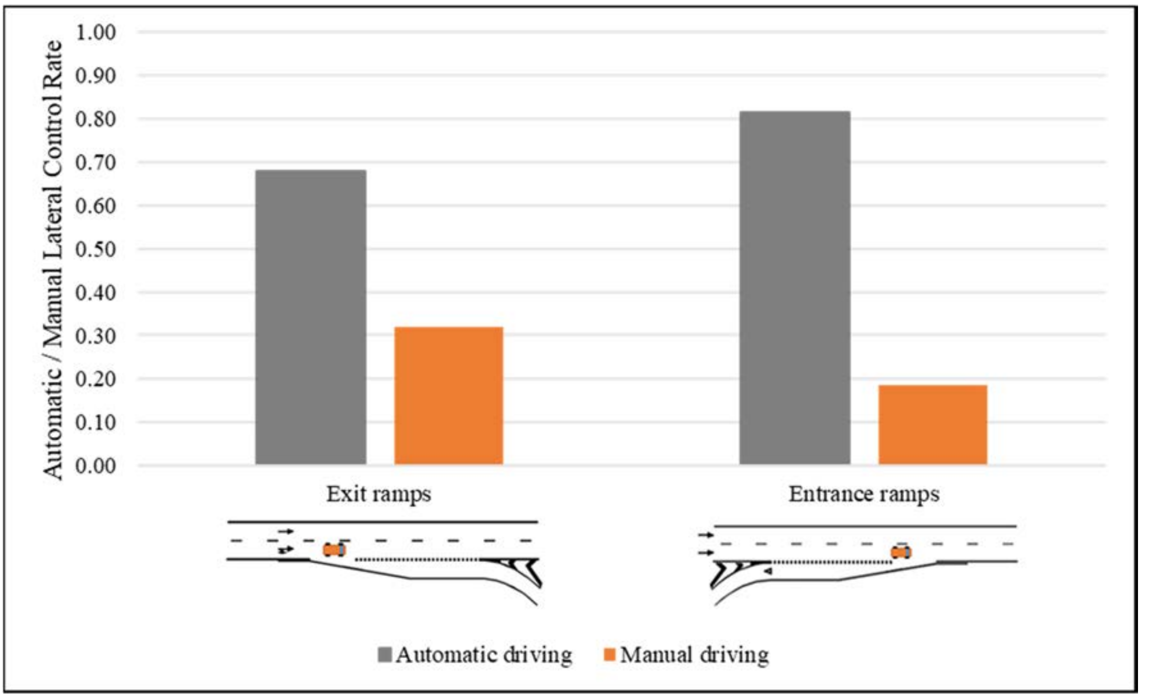

Figure 6: Influence of road markings on driving experience.

3.5 Pavement

In addition to the geometric design and road markings, another important factor affecting the effectiveness of the system of semi-autonomous vehicles is the road surface. As a result of the data collection described in the previous sections, some issues related to the condition of the pavement were also identified.

It was observed that the system often transferred the vehicle control to the driver when the pavement presented longitudinal cracking sealing along East-West sections. Regarding this, the reflection of the sun on this type of surfaces led to confusion to the vehicle system, which could not properly identify the lane markings.

Another feature of the pavement that showed a substantive influence on the performance of semi-autonomous vehicles was the road surface evenness. Particularly, those road segments with sharp unevenness caused a manual driving performance, so road maintenance is becoming more important as the number of automated vehicles increases.

Finally, a special mention should be given to work zones. Although these type of road sections have not been studied yet, they usually present a lack or deficiency of road markings, which will most likely result in the failure of the vehicle system leading to a manual driving performance.

4. NEW CRITERIA FOR ROAD SAFETY AUDITS

In view of these findings, some new criteria have been defined for both Road Safety Audit (RSA) and Road Safety Inspection (RSI), to determine whether a road segment is compatible with existing AVs.

Regarding RSA, the following criteria should be incorporated:

- minimum radius of horizontal curves (Rmin)
- minimum K-value of crest vertical curves (Kmin)
- minimum lane width (wmin)
- continuity of edge road markings.

On the other hand, the following issues should be taken into account in Road Safety Inspection:

- road marking performance, referred to visibility
- cracking sealing
- unevenness
- temporary road marking and pre-marking.

Taking into account that the current automated vehicles reach automation levels 2 or 3, the following thresholds to minimize disengagements are defined:

- Rmin = 500 m.
- Kmin = 30 m/%.
- wmin = 2.75 m.
- wmax = 4.50 m.

According to these geometric thresholds, it is expected that the existing Spanish motorways with a design speed greater than 100 km/h allow an automated driving to the current semi-autonomous vehicles.

Finally, Table 1 shows some questions that should be included in RSA and RSI checklists. These questions are preferred to be included in a new chapter or block of questions, which is proposed to be called “Autonomous driving performance”.

Based on the outcomes of this chapter, the capability of the road to hold autonomous vehicles might be determined. It should be noted that question block 4 only applied to existing roads, i.e., for RSI.

Issue	Yes	No	Comment
1. Horizontal and vertical alignment			
1.1 Does the road alignment have: • horizontal curves with a radius lower than 500 m? • crest vertical curves with a *K* parameter lower than 30 m/%?			
1.2 Is the curvature profile continuous?			
1.2 Is the automated speed lower than the design speed at: • horizontal curves? • crest vertical curves?			
2. Cross-section			
2.1 Is the width of traffic lanes constant?			
2.2 Is the lane width between 2.75 m and 4.50 m?			
3. Road markings			
3.1 Are edge line road markings continuous on: • entrance ramps? • exit ramps? • intersections? • transition sections?			
3.2 Is there any gap on: • entrance ramps (m) • exit ramps (m) • intersections (m) • transition sections (m)			
3.2 Are road markings in good condition?			
4. Pavement condition			
4.1 Does the pavement have cracking sealing?			
4.2 Does the road section consist of an uneven pavement?			
4.3 Are there any temporary road marking or pre-marking along the road?			

Table 1: Questions to be included in RSA and RSI.

Additionally, Table 1 should be complemented with the questions proposed by Austroads (2019) regarding line marking and road signs. Among all these questions, it should be highlighted those presented in Table 2.

Issue	Yes	No	Comment
1. Line marking			
1.1 Are the following lines present? • Left edge • Lane dividing line/s • Right edge • Centerline			
1.2 Are line widths nearing 150 mm, no narrower than 100 mm?			
1.3 Line contrast with surrounding roadway, • As relevant to machine vision during dry daytime conditions? • As relevant to machine vision during wet daytime conditions? • As relevant to machine vision during dry night-time conditions? • As relevant to machine vision during wet night-time conditions?			
2. Road signs			
2.1 Are there: • Static speed limits? • Electronic speed limits?			
2.2 Are road signs of good readability in daytime?			
2.3 Are road signs of good retro-reflectivity in night-time?			
2.4 Are road signs in their expected position?			
2.5 Are road signs obscured?			

Table 2: Questions for RSA and RSI proposed by Austroads (2019).

5. DISCUSSION

Fully automated vehicles (SAE level 5) will ensure an automated experience to their passengers, without the need to take control of the vehicle from any infrastructural condition. This technology is far from being reached, so existing technology is only able to produce partial automated experience. An adequate automated experience should ideally comply with:

- safe, meaning that no disengagements are produced without previous awareness or request to the driver
- reliable, meaning that the driving automation system is able to provide valuable information on how well it is performing (or whether a Take Over Request (TOR) is expected
- comfort, i.e. the frequency of disengagements/TOR should not be so high that drivers preferred to disconnect the system.

Comfortable speed and speed transitions should be met as well. Road infrastructure – combined with vehicle technology – can act on safety and comfort, while reliability can only be addressed with vehicle technology.

Therefore, a RSA/RSI including automated vehicles should explore how safe and comfortable is automation along a road segment, which can be done by analyzing how and how frequent disengagements are produced. A road segment whose geometry ensures performance without any disengagement, combined with adequate environmental conditions, defines an Operational Design Domain (ODD) able to support SAE level 4, which would be extremely safe and comfortable. On the contrary, a road segment with very frequent disengagements is not comfortable, but it would probably be safe from a driving automation perspective. This is because too many disengagements would discourage drivers from connecting the system thus staying in manual driving.

The worst scenario is, in fact, a road segment that causes a low number of disengagements. In this case, drivers might be willing to use the driving automation system, which will probably lead to distractions while the vehicle is performing the driving task (level 3). This increases perception-reaction time, which would be critical in case a disengagement/TOR arrives.

This research, beyond proposing specific thresholds which might be influenced by the vehicle used, aims at identifying the geometric-related aspects that might be the cause of these disengagements. Therefore, its major contribution is the proposal of the new speed concept named automated speed (Va) and the proposed methodologies to address semi-autonomous vehicle disengagements.

RSA should not focus on detecting whether the thresholds defined in the previous section are met or not, but on ensuring that these violations are not isolated, taking place after kilometers of automated driving. Auditors should pursue that high-end road segments meet all requirements for automation and ensure that adequate countermeasures are set in segments where a few disengagements are expected. Some examples of countermeasures might be an adequate signing (e.g. “Warning: Disengagements expected”), texturized pavement, etc. Specific electronic signs could also be proposed, if vehicles are adapted to read them and inform the driver about an oncoming disengagement. These measures would also be valid for transitions from ODDs valid from level 4 to other ODDs not compatible with this automation level. It is important to highlight that these measures must be reliable too, i.e. they should not be too conservative or relaxed. Too frequent signs warning about a possible oncoming disengagement without further becoming true would result in lower trust and, finally, in lower effect when actual disengagements take place.

While these measures would ensure a better performance of automated vehicles, there are two important shortcomings that affect their application:

- a) the diversity of driving automation systems
- b) their technological evolution.

The disparity of driving automation systems – which includes sensors, processing, and Human Machine Interfaces – makes it impossible to define an automated speed threshold that applies to all driving automation systems. In other words, a system might be able to perform autonomously along a horizontal curve of 400 m of radius, but another system might fail. Thus, the thresholds to define clear level 4 ODDs for most driving automation systems should be very conservative, set where the design speed of the road segment is clearly below the automated speeds measured for a wide range of driving automation systems. The main reason of proposing conservative thresholds is to avoid an overconfidence in drivers. As previously mentioned, when the road is prone to cause a lot of disengagements, manual driving might become safer than an automated driving.

In addition, these systems are evolving very fast. Existing limitations might be overcome in months, which hinders defining adequate ODDs, since these might be outdated soon and therefore become ineffective.

Defining the operational thresholds for the driving automation systems therefore becomes necessary. Given the plethora of technologies, harmonized testing protocols focused on determining the limitations of driving automation systems in real world should be developed by Administrations. These tests, combined with adequate thresholds, could be used to certify driving automation systems, ensuring that these will not disengage under some given circumstances. These limitations could also be used as an aim for Vehicle Original Equipment Manufacturers (OEMs) and their suppliers.

The above mentioned limitations would be present while the road infrastructure is only physical, which is barely resilient to changes. A Digital Infrastructure and an adequate communication between road infrastructure and CAVs could provide vehicles information about the ODD, allowing these to adopt and inform the driver about oncoming TORs. This would allow ODDs to change in definition, extension, and incorporate parameters such as traffic and weather conditions. An important effort should be done in advance to define harmonized and standardized vehicle limitations and ODDs. Thanks to it, the automated driving system, combined with HD map, would be able to anticipate the geometric-related disengagements and therefore inform about TOR with sufficient time.

If the digital infrastructure is not present, Variable Message Signs could inform the drivers about road readiness for AVs. Given the variety of vehicle technologies, some pictograms should be developed to show how the road interacts which each of them.

A standardization effort will be required as well to match road infrastructure with vehicle technology, provided that the number of pictograms should be limited since they have to be interpreted by drivers. Moreover, a driver should easily adapt to different vehicles which might obey to different of these pictograms.

In this scenario the role of auditors becomes challenging, since they should check adequacy of the pictograms to the different automation types, which implies readability of the signs, their frequency, and variation in time.

Finally, auditors should also be trained in V2X communications. New possibilities of CAVs, especially vehicle platoons and automated intersections would benefit from these communications but could generate new – and very important – problems if these fail. Degradation of Cooperative Active Cruise Control (dCACC) has been proven to suddenly increase decelerations on the traffic stream, which might not be supported by all autonomous technologies. Hence, auditors should check the strength of these communications and the possibilities of their blackout.

6. CONCLUSIONS

This study identifies some needs for improvement on current RSA/RSI procedures to host semi-autonomous vehicles. These are urgent needs, due to their fast market growth. Limitations regarding road design, road markings, and pavement condition have been identified, and some insight on how these should be incorporated is provided.

A new concept, the Automated Speed (Va), is introduced as the maximum speed at which semi-autonomous vehicles can perform autonomously. The relationship between this parameter and the design speed is of great importance, since a road feature in which the design speed exceeds the automated speed would result in massive disengagements and, therefore, hazards.

Several research of the authors on geometric and cross-section limitations of AVs have been summarized, highlighting how these should be applied by road safety auditors. At first, RSA/RSI should be based on conservative thresholds to ensure that a road feature produces no disengagements to any marketed semi-autonomous vehicle. Vehicle technological development and a better characterization of road-AV interaction will allow to define dynamic ODDs that will be transferred to vehicles via V2X. By doing so, RSA/RSI should adapt to ensure that these dynamic conditions are in line with all vehicles, regardless their automation level.

Existing RSAs already require the intervention of multidisciplinary teams to assess the road quality from different perspectives. Thus, adding autonomous vehicles to the picture might either require specialization of the team or increasing its number with more specialists.

Therefore, efforts must be made to gradually introduce new training on AVs and V2X communications to auditors. They should be able to analyze the potential shortcomings of communication failures, such as degraded CACC. A huge effort should be carried out first by Administrations, OEMs and suppliers to harmonize uniform communication, signage, and HMI protocols that are valid for current and further automation and infrastructure developments.

Further research should concentrate on determining the limitations of the different automation technologies, as well as on defining testing protocols to ensure their harmonization. These will establish a clearer goal for vehicle manufacturers in matching automation with road infrastructure, and a first step to group automation technologies and defining adequate ODDs. These ODDs, combined with the digital infrastructure, will ensure a safe scenario while transitioning from manual to fully-automated driving.

RESUMEN

La seguridad y calidad de la movilidad de los peatones en un ámbito urbano donde conviven con otros modos de desplazamiento debe ser una de las prioridades para cualquier gestor público. Para ello es fundamental disponer de una caracterización precisa de los recorridos peatonales y de los elementos urbanos que forman parte de estos recorridos, como pueden ser los pasos de cebra o los bordillos de separación entre diferentes espacios de movilidad, por ejemplo.

El presente trabajo presenta los avances en la clasificación y caracterización de algunos de estos elementos gracias al análisis de los datos obtenidos mediante un escaneado terrestre realizado por un *Mobile LiDAR Scanner* (MLS) en las calles cercanas a un colegio de la ciudad de A Coruña. Estos análisis se enmarcan dentro de las actividades desarrolladas en el proyecto BIG-GEOMOVE para el análisis de indicadores BIG GeoDATA sobre viarios urbanos para el diseño dinámico de caminos escolares seguros, y que fue financiado en 2017 por la Dirección General de Tráfico.

En este texto se muestran los procesos de tratamiento realizados sobre los datos LiDAR y los diferentes algoritmos desarrollados para clasificar la nube de puntos y diferenciar elementos urbanos importantes en los recorridos peatonales, en especial pasos de cebra y bordillos.

Además, se presentan los procesos de identificación, cálculo y análisis estadísticos de las caracterizaciones geométricas de los pasos de cebra reconocidos mediante los datos LiDAR. También se avanza en nuevas líneas de trabajo para analizar la calidad y el estado del firme de los recorridos. Los resultados alcanzados muestran un extraordinario potencial para definir con rapidez el estado de los elementos en los recorridos peatonales e identificar lugares y puntos donde es necesario realizar una actuación o mejora en comparación con el resto de elementos caracterizados.

1. INTRODUCCIÓN Y ANTECEDENTES DEL PROYECTO

Este estudio se integra dentro de los trabajos desarrollados en el proyecto denominado “Análisis de indicadores big geo-data sobre viarios urbanos para el diseño dinámico de caminos escolares seguros (BIG-GEOMOVE)” que recibió financiación de la convocatoria de 2017 de la Dirección General de Tráfico del Ministerio del Interior para subvenciones al desarrollo de proyectos de investigación en el área de tráfico, movilidad y seguridad vial. El equipo de investigación de este proyecto, además de los dos grupos redactores de esta comunicación, estaba formado por otros tres grupos de la *Universidade da Coruña* (del grupo de Ferrocarriles y Transportes, del grupo de Estudios Territoriales y del departamento de matemáticas), además del Dpto. de Sociología y Antropología de la *Universitat de Valencia*.

El objetivo principal de ese proyecto era obtener indicadores de caracterización de espacios peatonales en ámbitos urbanos para establecer rutas óptimas seguras y de calidad, centrándose especialmente en caracterizar espacios viarios para definir recorridos peatonales que permitan llegar andando a centros educativos. Su definición y desarrollo parte del proyecto previo “Estudio dinámico de la movilidad escolar mediante tecnologías web de geolocalización (GEOMOVE)”, también financiado por la DGT en la convocatoria de 2015 (Varela-García et al, 2018), completando y ampliando las líneas de investigación iniciadas entonces como se recoge en la web del proyecto http://geomove.es. Mientras en el primer trabajo se avanzaba en técnicas de recogida de información de hábitos de movilidad en los centros escolares mediante sistemas web de participación con mapas, en este segundo proyecto se profundiza en la integración de múltiples fuentes de datos para la parametrización de las características de los viarios urbanos. Se emplearon principalmente, además de la información adquirida mediante encuestas geolocalizadas sobre movilidad (como en el proyecto previo), datos procedentes de sensores LiDAR (*Light Detection and Ranging*), imágenes satelitales adquiridas por el sensor Worldview2 con 8 bandas espectrales y resolución espacial de 50 cm, así como imágenes del Plan Nacional de

Ortofotografía Aérea con una resolución espacial de hasta 25 cm, y otras fuentes de información vectorial y raster, como OpenStreetMap, Catastro, etc., que alimentan el análisis de accesibilidad peatonal que finalmente se realizaba.

Para el cálculo de los recorridos peatonales, además de identificar obstáculos a la movilidad, se observó la necesidad de poder diferenciar en los viales, los espacios destinados al peatón, como pueden ser las aceras o los pasos de cebra. En esta línea se estableció un trabajo específico entre el grupo de Arquitectura de Computadores de la Universidad de Santiago de Compostela (USC) y el grupo de investigación sobre Visualización Avanzada y Cartografía de la Universidade da Coruña (UDC) para desarrollar una metodología que pudiese identificar los bordillos que limitan la zona peatonal de la zona destinada a los vehículos motorizados, y también pudiesen caracterizar los pasos de cebra además de identificarlos, a partir de datos LiDAR, como describiremos en este texto.

La gestión y el mantenimiento adecuado de las carreteras, independientemente de su tipología y ubicación, requiere labores de inspección periódicas a fin de verificar su correcta conservación. Aunque a nivel tecnológico se ha avanzado significativamente, la mayor parte de las labores de inspección de viario siguen realizándose de manera subjetiva, frecuentemente mediante simples controles visuales que dependen de los criterios personales de los operarios encargados. En este sentido, las administraciones responsables del mantenimiento viario demandan cada vez más una información objetiva y actualizada a fin de asegurar su correcta conservación.

La llegada de la tecnología LiDAR ha facilitado notablemente estas labores de inspección gracias a la gran capacidad para capturar datos viarios con gran rapidez y precisión geométrica. LiDAR es un sensor de teledetección activo que emite pulsos de luz polarizada entre el ultravioleta y el infrarrojo cercano (Chuvieco, 2010) empleado tanto en el estudio y la exploración atmosférica (detección de aerosoles y partículas en suspensión, humedad, temperatura, etc.) como en el análisis de la topografía terrestre, ya que permite medir distancias desde un punto emisor.

Aunque su uso es más habitual en otros campos (inventario forestal, modelado del terreno, arqueología, conservación del patrimonio, etc.), en el área de infraestructuras viarias también existe un importante número de investigaciones que estudian la caracterización de carreteras mediante el empleo conjunto de datos LiDAR e información procedente de sensores pasivos y muchas de ellas emplean exclusivamente datos LiDAR, como pueden ser estudios sobre la construcción y el mantenimiento de viales (Akay, 2003; Collins y Sitar, 2010), la actualización automática de datos de navegación 2D y 3D para aplicaciones de consumo (Jaakkola et al., 2008), o la conducción autónoma de vehículos (Bendett y Aral, 1999; Kim et al., 2015; Lee et al., 2009; Park et al., 2011), además de una línea intensa en el control geométrico de infraestructuras singulares como puentes o túneles (Chen et al., 2014; Han et al., 2013; Martínez et al, 2014).

2. METODOLOGÍA

2.1 Datos

Para analizar físicamente los viarios se han escaneado múltiples calles de A Coruña del entorno de Colegio *Fogar de Santa Margarida*, que conforman un total de 12 km de viario, adquiriendo una nube de puntos LiDAR 3D mediante un sistema de captura de datos *Mobile Mapping* (MMS) ofertado por la empresa INSITU. El MMS empleado específicamente fue el Lynx Mobile Mapper M1 de la casa Optech. El sistema permite capturar nubes de puntos en coordenadas 3D a medida que se desplaza por el viario, y consta principalmente de dos sensores LiDAR y 4 cámaras RGB que permiten medir distancias a diferentes objetos del terreno para adquirir puntos en coordenadas X, Y, Z con un rango de precisión de 8 mm, además de información añadida, como valores de intensidad de retorno, tiempo de adquisición, ángulo de escaneo, etc., para obtener una nube de puntos densa que permite caracterizar el entorno analizado.

2.2 Tratamiento automático inicial de datos LiDAR

Para identificar los elementos de interés a partir de la nube de puntos LiDAR se ha desarrollado un método que en primer lugar clasifica los puntos en las clases “suelo” o “no suelo”, con el objetivo de obtener diferentes productos geomáticos a partir de ellas, que puedan servir como parámetros de entrada en sucesivos cálculos y análisis hasta la obtención de los indicadores de accesibilidad (que no son objeto de esta comunicación).

Este proceso parte de las nubes de puntos de los dos sensores en cada una de las escenas estudiadas, y se completa mediante cuatro etapas:

- segmentación grosera de la nube de puntos en suelo/no suelo
- depuración de la nube de puntos segmentada
- segmentación precisa de la nube de puntos
- generación de productos geomáticos.

Para realizar esta tarea se ha empleado la librería de tratamiento de nubes de puntos Point Data Abstraction Library (PDAL), sobre la que se han creado diferentes procesos y plugins para realizar el tratamiento de los datos y los análisis precisos para los cálculos de recorridos óptimos. Se muestra a continuación el modelo cartográfico empleado, que puede verse en la Figura 1, y se describe el procedimiento seguido. El código empleado con más detalles está disponible en el repositorio de código de cartoLAB: https://gitlab.com/cartolab. El código generado puede ejecutarse directamente desde la línea de comandos en cualquier ordenador que tenga instalada una versión de PDAL. Para hacer más sencilla la ejecución del algoritmo y que cualquier usuario no experto pudiese replicar los análisis, se ha optado por implementar el algoritmo en el software QGIS, por ser una herramienta de SIG muy extendida dentro da la comunidad geomática. De esta manera se dispone de todas las funcionalidades de PDAL dentro de QGIS, mediante el plugin PDALtools y el Geomove Processing Provider.

Una decisión alternativa hubiese sido crear un plugin de procesamiento a propósito para Geomove, ganando tiempo de análisis de datos, pero optamos por mejorar QGIS para un uso más estable en el futuro, y mayor beneficio para la comunidad de usuarios. Una vez aplicadas las mejoras pertinentes en el código fuente de QGIS, se implementa el algoritmo de Geomove mediante el plugin PDALtools y el Geomove Processing Provider. PDALtools permite instalar todas las herramientas necesarias para integrar PDAL dentro de Processing Toolbox, mientras que Geomove Processing Provider instala los modelos y algoritmos empleados en el proyecto Geomove dentro del Processing Toolbox. Para replicar los análisis realizados en este estudio es requisito imprescindible tener ambos instalados, así como una versión de PDAL en el ordenador.

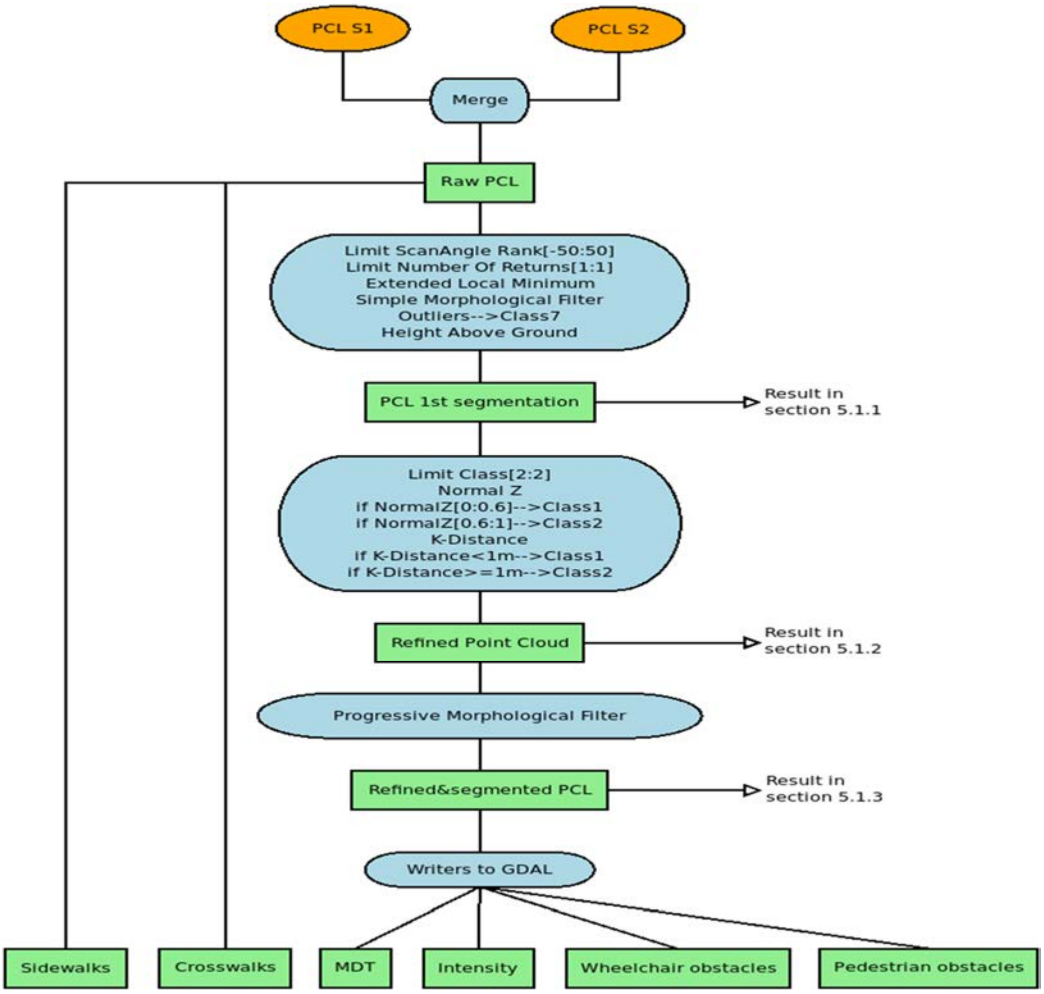

Figura 1: Modelo cartográfico empleado para la generación de la nube de puntos depurada y segmentada.

2.2.1 Segmentación grosera de la nube de puntos en suelo/no suelo

Los datos de entrada son las dos nubes de puntos crudas capturadas por los dos sensores S1 y S2 del sistema MMS, que tienen un formato de punto de tipo P={x,y,z,I,ts}, correspondientes a las coordenadas en 3D, un valor de Intensidad y otro de *time stamp*, respectivamente.

El objetivo de esta parte del algoritmo es segmentar de forma grosera puntos que pertenecen al viario de los que no. Para ello se agruparon los puntos de la nube analizada en dos categorías numéricas "2" y "1" correspondientes a *Ground* y *Unclassified points*, según las especificaciones del estándar ASPRS para las nubes de puntos puntos LiDAR (ASPRS las specification), a partir de ahora llamadas Class2 y Class1.

El proceso se inicia fusionando las dos nubes de puntos para conseguir una única nube [PCL]. Posteriormente se seleccionan sólo los puntos con un único retorno (se ha comprobado que pertenecen a áreas de vegetación, esquinas de edificios y retornos de cristales de vehículos, provocando problemas en la segmentación), y con un *ScanAngleRank* comprendido entre (-50,50), a fin de eliminar puntos demasiado altos que no interesan para la identificación de elementos viarios. Sobre estos puntos se aplican un *Extended Local Minimum Filter* (Chen, 2012) para identificar ciertos puntos como ruido y un *SimpleMorphologicalFilter* (Pingel, 2013) para obtener una nube segmentada en puntos de suelo y no suelo.

Se seleccionan los puntos pertenecientes a no suelo Class1, se les aplica un filtro *Outlier-Statistical Method* (Rusu, 2008) para identificar puntos con valores atípicos y se les asigna un valor de Class7 (*low point-noise*). Por último, sobre los puntos de Class2, se calcula la *Height Above Ground* (HAG), que es un valor de altura relativa desde cada punto respecto a sus vecinos. Este cálculo se realiza iterando sobre todos los puntos, encontrando el vecino más cercano en planimetría entre los puntos del terreno y calculando la distancia entre los dos valores de la componente Z.

2.2.2 Depuración de la nube de puntos segmentada

En este proceso se filtra la nube de puntos anterior, como paso previo a una segmentación más precisa. El primer paso es aplicar un filtro de normales. Se seleccionan sólo los puntos de suelo y se calcula el vector normal en las componentes x,y,z a cada punto en función de sus 30 vecinos más próximos. Con la aplicación del filtro de normales en la componente Z se identifican de manera clara los puntos de transición entre el terreno y los planos verticales. En la Figura 2 se muestran en color rojo los puntos pertenecientes al terreno Class2, en azul los no clasificados, Class1, y en verde las regiones de transición, que son el objeto de estudio en este paso del algoritmo.

Si la normal en la componente z está dentro del intervalo (0, 0.6) se considera que es bastante horizontal y por tanto el punto se asigna a un elemento vertical (fachada de edificio, obstáculo, etc.) con Class1. En el caso de que los puntos tengan una normal en la componente z prácticamente vertical (0.6, 1) se tomarán como puntos de terreno con Class2.

El siguiente paso es calcular *K-distance*. Sobre los puntos Class2 se calcula la distancia euclidea desde cada punto analizado a sus "k" vecinos (en este caso k=300) mediante el filtro *K-distance*.

Se establece que si esta distancia entre ellos es inferior a 1m, los puntos pertenecen a una misma clase (Class2) y si la distancia es superior, pertenecerán a clases diferentes y por tanto se asignan a Class1.

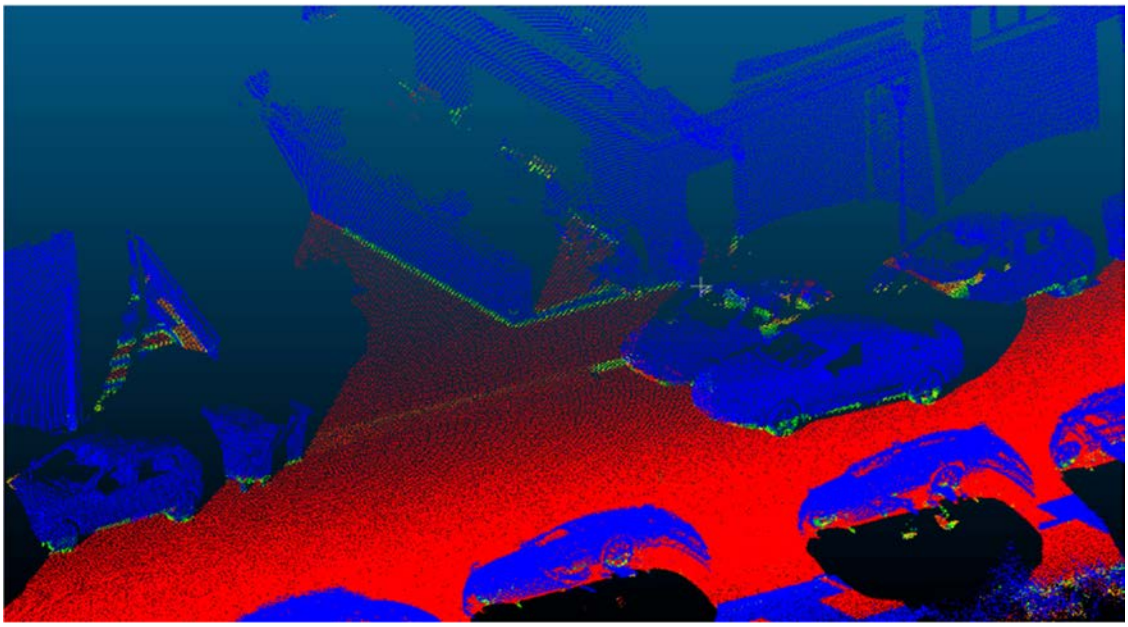

Figura 2: Cálculo del vector normal en la componente Z de cada punto de la nube.

2.2.3 Segmentación precisa de la nube de puntos

Se realiza la última segmentación de la nube de puntos ya filtrada mediante la aplicación de un *Progressive Morphological Filter* que permite segmentar puntos de suelo y no suelo mediante la implementación del método descrito en (Zhang, 2003).

2.2.4 Generación de productos geomáticos

Con la nube de puntos filtrada y adecuadamente segmentada se generan diferentes productos geomáticos, que son la base para crear las superficies de fricción al desplazamiento peatonal en el análisis de accesibilidad. Se generan cuatro archivos en formato raster con un tamaño de pixel de 18 cm: MDT, raster de intensidad, raster de obstáculos para peatones y raster de obstáculos para usuarios de sillas de ruedas. El MDT y el raster de intensidades tienen como valores de pixel las alturas e intensidades medias, respectivamente, de los puntos que se encuentran sobre dicho pixel. En ciertas escenas existen gran cantidad de vehículos aparcados en los laterales de la calzada que provocan zonas de sombra en las nubes de puntos LiDAR y que dificultan enormemente la labor de identificar con precisión la geometría de las aceras. Para solucionar este problema se ha optado por realizar una interpolación cuyo procedimiento no es objeto de esta comunicación.

Para generar los rasters de obstáculos para peatones y usuarios sillas de ruedas se han identificado y rasterizado todos los puntos cuyos valores de HAG están comprendidos entre 5 y 220 cm. Se ha considerado que todos los puntos con HAG >= 5 cm son obstáculos para usuarios de sillas de ruedas y HAG >= 25 cm para peatones.

Además de estos productos generados a partir de la nube de puntos filtrada y depurada, también se ha identificado la ubicación de los pasos de peatones y de los bordillos o delimitaciones calzada-acera, en este caso directamente desde las propias nubes de puntos LiDAR, como detallaremos a continuación.

2.3 Tratamiento automático específico de datos LiDAR

El tratamiento de los datos LiDAR ha sido sin duda el que ha significado un mayor número de horas de trabajo y esfuerzo realizado en este proyecto BIG-GEOMOVE, tanto en los procesos ya comentados, como en otros análisis pormenorizados de los parámetros ofrecidos por la nube de puntos de escaneo láser.

Entre ellos cabe destacar los implementados especialmente para la detección de pasos de peatones y la identificación de bordillos que delimiten convenientemente las aceras y ayuden a definir la zona de desplazamiento peatonal diferenciada de la calzada para los vehículos motorizados.

Los avances realizados han sido muy significativos en ambos casos, así como en otros procesos de detección e identificación de elementos de interés para los desplazamientos a pie, y por ello se han generado y se están generando distintos TFG y TFM con magníficos resultados en distintas líneas de investigación. Aquí expondremos brevemente una parte de estos estudios.

Un reto de estos análisis es la reducción del alto coste computacional del procesamiento de nubes de puntos LiDAR terrestre, donde se pueden alcanzar fácilmente densidades de varios cientos de puntos –e incluso miles– por metro cuadrado.

Debido a la propia naturaleza de los datos, el tratamiento de los mismos implica realizar un gran número de operaciones para llevar a cabo las tareas de segmentación y clasificación, por lo que se recurre a técnicas del ámbito de la computación de altas prestaciones, y se utiliza la infraestructura del Centro de Supercomputación de Galicia (CESGA) para realizar algunos de los procesamientos.

El punto de partida de este trabajo es un código secuencial que recibe como entrada los datos obtenidos tras la segmentación de la nube de puntos LiDAR, a partir de los métodos ya comentados, así como de los análisis de segmentación de datos LiDAR terrestre aplicada a seguridad vial implementados por (Soutullo, 2018) dentro del grupo de la USC.

El programa implementado se encarga de procesar los datos para realizar labores de detección de pasos de cebra y bordillos en entornos urbanos siguiendo un flujo de trabajo basado en la aplicación de distintas etapas de procesamiento consecutivas, obteniendo dos nubes de puntos (*bounding boxes* y elementos viales), que son:

- Algoritmo de adyacencia: Algoritmo que itera sobre la nube de puntos y marca aquellos que son susceptibles de pertenecer a un bordillo. Se basa en la suposición de que los bordillos son adyacentes a terreno (puntos cuya planaridad hace suponer que pertenecen a aceras o carreteras).
- Cálculo de línea virtual: Obtención de una línea compuesta por puntos ajenos a la nube de puntos que se ajusta a la geometría de un bordillo dado.
- Proporcionalidad por tipo de punto: Etapa que descarta grupos etiquetados como señales horizontales cuya proporción de puntos propiamente de señal supera un umbral dinámico.
- Generación de datos de bounding boxes: El principal uso de las bounding boxes consiste en envolver las señales horizontales para realizar un análisis local de las mismas, gracias al cual es posible identificar individualmente las franjas de los pasos de cebra.
- Generación de datos completos: Transformar los datos de pasos de cebra y bordillos a un formato interpretable para su visualización (especialmente usándose el visualizador "Olivia" desarrollado por el grupo de la USC).
- Otros procesamientos: Cálculo de diferentes parámetros asociados a los elementos identificados, como por ejemplo datos geométricos de los mismos (longitud, ancho, pendiente, etc.) para la caracterización final de los elementos clasificados.

En la Figura 3 se observa la nube de puntos LiDAR en una escena del viario estudiado, mostrando la zona según intensidad en la figura de la izquierda, y en la figura de la derecha se identifican con color morado las bandas del paso de cebra y con color blanco la alineación de los bordillos.

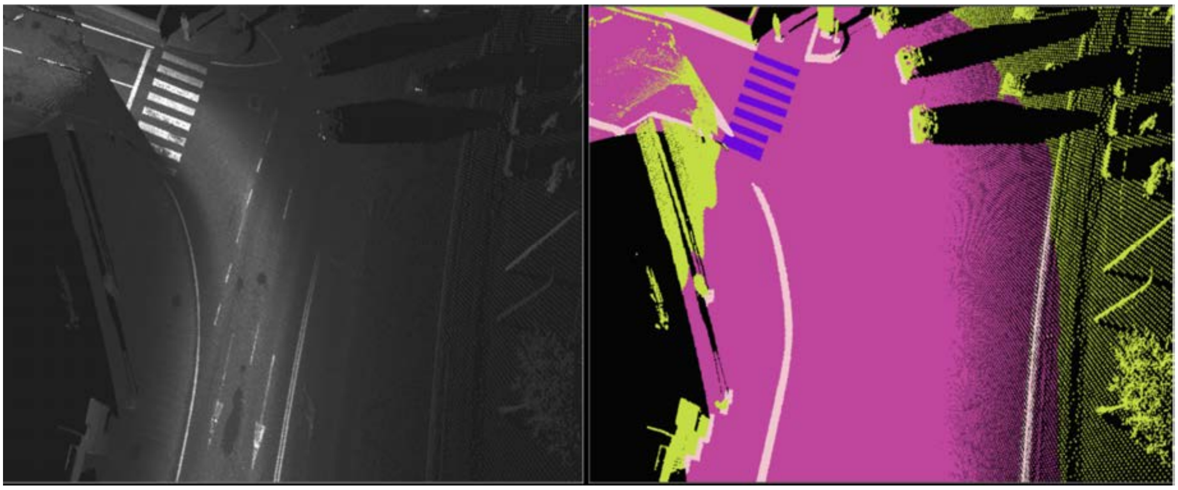

Figura 3: Ejemplo de identificación de paso de cebra y bordillos.

3. RESULTADOS

Aunque seguimos trabajando en la mejora técnicas ya se han obtenido resultados satisfactorios en diferentes entornos geográficos, a partir de distintas escenas de nubes de puntos LiDAR. En el caso de las calles del entorno del colegio de A Coruña, se han conseguido identificar los 37 pasos de cebra existentes, aunque las características de los mismos han hecho que su caracterización no siempre pudiese corresponderse con las geometrías de los mismos. En la Figura 4 puede verse la localización de estos pasos de peatones, identificando aquellos que presentan mejores resultados en cuanto a la geometría final obtenida de forma automática en el proceso de clasificación.

Figura 4: Mapa de localización de los 37 pasos de cebra identificados. En verde aparecen los que consiguen una geometría final similar a la existente y en morado los que presentan algún tipo de problema.

Los problemas de definición final de los pasos de cebra hemos comprobado que no son debidos a deficiencias en el proceso de identificación empleado, sino a las irregularidades y deficiencias presentes en estos elementos de señalización vial, como podemos observar en los ejemplos mostrados en la Figura 5. En general se deben a pérdida de calidad en la pintura de las bandas del paso de cebra, pero también nos encontramos con problemas adicionales cuando hay un cambio de pavimento en el entorno del paso de cebra, o en parte de él, lo que provoca intensidades muy altas de alguna zona del firme.

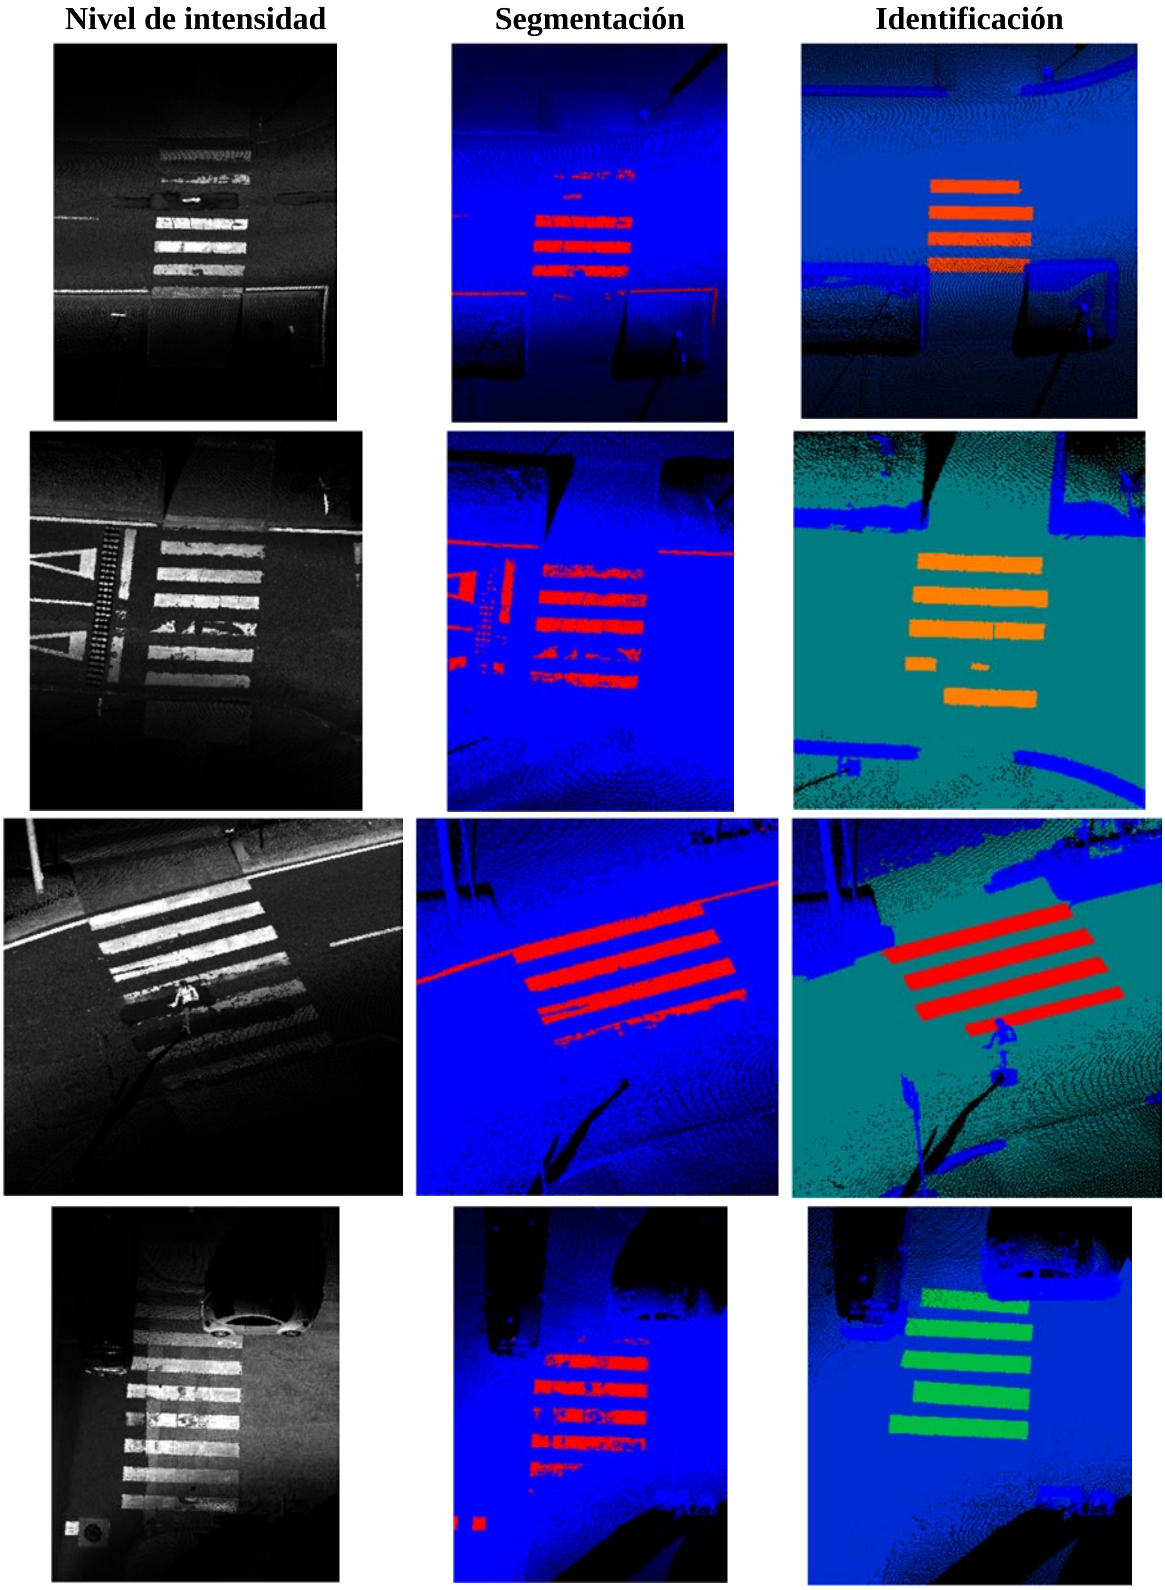

Figura 5: Ejemplos de pasos de cebra no caracterizados en su globalidad debido a distintos factores. Se presentan 3 imágenes de cada paso de cebra, para ver su nivel de intensidad, su segmentación y la detección final realizada.

Además, podemos observar como la presencia de un peatón, o de un vehículo sobre el paso de cebra, imposibilita la reconstrucción completa de parte de este elemento.

Sin embargo, lo que podría considerarse un problema en una primera interpretación de los resultados, creemos que esta circunstancia permite que con el sistema de análisis empleado, no sólo se puedan identificar los pasos de cebra de forma automática en una nube de puntos LiDAR, sino que se puedan clasificar automáticamente aquellos pasos de cebra que presentan irregularidades en su estado. Este hecho, sin duda es de especial interés para cualquier gestor o administrador de la integridad de la señalización viaria, especialmente en ámbitos urbanos, para conocer el grado de calidad de los pasos de cebra de una forma eficiente y objetiva, y poder plantear con ello medidas paliativas para solucionar los problemas detectados.

Pero el proceso de identificación automática de los pasos de cebra, también nos ha permitido caracterizar ciertos parámetros de cada uno de estos elementos de señalización viaria horizontal. Estos parámetros se corresponden tanto con los valores de los datos obtenidos directamente por el LiDAR, como la intensidad o el ángulo de incidencia, como de las métricas calculadas a partir de las coordenadas X, Y, Z de los puntos que caracterizan un paso de cebra, y cada una de sus bandas. Así, podemos obtener el ancho y la longitud de cada paso de peatones, y de cada una de sus bandas de pintura, la pendientes longitudinal y transversal de estos elementos, la diferencia de altura con las aceras de sus extremos, los valores estadísticos (medio, máximo, mínimo, desviación, etc.) de cada valor de intensidad o ángulo de incidencia de todos los puntos LiDAR que forman cada elemento, indicadores calculados a partir de esos datos, como la rugosidad o calidad de la pintura, y un largo etcétera. A modo de ejemplo, se incluye una Tabla 1 con las características más significativas de los pasos de cebra que se consideraron bien clasificados con respecto a los existentes.

PARÁMETRO CALCULADO	VALOR
Media del área real medida	31,85
Media del área calculada	32,19
Longitud media del paso de cebra	7,88
Ancho medio del paso de cebra	4,07
Relación media entre longitud y anchura	1,93
Número medio de barras	8,15
Longitud entre el número de barras	0,97
Longitud máxima de una barra	4,05
Ancho máximo de una barra	0,65
Longitud mínima de una barra	1,49
Ancho mínimo de una barra	0,38
Longitud media de una barra	3,82
Ancho medio de una barra	0,54
Relación media entre longitud y anchura por barra	7,04
Calidad media de la pintura por barra (máx 1)	0,91
Intensidad media por barra	2197,34
Intensidad máxima por barra	3446,03
Intensidad mínima por barra	400,84
Desviación estandar de la intensidad por barra	491,59

Tabla 1: Resumen de parámetros obtenidos sobre los 18 pasos de cebra bien caracterizados.

Además de estos análisis, también se iniciaron procedimientos para la identificación de obstáculos en el recorrido peatonal (farolas, árboles, papeleras, etc.) con el objetivo de definir espacios donde el peatón pueda desplazarse, y lugares donde la movilidad es imposible o presenta limitaciones. En este sentido, también se está estudiando la identificación de deficiencias en el pavimento mediante el análisis de la nube de puntos LiDAR, observándose incluso ligeras anomalías en ciertas zonas de las calles, por lo que sería posible no sólo detectar baches consolidados, sino también aquellas regiones del pavimento donde están empezando a formarse desperfectos significativos, y calcular las características de los mismos (longitudes, profundidades, volúmenes de deterioro, etc.).

4. CONCLUSIONES

La integración de diferentes fuentes de datos para el análisis y gestión de las infraestructuras viarias debe ser una línea de investigación importante en los próximos años, pues las posibilidades que ofrecen los nuevos sensores de captura de datos geográficos mediante técnicas de teledetección (LiDAR, radar, imágenes multiespectrales, etc.) amplían enormemente las posibilidades de identificación, clasificación y caracterización de cualquier elemento territorial. La coordinación de diferentes grupos de investigación, combinando conocimientos en tecnologías diversas y experiencias y capacidades compatibles para abordar estudios diferentes sobre infraestructuras viarias, debe ser también potenciada para encontrar nuevas líneas de análisis.

El ejemplo mostrado en este texto, es sólo una muestra de las iniciativas que con tiempo y recursos, se podrían conseguir para disponer de métodos rápidos y eficaces para aumentar las capacidades de gestión de los siempre complicados procesos de conservación y mantenimiento de las infraestructuras, especialmente las viarias.

Los resultados alcanzados en la identificación y caracterización de bordillos y pasos de cebra, así como de otros elementos relacionados con los recorridos peatonales en zonas urbanas, muestran unos niveles de eficiencia de alto interés para seguir avanzando en las líneas de investigación marcadas desde un proyecto financiado inicialmente por la DGT. Además, los problemas identificados abren líneas de mejora en las características de obtención de los datos, que podrían ser implementadas en futuros trabajos.

AGRADECIMIENTOS

Debemos agradecer la financiación conseguida en la convocatoria de subvenciones a proyectos de investigación 2017 de la DGT con el proyecto de referencia SPIP2017-02340 con el título de “Análisis de indicadores big geo-data sobre viarios urbanos para el diseño dinámico de caminos escolares seguros (BIG-GEOMOVE)” que ha servido de base para gran parte de los análisis mostrados en esta comunicación.

Además, parte de este trabajo ha recibido el soporte de la Consellería de Educación, Universidade e Formación Profesional de Galicia a través de la acreditación ED431G-2019/04 y del grupo competitivo ED431C-2018, y por el Ministerio de Economía y Competitividad con el proyecto PID2019-104834GB-I00 y fondos FEDER.

ABSTRACT

Different studies over the past 30 years have shown an increase in the rates of crash frequencies during road construction time, but this trend is not reported as valid for all cities. A question is raised whether higher rates are observed in arterial roads in Bogotá, Colombia. It is possible to apply descriptive statistics and hypothesis tests to prove them and identify the variables that affect the accident rate during road construction. Our research aims to verify the incidence of high impact construction zones, in the crash rate at the arterial road network of Bogotá. We use descriptive statistics and inferential statistical tests to analyze whether crash rates are statistically higher during construction time than during non-construction time at the same highway sections considering different crash severities (damages-only, injuries, and fatalities). Our database considered 871 road links that make up 68 artery corridors for the city of Bogota, and 5.450 road construction zones, from 2015 to 2019. An analysis by corridor was performed, in which we identified seven patterns in the behavior of accident rates influenced by the presence of a road intervention in the corridor. Within the patterns, it was evident that some corridors reported an increase in the accident rate during the time of construction, while others showed a decrease in the same comparison. We used the Wilcoxon test to establish the statistical significance of our conclusions, with a significance level of 10%. We also found that those construction interventions that do not require excavation of more than half a meter there was a decrease in the accident severity, as damages-only crashes, diminished during the construction time, while for those interventions that include excavation greater than half a meter there was an increase in overall accident rates during construction time.

1. INTRODUCTION

According to the World Health Organization, road crashes are the first leading cause of death and disabling injury among children and young adults between the ages of 5 and 29 and are the 8th leading cause of death in the world at all ages, with 1.35 million deaths each year. It is also a problem that affects 3 times more the countries of emerging economies than the countries with advanced economies (World Health Organization, 2018).

Traffic crashes in construction sites are continuing a problem in many countries around the world. For example, 87,606 crashes occurred in work zones, which led to over 37,000 injuries and 576 fatalities in 2010 in the US (National Highway Traffic Safety Administration, 2013). Large cities in the developing world carry out large-scale construction projects continually e.g., approximately 45% of the roads will be under construction in the next 4 years in Bogota Colombia. The main safety concerns are the road users and the construction workers.

The findings of previous studies that examine the safety impacts of work zones varied significantly because of the differences in locations, data size, data quality, and analysis approaches. Traffic-related crash rates and behavior depend on city-specific conditions such as drivers' behaviors, safety regulations and standards during construction, environmental conditions, and soon (Yang, Ozbay, 0zturk and Xie, 2015).

Road construction safety regulation requires that contractors take sufficient safety measures to protect human lives. Construction works always affect mobility conditions, even when a large part of the work aims to improve the conditions of the existing roads and the city mobility in general, but contractors are required to maintain safety and smoothness in traffic flow on the road construction site, (Instituto de Desarrollo Urbano IDU, 2016).

Construction of new infrastructure and building projects in Bogota are required to present a traffic management plan -PMT (for its words in Spanish) to the local mobility authority. A PMT should include strategies and technical alternatives to provide safe, and operational conditions to the different road users through optimized planning, scheduling, and operating mechanisms. In the particular case of Bogotá, those plans are classified into two main categories COI (Consolidation of infrastructure works) and COOS (Consolidated public service infrastructure works) (Movilidad, 2021).

To establish whether the PMT mechanisms implemented in the working zone are efficient and effective in mitigating work zone safety impacts on the traveling public and the workers we perform a long-term analysis for arterial roads in Bogota. We were interested in investigating changes in vehicle crashes by three different severities, questioning whether the rates of registered road crashes are higher during construction periods and non-construction time.

Several studies have been carried out at the global level to develop an understanding of the potential risk factors associated with work zone crash occurrences (Di, Shi, Zhang, Svirchev, & Hu, 2016; Jin, Saito, & Eggett, 2008; Rao, Wu, Xia, Ou, & Kluger, 2018; Rouphail, Yang, & Fazio, 1988; Theofilatos, Ziakopoulos, Papadimitriou, Yannis, & Diamandouros, 2017; Ullman, Finley, & Ullman, 2004; Zhang & Hassan, 2019).

The findings from these studies varied significantly because of the differences in data availability, locations, methods of analysis, but there is a general agreement about accident rates being higher during construction time when compared to non-construction rates in most advanced economies (Yang, Ozbay, 0zturk and Xie, 2015).

However, there is very little research on this topic in large Latin-American cities as is the case of Bogota, Colombia. Considering that Bogota has a vision zero plan towards road safety to reduce the number of crashes with fatalities by the year 2038, and in addition, during the next few years the city will begin the construction of multiple high-impact projects including the first Metro line, regional light rail (REGIOTRAM), new BRT corridors our research takes relevance.

Our study focuses on comparing long-term traffic crash rates in the arterial road network of the city of Bogota during construction and non-construction time using data for 2015 to 2018. Different statistical methods are applied to test statically significant differences of central trend measures.

We used non-parametric tests such as the Wilcoxon test (Wilcoxon, 1945), to test our hypothesis discriminating by different crash severities, different road types, and for different arterial corridors in the city of Bogota.

2. METHOD

2.1 Research framework

This study uses statistical techniques to identify patterns of behavior in accident rates during construction and non-construction time in Bogotá, Colombia. This statistical analysis is carried out through descriptive statistics (minimum, maximum, mean, standard deviation) and non-parametric statistical tests such as the Wilcoxon test. Crash rates were calculated using per million vehicle miles traveled (MVMT).

Our research consisted of two phases: First, the construction of the database needed; second one the statistical data analysis and hypothesis testing. From this point forward, a brief description of the process is made considering the main components of our research framework: road infrastructure description, types of construction zones, crash severity and time windows, the data sources, data grouping, and methods of analysis.

2.1.1 Road Infrastructure

The road subsystem in the city of Bogota is divided into 4 main types of the road network, the first one refers to the main arterial road network, which is responsible for providing accessibility and connection for the city with the region and the country. The second type is the complementary arterial road network, which is intended for medium and long-range travel within the city.

These first two networks add up in total 2.634 km. The third type is the intermediate road network, which functions as an alternative to decongest the city and has a total length of 3.204 km. Finally, there is the local road network to connect the housing units with the other arterial roads and is composed of 6.134 km of small streets. Our research analyses included the main and intermediate arterial networks with a total of 68 road corridors, and 400 kilometers (figure 1).

Figure 1: Main and complementary arterial network included in research analysis.

2.1.2 Types of construction interventions and their traffic management plan

As stated before, the traffic management plan (PMT) is a technical tool used to propose the strategies, alternatives, and different activities needed to reduce the impacts on traffic flow and safety during construction time. PMT contains actions required to deal with infrastructure closures and displacement of road users, as pedestrians, cyclists, transit buses, trucks, and light-duty vehicles.

All actions contained in the PMT must favor the road safety of all users and construction workers. These traffic management plans are classified according to the type of intervention which can be works or events.

They are also classified by the intensity of the impacts and the complexity of the construction process as high, medium, and low. In our investigation, three different types of PMT were considered, which are:

2.1.2.1 COI-ALTA

The Consolidated Works of Infrastructure (COI) is a standard regulation instruction manual designed by the District Secretariat of Mobility of Bogota for those PMT that does not require an excavation license for their execution. A total of 3708 COI PMT were included for our study.

COI-high denomination used in our research refers to the type of complexity. Impacts include traffic lights on road corridors, partial or total closure of lanes, partial or total use of the access platform, partial or total closures to pedestrian bridges, and total closures of bike paths located on the road.

2.1.2.2 COOS-ALTA

The Consolidated Public Service Infrastructure Works (COOS) is the PMT instruction manual developed by the District Secretariat of Mobility of Bogota for works that require an excavation license with a depth greater than 0.5. In this type of works, the width and depth of the excavation must be specified to determine the safety distances and type of element to be used for the enclosure.

COOS-high denomination refers again to the impact or level of affectation explained for the COI-ALTA. There were 1729 PMT considered for this investigation.

2.1.2.3 COI-TRONCAL

The Consolidated Works of Infrastructure (COI) is the type of PMT that applies to construction zones in Bogota´s BRT system - TransMilenio There were only 13 COI-TRONCAL PMT included in our analysis.

2.1.3 Crash severity and time windows

Crashes were classified by severity into 3 categories, the crashes that caused fatalities were defined as "Fatalities (DE)". If the crash caused injuries, or injuries and material damage, the severity will be defined as "Injuries (WO)". If only material damage occurred, the severity of the crash will be defined as "damage only (DO)".

Three different time windows of analysis were defined: Before construction time (BF), corresponding to crash rates before a road intervention happened and a work zone was established. During construction time labeled as PMT), corresponding to crash rates while the work zone was active. After construction time (AF), corresponding to crash rates after road intervention was finished.

The before and after time windows had the same duration as every intervention, to avoid bias. They were also placed immediately before and after each intervention for a better understanding of the direct impact they have on road safety conditions.

2.2 Data sources

2.2.1 IPAT

The Police Report on Traffic Accidents (Informe Policial de Accidentes de Tránsito, IPAT) is an official record used in Bogotá by the specialized bodies of Urban Traffic Police, as a tool that allows the primary collection of crash data. This report is aimed at allowing clear and probable identification of causes hypotheses and at facilitating the implementation of actions related to road safety for the national, departmental, municipal, or local government and representatives of civil society. (For more information about IPAT, its manual is available online)

2.2.2 SIGAT

SIGAT is the acronym for Sistema de Información Geográfica de Accidentes de Tránsito (Geographic Information System for Traffic Accidents). This database is linked to Registro Nacional de Accidentes - RNAT (National Registry of Traffic Accidents, in English) and its main function is to consult if a vehicle is reported in the database of Police Reports of Traffic Accidents (IPAT) registered in the District Secretary of Mobility of Bogotá. We used this database as our main source to compute crash rates between 2015 and 2018.

2.3 Grouping of data for construction and non-construction time

The database used to make the descriptive statistics and run the nonparametric test had 22 variables, and 5.450 entries, corresponding to the number of PMT or construction work zones in the 68 road corridors that were considered for the study. Table 1 shows the variables considered in our analysis.

VARIABLE	DESCRIPTION
COD	Corresponds to the number or key assigned to each PMT.
ADDRESS	Place where the PMT is developed, and the accident record is kept.
CORRIDOR	Name of road corridor.
PMT TYPE	Typology of the PMT that was carried out.
SECTION	Code assigned to each road section belonging to a particular corridor.
START	Start date of PMT implementation.
END	End date of PMT implementation.
DURATION	Time in days when the PMT was applied.
LENGHT	Distance in meters in which the PMT was applied.
VOL VEH	Corresponds to the average daily hourly traffic (TPDH).
BF_DO	Accidents before construction time with damages only.
BF_WO	Accidents before construction time with wounded people.
BF_DE	Accidents before construction time with deceased people.
BF_TO	The total number of accidents before construction time.
PMT_DO	Accidents during construction time with damages only.
PMT_WO	Accidents during construction time with wounded people.
PMT_DE	Accidents during construction time with deceased people.
PMT_TO	The total number of accidents during construction time.
AF_DO	Accidents after construction time with damages only.
AF_WO	Accidents after construction time with wounded people.
AF_DE	Accidents after construction time with deceased people.
AF_TO	The total number of accidents after construction time.

Table 1: Attributes of the database.

2.4 Method of analysis

We used R Studio, a statistical software (Gentelman and Ihaka, 1993) with packages as dplyr (Wickham and François, 2020), ggplot2 (Wickham, 2016), lubridate (Wickham and Grolemund, 2011), reshape2 (Wickham, 2011), nortest (Gross and Ligges, 2015), car (Fox and Weisberg, 2019), MVN (Korkmaz, Goksuluk, and Zararsiz, 2014) among other packages to analyze the crash rates associated with the 5450 construction work zones. We developed a descriptive statistical analysis, including mean, standard deviation, minimum value, and maximum value. We used Wilcoxon test (Wilcoxon, 1945) a non-parametric test to perform hypothesis testing, to probe statistical significance difference between crash rates in different time windows, discriminating t by severity, (Damage Only (DO), Injuries (WO), Fatalities (DE), and total (TO)). We used Wilcoxon for the hypothesis testing at the city level, by the corridor, and by type of PMT.

The Wilcoxon test used is also known as the Wilcoxon range sum test or Mann-Whitney test and represents a non-parametric alternative to the t-test of two unpaired samples, where it is checked whether two samples come from equidistributed populations. Some conditions that must be considered for the application of this test are that the data must be independent, ordinal, and the phenomenon of homoscedasticity must be presented among the groups to be compared.

For the Wilcoxon test, the equality in the averages of the accident rates during construction times and not construction was adopted as a null hypothesis, which would mean that there would be no statistically significant evidence that the rates were different; in addition, two alternative scenarios were adopted, the first of which was determined by greater, in which, if the null hypothesis was rejected, the hypothesis that the accident rate of the non-construction time was higher was accepted, compared to the accident rate in construction times; the second alternative hypothesis consists of less and is the opposite of the first because in this case there would be a statistically significant difference in the rates which would lead to the conclusion that the crash rates at construction time are lower than the rates under construction.

3. RESULTS

Our results are presented in tables by city level, by corridors, and by PMT type. These results are presented as follows. First, descriptive statistics and Wilcoxon test results for the entire city. The second will follow the Wilcoxon test results of crash rate difference sorted by corridors. Third, we present descriptive statistics and Wilcoxon test results of crashes sorted by PMT.

Tables 3, 4, 5, 6, 9, and 10 present a summary of the results of the Wilcoxon tests for two different alternative hypotheses: i) depending on the case one of the rates (before or after the construction zone) is greater than the crash rate during construction; ii) one of the rates (before or after the construction zone) is less than the crash rate during construction.

The columns of all tables show the previously described accident rates, and its rows vary according to the classification of accidents used. At the city level, there is only one row corresponding to its name: Bogotá D.C. In the case of accidents sorted by corridors, each row corresponds to the name of the 58 corridors that make part of the arterial network of Bogotá. In the case of accidents sorted by PMT, each row corresponds to the type of traffic management plan.

3.1 City level

Table 2 shows a summary of the descriptive statistics for the previously described crash rates, according to the defined classification of accidents. These statistics show the range, mean, standard deviation, and sum of these variables.

Bogotá	BF_DO	BF_WO	BF_DE	BF_TO	PMT_DO	PMT_WO	PMT_DE	PMT_TO	AF_DO	AF_WO	AF_DE	AF_TO
Minimum	0	0	0	0	0	0	0	0	0	0	0	0
Maximum	3344.999186	5163.536933	395.9703834	5163.536933	3297.470898	1584.079157	2059.077505	3297.470898	15733.43452	1374.36379	271.3092127	15733.43452

Table 2: Results of descriptive statistics at the city level.

At the city level of the city, the Wilcoxon test was run with a total of 5,450 work zones in arterial corridors. In general, we could not find statistical differences in crash rates during construction and non-construction times. We observed a raised in Damages Only (DO) crash rates after the construction zone is lifted but this test is considered inconclusive. Therefore, we decided to analyze by Corridor and by type of PMT.

CITY LEVEL	N	PMT_DO/BF_DO	PMT_DO/AF_DO	BF_DO/AF_DO	PMT_WO/BF_WO	PMT_WO/AF_WO	BF_WO/AF_WO	PMT_DE/BF_DE	PMT_DE/AF_DE	BF_DE/AF_DE	PMT_TOT/BF_TOT	PMT_TOT/AF_TOT	BF_TOT/AF_TOT
Bogota DC	5450	0,206	0,096	0,223	0,105	0,177	0,662	0,751	0,413	0,206	0,139	0,106	0,247

Table 3: Wilcoxon test results at a city level for alternative hypothesis where the crash rate in non-construction is greater than the crash rate during construction.

Note: Values shown are p-values. The green value corresponds to p-values less than 0.1. Damage ONLY (DO), Wounded (WO), Deceased (DE), and Total (TO) severities are considered when comparing each of the temporary windows: Before (BF), During (PMT), and After (AF).

CITY LEVEL	N	PMT_DO/BF_DO	PMT_DO/AF_DO	BF_DO/AF_DO	PMT_WO/BF_WO	PMT_WO/AF_WO	BF_WO/AF_WO	PMT_DE/BF_DE	PMT_DE/AF_DE	BF_DE/AF_DE	PMT_TOT/BF_TOT	PMT_TOT/AF_TOT	BF_TOT/AF_TOT
Bogota DC	5450	0,794	0,904	0,777	0,894	0,823	0,338	0,250	0,588	0,795	0,861	0,894	0,753

Table 4: Wilcoxon test results at a city level for alternative hypothesis where the crash rate in non-construction is less than the crash rate during construction.

Note: Values shown are p-values. The yellow value corresponds to p-values bigger than 0.9. Damage ONLY (DO), Wounded (WO), Deceased (DE), and Total (TO) severities are considered when comparing each of the temporary windows: Before (BF), During (PMT), and After (AF).

3.2 By corridor

We perform the hypothesis analysis in 58 arterial corridors. Table 5 shows, the p-value of the Wilcoxon test, performed to find statistically significant differences between the crash rates of the different time windows considering the three levels of crash severities.

Tables 5 and 6 shows p-values smaller than 0.1 in green color, and p-values bigger than 0.9 in yellow color. P-values equal to 1 are shown in red color as this was an indication that the hypothesis was completely rejected. Cells without color correspond to those p-values that do not fit any of the previously described categories.

4. DISCUSSION

The results of the hypothesis testing, using the Wilcoxon test allow us to identify a total of 7 patterns when considering the behavior of the crash rates during construction and non-construction periods. Patterns describe growth or decrease in the crash rates, influenced by work zone in the arterial corridors. Figure 2 shows a diagram that describes the seven different patterns:

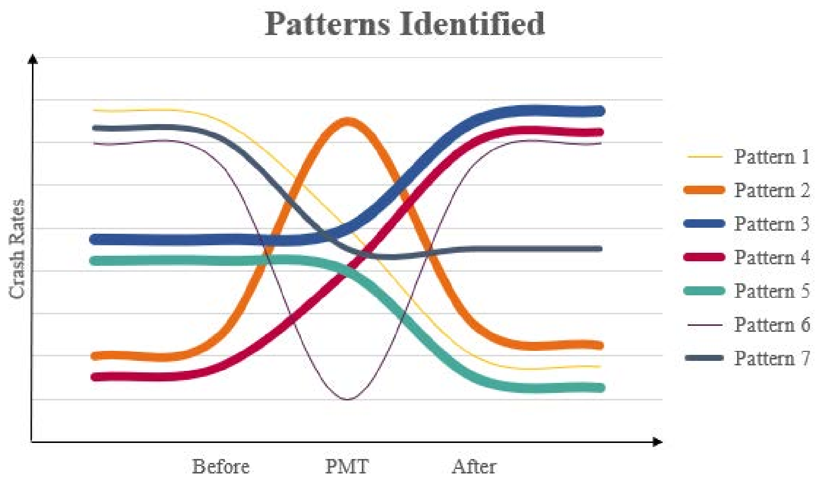

Figure 2: Patterns identified in crash rates during construction time.

The first pattern is represented in yellow in Figure 2. Includes the behavior observed in the CL26SUR-KR78K corridor, where it is evident that during the application of the PMT (construction time) the crash rate is lower than the rate observed before the intervention. Besides, there is also a downward trend in the crash rates, compared with the rates before and during construction time.

The second pattern Figure 2 (orange) includes the behavior observed in 5 corridors with two different severity (DO and WO). We observed a higher crash rate during construction time than the rates observed during periods of non-construction, whether before or after the road intervention.

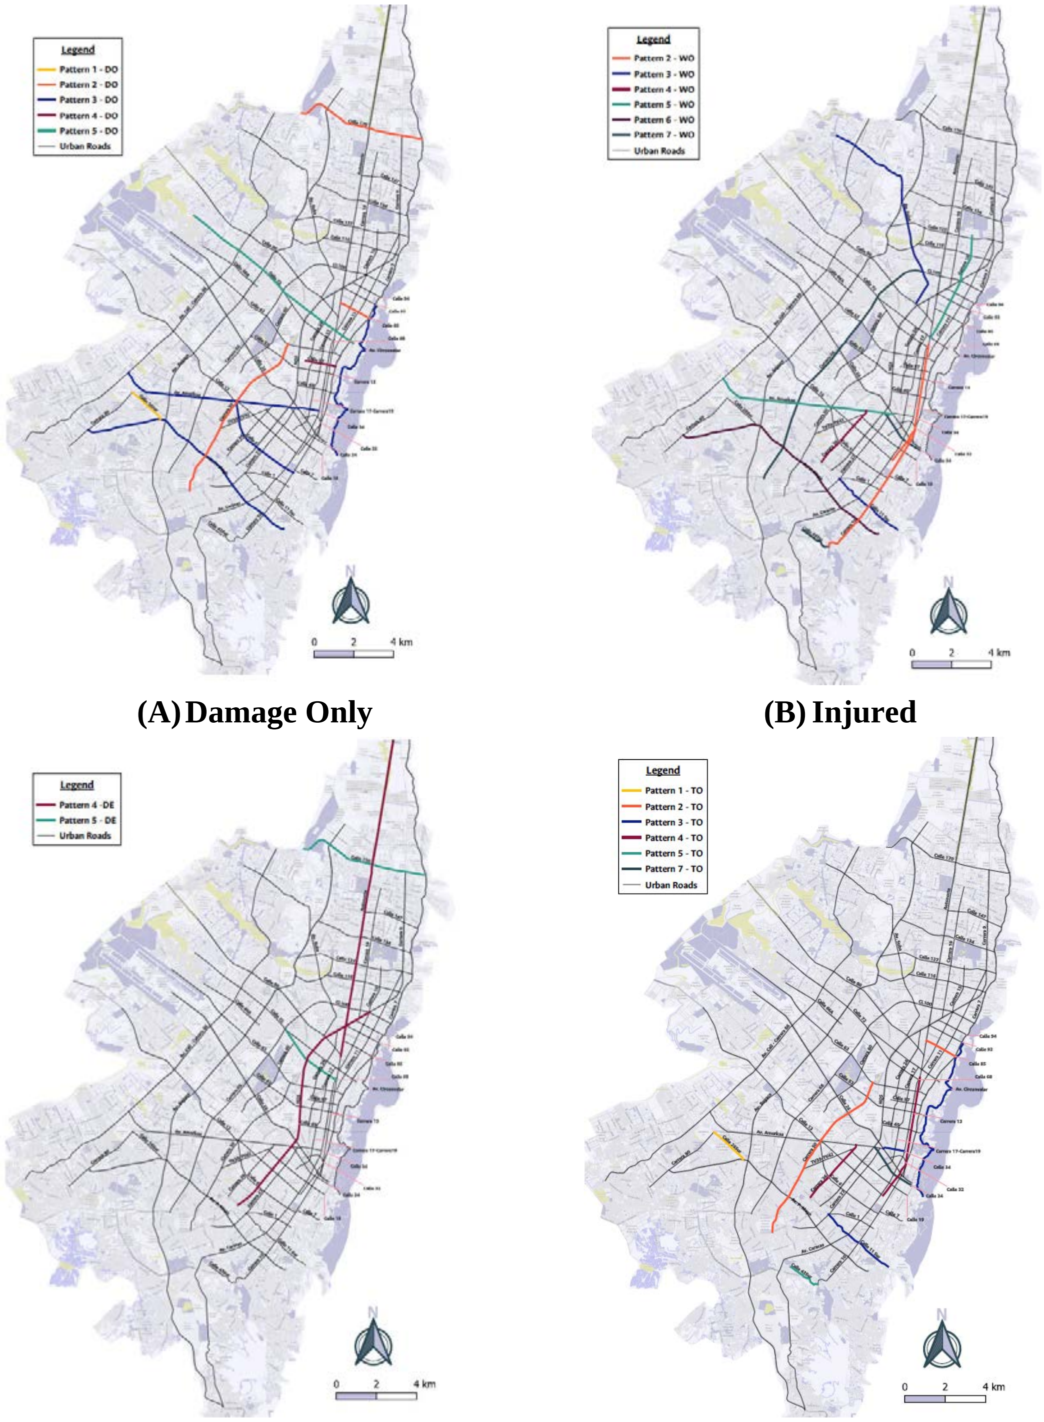
The third pattern, represented in blue in Figure 2 and includes seven arterial corridors, in different severities. These corridors show an increase in the crash rates after construction, and those rates are higher than the rates from before the construction.

A fourth pattern, represented in burgundy in Figure 2, includes the behavior of five arterial corridors. We observed an increase in crash rates, during and after the construction time.

The fifth pattern groups those corridors with smaller crash rates during and after construction. We found six corridors whit this pattern marked in green mint color in Figure 2.

A single arterial corridor presented the sixth pattern when we observe crash rates are significantly lower during construction, and greater crash rates before and after construction (Figure 2 dark purple color).

In the seventh and last pattern crash rates during the construction time decreased compared to before the intervention started, and after the construction zone was lifted these remained lower than before the constructions (Figure 2. dark grey).



(A) Damage Only **(B) Injured**

(C) Fatalities **(D) Total crashes**

Figure 3: Maps of crash rates behavioral patterns in arterial corridors for Bogotá.

Figure 3 shows the map with the arterial streets of the city of Bogota, where the different patterns of crash rates during construction and non-construction time are highlighted, according to the severity of the accident (Damaged Only(A), Injuries (B), and Fatalities (C)) and in all records(D). Pattern one was depicted with a yellow color, pattern two with an orange color, pattern three with blue, pattern four with burgundy, pattern five with mint green, and pattern seven with a dark blue tone.

4.1 By PMT type

Performing the Wilcoxon test by type of PMT, we find results and p-values that allow us to reject the null hypothesis of equality in the crash rates and suggest a statistically significant difference among the crash rates, at least in two out of three types of intervention.

For the typology of COI-ALTA (construction that does not require excavation) it is evident that, for the severity of OD, WO, and TO there was a decrease in the accident rates during the construction time, compared to before and after the work began, this behavior resembles pattern 6 identified for the corridors. This result might be associated with a lower speed that is common during construction. Besides, for the severity of DE, there is behavior pattern 3, being greater the accident rate once the construction is finished.

For interventions that required a PMT of type COOS-ALTA (construction that does require excavation), we found a lower crash rate during construction for damage-only crashes. Injuries and fatalities crash rates after the intervention are lower than during the active construction period. For all construction types considering all crash severities, a behavior pattern 2 was identified, in which the average of accidents is greater during the construction than in times of non-construction.

We choose to use a non-parametric hypothesis test method because we did not assume normality on crash rates, as the articles in the literature did (Jin, Saito, and Eggett, 2008). Assuming normality can bring a clear bias towards lower rates, due to most of the city traffic is channeled through a few sections of the arterial network, leaving a lot of corridors with zero accidents in the time windows defined.

Some of the corridors with high traffic volumes and therefore high crash rates are Avenida Ciudad de Cali, Avenida Boyacá, Carrera 68, Calle 80 and Avenida Las Américas. According to Bogotá´s Secretary of mobility, “these five corridors gather nearly 25% of traffic in Bogota´s arterial streets ”.

As to the statistical tests used, instead of using a paired t-test, two-way ANOVA, and Tukey test, our research team decided to use the Wilcoxon test as these were a better suit for the properties of the studied population (Zimmerman and Zumbo, 1993).

5. CONCLUSIONS

Our research focused on the descriptive analysis of crash data to explore long-term work zone characteristics such as crash severity, crash rate, type, and location using the non-parametric Wilcoxon test to explore differences in accident rates on arterial roads in the city of Bogotá between 2015 and 2019.

A total of 5.450 works were analyzed in 58 arterial road corridors of the city, where it was found that for the severity of damage only, 3 corridors within them the Calle 170 and the Calle 85, show an increase in accident rates during the construction time, which is presumed to be a direct result of the intervention on the road, also presenting this same phenomenon with the severity of injuries for the corridors of Carrera 10 and Carrera 13.

A completely different behavior was found for the Primero de Mayo Avenue, where for crash with injuries it was statistically demonstrated that the accident rates were lower during construction time, which can be associated with a correct design and application of the PMT. The corridors of Calle 24, Calle 43Sur, and Carrera 68 also showed a correct application of the PMT, managing to reduce accidents with injuries in construction time and once the intervention is lifted.

As well as the patterns described above, a total of seven different patterns were found in the behavior of accident rates during construction time in a city as peculiar as Bogota, where its road planning was guided in a disorderly way by an inordinate growth in a very short time.

This study represents the first approach to understand the response of the city in terms of mobility, before a high-impact road intervention, whose importance lies in the current projection of the city to develop mega works for the next five years, such as the metro. Future research could include the study of crash characteristics before, during, and after the work zone periods to highlight both the safety similarities and differences between work zone and non–work zone locations. Additionally, undertaking analysis to explore the correlation of road conditions as determinants in the behavior of accident rates, or exploring if the problem lies in the structure of the traffic management plan.

ACKNOWLEDGMENTS

The research group wishes to thank the engineering faculty of the Universidad Nacional de Colombia, more specifically to the Vice-Dean of Research and Extension, which through the call for Support to Research Seedbeds of the Faculty of Engineering 2019, financed the total development of this research. To the seedbed of research in Infrastructure and Mobility (SIMUN) to which belong the members of this research, to generate the space and time for the development of the activities needed for this research.

RESUMEN

El presente artículo analiza la influencia de los recursos económicos invertidos en la red viaria, tanto en construcción como en mantenimiento, sobre el número de fallecimientos producidos en la misma. Dada la multitud de factores de los que depende el tema de estudio, además de los recursos económicos invertidos, se incluye una serie de variables explicativas que tratan de reflejar características de la red viaria, aspectos socioeconómicos, meteorológicos y legislativos. Para ello, se ha construido un modelo de datos de panel para 22 países europeos y para el período comprendido entre 1998 y 2016, para la red viaria interurbana. Los resultados muestran un efecto beneficioso del gasto en mantenimiento de carreteras sobre la mortalidad. También se han hallado resultados significativos para la construcción de carreteras, la proporción de vías de gran capacidad, el PIB per cápita y el carnet por puntos.

1. INTRODUCCIÓN

Las infraestructuras viarias han jugado un papel importante en el desarrollo económico de los países, así como en la cohesión territorial de los mismos. No obstante, el transporte por carretera lleva asociada una tasa de mortalidad que es necesario erradicar cuanto antes. En Europa, a pesar de contar con el menor índice de muertes por 100.000 habitantes en el mundo (9.3 según la WHO (2018)), la Unión Europea se reafirma en su ambicioso objetivo para 2050 de reducir el número de muertes en carretera a cero. Esto supone un gran reto, ya que, por una parte, esta última década ha estado marcada por varias crisis económicas que han afectado seriamente a los recursos económicos destinados a las carreteras, especialmente en los países del sur. Mientras tanto, la reducción en el número de muertes en carretera ha llevado un ritmo más lento de lo planeado: tan solo un 20% desde 2010 hasta 2017, estando planteado un objetivo de reducción del 50% de víctimas para 2020 (European Commission, 2018). Por todo ello, resulta de vital interés analizar la influencia de cualquier variable que influya en este problema del transporte. Así pues, en el estudio que se presenta a continuación, se analiza la influencia que los recursos económicos invertidos en carreteras (además de otros factores relacionados con el tema de estudio) puede tener sobre la mortalidad. Los resultados obtenidos pueden ser útiles de cara a planificar un gasto más eficiente en el contexto europeo, y como base en la que guiarse para cumplir objetivos de seguridad vial.

2. ESTADO DE LA CUESTIÓN

Existen multitud de factores que influyen en los accidentes de circulación, y generalmente, éstos se suelen englobar en tres categorías: imputables al factor humano, relacionados con el vehículo y relacionados con la carretera. De cara al estudio de su influencia en la seguridad vial, una forma de considerar los condicionantes de la carretera de forma aproximada y general, es a través de los recursos económicos invertidos en la infraestructura viaria. Así pues, una mayor inversión en construcción, y un mayor gasto en mantenimiento ayudan a conseguir una mejor y más segura red de carreteras, lo que necesariamente ha de influir en la mortandad en las mismas. Consecuentemente, existen estudios que incluyen este tipo de variables económicas en sus modelos de seguridad vial, tanto a nivel nacional, como a nivel internacional.

En este sentido, Fridstrøm e Ingebrigtsen (1991) incorporaron en su estudio sobre siniestralidad vial en Noruega la inversión en construcción y el gasto en mantenimiento de carreteras, encontrando un efecto favorable entre el gasto en mantenimiento y la mejora de la seguridad vial. Respecto a la inversión en construcción, hallaron resultados contradictorios en función de la titularidad de la vía. También obtuvieron correlaciones significativas para una serie de variables independientes relativas a la exposición, condiciones meteorológicas, luminosidad, longitud de la red de carreteras, partes de accidentes, inspección de vehículos, medidas legislativas y consumo de alcohol.

En España, Aparicio et al. (2011) identificaron una serie de factores que tenían influencia en el número de accidentes mortales y con heridos en España. Sin embargo, no obtuvieron resultados concluyentes respecto al gasto en mantenimiento y conservación de carreteras, ya que aparecía relacionado con disminuciones en los accidentes con heridos y aumentos en los accidentes con fallecidos. Sí que observaron que el aumento de la proporción de carreteras de gran capacidad estaba relacionado con una reducción del número de accidentes. Por su parte, Albalate et al. (2013) analizaron la influencia sobre la seguridad vial de los recursos económicos invertidos en construcción y mantenimiento de carreteras en España junto con otras variables, entre ellas los cambios normativos que afectan a la circulación. Hallaron una relación inversa entre la inversión en mantenimiento de carreteras y los fallecimientos, presentando también una relación negativa variables como la tasa de motorización, el nivel de desempleo y la ratio de doctores, mientras el porcentaje de personas mayores de 65 años dio una relación positiva.

Nguyen-Hoang y Yeung (2014) estudiaron los efectos de las inversiones realizadas en construcción y mantenimiento de carreteras en 48 estados de Estados Unidos sobre la mortalidad. Junto con las variables de recursos económicos invertidos en carreteras, añadieron otra serie de variables independientes con el fin de controlar los efectos de las características de los conductores, la normativa gubernamental, la exposición y las condiciones económicas de cada estado.

Los resultados obtenidos mostraron una relación inversa entre las variables de inversiones viarias, tanto en construcción como en mantenimiento, y el número fallecimientos. También hallaron relaciones significativas para los vehículo-milla, el porcentaje de vehículos pesados, la longitud de la red de carreteras, la velocidad máxima en carreteras interestatales, la legislación sobre el cinturón de seguridad, la edad mínima para comprar cerveza, el índice de precipitaciones y temperatura, la renta per cápita, la tasa de desempleo y la densidad de población.

Sánchez González et al. (2018), realizaron un estudio sobre la influencia de las características provinciales españolas en los accidentes de tráfico en vías interurbanas mediante el análisis de diferentes variables económicas, técnicas, sociales y legislativas. Como variables dependientes, consideraron tres indicadores de siniestralidad, los cuales definen en función de la gravedad del herido (leve, serio y fallecido) y el nivel de exposición (millón de vehículos-Km). Hallaron como significativas las relaciones de las inversiones realizadas tanto en construcción como en reposición de carreteras respecto a los tres indicadores. Sin embargo, dichas variables mostraban distinto comportamiento: negativo para la reposición y positivo para la construcción. También obtuvieron relaciones significativas para la implantación del sistema de penalización por puntos, el volumen de tráfico, la tasa de motorización, la variación anual de densidad de población, la tasa de desempleo y la proporción de carreteras de gran capacidad. Posteriormente, los autores realizaron un estudio similar y con los mismos indicadores de siniestralidad (Sánchez González et al., 2020), pero esta vez, utilizaron dos modelos para cada indicador: uno para provincias con renta per cápita alta y otro para los que tienen baja. También añaden como variables independientes una tasa del número de turistas, el porcentaje de vehículos con antigüedad superior a diez años, la proporción de población entre 20 y 29, la proporción de población mayor de 75 y la proporción de población con nivel educativo alto. Respecto a los resultados obtenidos para las variables de inversión de recursos económicos, se muestran relaciones significativas con diferentes efectos en función del indicador y de la renta per cápita de la provincia. Para la tasa de fallecidos, la inversión en construcción de carreteras muestra una relación inversa durante el año de ejecución del gasto y directa para el año siguiente. Para la tasa de heridos graves no se obtienen resultados significativos del gasto en reposición, pero sí se obtienen de la inversión en construcción, con una relación inversa. Por último, para la tasa de heridos leves, obtienen resultados significativos para el gasto en reposición durante el año de ejecución y los dos siguientes, con una relación inversa para las provincias de renta per cápita baja, sin embargo, para las provincias de renta alta, solo se obtiene como significativo el gasto durante el año siguiente, con relación directa.

En otro estudio en Chile, Sánchez-González et al. (2021) analizaron la influencia de las condiciones regionales sobre los accidentes de tráfico. Como variables dependientes utilizaron ocho indicadores de severidad, definidos según el número de víctimas, y dos medidas indirectas del nivel de exposición: el número de vehículos registrados y la población.

Como variables independientes incluyen recursos económicos invertidos en construcción y en reposición, reformas legislativas, tasa de motorización, densidad de población, tasa de desempleo, precipitaciones, proporción de carreteras sin pavimentar y proporción de vías de gran capacidad. Respecto a los resultados obtenidos para las variables de recursos económicos, el gasto en reposición resulta significativo en cuatro de los indicadores, mostrando relaciones inversas en todos ellos. Aunque en el caso de heridos graves por vehículo, refleja también una relación contradictoria: directa durante el año de ejecución del gasto e inversa para el retardo de dos años. Por otro lado, la inversión en construcción muestra una relación directa y significativa en tres de los ocho indicadores considerados.

A nivel internacional, numerosos estudios han tratado de identificar, utilizando datos agregados por países, los diversos factores que afectan a la seguridad vial. Así pues, Kopits y Cropper (2005) analizaron los efectos de la renta per cápita para un total de 32 países con un periodo de estudio comprendido entre 1963 y 2002, incluyendo también variables demográficas, sociales, de motorización y de longitud de la infraestructura. Los resultados no mostraron una influencia significativa de la renta per cápita. Sin embargo, el abuso de alcohol, la mejora de los servicios médicos y una menor cantidad de conductores jóvenes sí mostraron tener efecto en las tasas de mortalidad. Bishai et al. (2006), por su parte, analizaron la relación entre el desarrollo económico y la siniestralidad, utilizando datos de 41 países durante el periodo 1992-1996.

Estos autores hallaron una relación diferente según la renta per cápita del país: en países de baja renta per cápita un incremento de la misma induciría un incremento de la siniestralidad, mientras que en países con mayor renta per cápita se produciría el efecto contrario. También obtuvieron que un mayor consumo de petróleo y de alcohol estaban relacionados con mayores tasas de mortalidad en países ricos. Calvo-Poyo et al. (2020), realizaron un estudio acerca de la influencia de las inversiones en construcción y del gasto en mantenimiento sobre la mortalidad, con datos de 23 países europeos y para el período comprendido entre 1998 y

2016. Además, incluyeron una serie de variables de control de factores específicos del transporte, socioeconómicos y meteorológicos.

Los resultados obtenidos mostraron una relación directa para la inversión en construcción e inversa para el gasto en mantenimiento, siendo representativas ambas variables en el año posterior al de ejecución de los recursos económicos. También obtuvieron resultados significativos para la proporción de vías de gran capacidad, la tasa de motorización, el PIB, la proporción de personas mayores de 65 años y la precipitación media anual. Elvik (2021), utilizó una serie de indicadores democráticos y de gobernabilidad junto a otras variables explicativas (consumo de alcohol y tasa de motorización), para comprobar la relación de dichos índices con las tasas de mortalidad de 148 países. Aunque no justifica una relación causal, encuentra una relación estadísticamente significativa del nivel de democracia de un país, el índice de eficiencia de gobierno, la tasa de motorización, el consumo de alcohol per cápita respecto a la siniestralidad vial.

Por tanto, teniendo en cuenta lo anteriormente expuesto, no se han encontrado estudios a nivel internacional, que analicen, con datos de distintos países, la influencia que pueden tener los recursos económicos invertidos en carreteras sobre la mortalidad y que controlen posibles cambios legislativos. Por ello, con el presente estudio, se pretende aportar a la literatura un análisis que incluya este tipo de variables para el contexto europeo.

3. METODOLOGÍA

Para modelos de siniestralidad vial, Hakkert y Braimaister (2002) recomiendan utilizar una ratio en función del nivel de exposición como variable dependiente, por lo tanto, en el presente estudio se utiliza una tasa de mortalidad, definida como el número de fallecidos por cada mil millones de pasajeros-km. Por otro lado, se utilizan una serie de variables para controlar los efectos de los recursos económicos invertidos en carreteras, de las características de la red viaria, de las condiciones socioeconómicas, de la meteorología y legislativos.

Como principales variables independientes que controlen los efectos de las inversiones en carreteras sobre la mortalidad, se incluyen tanto las inversiones en construcción de carreteras por kilómetro de red, como el gasto en mantenimiento por kilómetro, ambas para el año en curso y para un retardo de un año. Como variables independientes que controlen los factores mencionados anteriormente se incluyen la proporción de vías de gran capacidad, la variación anual de la tasa de motorización (se ha diferenciado la serie para eliminar los efectos de la tendencia creciente en la serie), el PIB per cápita, el consumo de alcohol, la precipitación media y la existencia de un sistema de carnet por puntos.

La codificación de las variables, así como sus unidades de medida y los principales estadísticos descriptivos se encuentran en la Tabla 1. Todas las variables económicas han sido convertidas a valores constantes de 2015.

Código	Unidad	Media	dt	Min.	Mediana	Máx.
Fatal_pkm	Fallecidos/ mil millones de pkm	7.60	5.9	1.46795	5.43325	35.3
Road_inv	Miles de €/km	21.82	35.8	.03284	12.97648	279.8903
Road_maint	Miles de €/km	8.36	10.9	.246996	5.25882	83.75754

DPS	*(Dummy)*	0.59	0.5	0	1	1

Tabla 1. Codificación y descripción de las variables

Se han recopilado datos desde 1998 hasta 2016 de los siguientes países: Alemania, Austria, Bélgica, Dinamarca, Eslovaquia, Eslovenia, España, Estonia, Finlandia, Francia, Irlanda, Italia, Letonia, Lituania, Luxemburgo, Noruega, Países Bajos, Polonia, Portugal, Reino Unido, República Checa y Suecia. Dada la naturaleza de estos datos, con 22 países distintos y durante 19 años, se opta por formular un modelo de panel cuyo objetivo es explicar los fallecimientos ocurridos en carreteras a lo largo del tiempo y países seleccionados. De los países considerados, tan solo dos no forman parte de la UE: Noruega y Reino Unido. Se ha intentado incluir al resto de países de la UE (Bulgaria, Croacia, Chipre, Grecia, Hungría, Malta y Rumanía), pero no se han podido obtener datos suficientemente desagregados, bien del número de fallecidos en carreteras interurbanas o bien de los recursos económicos invertidos en carreteras.

Los modelos de datos de panel son ampliamente utilizados en la literatura sobre seguridad vial a nivel macro, sin embargo, cuentan con una serie de fenómenos propios que deben ser analizados con el fin de obtener estimadores robustos. Para ello, se han realizado una serie de test. El test de Levene (Levene, 1960) se utiliza para comprobar la homocedasticidad a lo largo del corte transversal, mostrando los siguientes resultados: W0 = 25.300 (p-valor = 0.000), W50 = 14.644 (p-valor = 0.000) y W10 = 24.438 (p-valor = 0.000). Por tanto, se rechaza la hipótesis nula de homocedasticidad. Para comprobar la correlación serial, se usa el test de Wooldridge (Wooldridge, 2007) en el que la hipótesis nula supone la no existencia de autocorrelación de primer orden. Los resultados del test, F = 173.54 (p-valor = 0.000), descartan la validez de dicha hipótesis nula. Y, por último, para comprobar la independencia de corte transversal, se utiliza el test de Pesaran (Pesaran, 2020), suponiendo dicha independencia en la hipótesis nula. El resultado del test, 31.575 (p-valor = 0.000), junto con el valor absoluto medio de la correlación de los residuos, 0.568, hacen rechazar la hipótesis nula. Como consecuencia de los resultados obtenidos en los test, se considera la existencia en el panel de heterocedasticidad grupal, de autocorrelación de primer orden, y de correlación contemporánea.

Por tanto, para solventar estos problemas y obtener una mejor inferencia del modelo lineal estimado a partir de datos de series temporales, se utiliza el método de errores estándar corregidos para panel (PCSE) propuesto por Beck y Katz (1995), con un autocorrelación de primer orden específica para cada país. Así, el modelo empleado de panel de datos adopta la siguiente forma:

$$y_{it} = \beta_0 + \beta_1 X_{1it} + \beta_2 X_{2it} + \cdots + \beta_k X_{kit} + \mu_{it} \quad (1)$$

en el cual, y_{it} representa la variable dependiente, con subíndices *i* para cada país y *t* por cada año. X_{Kit} son las variables independientes, β_K son los coeficientes estimables y μ_{it} el término de error:

$$\mu_{it} = \rho_i \mu_{it-1} + e_{it} \quad (2)$$

siendo ρ_i el parámetro de autocorrelación específico para cada país y e_{it} se corresponde con los errores independientes e idénticamente distribuidos. El software utilizado para estimar el modelo es STATA versión 12.1, el cual aplica una regresión de Prais-Winsten para estimar los parámetros.

De esta forma, el modelo queda de la siguiente manera:

$$atal\_pkm = \beta_0 + \beta_1\, Road\_inv + \beta_2\, Road\_inv_{lag1} + \beta_3\, Road\_maint + \beta_4\, Road\_maint_{lag1} + \beta_5\, Prop\_motorwa + \beta_6\, Mot\_index + \beta_7\, GDP\_Cap + \beta_8\, Acohol + \beta_9\, Precipit + \beta_{10}\, DPS + \mu it \quad (3)$$

4. RESULTADOS

4.1 Modelo

Los resultados obtenidos de la regresión se muestran en la Tabla 2.

Tabla 2. Resultados

4.2. Discusión de resultados

4.2.1 Inversión en construcción de carreteras (*Road_inv*)

En primer lugar, la variable de inversión en construcción de carreteras ha obtenido resultados significativos solo en el caso con un año de retardo. Los resultados muestran una relación de signo positivo para la variable de construcción, en consonancia con otros estudios (Fridstrøm e Ingebrigtsen, 1991; Sánchez González et al., 2018), y sugieren un aumento en la tasa de fallecidos de 0.0231607 por cada mil euros por kilómetro invertidos durante el año anterior al considerado. Este retardo en la influencia puede deberse al tiempo necesario para la ejecución de la obra y puesta en servicio de la misma, a partir de la cual empezarán a notarse los efectos.

Por otro lado, Albalate et al. (2013) señalaron la posibilidad de que el efecto de la inversión en construcción esté sobreestimado en los modelos en los que no se incluyen variables de control de cambios legislativos, y que al incluir éstas, la inversión en construcción pueda perder nivel de significancia. Sin embargo, en el presente estudio se ha incluido la introducción del sistema de carnet por puntos, sin que ello haya afectado al nivel de significancia de la variable.

4.2.2. Gasto en mantenimiento (*Road_maint*)

Los resultados muestran una relación de signo negativo para la variable de gasto en mantenimiento. Al igual que para la variable de inversión en construcción, solo se obtienen resultados significativos para el gasto en mantenimiento con un retardo de un año. Al igual que en la inversión en construcción, resulta lógico pensar que una parte de la ejecución del gasto en mantenimiento puede llevarse a cabo en el último periodo del año, con lo que sus efectos no son esperables inmediatamente, sino durante el año siguiente.

Según los resultados, por cada mil euros por kilómetro en gasto en mantenimiento se espera una reducción de -0.0383305 en la tasa de mortalidad. Este efecto beneficioso para la reducción de la siniestralidad vial también se encuentra reflejado en la literatura en estudios realizados en EE.UU (Nguyen-Hoang y Yeung, 2014), España (Albalate et al., 2013; Sánchez González et al., 2018) y Noruega (Fridstrøm e Ingebrigtsen, 1991).

4.2.3. Proporción de vías de gran capacidad (*Prop_motorwa*)

La proporción de vías de gran capacidad, como variable de control de las características generales de la red viaria, ha resultado significativa con signo negativo, es decir, que el aumento de la proporción de vías de gran capacidad contribuye a la disminución de la mortalidad en la carretera. Esta relación se halla en consonancia con resultados de estudios previos (Albalate et al., 2013; Sánchez González et al., 2018), y pone de manifiesto los beneficios que para la seguridad vial que conlleva la extensión de este tipo de red. En este sentido, Albalate y Bel (2012) señalaban que este tipo de vías son las únicas que pueden relacionarse con reducciones en la tasa de mortalidad.

4.2.4. Variación anual de la tasa de motorización (*Mot_index*)

Respecto a la primera de las variables socioeconómicas, la tasa de motorización se ha considerado como variación anual, con el objetivo de eliminar los efectos de tendencia creciente que presenta y transformar la serie en estacionaria (lo cual es conveniente para aplicar la metodología de PCSE). De todos modos, no se han obtenido resultados significativos para esta variable.

4.2.5. PIB per cápita (*GDP_cap*)

Siguiendo con las variables socioeconómicas, se obtiene un resultado significativo para el PIB per cápita y con relación inversa respecto a la tasa de mortalidad. Esta relación puede ser consecuencia de los mejores servicios sanitarios y de atención post accidente (Bishai et al., 2006), y de la mejor red de carreteras y mejor parque de vehículos inherentes al mayor nivel de riqueza de un país.

4.2.6. Consumo de alcohol (*Alcohol*)

El consumo de alcohol per cápita muestra una relación negativa con la tasa de mortalidad, similar a lo reflejado en estudios previos (Elvik, 2021), sin embargo no resulta significativa. Esta falta de significancia estadística suficiente puede deberse a que, el hecho de aumentar el consumo de alcohol anual en un país, no tiene por qué representar la predisposición de los usuarios de la vía a conducir bajo los efectos del alcohol. Hay otros factores adicionales (culturales, punitivos, …) que influyen en esta decisión por parte de los conductores.

4.2.7. Precipitación media (*Precipit*)

Como control de factores meteorológicos, la precipitación media anual ha resultado significativa y con signo negativo. Estos resultados se hayan en sintonía con estudios previos (Aparicio Izquierdo et al., 2013), y ponen de manifiesto la posibilidad de que se produzca un aumento de la precaución por parte de los conductores ante esta situación meteorológica adversa, reduciendo generalmente la velocidad y, como consecuencia de ello, la severidad de un posible accidente.

4.2.8. Carnet por puntos (*DPS*)

Por último, la variable que controla un cambio legislativo como es la introducción de un sistema de carnet por puntos ha resultado significativa y de signo negativo. Diversos autores han resaltado la influencia de este sistema en la reducción de la siniestralidad en estudios realizados en España (Albalate et al., 2013; Izquierdo et al., 2011; Sánchez González et al., 2018), el presente estudio constata dichos resultados, pero a nivel europeo.

5. CONCLUSIONES

El estudio ha puesto de manifiesto que el gasto en mantenimiento de carreteras tiene un efecto reductor de la mortalidad en las carreteras a nivel europeo, produciéndose este efecto principalmente en el año posterior al de ejecución del gasto. Como aportación a la literatura, destaca la obtención de resultados que reflejan este efecto beneficioso para 22 países europeos. Se corrobora así, a nivel internacional, la relación inversa entre gasto en mantenimiento y mortalidad que estudios previos habían hallado con datos de un solo país (Albalate et al., 2013; Fridstrøm e Ingebrigtsen, 1991; Nguyen-Hoang y Yeung, 2014; Sánchez González et al., 2018).

Además, otras variables han resultado significativas en el estudio realizado. Así pues, la inversión en construcción de carreteras ha mostrado una relación directa con la tasa de mortalidad, mientras que la proporción de vías de gran capacidad, el PIB per cápita y el carnet por puntos han mostrado una relación inversa con el número de fallecidos en carretera. Este artículo complementa el estudio publicado por Calvo-Poyo et al. (2020) al añadir las variables de consumo de alcohol per cápita (que no resulta significativa) y la de carnet por puntos.

AGRADECIMIENTOS

Este estudio ha sido realizado en el marco del proyecto “Inversión en carreteras y seguridad vial: un análisis internacional (INCASE)”, financiado por: FEDER/Ministerio de Ciencia, Innovación y Universidades–Agencia Estatal de Investigación/ Proyecto RTI2018-101770-B-I00, dentro del Programa Estatal de I+D+i Orientado a los Retos de la Sociedad.

Las variables incluidas en el estudio han sido obtenidas de las siguientes fuentes oficiales: Eurostat, OECD/ITF, EU DG Mobility and Transport, UNECE, IRTAD, World Bank, Copernicus Climate Change Service, institutos nacionales de estadística y ministerios de transportes.

RESUMEN

Cada vehículo automatizado y conectado posee su propio Dominio de Diseño Operativo (ODD) debido a las particularidades de su sistema automatizado – sensores, algoritmos de percepción y decisión, y actuadores –. Para garantizar que este tipo de vehículos opere de forma segura es fundamental el diseño de Maniobras de Riesgo Mínimo (MRM) que permitan al sistema, cuando finalice un ODD, lograr una Condición de Riesgo Mínimo (MRC).

Hasta ahora, se han planteado, pero no concretado, distintas alternativas relacionadas con la configuración y el diseño de carreteras para facilitar a los sistemas automatizados alcanzar un MRC. Concretamente, este trabajo propone, para distintas tipologías de carretera – autopistas, autovías y carreteras 2+1 –, diferentes soluciones de apartaderos de emergencia y zonas de detención segura, analizando sus fortalezas y debilidades. La alternativa más segura y con mayor capacidad para una MRC será una zona de detención segura, localizada fuera de los ámbitos de las calzadas principales, aprovechando las conexiones, los ramales o las zonas intermedias de enlaces. Esta nueva necesidad ligada a los vehículos automatizados y conectados requiere indudablemente replantearse el diseño y configuración de la red de carreteras, especialmente de los nudos viarios, con el fin de fomentar una movilidad inteligente y segura.

1. INTRODUCCIÓN

Para un mismo tramo de carretera, cada vehículo automatizado puede tener sus propios Dominios de Diseño Operativo (Operational Design Domains, ODDs) que se manifestarán en diversas secciones inconexas de esa carretera que le permiten operar de forma automatizada. Son inconexas porque no tienen continuidad, es decir, se pueden producir desconexiones o cesiones al conductor, que se pueden deber a factores limitantes distintos, para luego volver a recobrar el control.

Ante la problemática de las finalizaciones de los ODDs por sus desconexiones, debidas a algunos de los factores limitantes, se hace muy necesario que el sistema automatizado aplique dos principios fundamentales: la monitorización continua de los factores subyacentes del ODD del vehículo y la capacidad de autoadaptación.

Si se detecta una alteración que comporta un ODD potencialmente restringido, algunos sistemas pueden ser capaces de adaptar dinámicamente su comportamiento para permanecer dentro de este dominio. En cualquier caso, si no le fuera posible, se espera que los niveles 4 y en muchas ocasiones también los de nivel 3 funcionen de manera segura incluso en el caso de fallos del propio sistema o con condiciones externas peligrosas, como una adversidad meteorológica importante.

Un sistema automatizado de nivel 4 debe poder lograr una condición de riesgo mínimo – como apartarse y detenerse en el arcén – si detecta algún problema con su propio funcionamiento o por condiciones externas que impidan una operación segura. Se trata, por tanto, de una detención segura, no una detención de emergencia.

La terminación de la tarea de conducción automatizada, por un fallo repentino del sistema automatizado, un cambio súbito de un factor ambiental o de entorno, o la finalización del ODD, supone el necesario desarrollo de una tarea dinámica de conducción (Dynamic Driving Task, DDT) para la retirada del vehículo a una Condición de Riesgo Mínimo (Minimal Risk Condition, MRC), donde se pueda producir su detención segura o que conlleve un riesgo mínimo. Luego se trata de localizaciones viarias.

El concepto es sencillo, pero el problema radica en de qué forma práctica y segura se pueden establecer y habilitar esas condiciones de riesgo mínimo sobre la infraestructura viaria. El sistema automatizado, en función de las condiciones que han ocasionado la necesidad de buscarlas, así como del estado del vehículo, carretera y entorno, decidirá de entre una serie de opciones posibles, cuál es la que conlleva el mínimo riesgo. Por ejemplo, detener el vehículo automatizado en el mismo carril por donde estaba circulando (activando de forma automática las luces de emergencia, como hacen los vehículos automatizados actuales de nivel 2) es una opción que presenta un riesgo importante y por ello únicamente debería ser activada bajo circunstancias extremas. Preferentemente, y si el vehículo lo permite, el sistema debería ser capaz de llevar el coche a zonas de aparcamiento seguro que se habiliten cada cierta distancia, fuera del ámbito de los arcenes.

Para llevar el vehículo automatizado a un estado o situación segura, las MRC se convierten en la base para definir las maniobras de riesgo mínimo (Minimal Risk Maneuvers, MRM). Luego, el sistema automatizado ha de ser capaz, en primer lugar, de analizar y decidir la mejor opción para alcanzar una MRC, entre todas las posibles en cada lugar y momento, en función de la causa, de las características de la sección de carretera y de las condiciones operacionales y ambientales.

Una vez adoptada la decisión de qué MRC se va a alcanzar, se han de analizar las distintas maniobras de riesgo mínimo (MRM) para optar por las más seguras.

Por tanto, se trata de un balance global para minimizar los riesgos, tanto de las maniobras evasivas (MRM), como de la situación o condición final (MRC).

2. ALTERNATIVAS VIARIAS PARA ACOGER CONDICIONES DE RIESGO MÍNIMO

Ante tanta incertidumbre relacionada con la nueva movilidad conectada y automatizada, tanto tecnológica como técnica y regulatoria, se sigue avanzando en los estudios y desarrollos, así como en las discusiones entre los diversos agentes o partes interesadas. Uno de los ámbitos principales de avance necesario es el de las interrupciones o finalizaciones de los ODDs, con las consiguientes maniobras de riesgo mínimo (MRM) para llevar al vehículo a una condición de riesgo mínimo (MRC).

De hecho, para aumentar la seguridad en estas maniobras de los sistemas automatizados, se están incorporando elementos y procesamientos redundantes relacionados con la tarea de conducción (como los relacionados con la frenada, el giro del volante, la detección de obstáculos, etc.).

Otro de los elementos en discusión está muy relacionado con la configuración y diseño de las carreteras. Se trata de las zonas donde poder acoger con seguridad los vehículos automatizados que necesiten alcanzar una MRC. Hasta ahora, se han planteado diversas alternativas, de menor a mayor seguridad: el uso del arcén exterior, la disposición de apartaderos de emergencia y el desarrollo de nuevas zonas de detención segura fuera de la plataforma viaria (Transport Systems Catapult, 2017; SAE, 2018; Liu et al., 2019). Estas medidas van, además, de mayor a menor proximidad respecto a la localización del vehículo en el momento de la activación de la causa.

En esta nueva necesidad viaria, lo primero que habría que tener en cuenta es la estimación de la posible demanda de alojamiento para las maniobras de riesgo mínimo (generadas por los vehículos con un alto nivel de automatización, de niveles 4 y 5 y ocasionalmente el 3), así como las necesidades para maniobras de mitigación de riesgo (algunos niveles 2 y 3, así como niveles superiores en condiciones excepcionales).

Estimar la demanda real de estas maniobras resulta especialmente complicado en la actualidad, pues los ODDs no están enunciados de forma explícita y por lo tanto no es posible determinar cuántos vehículos podrían verse afectados por una variación de un factor del entorno (como una inclemencia meteorológica, que podría provocar que muchos sistemas automatizados se salieran de sus ODDs).

Además, siempre habría cierta demanda ante fallos de funcionamiento del propio sistema automatizado, aparte de los fallos mecánicos que ya existen en los vehículos.

Por tanto, habría que hacer una provisión importante de plazas o posiciones de detención segura y uniformemente repartidas, para que los vehículos automatizados puedan alcanzar con facilidad una MRC para retirarse con un riesgo mínimo, en caso de no recibir respuesta por parte del conductor.

Para que el arcén pudiera servir para esta función, tendría que disponer de una anchura mínima de 2,5 m, aunque siempre sería una opción peligrosa, por la proximidad a la circulación en el carril adyacente. De hecho, el Protocolo de Auxilio en Carretera (DGT, 2015) califica de alto riesgo el que un vehículo averiado haya quedado inmovilizado en un arcén. Sin embargo, el arcén presenta la ventaja de su disponibilidad continua a lo largo de la carretera.

Según la Ley de Carreteras (2015), se define el arcén como la “franja longitudinal pavimentada, contigua a la calzada, no destinada al uso de vehículos más que en circunstancias excepcionales”. Por tanto, con la función establecida en la regulación actual, el arcén podría emplearse como MRC. Pero, ante una inclemencia ambiental intensa, los arcenes podrían ser ocupados de forma densa por lo que los vehículos automatizados detenidos podrían bloquear el paso necesario de vehículos de emergencia.

Todo ello hace necesario que se habiliten otras soluciones viarias que supongan unas localizaciones más seguras para los vehículos automatizados, sin ocupar ni bloquear los arcenes.

3. APARTADEROS DE EMERGENCIA

Los apartaderos de emergencia ya existen en algunas autovías y autopistas, donde el arcén no tiene una anchura suficiente (Figura 1). Se trata de un ensanche de la plataforma de la carretera destinado a permitir la detención o el estacionamiento temporal de los vehículos (Ministerio de Fomento, 2016).

Figura 1: Apartadero de emergencia.

Según la tipología de carretera, se podrían plantear diferentes tipologías de apartaderos:

- Autopistas y autovías:
    - Apartadero exterior para varios vehículos.
    - Apartadero exterior para un coche como ampliación del arcén.
    - Apartadero interior en la mediana para varios vehículos.
- Carretera 2+1:
    - Apartadero exterior para varios vehículos.
    - Apartadero exterior para un coche como ampliación del arcén.
    - Apartadero interior en las zonas de transición no críticas para varios vehículos.

3.1 Apartadero exterior para vehículos

Estos apartaderos exteriores existentes están diseñados para hacer posible la detención de vehículos averiados, como se menciona en la Instrucción 3.1-IC (2016). Antes de esta nueva versión de la Instrucción, se construyeron con dimensiones más reducidas.

La Instrucción de Trazado establece que el ancho total de estos apartaderos será al menos de 4,5 m, con la siguiente distribución: 3,5 m para el apartadero, propiamente dicho, y al menos 1,0 m de cebreado de separación de la calzada (Figura 2). Además, la longitud de los apartaderos y de la zona cebreada será de 30 m, con cuñas de transición al inicio y final, de longitud mínima 30 m, cada una.

Figura 2: Definición geométrica de un apartadero de emergencia según la Instrucción 3.1-IC (2016).

Además, se establece que el número de apartaderos necesarios y su ubicación será objeto de un estudio. Por tanto, refleja lo que esta nueva función va a requerir: un estudio detallado de la demanda, tanto del número de vehículos a acoger, como su distribución espacial y temporal. Para ello, habrá que esperar la evolución de los desarrollos de los sistemas automatizados de conducción para poder contar con las bases técnicas suficientes para poder hacer esos estudios.

En Inglaterra (Highways England, 2020), la regulación de las áreas de emergencia para autopistas inteligentes (con regulación variable de velocidad) es similar, pero con forma de trapecio escaleno, donde la cuña de entrada ha de tener 25 m de longitud y la de salida 45 m, mientras que la zona de parada ha de ser de 30 m. La anchura está establecida en 4,6 m. También se regula el espaciamiento máximo entre las áreas de emergencia, debiendo ser no mayor de 1,6 km y de forma recomendable cada 1,2 km. Todo ello es de aplicación cuando no exista un arcén exterior de 3 m de anchura mínima o cuando existiendo pueda ser abierto a la circulación en horas punta (Figura 3).

Figura 3: Área de emergencia en Inglaterra.

Uno de los parámetros que seguro habrá que ajustar, según las demandas estimadas, será la longitud de los apartaderos, no teniendo sentido que sean de esa longitud fija de 30 m. Tampoco está claro que tengan que reincorporarse por la cuña final, ya que el orden de regreso a la circulación no tiene por qué coincidir con el de entrada en el apartadero. Esta sería una de las limitaciones de esta alternativa, ya que no habría espacio para acelerar y entrar a una cierta velocidad, aumentando el riesgo de esas maniobras.

Esta necesidad de entradas y salidas a los apartaderos, sin un orden de posicionamiento, haría que las marcas viales de separación hubiera que replantearlas para que se permitiera su cruzamiento. Por ejemplo, se podrían disponer de forma paralela pero discontinuas, con una relación trazo/vano a estudiar.

Además, se podrían aprovechar las secciones en desmonte que cuentan con cunetas de seguridad amplias y suaves para adaptarlas como apartaderos para este fin, con la única necesidad de pavimentar las bermas para darle continuidad al pavimento, pero sin tener que regularizar la geometría de la zona de cuneta. En la fotografía de la Figura 4 se puede observar el resultado al haber pavimentado la berma y así garantizar la continuidad transversal de la superficie de rodadura para vehículos ligeros. Esta disposición tiene la ventaja adicional de su gran capacidad al ser tramos normalmente largos.

Figura 4: Apartadero exterior sobre cuneta de seguridad.

También se podría aprovechar para ubicar un apartadero exterior el sobreancho de estructuras de pasos inferiores que se construyeron previendo una futura ampliación de calzada, como se puede observar en la Figura 5.

Figura 5: Apartadero exterior sobre sobreancho de estructura de paso inferior. Fuente: Google.

Todas estas diversas tipologías de apartadero se podrían aplicar a cualquier otro tipo de carretera.

3.2 Apartadero exterior para un coche como ampliación del arcén

En algunos tramos de autopistas y autovías existen pequeños apartaderos para estacionar vehículos de conservación y explotación, así como de vigilancia y control (Figura 6).

Figura 6: Apartadero exterior reducido.

Suelen tener forma trapecial, con unas dimensiones reducidas: unos 20 m de longitud total y 2,5 m de anchura, incluyendo sendas cuñas de transición de 5 m cada una y dejando 10 m para la zona de parada. Hasta ahora se han desarrollado en secciones con disponibilidad y facilidad de espacio en el margen para reducir su coste.

La ventaja de este tipo de apartadero, para la nueva necesidad que va a surgir, radica en el bajo coste y su facilidad de ejecución, para poder ofrecer localizaciones de detención segura numerosas y muy uniformemente distribuidas, que compensen su capacidad unitaria con una mayor accesibilidad. No precisan de mayores dimensiones si se distribuyen con cierta regularidad y sus cuñas de transición no han de ser más largas porque se trata de que un vehículo automatizado que precise apartarse a una MRC pueda inicialmente reducir su velocidad, incorporarse y circular por el arcén a una velocidad de unos 30 km/h, hasta alcanzar el siguiente apartadero libre, entrando en él para su detención segura, dejando totalmente libre el arcén.

Estos apartaderos más reducidos pero frecuentes, se podrían desarrollar en cualquier otro tipo de carretera, siendo más fáciles de integrar que los anteriores en carreteras de calzada única.

3.3 Apartadero interior en la mediana para varios vehículos

Teniendo en cuenta que puede haber autopistas donde se asigne en exclusiva para los vehículos automatizados el carril izquierdo, no sería descartable la necesidad de disponer los apartaderos directamente en la mediana. Esta opción podría ser la preferida por vehículos que circulasen por el carril izquierdo. De este modo, aparcando en la mediana se ahorra cruzar los otros carriles para alcanzar el arcén o un apartadero exterior.

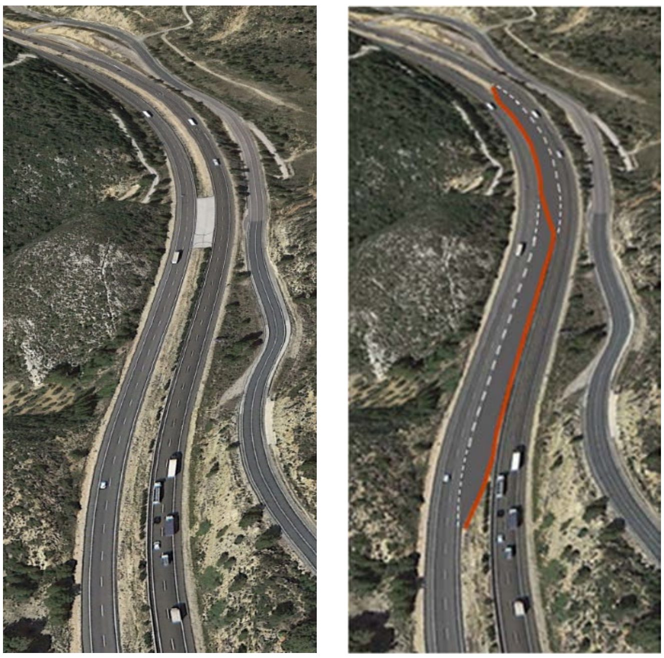

Figura 7: Apartadero interior en la mediana. Fuente: Adaptada de Google.

En este sentido, se podrían aprovechar los pasos de mediana, extendiéndolos como apartaderos para cada uno de los sentidos, siempre y cuando la mediana tenga anchura suficiente para poder acoger los apartaderos. En la Figura 7 se puede observar una posible solución para estos apartaderos de mediana.

Adicionalmente, se podrían utilizar estos apartaderos como pasos de mediana decalados para los dos sentidos, con la ventaja adicional de contar con sendos carriles de deceleración. Para ello, habría que añadir las cuñas finales triangulares pavimentadas que faciliten la incorporación final a la otra calzada. Para su apertura, habría que retirar o mover el sistema de contención de la parte final del apartadero.

3.4 Apartadero interior en las zonas de transición no críticas de carreteras 2+1 para varios vehículos

En las carreteras 2+1 surgen las zonas de transiciones no críticas acopladas para la apertura de los carriles de adelantamiento para cada uno de los sentidos (MITMA, 2021). Según las nuevas Recomendaciones para su diseño, "la longitud de cada carril adicional de adelantamiento debe ser tal que diluya la cola estimada en la hora de proyecto con una longitud en un rango estimado de entre 800 m y 2000 m, sin perjuicio de estudios más detallados al respecto". Luego, como es habitual, se diseñan para las mayores demandas de tráfico estimadas, por lo que habrá una mayoría de horas al año donde no sea necesaria tanta longitud de carril de adelantamiento para facilitar toda la demanda de adelantamiento que se haya podido acumular en el tramo anterior de un solo carril.

Por tanto, se podría plantear la posibilidad de darle un uso temporal al inicio de los carriles de adelantamiento para alojar vehículos automatizados que precisen alcanzar una condición o localización de riesgo mínimo. En la Figura 8 (adaptada de la Figura A1.1 de las Recomendaciones), se puede observar una propuesta para facilitar apartaderos interiores en el inicio de los carriles de adelantamiento.

Para diferenciar la zona correspondiente al apartadero, se podría emplear la marca vial M-1.4 establecida para la "delimitación de carril que pueda utilizarse en un sentido o en el contrario, solo cuando este regulado por medio de semáforo de carril" (MOPU, 1987). El borrador de la nueva Instrucción 8.2-IC define la función de esta marca vial: "delimita por ambos lados los carriles reversibles, en los que el sentido de circulación está reglamentado en uno u otro sentido mediante semáforos de carril u otros medios" (MITMA, 2020).

Aunque su función hasta ahora estaba orientada a la delimitación lateral de los carriles reversibles, teniendo en cuenta la prevención que transmiten a los conductores para su cruce y que habría que señalizar dinámicamente el uso o no de la zona inicial como carril de adelantamiento, sería una buena opción para la señalización.

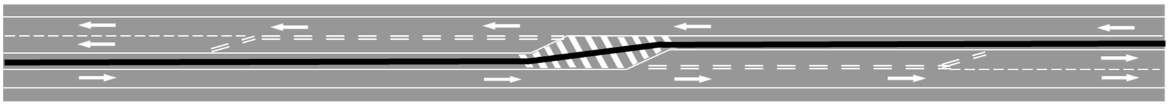

Fig. 8 – Apartaderos interiores en el inicio de carriles de adelantamiento de carreteras 2+1.

4. ZONAS DE DETENCIÓN SEGURA

La alternativa más segura y con mayor capacidad para una MRC será una zona de detención segura, localizada fuera de los ámbitos de las calzadas principales, aprovechando las conexiones, los ramales o las zonas intermedias de enlaces.

Para estas zonas de detención segura caben diversas alternativas según la tipología de carretera:

- Una vía colectora existente a la que se adose un apartadero lineal o una batería de aparcamientos. Si la vía colectora no tuviera suficiente desarrollo, cabría la posibilidad de adelantar la salida y extender la vía colectora de forma anticipada para poder disponer la zona de detención en esa zona nueva (Figura 9).
- Una nueva vía colectora que conecte un ramal de salida con un ramal de entrada (Figura 10).
- Un ramal de salida con apartadero de emergencia, preferentemente cuando los vehículos automatizados puedan tener continuidad en la intersección con la carretera secundaria para volver a reincorporarse a la calzada principal. Si el ramal no tuviera suficiente desarrollo, cabría la posibilidad de adelantar la salida y extender el ramal de forma paralela a la calzada principal para poder disponer la zona de detención en esa parte nueva (Figura 11).
- Un nuevo ramal específico para dar acceso a la zona de detención segura, que pueda tener continuidad en la intersección con la carretera secundaria para volver a reincorporarse a la calzada principal (Figura 12).

Figura 11: Zona de detención segura en un ramal de salida con apartadero. Fuente: Adaptada de Google.

Figura 12: Zona de detención segura en un nuevo ramal de uso específico. Fuente: Adaptada de Google.

5. NUEVOS CRITERIOS DE DISEÑO Y ORDENACIÓN

Ante la nueva necesidad que va a surgir y las diversas alternativas viarias para facilitar las zonas de detención segura de los vehículos automatizados, habrá que añadir este nuevo criterio a la hora de diseñar los nudos, especialmente los enlaces, pero también las intersecciones.

Uno de los posibles cambios será que en los enlaces difusores con una carretera secundaria se diseñen las intersecciones de los ramales con la misma empleando glorietas, que faciliten la reincorporación de los vehículos automatizados desde las zonas de detención segura a la carretera principal. Adicionalmente, se deberán separar más los ramales directos de giro a derecha para dejar espacios intermedios que permitan integrar en ellos las zonas de detención segura.

La necesaria señalización horizontal y vertical requerirá de un estudio amplio y armonizado, al menos, a nivel europeo, conjuntamente con la industria del automóvil. Igualmente, para la ordenación de su uso, incluyendo la necesaria conectividad V2I e I2V de tal forma que cada vehículo que adopte una posición MRC comunique su posición georreferenciada a un centro de control, para que, a su vez, sea comunicada al resto de vehículos que precisen localizar otra MRC en esa zona. Además, habrá que establecer una regulación clara que prevenga del mal uso de las zonas de detención segura.

6. CONCLUSIONES

Para el desarrollo de un sistema automatizado seguro, el diseño de las maniobras posibles para lograr una condición de riesgo mínimo cuando finalice un ODD sin que el conductor recupere el control, es una parte fundamental. Pero, se hace necesario el estudio, para cada tramo de carretera donde se habilite la circulación de vehículos automatizados de nivel 3 o superior, de las posibles localizaciones que cumplan los requisitos para las condiciones de riesgo mínimo.

Hasta ahora, se han planteado diversas alternativas, de menor a mayor seguridad, pero de mayor a menor proximidad respecto a la localización del vehículo en el momento de la activación de la causa, respectivamente: el uso del arcén exterior, la disposición de apartaderos de emergencia y el desarrollo de nuevas zonas de detención segura fuera de la plataforma viaria.

Los arcenes presentan la ventaja de su disponibilidad continua a lo largo de la carretera y serían posibles localizaciones, siempre que dispusieran de una anchura mínima de 2,5 m, aunque siempre sería una opción peligrosa, por la proximidad a la circulación en el carril adyacente.

Además, ante una inclemencia ambiental intensa, los arcenes pasarían a ser ocupados de forma densa por lo que los vehículos automatizados detenidos podrían bloquear el paso necesario de vehículos de emergencia.

Según la tipología de carretera, se han planteado diferentes tipologías de apartaderos de emergencia para servir como MRCs. En autopistas y autovías se pueden desarrollar: apartaderos exteriores para varios vehículos, como los actuales, pero también aprovechando zonas con cunetas de seguridad amplias y sobreanchos de estructuras en pasos inferiores; apartaderos exteriores para un solo coche como ampliación del arcén; y apartaderos interiores en la mediana para varios vehículos, que además pueden servir como pasos de mediana de mejores prestaciones que los actuales. En carreteras 2+1, además de los anteriores, se podrían integrar apartaderos interiores en las zonas de transición no críticas para varios vehículos.

La alternativa más segura y con mayor capacidad para una MRC será una zona de detención segura, localizada fuera de los ámbitos de las calzadas principales, aprovechando las conexiones, los ramales o las zonas intermedias de enlaces. Para estas zonas de detención segura se han propuesto diversas alternativas: una vía colectora existente a la que se adose un apartadero; una nueva vía colectora que conecte un ramal de salida con un ramal de entrada; un ramal de salida con apartadero de emergencia; un nuevo ramal específico para dar acceso a la zona de detención segura, que pueda tener continuidad en la intersección con la carretera secundaria para volver a reincorporarse a la calzada principal.

Ante la nueva necesidad que va a surgir y las diversas alternativas viarias para facilitar las zonas de detención segura de los vehículos automatizados, habrá que añadir este nuevo criterio a la hora de diseñar los nudos, especialmente los enlaces, pero también las intersecciones.

Además, la necesaria señalización horizontal y vertical requerirá de un estudio amplio y armonizado, al menos, a nivel europeo, conjuntamente con la industria del automóvil. Igualmente, para la ordenación y regulación de su uso, incluyendo la necesaria conectividad V2I y V2I de tal forma que cada vehículo que adopte una posición MRC comunique su posición georreferenciada a un centro de control, para que, a su vez, sea comunicada al resto de vehículos que precisen localizar otra MRC en esa zona. Habrá que establecer una regulación clara para prevenir el mal uso de las zonas de detención segura.

Todas las localizaciones para alojar vehículos automatizados, ya sean apartaderos o zonas de detención segura, deberán estar incorporadas en los mapas de alta definición dinámicos.

Senior Lecturer, University of Burgos, Spain

ABSTRACT

The density of traffic within urban areas depends on multiple factors, and among those; one that has major impact is the weather. This paper presents a study that empirically analyzes the traffic flow velocity depending on the atmospherically conditions and the day schedule. The objective is to assess systematically to which extent there is a correlation between the vehicle velocity on an urban environment and the weather, depending on the time of day. The presented case of study uses a set of real data, specifically the trips made by taxis in the city of Porto (Portugal). First, the vehicle GPS routes are analyzed to identify departure and arrival points and estimate the route average velocity and adding weather and time conditions. The data is processed with different regressive techniques to obtain the influence of the variables on the velocity. The results show differences between days of the day and weekends, as well as differences in speeds with a favorable climate for driving compared to other more adverse ones.

1. INTRODUCTION

Traffic within cities can be considered as a living being that grows and evolves over time. Cities grow, and it is necessary to designs a good urban planning and road traffic management according to this evolution. Likewise, in recent years with the advancement of technologies and the appearance of concepts such as smart cities, the different municipal corporations invest large amounts of money in putting technologies at the service of their inhabitants to improve their quality of life.

Urban traffic management is a challenging problem nowadays; it is difficult to find a management system or a generic solution to this problem, as each urban area presents a different problem.

This is due to factors as diverse as the available infrastructures, the demography, geographical situation and orography of the city, issues such as the cultural customs of the inhabitants, the economic power or the vehicle fleet, among others.

A determining factor that affects the variation in traffic flow is the weather conditions (Cools, Moons et al. 2010). In the present work, a study is performed to see how different weather conditions affect the way in which users of urban roads move in the city of Porto (Portugal). With this, we want to observe how this behaviour varies at different times and days of the week and depending on the atmospheric climate and analyse if there are significant differences between some conditions and others. With this, it will be possible to make a forecast of the traffic state, which will facilitate its management, being able to avoid traffic jams and accidents (Maze, Agarwal et al. 2006).

The rest of the work is divided in, related work, dataset explanation methodology employed, experiment results, conclusions and future work.

2. RELATED WORK

Traffic flows within urban areas have been widely studied in the literature and encompass different problems that all affect the traffic of vehicles in cities. Examples of them can be found in traffic light management (Gupta, Kumar et al. 2017), accident prevention (Aldegheishem, Yasmeen et al. 2018), contaminant emissions reduction (Anjum, Noor et al. 2019), or traffic flow predictions to avoid traffic congestion (Hu, Wang et al. 2018).

In our specific case, we want to analyse the state and variation of traffic flows velocity depending on the atmospheric conditions due to it is one of the factors that most influence the behaviour of drivers.(Kilpeläinen and Summala 2007).

In this field one of the pioneering works in this field was (Tanner 1952) in which they analyse the correlation between the use of different vehicles under the effect of rain, distinguishing between working days and holidays. As technology advances, more scientific articles related to traffic and weather have appeared.

Golob and Recker (2003) demonstrate with multivariate statistical methods such as weather, traffic flow and lighting influence on accidents on the highways of California.

The effect of the snow or precipitations in the traffic flow congestion using video recordings is studied in (Asamer and Van Zuylen 2011). Tsapakis, Cheng et al. (2013), show the variation in the speed of London drivers under various conditions of snow, rain, and temperature.

Paying attention to snow and how it affects traffic we can find the case of Beijing (Weng, Liu et al. 2013) . Authors highlight the reduction in speed and capacity of urban roads, as well as the increase in travel times; in addition, these effects are noticeable in the following days due to the ice although no longer snow.

In (Stamos, Salanova Grau et al. 2016) the effect of heavy rains and how it affects the speed of vehicles in Thessaloniki (Greece) is analyze from data of 1,200-taxi fleet that contained GPS coordinates and speed information. under certain atmospheric conditions (Yasanthi and Mehran 2020), in this case traffic data is crossed with atmospheric data, including data such as temperature and the condition of the pavement or wind speed.

Finally, congestion is studied in Porto, (Portugal) with diagrams and probabilistic models (Silva, d'Orey et al. 2018), for this they use data obtained from taxis and the weather, but only focusing on a small central area.

3. DATA SET DESCRIPTION

The data set used contains GPS routes of taxis in the city of Porto (Kaggle 2018). The TRAVISANA software has been used to process it (Cogollos, Porras et al. 2020). In it the routes are pre-processed, filtered, and speeds are calculated. In Figure 1 the application pipeline process is shown.

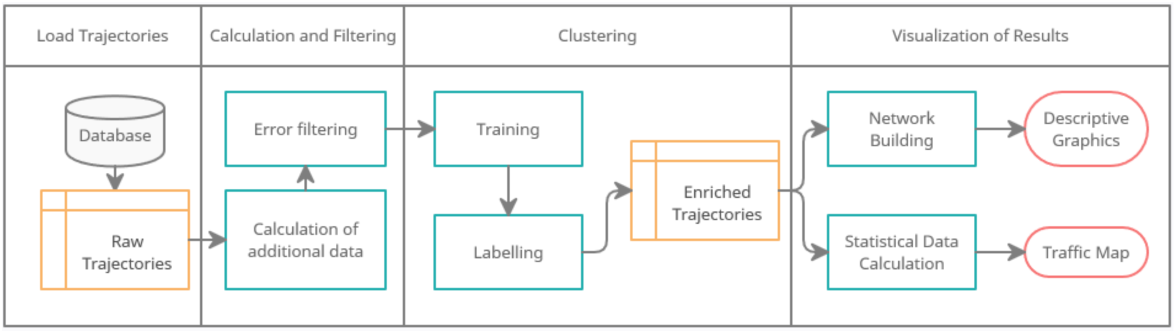

Figure 1: TRAVISANA Pipeline.

In this specific case, the atmospheric data, extracted from(Ltd 2020), are also added to the routes. All the data is combined in the application to obtain the complete data set with the speeds of each vehicle in each trip and the atmospheric conditions of that moment.

Specifically, the set consists of the following variables:

- Id: Route identifier.
- Velocity: Average speed of the vehicle during the trip in kilometers per hour.
- Day: Day of the week from 1 Monday to 7 Sunday.
- Temperature: Temperature at that moment in Celsius degrees.
- Precipitation: Amount of rain in milliliters.
- Visibility: Range of visible space in kilometers.
- Humidity: Grams of water for each cubic meter of air.

Finally, Weather: categorical variable, with 20 values: clear, cloudy, fog, heavy rain, heavy rain at times, light drizzle, light rain, light rain shower, mist, moderate or heavy rain shower, moderate or heavy rain with thunder, moderate rain, moderate rain at times, overcast, partly cloudy, patchy light drizzle, patchy light rain, patchy rain possible, sunny and torrential rain shower.

4. METHODOLOGY

To see the influence of each variable on t the vehicles velocity, the following regression techniques are used.

- Multiple regression: This method explains the variable under study as far as possible, using a group of variables that, directly and indirectly, participate in its value.
- Principal component regression (PCR): This method differs from the classical multiple linear regression in that first a principal component analysis is performed on the dependent variables and later the multiple regression is applied using the obtained factors.
- Partial least squares regression (PLS Regression): This technique combines the multiple regression ant the principal component analysis but is focused on reduce the multicolinearity and obtain more accurate predictions, as difference PCR is more focused on reduce the number of dependent variables.
- Regularized regression: Also known as regulated or constrained regression, specifically the elastic net regression has been used in this paper. This family of regression methods adds a penalty term to the best fit trying to obtain less variance achieve and restricting the influence the dependent variables over the independent one by compressing their coefficients.
- Multiple adaptative regression splines (MARS): It is an algorithm that automatically creates a piecewise linear model which provides an intuitive stepping block into nonlinearity. In order to identify the nonlinear relationships MARS assesses each data point for each predictor as a knot and creates a linear regression model with the candidate features.
- Bagged MARS: Bagging it is a machine learning technique that raises the stability of models by reducing the variance and improving the accuracy, avoiding overfitting.
- Bagged MARS with gCV Pruning: In this version, a generalized cross-validation is added to a Bagging MARS. In addition, a pruning step is executed in every iteration, removing the term in the model that gives the smallest increase in the sum of squared error.

5. EXPERIMENTS RESULTS AND DISCUSSION

To apply the methods to the data set, the caret package from R has been used(Kuhn 2008). All the techniques have been applied with a general cross validation process, with *k=10*. The root mean square error (RMSE) after the general cross validation process (GVC) and the root square sum of the errors (RSS) are used as performing metrics.

The aim of the study it is investigate the relationship between the velocity and the weather conditions in different days of the week.

Initially, all the data have been processes for a first approximation using MARS. Results can be observed, in Table 1 and Figure 2. According with them we can distinguish that the factor with more influence in the velocity are the sunny weather, humidity, and the weekend's days. Therefore, we can conclude that the daily days and weekends has an influence on vehicle velocity in weekends the velocity is higher than in daily days. For a further exploration and more accuracy study of weather influence, the data has been split in daily days and weekends.

Variable	GVC	RSS
WeatherSunny	100.0	100.0
Humidity	100.0	100.0
Day7 (Sunday)	68.0	68.2
Day6 (Saturday)	55.1	55.3
Temperature	48.0	48.3
Precipitation	37.9	38.2
WeatherCloudy	37.4	37.7
WeatherPartly cloudy	32.6	32.9
WeatherOvercast	27.2	27.4

Table 1: GVC and RSS Values for all data.

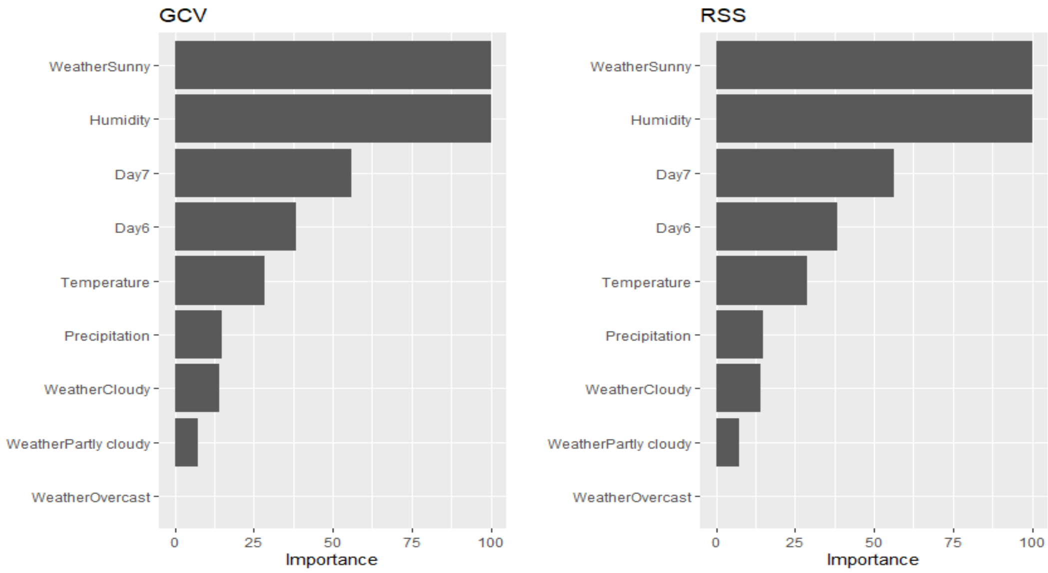

Figure 2: Variable importance according to the contribution to GCV and RSS values as predictors for all data.

In Table 2 the RMSE of predicted velocity for all methods are presented, according with them, the methods who best fit are MARS for daily days and PLS regression for weekends.

	RMSE	
Method	**Daily**	**Weekend**
Multiple regression	12.64511	12.77780
PCR regression	12.64583	12.94490
PLS regression	12.64511	**12.77776**
Regularized regression	12.64522	12.77780
Bagged MARS	12.67633	12.92724
Bagged MARS with gCV Pruning	12.67451	12.90767
MARS	**12.55634**	12.79040

Table 2: RMSE values for Daily days and weekends.

Daily days study: Figure 2 and Table 3 shows the variable importance. According with them it can be observed that sunny weather and humidity have a great influence over velocity as expected according to the initial analysis, but it is observed that between days the temperature and that the weather is cloudy contributes to a higher speed. Analysing the combinations of the variables in Table 4, it is noticeable that the speed increases with temperatures above 9 degrees, and humidity levels below 57 either with sunny or cloudy weather. On the other hand, when precipitation appears, speeds decrease.

Variable	GCV	RSS
WeatherSunny	100.0	100.0
Humidity	100.0	100.0
Temperature	54.7	55.1
WeatherCloudy	43.7	44.2
Precipitation	37.4	37.9

Table 3: GVC and RSS Values for daily data.

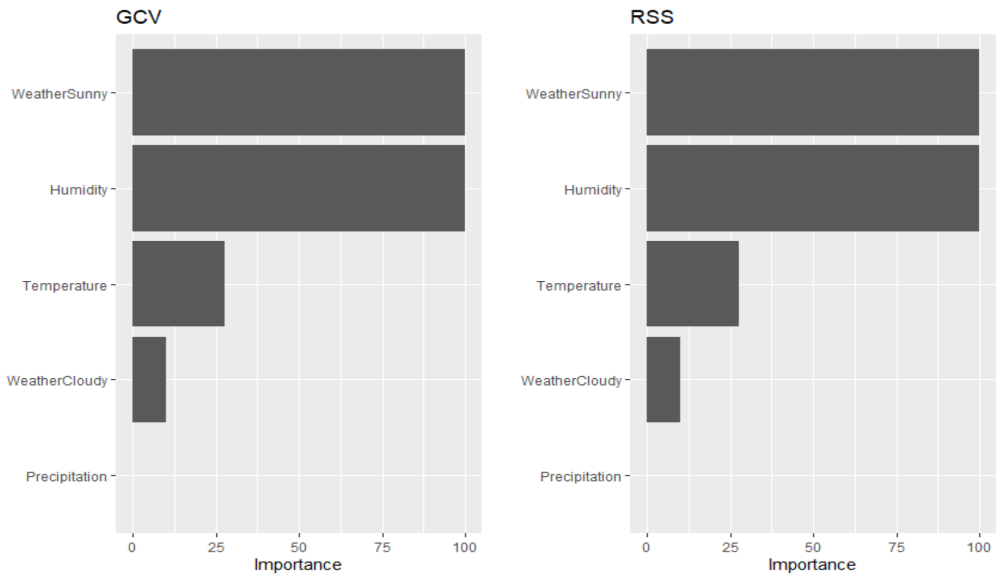

Figure 3: Variable importance according to the contribution to GCV and RSS values as predictors for daily days.

Variable	Coefficent
(Intercept)	22.95928
WeatherSunny	0.82939
WeatherSunny*h(Humidity-57)	0.55996
h(Temperature-9)	0.17940
h(9-Temperature)	12.73014
WeatherCloudy*h(Temperature-9)	1.42678
h(9-Temperature)*h(87-Humidity)	0.11849
h(9-Temperature)*h(Precipitation-0.8)	-5.37981
h(9-Temperature)*h(0.8-Precipitation)	-15.80329
WeatherCloudy*h(Temperature-9)*h(Humidity-97)	-1.34813

Table 4: Mars coefficients for Daily Days.

Weekend study: We used PLS as it is the method with less RMSE. In Table 5 can be seen as more atmospheric states influence the speed, as in the previous case, the most influential factors are sunny weather and humidity. However, visibility and rainfall are important; this can be related to rainy climates. Our PLS result only gives us one level and we do not see the iterations between the variables, but by analyzing the coefficients, we can say that the velocity is higher with sunny and cloudy weather and decreases with light rain or fog. The positive weight of rainfall suggests that speed increases with rainfall and the negative of visibility that decreases the more visibility there is. These factors seem contradictory and would require a more complete study.

Variable	GCV	RSS	Coefficent
WeatherSunny	100	100	3.05085
Humidity	27,9	27,9	0.19905
WeatherLight rain	25,8	25,8	-0.17142
Visibility	24,9	24,9	-0.06000
Precipitation	21,5	21,5	0.36494
WeatherOvercast	21,1	21,1	0.91770
Temperature	18,4	18,4	-0.72814
WeatherPartly cloudy	17,7	17,7	1.19975
WeatherModerate rain	15,4	15,4	0.63879
WeatherModerate or heavy rain shower	11,7	11,7	0.06692
WeatherTorrential rain shower	11,6	11,6	-0.22982
WeatherLight rain shower	5,1	5,1	0.728437
WeatherLight drizzle	2,6	2,6	-0.08700
WeatherMist	1,3	1,3	-0.12495
WeatherCloudy	1,29	1,29	0.43920
WeatherPatchy rain possible	0	0	0.67629

Table 5: PLS regression coefficients for Daily Days.

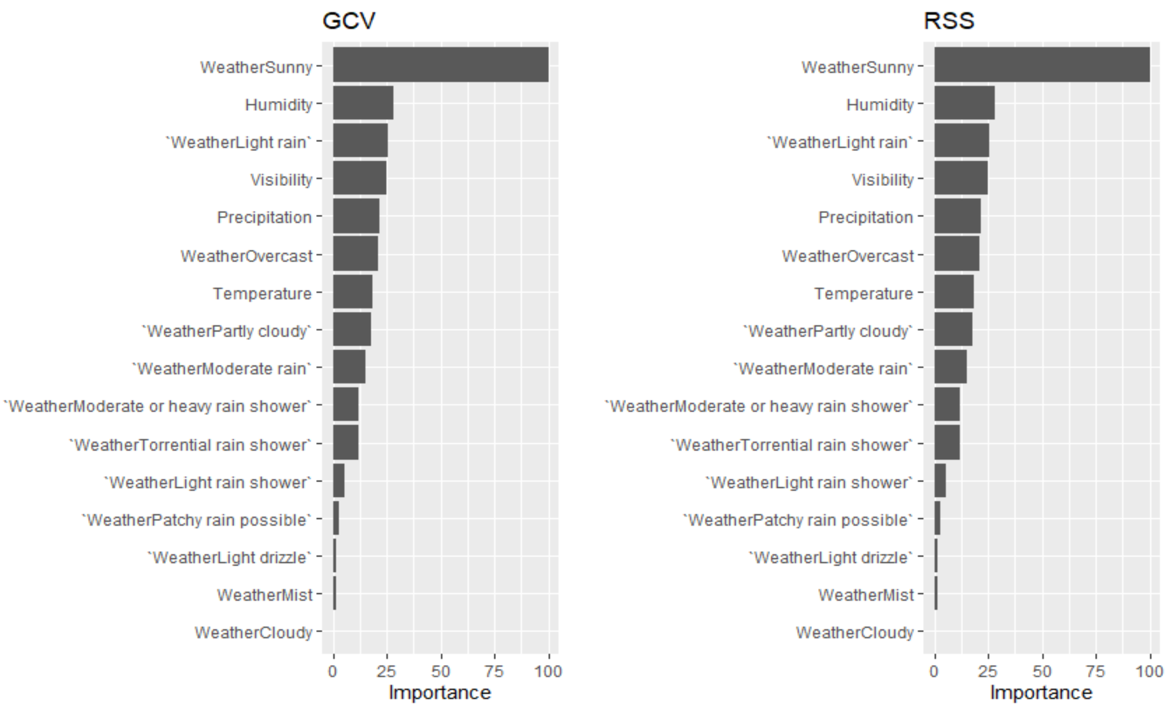

Figure 4: Variable importance according to the contribution to GCV and RSS values as predictors for weekends.

6. CONCLUSIONS AND FUTURE WORK

As seen in the results section, atmospheric conditions and the day of the week significantly influence the average speed at which Porto taxis circulation. It can be concluded that under sunny or cloudy days without rainfall, taxis travel at a higher speed, as conditions worsen the speed is reduced. For daily analysis, the speed is higher on weekends than on daily days, this could be due to a lower volume of circulation, regardless of the weather. We must highlight humidity importance; we assume that it will be due to the geographical situation of Porto.

This study has its limitations, evidently factors such as the volume of vehicles, the type of road, the speed limit, the lighting or the time of day also affect the flow of traffic. Collecting these data and obtaining data from different types of vehicles to build a better model is one future line of work in order achieve more precise results.

In addition, it is also limited by the characteristics and climate of Porto, as future work we plan to compare it with other cities with different climates and orography.

WORKING HOURS AND TRAFFIC ACCIDENT INJURIES: CASE STUDY IN BARCELONA

Ahmad Aiash
PhD student, Civil Engineering School, Technical University of Catalonia – BarcelonaTech (Spain)
Francesc Robusté
Professor of Transportation, Civil Engineering School, Technical University of Catalonia – BarcelonaTech (Spain)

ABSTRACT

Working hours in Spain is generally last for 8 hours per day with a maximum of 40 hours per week. Working hours, therefore, can impact the traffic flow and characteristics due to the intensity of road usage by different road users. On the other side, traffic accidents can also be impacted by several temporal factors that may lead to a higher number of traffic accidents or may increase the level of injury alongside other risk factors. In this study, these timings are examined to comprehend the influence of the temporal factors represented by the working hours scheme on traffic accident injuries in Barcelona. Another temporal factor which is the season of the year is included to provide a wider and clearer image for the conducted results and the current situation. The data is collected from the open data service provided by the City Hall of Barcelona. Data preparation and segregation to include the categories of working hours that may lead to a different level of injury resulted from a traffic accident is, firstly, carried. Then, a machine learning model is applied to classify the correlations for both the temporal factors and traffic accidents. Eventually, a Tree Augmented Naïve Bayes model is applied. The results showed that both working hours timing and summer season have higher probabilities of having traffic accidents slight injuries with different medical care assistance provided compared to other timings.

1. INTRODUCTION

Spain has set a comprehensive labor law to organize and regulate the whole working employees' and employers' relationships with covering other aspects including health and safety at work, Social Security, the procedural law, and special relationships conditions for employment (de Vivero, 2019). As part of these regulations and rules, the maximum number of hours per week has been set to be 40 hours which is estimated based on an average over an annual period. Generally, the working time periods each day is set to start at 9:00 a.m. and end at 7:00 p.m. with having two hours break during the working period. This break period usually starts at 2:00 p.m. and ends at 4:00 p.m. for most employees. These timings, indeed, can be a reason for traffic congestion or flow intensity on different roads due to the fact that several groups of people are heading to different destinations at the same time throughout the day.

Real- time traffic data can be affected by different temporal factors similar to the working hours timings and other temporal factors besides the spatial factors. Several studies have examined the effect of the temporal factors on traffic real-time data. In some European countries, holidays' periods shown lower traffic compared to other seasons (Stathopoulos & Karlaftis, 2001). Peak hours have shown to be another influential factor related to traffic flow. Based on a study that is conducted to examine traffic flow patterns in Shanghai, China (Yang, Wu, Xu, & Yang, 2019), the results showed that peak hours had worse traffic congestion compared to non-peak hours.

Traffic accidents, on the other hand, can also be correlated with different temporal factors that can increase the occurrence of them or affect the level of injury. A study (Kashani & Zandi , 2020) shown that weekends can be correlated with a higher number of traffic accidents compared to weekdays.

The same study also revealed that hot timing had more accidents during weekdays. These timings were found to be 8 a.m. and 2 p.m. While for weekends, these timings differ from weekdays' hot timings. 1 p.m., 8 p.m., and 10 p.m. were the hot timings for accidents during weekends. Slight injuries accidents were found to be more likely to happen when the traffic flow is high (Quddus, Wang, & Ison, 2010). Similar to traffic flow, traffic accidents were found to vary according to the season of the year (Harirforoush, 2017) (Le, Liu, & Lin, 2019). Morning, afternoon, or late-night timings were found to have lower probabilities of having fatal injuries compared to early morning timing in Cartagena, Colombia (Cantillo, Márquez, & Díaz, 2020). Consistently, time was found to be an important independent variable related to traffic accidents severities (Li, Prato, & Wang, 2020). As mentioned earlier, traffic congestion can be highly affected by the timing of the day. Therefore, a study (Hyodo & Todoroki, 2018) showed congested and the mixed flow state can increase the risk of having traffic accidents different types including property damages and slight injury accidents.

The objective of conducting this study is to examine the influence of certain temporal factors represented by the working hours and the season of the year in Barcelona, Spain. Data collected and preparation process is carried. Then, a Bayesian network is applied to the exploited data to extract the results.

2. METHODOLOGY

2.1 Data description

The data the is exploited in this study is collected from the Barcelona open data service which is called Barcelona's City Hall Open Data Service (Ajuntament de Barcelona's open data service, 2019). The data that is gathered consists of different traffic injuries. In this study, slight injury levels with different categories are selected for this purpose that occurred in Barcelona in 2019.

Two temporal factors are selected for the objective of this study including the working hours timing and the season of the year. Beginning with the season potential temporal risk factor, the four seasons are included in the examined period and categorized based on their climate (The main climate data of Barcelona, 2020). The summer season is considered to start in May and end in August. Followed by the autumn season that begins in September and ends in November. The winter season is considered to start in December and end in February. Spring, therefore, is considered to start in March and end in April. For the working hours, two categories are included: during work and the other rest time. Working hours are considered to start at 9 a.m. and end at 7 p.m. with having two hours break. These two hours are considered to start at 2 p.m. and end at 4 p.m. with considering them with the other rest category when the initiation of the analysis part is established. However, during the data analysis, this time-period is considered to start from 2:01 p.m. to 4 p.m.

These previously mentioned categorizations are for the independent variables, while for the dependent variable, three categories are included. The first category is represented by the person who had a slight injury with medical assistance. The second category is represented by the person who had a slight injury but rejected health care. The third and last category is represented by the person who had a slight injury with having a hospitalization up to 24 hours. Table 1 is displaying the two different independent variables' general statistics. The total number for both predictors is 11620 accidents that occurred in 2019 in Barcelona and belonged to the slight injuries that required different levels of medical care. As mentioned earlier, the working hours variable consists of two categories, while the season has three categories. Both predictors are considered as categorical type variables alongside the dependent variable when the analysis part is carried.

	Count	Mean	Min	Max	Range	Variance	Standard Deviation	Standard Error of Mean
Working hours	11620	1.55	1	2	1	0.247	0.497	0.005
Season	11620	2.68	1	4	3	1.405	1.185	0.011

Table 1: Main independent variables statistics.

2.2 Bayesian network

Bayesian network is a member of probabilistic graphical models (GM)s that provides laconic descriptions of the distribution of joint probability for the given random variables. Two methods can be exploited when applying Bayesian network models when using IBM Watson Studio software platform with utilizing SPSS modeler. Tree Augmented Naïve Bayes and Markov Blanket estimation are both methods that can be utilized. In this study, Tree Augmented Naïve Bayes is implemented to classify the correlation between the two predictors and the level of medical care that is provided for persons that are involved in traffic accidents.

The reason for choosing Tree Augmented Naïve Bayes is for its simplicity as the number of variables is only two and the aim of this study is only to examine the correlation with considering the prediction part. Moreover, the two independent variables are classified under the same category which is the temporal variables category. The classifier of Tree Augmented Naïve Bayes that is exploited through the IBM software platform is based on this book (Friedman, Geiger, & Goldszmidt, 1997). The conditional probabilities are calculated, in general, by SPSS modeler as follows:

$$\{[Pr(Y_i|X_1 = x_1^j, X_2 = x_2^j, \dots, X_n = x_n^j) = (Pr(Y_i)(X_1 = x_1^j, X_2 = x_2^j, \dots, X_n = x_n^j|Y_i))/ (Pr(X_1 = x_1^j, X_2 = x_2^j, \dots, X_n = x_n^j))], [\propto \Pr(Y_i) \prod_{k=1}^{n} Pr(X_k = x_k^j|\pi_k^j, Y_i)]\} \quad (1)$$

For $d_j = (x_1^j, x_2^j, \dots, x_n^j)$ where d is the data set. d_j is the case that is classified to which it belongs to i^{th} target category, which in this study, the target Y_i is the medical care three levels provided for slightly injured persons. x is the predictor. n is the number of predictors which is two in this study. K is the number of non-redundant parameters. π_k is the parent set of the independent variable alongside the dependent variable, it maybe empty for Tree Augmented Naïve Bayes. The conditional probability is $Pr(X_k = x_k^j|\pi_k^j, Y_i)$ that is associated with each node, which in this study, there are two nodes for predictors.

2.3 Results and discussions

The structure of the applied Tree Augmented Naïve Bayes structure consists of three nodes including medical care level, season, and time which is the working hours as shown in figure 1. The parent node for the season independent variable is only the medical care level. For the time node, this node is linked to two nodes including medical care level and the season. This makes sense since the fact that working hours are already part of the season of the year. Time has a higher importance value compared to season based on the applied model.

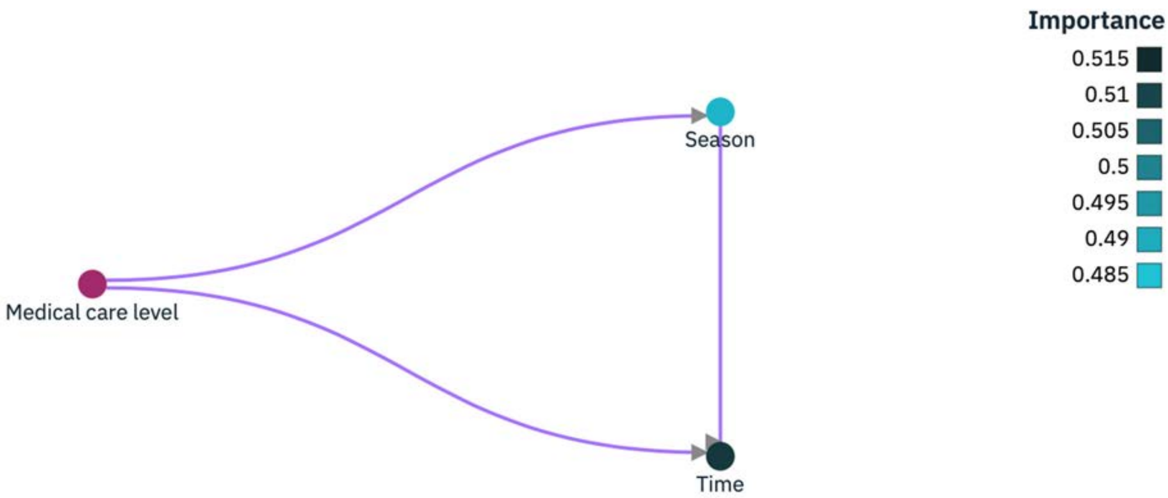

Figure 1: Tree Augmented Naïve Bayes structure.

Table 2 and table 3 are both displaying the estimated conditional probabilities based on the applied Tree Augmented Naïve Bayes for season and time, respectively. For the season, summer has a higher conditional probability compared to all other seasons of the year, followed by autumn, winter, and lastly, the spring season. For the time variable, the working hours category has the highest conditional probabilities during all seasons for all medical care categories that are provided for the slightly injured person except spring season when a person got a slight injury, but this injured person rejected medical assistance.

Parents		Season Probability			
Medical care level	Autumn	Winter	Spring	Summer	Total
With medical assistance	0.245	0.233	0.180	0.341	2,263
Rejected health care	0.243	0.231	0.188	0.338	420
Hospitalization up to 24 hours	0.255	0.235	0.164	0.346	5,428

Table 2: Season conditional probability.

Parents		Time Probability		
Season	Medical care level	Working hours	Rest of the day	Total
Autumn	With medical assistance	0.514	0.486	555
Autumn	Rejected health care	0.520	0.480	102
Autumn	Hospitalization up to 24 hours	0.525	0.475	1,384
Spring	With medical assistance	0.576	0.424	408
Spring	Rejected health care	0.468	0.532	79
Spring	Hospitalization up to 24 hours	0.552	0.448	888
Winter	With medical assistance	0.547	0.453	528
Winter	Rejected health care	0.619	0.381	97
Winter	Hospitalization up to 24 hours	0.558	0.442	1,277
Summer	With medical assistance	0.585	0.415	772
Summer	Rejected health care	0.549	0.451	142
Summer	Hospitalization up to 24 hours	0.559	0.441	1,879

Table 3: Time conditional probability.

3. CONCLUSIONS

The fact that there are enormous factors that influence traffic accident occurrences and severities is leading to conducting several studies to examine these potential risk factors. Temporal factors are part of these factors that can impact traffic accidents. Working hours and the season of the year are part of these temporal factors that may lead to traffic accidents. Therefore, this study has exploited traffic accident injuries by focusing on the level of medical care that is provided for the slightly injured person in Barcelona in the year 2019.

Tree Augmented Naïve Bayes based on Bayesian network is employed to classify the correlations between the two predictors and the dependent variable.

Four seasons are included to understand its temporal impact on the three levels of medical care. Two timings are included the working hours which starts at 9 a.m. and ends at 7 p.m. with having 2 hours break that is not included in this category which is from 2 p.m. to 4 p.m. period. The results show that the summer season has higher conditional probabilities of having slight injuries with including different medical care assistance compared to other seasons. For the timing, the working hours period, similar to the summer season, has the highest conditional probabilities for traffic accidents with being involved in slight injuries with different medical care assistance. For the future work and based on the concluded results, data from delivery operating firms is needed to grasp the impact of these different timings on traffic accidents occurring while the operation is maintained. Then, similar data analysis can be carried out to detect the impact of working hours on this category of employees as they may have a higher risk of being involved in traffic accidents compared to other categories during these timings. Other levels of injury resulted from traffic accidents may also be considered in the future work.

TRANSPORTE PÚBLICO
PUBLIC TRANSPORT

ANÁLISIS ESTRUCTURAL DE REDES DE TRANSPORTE PÚBLICO USANDO TEORÍA DE REDES. CASO DE GUADALAJARA MÉXICO.

Orlando Barraza
Estudiante de doctorado, Universidad Politécnica de Cataluña, España
Miquel Estrada
Profesor agregado, Universidad Politécnica de Cataluña, España

RESUMEN

Dentro del contexto de planeación de transporte público el análisis estructural es clave para entender la eficiencia del sistema. En este trabajo se propone una metodología de análisis estructural aplicada a una red alternativa de transporte público en Guadalajara México. El análisis se deriva de teoría de redes y se enfoca en 3 propiedades: accesibilidad, resiliencia y fricción espacial.

En el caso de la accesibilidad, esta se vincula con el Shimbel index que mide el promedio de tiempos de viajes de cada nodo al resto de los nodos. Por ende, el grado de accesibilidad brindará un parámetro de la efectividad en términos de tiempo de traslado que brinda cada red. Por otra parte, la resiliencia integra 3 propiedades de red los cuales son: betwenness centrality, central point dominance y average path length. El betwenness centrality mide la frecuencia en la que un área de la ciudad es usada como el camino más corto entre 2 destinos.Con esto se identifica las zonas con mayor polarización de uso. Mayores polarizaciones corresponderían a problemáticas de vulnerabilidades.

Por otro lado, el central point dominance mide la variabilidad de la media del betwnneess centrality y el mayor betwness centrality. Una mayor variación se traduce en una mayor vulnerabilidad. Finalmente, el average path length mide el grado de conectividad de la red. Este se mide en un escenario base y se mide nuevamente cuando los principales nodos de la red fallan, esto con objeto de verificar el impacto que tiene la conectividad de la red cuando ciertos nodos fallan. Finalmente, se aborda la fricción espacial donde se toma el parámetro del índice deuter el cual compara la distancia euclidiana entre todos los posibles viajes y su distancia sobre la red de transporte. Esto otorgará un indicador de la eficiencia espacial.

1. INTRODUCCIÓN

Dentro de los procesos de planeación de sistemas de transporte público existen temas claves de integración como lo son análisis de patrones de movilidad, uso de suelo, modelación, análisis económico y ambiental entre otros. Sin embargo, existen propiedades de los sistemas de transporte público que son claves para la evaluación de su eficiencia y por ende para la toma de decisiones los cuales son los análisis del rendimiento en términos estructurales. Para medir dichos aspectos estructurales los planeadores de transporte han recurrido al uso de teoría de redes. Teoría de redes es raramente aplicado a planeación de sistemas de transporte a pesar de la gran importancia en los resultados de los análisis.

La Teoría de Redes (TR) es un campo de la ciencia que usa matemáticas discretas para comprender las propiedades estructurales de una red. Para realizar dichos análisis es necesario tener una representación de red de un sistema lo cual se sintetiza generación de nodos y links que representan las vinculaciones que existen entre objetos, entes o individuos. En el caso de las redes de transporte público la representación puede generarse por dos vías. La primera en donde cada parada funge como nodos y la conectividad de las paradas son los links. La segunda en la que cada zona de la ciudad (previamente generadas) es un nodo y la conectividad entre cada zona vía la red de transporte funge como links. Esta concepción se puede visualizar en la siguiente imagen:

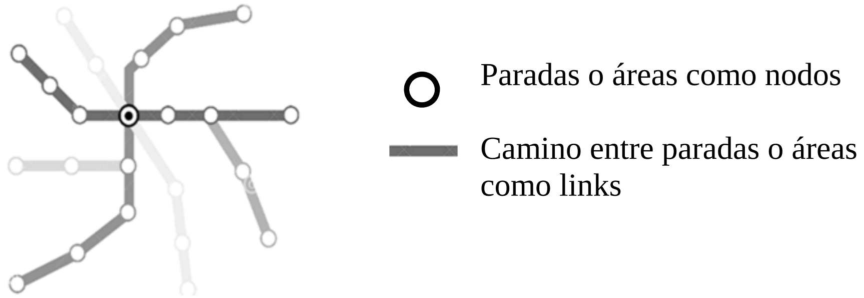

Figura 1: Ejemplo de la representación de sistemas de transporte público a redes

Dentro del campo de teoría de redes existe una gran cantidad de propiedades redes (atributos de redes) las cuales están sujetas a medición. En el contexto de redes de transporte publico las principales son: Diámetro de la red, Índice Deuter, Densidad de red, Índice Pi, Índice Eta, Índice Theta, Índice Beta, Índice Alpha, Índice Gamma, Índice Shimbel, dependencia central entre otras Rodrigue (2020).

Sin embargo, en este trabajo nos enfocaremos a 3 propiedades de red principales las cuales son: Grado de accesibilidad (vinculado a el índice de Shimbel), fricción espacia (vinculado al índice deuter) y la resiliencia de la red (vinculado a betweness centrality, central point dominance, average path length and spectral gap.)

El índice Shimbel está vinculado al concepto llamado grado de accesibilidad el cual es una medida de eficiencia en términos de tiempo de desplazamiento que una red de transporte ofrece. Una red de transporte dada sus características estructurales como el trazado geométrico de sus líneas, las velocidades comerciales, la frecuencia de paso, la conectividad entre líneas entre otros aspectos determinará en gran medida los tiempos de desplazamiento que esa red ofrece a los usuarios. Esta propiedad de eficiencia en términos de tiempos de desplazamiento es la que mide el grado de accesibilidad.

Por otro lado, la fricción espacial vinculado al índice deuter mide la eficiencia en términos espaciales de los viajes realizados en la red. Es decir, que tan directos espacialmente son los viajes. Finalmente, la resiliencia de la red lo vincularemos a las siguientes propiedades de red: betweenness centrality, central point dominance, average path length and spectral gap. Estas propiedades se explicarán cada una de ellas a detalle. Sin embargo, en conjunto forman una batería de propiedades que reflejaran el grado de resiliencia que tiene la red de transporte.

La importancia de la medición de estas propiedades de red recae en que la medición de las propiedades estructurales de una red de transporte es otro de los grandes campos de análisis que deberían de estar integrados a la evaluación del desempeño general del sistema de transporte. Dado que la estructura de la red y la tecnología de propulsión determinará en gran medida la eficiencia de la red en los principales ámbitos de rendimiento. Esta vinculación se puede observar en la siguiente figura:

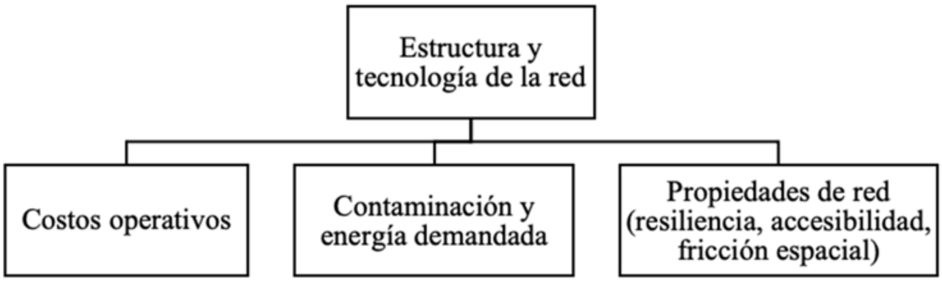

Figura 2: Vinculación entre los principales aspectos a evaluar de una red de transporte con su estructura y tecnología de propulsión

Para la evaluación estructural se tomará como sistema de transporte público la red superficial propuesta por Barraza (2018). Con esta red base se generaron los archivos GTFS (General Transit Feed Spesification) que fungirán como la representación de red del sistema de transporte. Los GTFS son una excelente opción para la representación del sistema de transporte dado los grandes detalles estructurales que otorgan de la red (las paradas, la secuenciación de paradas, el tiempo de traslado entre paradas, la frecuencia, la geometría de las líneas entre otros).

Para realizar una profunda explotación de los GTFS se usaran 2 principales herramientas. La primera es R el cual es un lenguaje de programación de código libre. La segunda es OTP (Open Trip Planner) el cual es una herramienta de motor de búsqueda multimodal. Esta ponencia está dividida en 5 secciones. La sección 1 es la parte de introducción donde se expone de manera general el contenido del trabajo. La sección 2 contempla el objetivo general del trabajo, la sección 3 expone la metodología seguida, sección 4 expone resultados y discusiones y finalmente sección 5 es de conclusiones.

2. OBJETIVOS

El objetivo principal de este trabajo es analizar las propiedades de red del sistema de transporte propuesto para Guadalajara México en lo relativo al grado de accesibilidad, resiliencia y fricción espacial; con la finalidad de tener una evaluación puntual de la eficiencia estructural de dicha red.

3. MATERIALES Y METODOLOGÍA

3.1 Materiales

Para lograr hacer el análisis de redes propuesto es necesario contar con 3 datos fundamentales los cuales son la representación de la red de transporte público en formato GTFS, una zonificación del área de estudio y la red vial de la zona. La siguiente figura muestra la zonificación propuesta para el área de servicio:

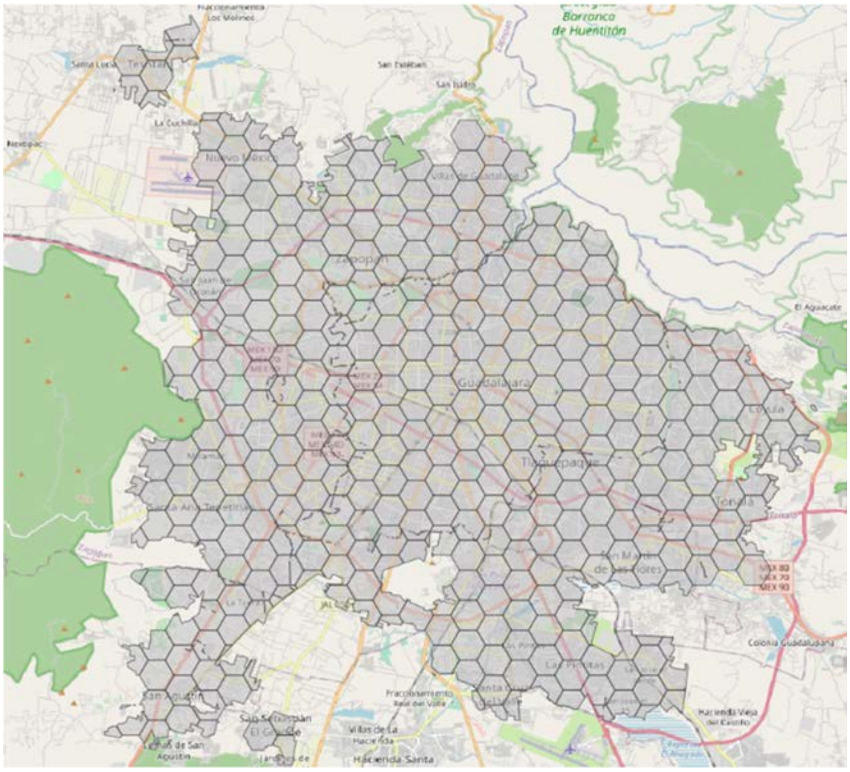

Figura 3: Zonificación propuesta para el área de servicio

La figura 3 muestra la zonificación propuesta para el área de estudio, consta de 398 hexágonos con un diámetro de 670 metros. Adicionalmente, se obtuvo la red vial del área de estudio por medio de OSM. Finalmente, la generación del los GTFS se resumen en los siguientes elementos:

Concepto	**Magnitud**
Stops	1,970
Agency	1
Routes	39
Trips	78
Stop times	4,666
Shapes	4,666
Frecuencies	78

Tabla 1: Resumen de los GTFS

3.2 Descripción conceptual y matemática

En este trabajo se aborda el análisis estructural de tres principales aspectos: accesibilidad, fricción espacial y finalmente resiliencia de la red. Cada una de estas propiedades de red serán descritas en los siguientes puntos:

3.2.1 Grado de accesibilidad

El grado de accesibilidad es una propiedad de red que representa la eficiencia en términos de tiempos de desplazamientos que una red de transporte ofrece. Para generar este indicador se toma como nodo a cada centroide de la zonificación propuesta para posteriormente sacar la suma de los tiempos de traslado de ese nodo hacia el resto de los nodos esto generara una media de tiempo de desplazamiento de dicho nodo (zona del área de servicio al resto de los nodos (el resto de las áreas de servicio). Esto se puede replicar para toda la red y queda expresado en la siguiente ecuación:

$$C(x) = \Sigma_y d(a \dots z)/(N-1) \tag{1}$$

donde:

- C(x): Es el indicador shimbel para el nodo x
- d(x,y): Es el tiempo de viaje entre los nodos a….z
- N: Número total de nodos

3.2.2 Índice Deuter

El índice deuter se vincula con la eficiencia en términos espaciales. Es decir, es una propiedad de red que hace referencia a que tan directos son los viajes en términos espaciales (fricción espacial), para lograr esto se obtienen la distancia euclidiana (distancia en línea recta) de un origen y un destino así como la distancia que sobre la red en tomando la ruta optima. Los orígenes y destinos en este caso son los nodos (centroides de cada área de la zonificación) y la vinculación vía red de transporte público actúan como links. La siguiente ecuación expresa dicho índice:

$$DI = D(S)/D(T) \tag{2}$$

donde:

- DI: Índice deuter
- D(S): Distancia euclidiana entre dos puntos
- D(T): Distancia sobre la red de transporte público

3.2.3 Resiliencia

A diferencia de las propiedades de red presentadas anteriormente la resiliencia (en la literatura vinculado al concepto de hub dependence) puede integrar distanasias propiedades de red descritas en la literatura de teoría de redes. En este trabajo se tomará en consideración 4 propiedades de red que vincularemos a la resiliencia del sistema de transporte. Estas propiedades son: centralidad de intermediación (betweenness centrality), domino del punto central (central point dominance), longitud media del camino (average path length) y brecha espectral (spectral gap).

En el caso de la centralidad de intermediación esta propiedad mide la frecuencia en que un nodo es usado como parte del camino más corto entre otros 2 nodos. En este caso los nodos representarán zonas de la ciudad (creadas como un conjunto de paradas) y las vías de comunicación vía la red de transporte público como nodos. En este sentido esta propiedad puede identificar áreas concretas de la ciudad con altos flujos de viajes óptimos dentro de la red. En caso de que un nodo (un área de la ciudad) tenga una alta frecuencia de uso como puente entre 2 nodos esto significa que cualquier perturbación en esta zona (como puede ser tráfico, manifestaciones, accidentes viales entre otros) afectará en gran medida el rendimiento de una gran cantidad de viajes. La centralidad de intermediación se representa matemáticamente en la siguiente ecuación:

$$C_i = \Sigma_{(j,k)}(b_{ijk}/b_{jk}) \quad (3)$$

donde:

- Ci: Centralidad de intermediación para el nodo i
- bjik: Indica la frecuencia del total de caminos más cortos entre el nodo j y k que va usando el nodo i
- bjk: Representa el número total de rutas más cortas entre el nodo j y k

En el caso del domino del punto central este representa un indicador de la diferencia media entre el nodo con mayor centralidad de intermediación con el resto de los nodos, Yazdani (2011). En este sentido, el domino del punto central es una especial de desviación estándar de centralidad. En caso de que el valor sea alto significa que hay una polarización de centralidad a ciertos nodos lo cual a su vez refleja una red propensa a tener una baja resiliencia. Este indicador se expresa matemáticamente en la siguiente expresión:

$$C_B = 1/(n-1) \cdot \sum_1 (B_{max} - B_i) \qquad (4)$$

donde:

- n: número de nodos
- Bmax: centralidad máxima
- Bi: Centralidad del nodo i

Por otra parte, la longitud media del camino es un indicador de conectividad. Su valor representa la cantidad media de steps (secuencia de paradas) de un nodo al resto de los nodos. Generalmente este valor se expresa integrados todos los nodos de la red por lo que expresa la conectividad de la red completa. Menores valores de la longitud media de camino significan una mayor conectividad pues esto expresa que la red requiere pocas secuencias de nodos (paradas) para realizar los viajes. Este valor será evaluado en 2 escenarios. El primero en un escenario base con todos los nodos funcionando y el segundo escenario se removerán el 10 % de los nodos con mayor centralidad para ver la afectación a la conectividad que esta remoción tuvo. Esta propiedad puede observase en la siguiente expresión:

$$l_g = 1/(n \cdot (n-1)) \cdot \sum_{i \neq j} d(v_i, v_j) \qquad (5)$$

donde:

- lg: Longitud media de camino
- n: Número de nodos
- vi , vj: Caminos cortos entre vi y vj

Finalmente, la brecha espectral $\Delta\lambda$ es la diferencia entre el primer y el segundo autovalor de la matriz adyacente del grafo, Gutiérrez (2011). Esta propiedad proporciona información sobre la robustez de la red. La brecha espectral se usa con el propósito de detectar redes con propiedades de "buena expansión" (aquellas que poseen diseños de conectividad óptimos) y dicho valor debe ser suficientemente grande. Una pequeña brecha espectral probablemente indicaría la presencia de nodos o links que pueden causar serias interrupciones en el flujo de la red cuando remoto, Estrada (2006).

3.3 Metodología y procesos

Los puntos anteriores describieron los conceptos y las matemáticas que describen cada uno de las propiedades de red a evaluar en este trabajo. Sin embargo, el proceso de transformación y uso de GTFS como input de datos para su evaluación será descritos en los siguientes puntos.

3.3.1 Generación de row data y OTP

Los procesos de generación de datos base usados para evaluar las propiedades de accesibilidad y de fricción espacial se generaron a partir del uso de OTP y su integración en R. Ambas herramientas se utilizaron para generar una matriz de viajes N*N en el área de servicio (en transporte público y usando la zonificación presentada anteriormente). Este proceso puede ser resumido en los siguientes puntos:

- Selección del área de estudio
- Creación de la zonificación y generación de centroides
- Vinculación de OTP y R así como el input de datos requeridos (GTFS y vialidades)
- Generación de una matriz de viajes N*N
- Limpieza y procesado de datos
- Generación del grado de accesibilidad y fricción espacial

Los puntos anteriores resumen las etapas para la generación del grado de accesibilidad y la fricción espacial. En la figura 4 se observa el interfaz visual de OTP. OTP es un motor de búsqueda multimodal el cual se puede vincular a R, esta vinculación permite el procesamiento masivo de viajes dentro del área de estudio. Dicho procesamiento masivo de viajes genera una gran cantidad de datos vinculados a estos mismo los cuales fungen como los datos base para análisis más complejos vinculados a la red de transporte. La tabla 1 muestra un extracto de este cuadro de datos generado con el procesamiento masivo de viajes.

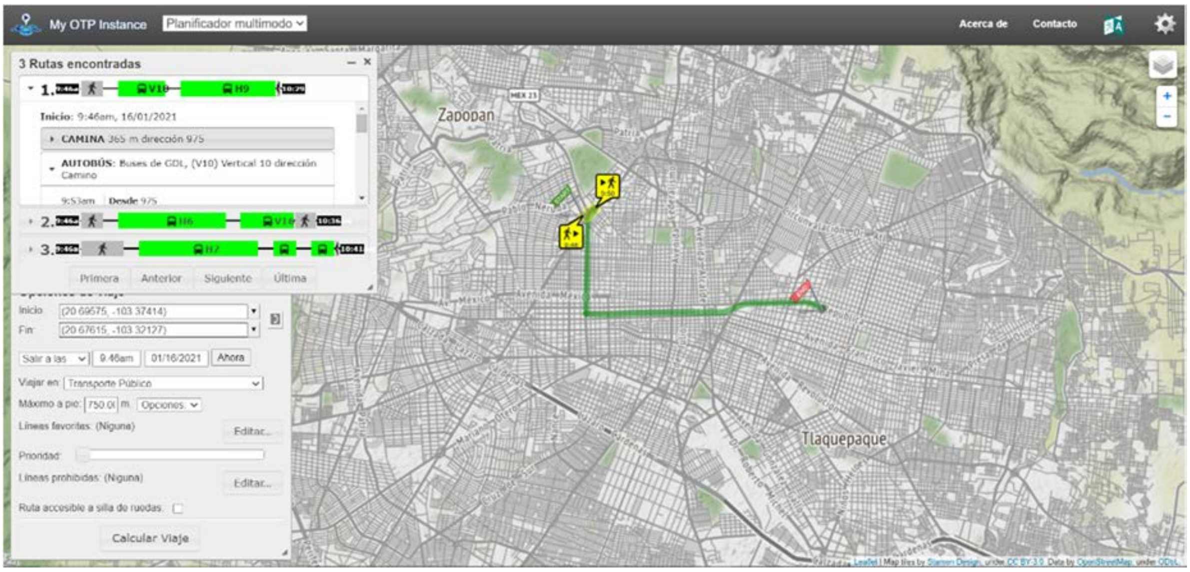

Figura 4: Visualización de OTP

Duration	**Start time**	**End time**	**Walk time**	**Transit time**	**Waiting time**	**Walk distance**
2680 s	14/01/2021 8:24	14/01/2021 9:08	368 s	2132 s	180 s	400 m
Transit distance	**Euclidian distance**	**Transfers**	**Route**	**From place**	**To place**	
12,436 m	9,142 m	0	H4	651	987	

Tabla 2: Datos generados por requerimientos de viajes en OTP

En la tabla 2 se puede observar una muestra del tipo de cuadro de datos que genera OTP vinculándolo con R. Cada requerimiento de información de viaje genera este tipo de datos en los que se puede destacar: distancia del recorrido, tiempo del recorrido, tiempo de espera, distancia caminando entre otros datos importantes vinculados al viaje. Este cuadro de datos será procesado para genera el grado de accesibilidad y la fricción espacial.

Por otra parte, se siguió otro procedimiento para generar las propiedades vinculadas a la resiliencia de la red. Este procedimiento se baso en el trabajo hecho por Pereira (2019). Dicho procedimiento contiene las siguientes etapas:

- Lectura de GTFS
- Unión de archivos
- Unión de paradas cercanas dentro un radio determinado de distancia }
- Actualización de coordenadas dado los clusters de paradas
- Identificación de modalidades de transporte y rutas de cada viaje
- Identificación y generación de links entre paradas
- Cálculo de tiempos de viaje entre paradas
- Remoción de paradas sin conexión de links
- Creación de objeto igraph
- Medición de propiedades de red

El procedimiento descrito anteriormente convierte a los GTFS en un objeto formato igraph el cual ya es sujeto de análisis de propiedades de redes clásica en la literatura de teoría de redes Pereira (2019).

4. RESULTADOS Y DISCUSIÓN

4.1 Grado de accesibilidad

Como se mencionó anteriormente el grado de accesibilidad está vinculado a la propiedad de red del índice Shimbel. Con el procesamiento de los datos obtenidos via OTP y R se generó la siguiente figura donde se muestra la media de tiempo de traslados de cada zonificación en el área de estudio:

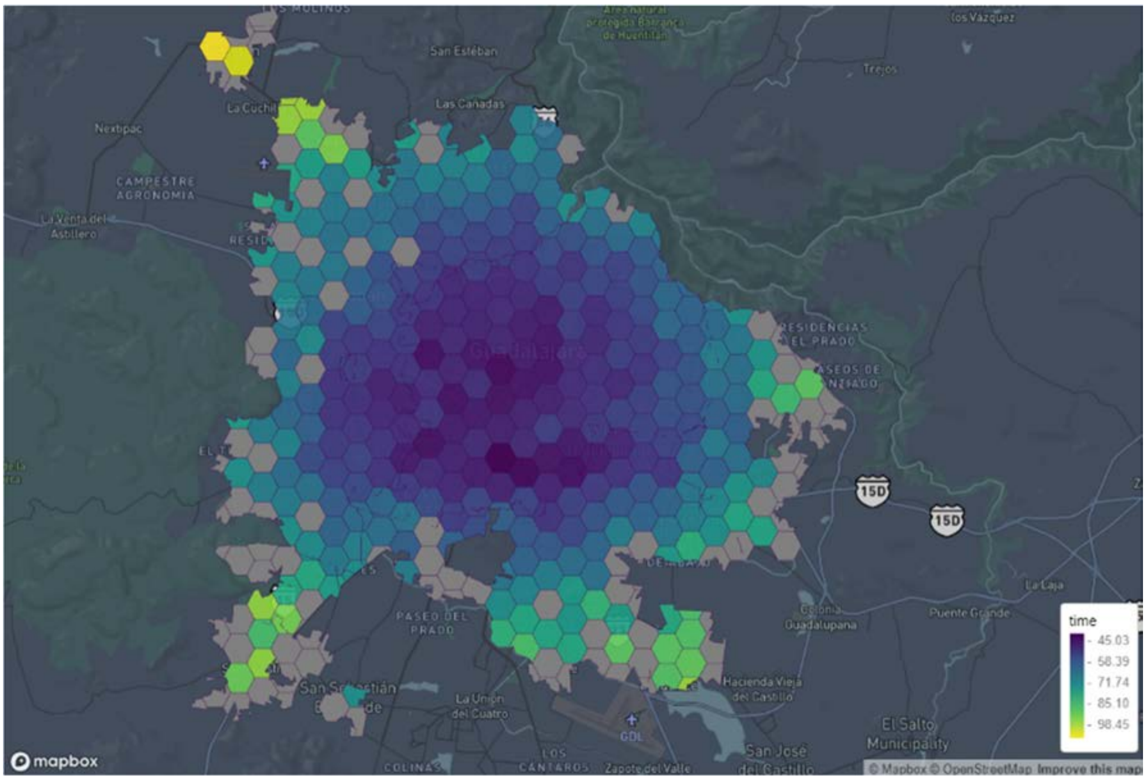

Figura 5: Grado de accesibilidad, red alternativa

La figura 5 muestra el grado de accesibilidad para cada uno de las zonas para el área de servicio. El rango de tiempos medio de traslado varía entre 45 – 98 minutos. Como se puede observar en la figura el centro de la ciudad por su posición geográfica en donde se encuentran menores tiempos de traslado medios en comparación con las periferias que tienen mayores tiempos de traslado. Estos tiempos de traslado no solo están sujetos a la ubicación de cada centroide, sino que en gran medida son afectados por las características geometrías, de frecuencia, de velocidad medias de las unidades, entre otras características estructurales de la red de transporte público. Variaciones en de estas características tendrán un impacto también en los tiempos de traslados de cada zona. Por esta razón el grado de accesibilidad es un indicador muy importante de evaluar de una red a otra. Finalmente, el indicador Shimbel para esta red sería de 66 minutos, esto realmente representaría los tiempos medios de viaje de toda la red.

4.2 Índice Deuter

La fricción espacial está vinculada a la propiedad llamada índice deuter. Con el procesado masivo de los datos obtenidos en la matriz N*N se elaboró la siguiente tabla:

Parámetro	Red alternativa	Unidades
Distancia media sobre la red	18.3	km
Distancia media euclidiana	11.68	km
Índice Deuter	0.63	Adimensional

Tabla 3: Resultados de la fricción espacial

En la tabla 3 se muestra los resultados del análisis sobre la distancia de los viajes generados en el área de servicio. Se puede observar que la distancia media de todos los viajes es de alrededor de 18.3 km, mientras que la distancia euclidiana media de todos los viajes es de 11.68. Esto genera un índice deuter con valor de 0.63. Este es otro indicador de eficiencia en la red de transporte. Redes de transporte con un mayor índice deuter significa que su trazo geométrico permite realizar los viajes más directos en términos espaciales.

4.3 Resiliencia

Como se mencionó anteriormente la resiliencia será abordara por una serie de propiedades las cuales serán indicadores del nivel de vulnerabilidad que tiene la red. Estos indicadores son: betweenness centrality, central point dominance, average path length y spectral gap. La siguiente tabla muestra los resultados vinculados a dichas propiedades:

Parámetros	**Red alternativa**	**Unidades**
Valor más alto de betweenness centrality	566,562	adimensional
Valor medio de betweenness centrality	65,153	adimensional
Valor más bajo del betweenness centrality	0	adimensional
Central point dominance	501,714	adimensional
Valor del Average path length en condiciones normales	40,65	Stops
Valor del Average path length removiendo el 10 % de los nodos más críticos	43,02	Stops
Spectral gap	0,1264	adimensional

Tabla 4: Resultados de propiedades de red vinculados a resiliencia

La table 4 muestra los principales resultados de las propiedades vinculadas a la resiliencia y vulnerabilidad de la red de transporte. En el caso del betweenness centrality la tabla 4 muestra 3 valores los cuales son el valor más alto, valor medio y valor más bajo. Esta propiedad genera una contabilización de la frecuencia en que ese nodo (conjunto de paradas) es utilizado como parte del camino más optimo entre 2 destinos. La contabilización y visualización del betweenness centrality puede generar una apreciación de las zonas más vulnerables de la red dado que perturbaciones de cualquier tipo de estas zonas provocarían afectaciones a una gran cantidad de viajes. En la siguiente figura se observa los valores del betweenness centrality espacialmente:

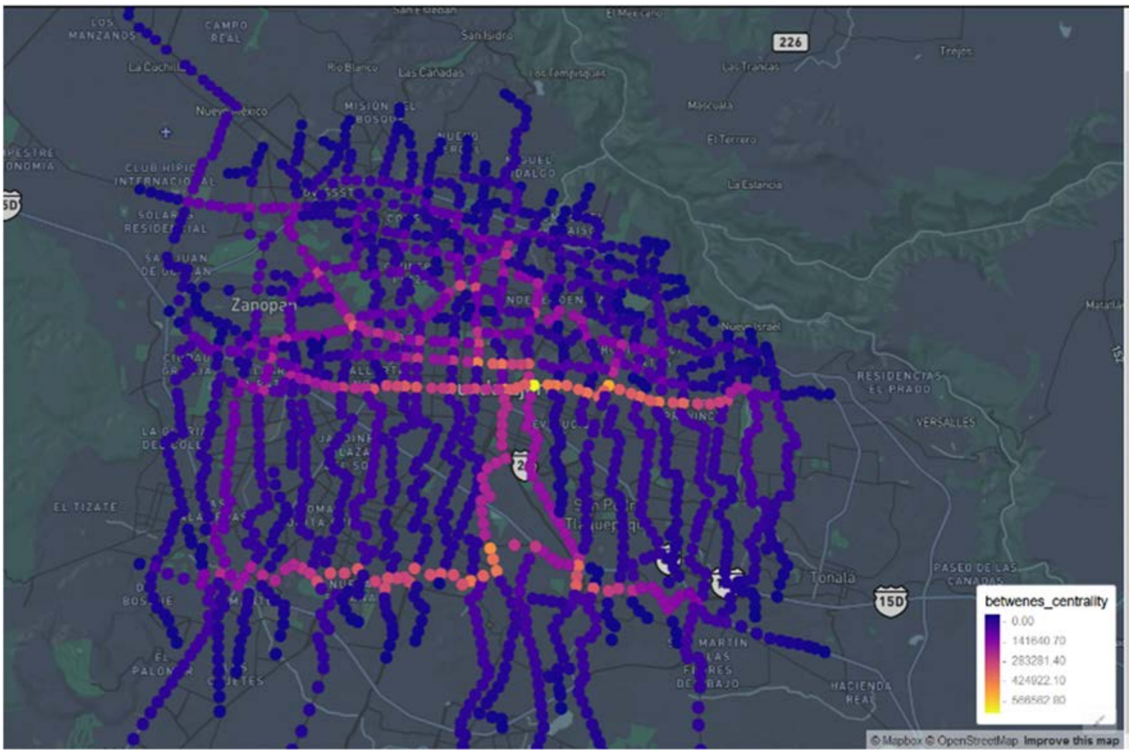

Figura 6: Visualización de los valores de betweenness centrality

Como se muestra en la figura 6 el valor del betweenness centrality en cada nodo varía considerablemente. Existen líneas de transporte con una mayor relevancia en este indicador. Se observa que la parte del centro de la ciudad tiene una especial relevancia. En este sentido los valores del betweenness centrality dan una guía de cuales son las áreas específicas de la ciudad donde se debe de cuidar el funcionamiento optimo de la red para evitar comprometer el rendimiento de gran parte de la red de transporte.

Por otra parte, otro de las propiedades evaluadas es el central point dominance. Como se expresó anteriormente el central point dominance indicar la diferencia media entre el nodo con mayor centralidad y el resto de los nodos por lo que es un indicador del grado de polarización de los valores de centralidad. En este caso el valor obtenido para la red alternativa fue de 501,714 unidades.

En cuanto al average path length, recordemos que este indicador esta vinculado a la conectividad de la red. En el caso del primer escenario el average path length fue de 40.6 stops. Esto quiere decir que la media de paradas efectuadas en todos los viajes posibles en la red es de 40.6 pardas. A medida que disminuye este valor indica una mayor conectividad de la red puesto que se requieren menos paradas para desplazarse a otros nodos (paradas) de la red. En el caso del segundo escenario se eliminó el 10% de los nodos con mayor centralidad o mayor relevancia dentro de la red para ver las afectaciones a la conectividad. En este caso se obtuvo un average path length de 43 paradas lo que representa un decrecimiento en la conectividad del 6.6%.

Finalmente, el valor del spectral gap obtenido es de 0.126. Dentro de la literatura expuesta en Estrada (2006) esto corresponde a un valor bajo que correspondería a una red con bajos grados de robustez. Para tener un mejor panorama este valor tendrá que ser comparado con el de la red operativa actual.

Los resultados de las propiedades presentados anteriormente obedecen a la red alternativa tomada del trabajo de Barraza (2018). Sin embargo, estos resultados tienen limitantes importantes al no estar comparados con la red operativa u otra red propuesta en el area de servicio. Para que los análisis de propiedades de red tengan sentido en el campo de planeación de la movilidad es necesario tener puntos de referencia como las condiciones de la red actualmente operativa u alguna otra propuesta de red de transporte. Desafortunadamente, para este trabajo no se logró tener acceso a los GTFS de la red actual. Este análisis comparativo quedará postergado y se espera que dentro de un par de meses se tenga acceso a los GTFS de la red actual.

5. CONCLUSIONES

El presente trabajo presenta una metodología para la medición de propiedades de red vinculados al rendimiento en términos de tiempo, espaciales y de resiliencia de los sistemas de transporte público. El análisis de las propiedades de red se realizó para la red alternativa superficial propuesta en Barraza 2018. Los resultados presentados fueron generados a partir de un proceso robusta que asegura la veracidad de los resultados. Sin embargo, dentro del trabajo no se cuenta con puntos de referencia es decir con redes de transporte distintas a esta (que puede ser la actual o alguna otra propuesta) por lo que no es posible de dimensionar si el rendimiento en términos de accesibilidad, fricción especial o resiliencia de la red analizada son positivos o negativos.

Este trabajo se plantea extender para poner en contexto esta comparativa entre la red alternativa ya analizada y la red de transporte actual para tener una mejor comprensión de las mejoras o perdidas de rendimiento entre ambas redes. Finalmente, este trabajo sirve como base metodológica para la evaluación de las propiedades de red de sistemas de transporte público.

RESUMEN

Este trabajo propone una metodología flexible para mejorar la caracterización de cada uno de los servicios ofrecidos por un sistema de transporte público, utilizando eventos de llegada de autobuses a nivel de parada y de embarque de pasajeros procedentes de sus sistemas automatizados de localización de vehículos y de cobro de billetes, así como la información del subsistema de planificación si está disponible. Se aplican diferentes técnicas para estructurar, corregir y completar los datos disponibles, con el objetivo de minimizar las distorsiones que aparecen debido a la naturaleza de estas fuentes.

El procedimiento descrito en este trabajo pretende ser adecuado en situaciones con diferente disponibilidad, integridad y fiabilidad de la información. En particular, los inicios de los servicios programados pueden ser conocidos o no, incluyendo opcionalmente qué vehículo había sido asignado inicialmente a la tarea. La información procedente de los diferentes subsistemas que integran un sistema de ayuda a la explotación se combina para crear una caracterización mejor y más útil de los servicios que han tenido lugar en un sistema de transporte.

Los datos del ejemplo de aplicación provienen de los eventos del sistema de ayuda a la explotación en la ciudad de Santander (España) durante un año. Los resultados se discuten con capturas de una herramienta de visualización web interactiva que se ha desarrollado para este trabajo.

1. ESTADO DEL ARTE

Los sistemas de transporte público inteligentes (*IPTS*) están construidos sobre varios subsistemas que se encargan de diferentes tareas, como proporcionar información a los viajeros o trabajadores, gestionar incidencias y eventos especiales, localizar los vehículos, programar, emitir billetes, contar pasajeros, información geográfica, nóminas, mantenimiento, meteorología, satisfacción del cliente o comunicaciones. Si se implantan con éxito, aumentan la calidad del servicio, disminuyen los costes de explotación, mejoran el proceso de toma de decisiones y facilitan la gestión de la flota [de Pablos Heredero et al., 2012].

Dejando a un lado los casos en los que no se dispone de horarios fijos (por ejemplo, las rutas de autobús en Jinan (China), con una gran incertidumbre en los tiempos de viaje, múltiples agencias y un horario de salida que cambia según la demanda observada in situ, donde un estudio empleó redes neuronales artificiales para mejorar la estimación de la llegada de los autobuses en tiempo real basándose en la información del sistema de billetaje automático (AFC) y de la ubicación histórica de los vehículos [Lin et al., 2013]), los datos que describen los servicios de tránsito (es decir, las rutas, sus horarios y la ubicación de las paradas) se publican con antelación. La herramienta más extendida para hacerlo es el componente estático de la especificación general de datos de tránsito (GTFS) [Google]. Sin embargo, aunque se ha propuesto una extensión [MobilityData], este formato aún no puede representar algunos cambios en tiempo real, como la definición de viajes adicionales. Además, es posible que las agencias de transporte no mantengan una recopilación de estos archivos a lo largo del tiempo, aunque en algunos casos pueden obtenerse de terceros (por ejemplo, OVapi [OVapi B.V], Transitland [Mapzen Foundation e Interline Technologies LLC], u OpenMobilityData [MobilityData IO,]).

Además de otras aplicaciones como la identificación de irregularidades en las cabeceras [Gokasar y Cetinel, 2019], la implementación de estrategias de prioridad vehicular más inteligentes [Hounsell y Shrestha, 2012], y la gestión de flotas y operaciones [Saghaei, 2016]; el satélite de navegación global por satélite (GNSS) se utiliza para estimar inicialmente y finalmente identificar la llegada del vehículo a cada punto de interés. Normalmente, ofrece una precisión de 5 m a cielo abierto, aunque hay varios factores que pueden empeorar su precisión [van Diggelen, Frank, Enge, 2015].

Por otro lado, los sistemas AFC tienen como principal objetivo mejorar el proceso de recaudación, pero también proporcionan datos valiosos, especialmente cuando se enriquecen con las posibilidades de seguimiento y caracterización de usuarios de la tecnología de tarjetas inteligentes (SC).

Cuatro aspectos clave caracterizan la información de los IPTS [Furth et al., 2003]: detalle espacial y temporal, cobertura (todos los eventos o sólo los excepcionales), representatividad (penetración de la flota y tasa de recuperación de datos) y calidad.

Los registros a nivel de parada, que pueden almacenarse en el IPTS con un coste incremental bastante bajo, han permitido estimar mejor los indicadores de rendimiento y las métricas de uso anteriormente utilizados (por ejemplo, los tiempos de viaje) [Trépanier et al., 2009], y también evaluar atributos antes casi imposibles de cuantificar debido a la escasez de datos, como los relacionados con la fiabilidad del servicio [Wilson et al., 2009]. Sin embargo, pueden requerir un esfuerzo importante para obtener conclusiones significativas [Ma et al., 2014]. Además, se necesitan herramientas de visualización adecuadas para poder comprender la gran cantidad de resultados que se pueden generar. Bertini y El-Geneidy, 2003].

En la literatura existente se proponen varias distribuciones de probabilidad para caracterizar la variabilidad de los tiempos de viaje de los enlaces [Dai et al., 2019], como la log-normal desplazada, la log-normal, la normal [Qu et al., 2014], la gamma, la de Weibull, la de Burr tipo XII [Taylor y Susilawati, 2012], la de valor extremo generalizado [Chepuri et al., 2018], etc. Numerosos estudios [Harsha et al., 2020, Dai et al., 2019, Li et al., 2017, Srinivasan et al., 2014] eligen la primera, que muestra una densidad de probabilidad de cero cuando el valor de la variable aleatoria cae por debajo de un umbral (que sería el tiempo de viaje del enlace de flujo libre) y puede ajustarse adecuadamente a los datos asimétricos y con sesgo positivo; y que para muchos enlaces es la función que más probablemente describe cómo se distribuyen los tiempos de viaje. Un estudio de 2017 realizado con datos del sistema de posicionamiento global (GPS) de los taxis durante las horas punta de la mañana de 5 días laborables en Wuhan (China) [Chen et al., 2017] descubrió que los tiempos de viaje de los enlaces pueden estar mejor representados por distribuciones logarítmicas normales, gamma o normales (en el 50 %, el 30 % y el 20 % de los enlaces analizados, respectivamente) y optó, para evitar cálculos intrincados desde el punto de vista informático, por asumir que los tiempos de viaje a lo largo de un trayecto pueden aproximarse mediante distribuciones normales.

En cuanto a los tiempos de permanencia, la mayoría de los trabajos sugieren que, debido a su naturaleza no negativa y a su posible asimetría, es probable que la distribución logarítmica normal sea la mejor alternativa (por ejemplo, un estudio de 18 meses de datos de una ruta de autobús en Nueva Jersey, Estados Unidos [Rajbhandari et al., 2003]; 6000 registros de un estudio de un día en Changzhou, China; o un análisis de datos de un mes de autobuses públicos en Jinan, China [Zhang et al., 2019]). Otras distribuciones posibles son la normal, utilizada por el software comercial de microsimulación de tráfico como AIMSUN [Aimsun, 2020] o VISSIM [PTV Group, 2020], y también elegida en algunos trabajos científicos (por ejemplo para caracterizar los datos de 1 día de una parada de autobús en la ciudad de Chennai, India [Koshy y Arasan, 2005]); Wakeby, que superó a la distribución log-normal en un estudio con 3 meses de datos de 4 paradas en Auckland,Nueva Zelanda [RASHIDI y RANJITKAR, 2013]; o Erlang, propuesta en un estudio que analizó 435 registros de 12 paradas de autobús en Shanghái, China [Jiang y Yang, 2014].

Los subsistemas que contribuyen a un IPTS a menudo no captan adecuadamente información que sería útil para un análisis posterior, porque suelen tener otros objetivos: apoyar la planificación táctica y la respuesta de emergencia en el caso del AFC, y gestionar las concesiones para el AFC. En consecuencia, suelen surgir una serie de cuestiones relacionadas con problemas internos de cada conjunto de datos o con incoherencias entre ellos. Los que entran en el ámbito de este trabajo son [Luo et al., 2018]:

- Registros AFC erróneos, que pueden ser causados por fallos de funcionamiento, comportamiento atípico de los viajeros, desvíos de rutas de emergencia o mal manejo de los equipos por parte de los conductores y operadores [Trépanier et al., 2007].
- Entradas erróneas en el sistema de localización automática de los vehículos (*AVL*) debido a fallos del del mismo, operaciones incorrectas del controlador o problemas específicos en las terminales.
- Múltiples registros para el mismo evento AVL, posiblemente con diferentes atributos (marca de tiempo, identificación del vehículo o de la ruta).
- Eventos perdidos.
- Falta de información que vincule los viajes reales con el programa de servicios vigente en ese momento.
- Ausencia de información o información errónea para relacionar los viajes con los desplazamientos de los vehículos.

En algunos casos, estos problemas pueden ser tan graves que los investigadores han desarrollado metodologías que modelan las características del transporte público de forma indirecta, en lugar de utilizar una alternativa más inmediata, pero propensa a errores (por ejemplo, utilizando AVL en lugar de AFC o registros de contadores de pasajeros automatizados para estimar la demanda de transporte público [Moreira-Matías, 2016]).

Hay muchos ejemplos publicados de la aplicación combinada de múltiples sistemas de datos de recogida automatizada en los diferentes aspectos de la gestión y planificación del tránsito urbano. Entre los que utilizan datos de AVL y AFC, algunos ejemplos destacables son:

- Perfiles de carga espaciotemporales de los vehículos de tránsito urbano durante un mes en La Haya (Países Bajos), integrando completamente los registros GTFS como tercera fuente de datos con la información AVL y AFC [Luo et al., 2018].
- Procesamiento fuera de línea de los sistemas de seguimiento automatizado de trenes y de cobro de billetes basados en tarjetas magnéticas de viaje en el área de la bahía de San Francisco (EE.UU.) [Buneman, 1984].

- Estimación de matrices origen-destino (OD) y modelos de elección de ruta para pasajeros de ferrocarril de la Autoridad de Tránsito de Chicago [Wilson et al., 2009].
- Modelización multimodal del propósito del viaje y estimación mejorada de la DO en Queensland (Australia) [Alsger y Eng, 2016].Matrices de OD de metro y autobús, perfiles de velocidad de los vehículos y calidad, indicadores de servicio, etc. para el sistema de transporte público Transantiago en Santiago de Chile [Gschwender et al., 2016]. "Entrevistas de autobús asistidas por el conductor": si los registros de SC están correctamente vinculados con la información de AVL, pueden funcionar como encuestas de preferencias reveladas [Chu et al., 2009].
- Seguimiento de los SC a lo largo del metro y el autobús para identificar el comportamiento de los transbordos en Shenzhen (China), haciendo uso de los registros del AFC del autobús que solo muestran la identificación de la tarjeta y el tiempo de barrido [Huang et al., 2019].

Sin embargo, no hemos encontrado en la literatura existente una metodología que se centre en mejorar la caracterización de los servicios que tienen lugar en un sistema de transporte público de autobuses combinando AFC, AVL, y arranques programados; con el objetivo de trabajar en torno a los problemas comunes de datos de IPTS y, lo suficientemente flexible como para ser aplicado en diferentes situaciones. Esperamos que sea útil para otros investigadores e ingenieros de transporte durante sus actividades; como la auditoría, el modelado del comportamiento de los usuarios o la estimación de los perfiles de carga de los vehículos.

2. METODOLOGÍA

Esta sección comienza especificando las fuentes y la estructura prevista de los datos de entrada. A continuación, se detallan los pasos de preprocesamiento que se aplican a la información AVL, AFC y de planificación; representando cada visita de un autobús a una parada como un único evento de cada fuente. A esto le sigue el análisis de los datos AVL como secuencias que se descomponen en fragmentos de sus respectivas líneas; y la implementación de modelos de distribución de tiempos de viaje de los enlaces y de tiempos de permanencia. A continuación, se lleva a cabo la caracterización inicial de los servicios realizados, que puede mejorarse si es necesario detectando cambios de id de los vehículos a mitad de servicio. A continuación, se vinculan los inicios programados para identificar los servicios planificados y los adicionales, distinguiendo en el primer caso si se utilizó el vehículo previsto o no; y también para mejorar la fidelidad de la recreación. A continuación, se asignan los eventos AFC a las visitas del autobús. Por último, se aceptarán aquellos servicios respaldados por suficiente información del IPTS. La figura 1 muestra un resumen general de todo el proceso.

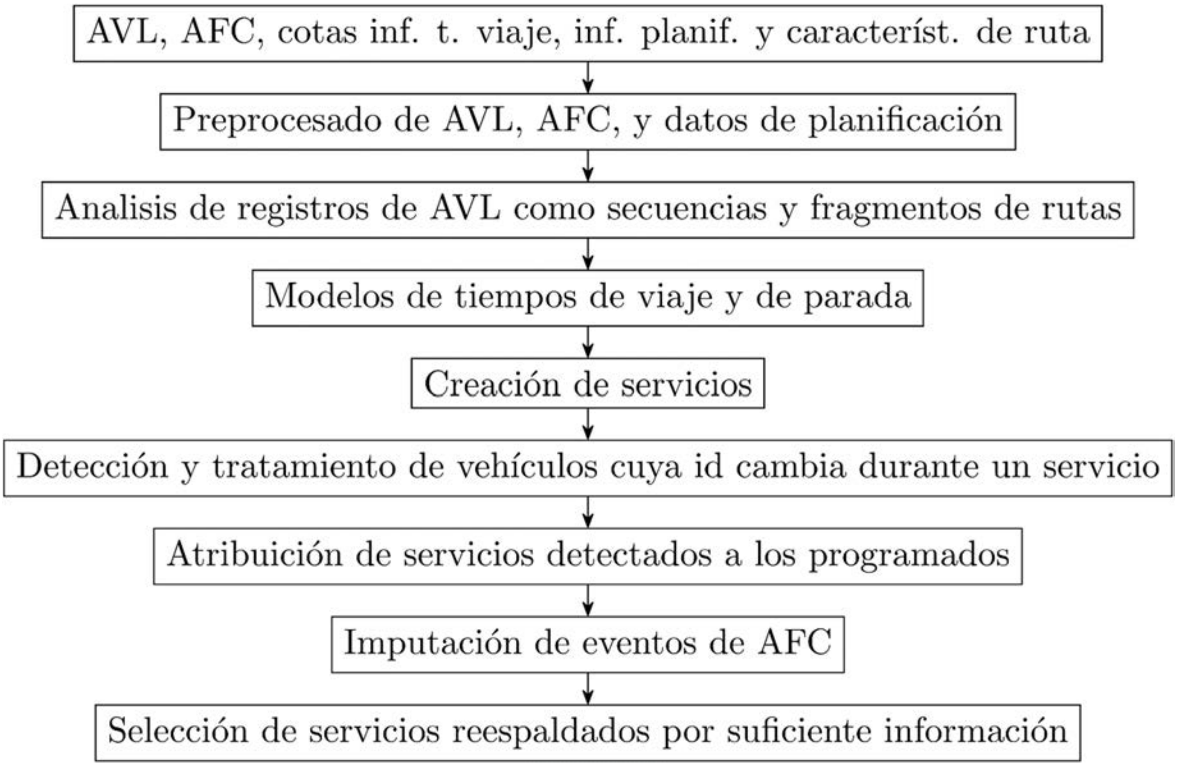

Figura 1: Esquema de la metodología

2.1 Datos de entrada

La Tabla 1 contiene un resumen de la información necesaria sobre las paradas de autobús, AFC, AVL, límites inferiores de los tiempos de viaje y el horario de inicio del servicio. Cabe señalar que los identificadores de las paradas de autobús, las rutas y los vehículos deben ser coherentes en todos los subsistemas. Las columnas llamadas “grupo” en AFC y AVL deben contener un identificador único para cada conjunto de valores presentes en su subsistema particular, que puede ayudar a diferenciar entre los recorridos de un vehículo.

En cuanto al horario, la metodología está diseñada para funcionar incluso cuando está incompleto, o para detectar recorridos de servicios no planificados. En esta sección se asumirá que las tres columnas con información temporal pueden estar disponibles en al menos parte del conjunto de datos.

Columna	*Tipo*	*Descripción*
id	entero	Id del bus en el IPTS.
localización	(real, real)	Coordenadas geográficas.
nombre	texto	Cómo es llamada por los usuarios.

(a) *paradas*

Columna	*Tipo*	*Descripción*
parada_0	entero	Id de la parada inicial.
parada_1	entero	Id de la parada final.
t_fluj_libr	tiempo	Cota inferior del t. necesario para este viaje.

(b) *cotas inferiores de los tiempos de viaje*

Columna	*Tipo*	*Descripción*
parada	entero	Id de la parada.
línea	entero	Id de la línea.
vehículo	entero	Id del vehículo.
t_validac	instante	Momento de validación.
grupo	entero	UID para cada conjunto de valores de otras cols. que varían en diferentes visitas del bus.

(c) *AFC en bruto*

Columna	*Tipo*	*Descripción*
parada	entero	Id de la parada.
línea	entero	Id de la línea.
vehículo	entero	Id de vehículo.
durac_parad	tiempo	Cuánto t. estuvo el bus en la parada.
llegada	instante	Momento de llegada a la parada.
grupo	entero	UID para cada conjunto de valores de otras cols. que diferencien distintas visitas de un bus.

(d) *AVL en bruto*

Columna	*Tipo*	*Descripción*
línea	entero	Id de línea.
vehículo	entero	Id de vehículo.
parada	entero	Id de parada.
comienzo_pl	instante	Instante planificado de inicio.
llegada_reg	instante	Detecc. llegada vehículo a parada inicial.
comienzo_reg	instante	Detecc. comienzo servicio.

(e) *planificación en bruto*

Columna	*Tipo*	*Descripción*
línea	entero	Id de línea.
term_dudos	lógico	Verdadero si AFC y AVL en cabec. poco fiables.
ini_srv_crrct	tiempo	T. medio entre 1^{er} evento AVL y detecc. inicio serv.
sep_max	tiempo	Cota superior entre el paso de dos servicios.
t_prds_max	tiempo	T. viaje máx. entre paradas consecutivas.
t_vuelt_min	tiempo	T. min. para dar una vuelta completa.

(f) *información de las líneas*

Tabla 1: Datos de partida de la metodología

2.2 Preprocesamiento

En esta sección se crean nuevas tablas para los conjuntos de datos AFC y AVL, sintetizando en una sola entrada la información que cada fuente bruta proporciona sobre una visita de autobús. Además, se utilizan límites inferiores de tiempos de viaje para filtrar los datos AVL poco fiables.

2.2.1 AFC

Se supone que no hay filas duplicadas en la información bruta de AFC, ya que debido a las repercusiones monetarias de los datos, la información de los billetes se gestiona de forma muy cuidadosa. Las operaciones de pago con tarjeta inteligente o manuales son atómicas: o se completan con éxito o no se producen.

Como se explicará en detalle en la sección 2.5, la información del AFC (que proporciona un dato por validación) se utiliza para hacer frente a las carencias de los datos del AVL (idealmente, un dato por visita al autobús). Así, el objetivo es clasificar como un único evento de embarque todas las validaciones que se producen cada vez que un autobús hace escala en una parada. El primer y último eventos de emisión de billetes de estos "grupos de embarque" pueden utilizarse como una aproximación de cuándo llegó y salió el autobús de la parada. Para crearlos, se lleva a cabo un proceso de tres partes:

2.2.1.1 Crear grupos de parada

Se analizan los registros en bruto de AFC correspondientes a cada autobús, buscando distinguir grupos de eventos consecutivos referidos a la misma visita a una parada.

id parada	*rango en conj.* -	*rango en subconj.* =	*variable clasiff.*	*grp. parad.*	*instante validación*	*sep. temp.*	*cumple lím. sup.*	*∄ AVL intermedio*	*cambio. grupo embarq.*	*grupo de embarq.*

*: No se encontró una visita intermedia a otra parada en la información AVL
**: Los registros AVL revelan que este vehículo visitó la parada K a las 14:01:51

Tabla 2: Preprocesado de AFC en bruto. Vehículo, línea y UID de grupo permanecen constantes durante este ejemplo.

Este procedimiento se basa en el hecho de que, tal y como se representa en la tabla 2, para un conjunto (en este caso, las entradas del AFC en bruto vinculadas a un único vehículo) en el que se puede utilizar una relación ("ocurrió antes") para establecer una jerarquía sobre todo éste (columna "rango sobre el conjunto") y también sobre los diferentes subconjuntos definidos por una partición (entradas con los mismos valores de *vehículo*, *línea*, *grupo*, e *id de parada*) la diferencia entre el rango sobre el conjunto y sobre un subconjunto particular (la columna "variable de clasificación") proporciona un valor que diferencia los miembros de ese subconjunto que aparecen consecutivamente al ordenar todos los elementos del conjunto (el grupo de paradas, mostrado en la columna "grp. parad."). El significado del resto de las columnas de la tabla 2 y la coloración de las celdas se explicará a medida que se mencione a lo largo del resto de esta descripción del preprocesamiento del AFC. El proceso se explica como tres tareas consecutivas:

2.2.1.1.1 Clasificación por vehículo

Las entradas del AFC se agrupan por vehículo, y luego se obtiene su rango según una ordenación cronológica.

2.2.1.1.2 Clasificación por vehículo, ruta, grupo y parada de autobús

Las entradas AFC se clasifican por vehículo, línea, grupo y parada de autobús; y de nuevo se almacena su rango tras una ordenación cronológica. Estas cuatro columnas de la tabla de datos brutos de AFC permanecen constantes durante todas las validaciones de un evento de embarque concreto.

2.2.1.1.3 Crear grupos de parada

La diferencia de los dos rangos descritos anteriormente, la ‘*variable de clasificación*’, es constante y única para cada grupo de filas que reportan los mismos valores de *vehículo, línea, grupo* y *parada*, y aparecen consecutivamente.

La columna ‘*grupo parada*’ de la tabla 2 muestra el resultado de esta primera aproximación al objetivo de identificar los grupos de embarque; mostrando una sola letra para todas las entradas de avl en bruto consecutivas que forman parte del mismo grupo de parada. La coloración de las columnas ‘*id. de parada*’, ‘*variable clasificación*’ y ‘*grupo de parada*’ ilustra el proceso de clasificación y su resultado. Por ejemplo, las filas correspondientes a las visitas a la parada D se reúnen en dos ‘*grupos de paradas*’, diferenciados por los valores de la ‘variable de clasificación’ de 2 y 5.

Una forma de comprobar cómo ha funcionado esta primera tarea es estudiar la ‘*separación temporal*’ (tabla 2) entre las entradas consecutivas del mismo ‘grupo de paradas’. A medida que este desfase aumenta, es más probable que esta última entrada haya tenido lugar durante una visita diferente del autobús (sin filas intermedias debido a que no se registraron validaciones hasta que el autobús regresó). En la siguiente sección se estudia esta situación.

2.2.1.2 Dividir grupos de parada en grupos de embarque

La cuestión relativa a los desfases temporales excesivos entre algunas de las entradas que forman parte del mismo grupo de paradas se aborda con los siguientes supuestos:

- En algunas ciudades, no es raro que el conductor permita a los pasajeros esperar el inicio de un servicio dentro del autobús, especialmente si hace mal tiempo. Sin embargo, si la separación entre dos entradas consecutivas del mismo grupo de paradas es mayor que el recorrido máximo de la ruta, su grupo se dividirá entre ellas. Esto ocurre en la penúltima fila de la tabla 2: el tiempo transcurrido desde la validación anterior es extremadamente largo (representado con el símbolo '✓' en la columna '*cumple límite superior*'), por lo que se puede estar seguro de que está describiendo un evento de embarque diferente y el grupo se divide, como se ha representado con el cambio de color de naranja a rojo. Un valor adecuado para este parámetro dependerá de las particularidades del caso analizado.
- Para todos los demás pares de entradas consecutivas del mismo grupo de paradas, si la tabla *avl_sintetizado* (definida más adelante durante la descripción del preprocesamiento de los datos AVL) muestra que el autobús visitó otra parada entremedias, pertenecen a grupos de embarque diferentes. Un ejemplo de esta situación se encuentra en la fila con '*rango en conjunto*' = 12 de la tabla 2, donde el grupo de paradas de 5 entradas (G,8) del que forma parte está dividido en dos grupos de embarque (993 y 994); porque, como denota el símbolo '✗' de la columna '*∄ registro AVL intermedio*', entre su marca de tiempo (14:11:11) y la de la entrada anterior (13:53:04) una búsqueda a través de los datos AVL brutos (no representados) ha concluido que el autobús pasó por la parada K a las 14:01:51.

Estas premisas se utilizan para definir la columna '*cambio de grupo de embarque*' de la tabla 2), un valor que será igual a 1 si una fila es la primera de un grupo de embarque, y 0 en los demás casos. Si las filas se ordenan por vehículo, rango cronológico, parada de autobús y cambio de grupo de embarque (de forma descendente), aparecerán consecutivamente si forman parte del mismo grupo de embarque, con un valor de cambio de grupo de 1 para la primera entrada y de 0 para las demás hasta su final. El identificador de grupo de embarque de cada fila es la suma total de todos los cambios de grupo hasta llegar a ella.

Volviendo a la Tabla 2, el contenido y los colores de las celdas de las columnas '*separación temporal*', 'cumple límite superior', '*∄ registro AVL intermedio*', '*cambio de grupo de embarque*' y '*grupo de embarque*', se han elegido para describir cómo se dividen los grupos de parada en grupos de embarque:

- Si una entrada es la primera de su grupo de parada ('*separación temporal*' = <nulo>), también debe comenzar un nuevo grupo de embarque (filas con '*rango sobre el conjunto*' ∈ {1,2,3,5, 6,8,9,45,46,47,49}). '*Cambio de grupo*' es igual a 1, y no es necesario comprobar las columnas '*cumple límite superior*' o '*∄ registro AVL intermedio*'. Para cada una de estas filas, las columnas que intervienen en la identificación de su grupo de parada y grupo de embarque se rellenan con el mismo color, diferente de sus respectivas predecesoras.

- Si el lapso entre dos validaciones sucesivas del mismo '*grupo de parada'* es demasiado largo, son el final y el principio de dos '*grupos de embarque'* diferentes. La última fila muestra el símbolo ✗ en '*cumple límite superior*', mientras que su columna '*∄ registro AVL intermedio*' no es necesaria, y "*cambio de grupo*" es 1. También representa todo su proceso de decisión, utilizando un color para 'id parada', 'parámetro de agrupación' y 'grupo de paradas'; y otro para '*cumple límite superior*' e '*identificación del grupo de embarque*', mostrando cómo se divide cada '*grupo de paradas*' en grupos de embarque.
- Para el resto de pares de filas consecutivas que comparten el mismo '*grupo de parada'*, el símbolo de la columna '*∄ registro AVL intermedio*' indicará si pertenecen al mismo grupo de embarque:

  ✗: El vehículo relacionado con ambas entradas se ha movido a otra parada (y eventualmente ha vuelto) entre ambas lecturas de tiempo, por lo que pertenecen a diferentes grupos de embarque. De nuevo, '*cambio de grupo*'=1, y los colores ilustran el razonamiento de esta decisión: un color para '*grupo de parada*' y el primer '*grupo de embarque'*, y otro diferente para el segundo '*grupo de embarque*' creado por la división.

  ✓: No hay evidencia de que el vehículo se haya movido entre los instantes de ambas entradas, por lo que se concluye que pertenecen al mismo '*grupo de embarque*': '*cambio de grupo*' = 0. Las columnas de la última fila que deciden su '*grupo de parada*' y su '*grupo de embarque*' muestran los mismos colores que en la primera.

Se considerará que los grupos de embarque que duren más que el recorrido máximo para su ruta provienen de datos no fiables, y no se utilizarán para deducir las visitas perdidas a paradas no registradas por el IPTS.

2.2.1.3 Resultado

Los resultados del preprocesamiento del AFC se recogen en grupos_de_embarque, estructurada como se muestra en la tabla 3, mientras que la fig. 2 representa la transición de 15 eventos individuales de emisión de billetes a 4 grupos de embarque que engloban diferentes paradas.

Columna	*Tipo*	*Descripción*
id	entero	Id del grupo de accesos.
parada	entero	Id de la parada.
vehículo	entero	Vehicle id.
línea	entero	Route id.
grupo	entero	AFC group UID.
rang_embarq	rango temp.	[1ª validac., última validac.]

Tabla 3: Resultado del preprocesado de AFC: grupos_de_embarque

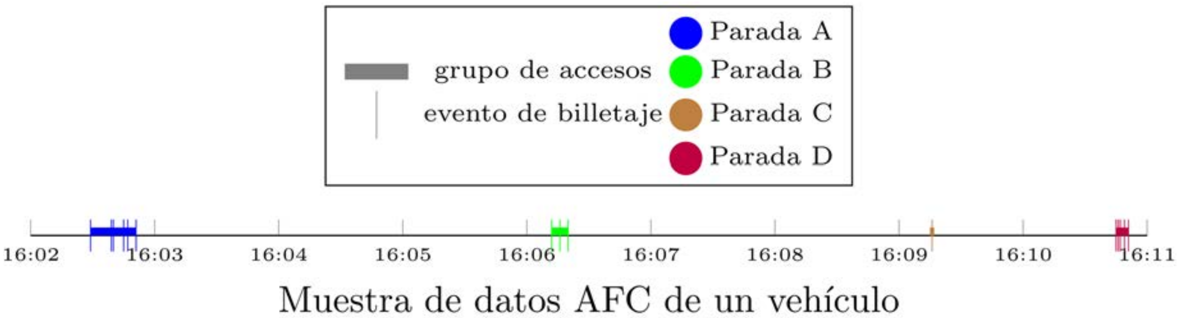

Figura 2: Recolección de eventos de billetaje individuales en grupos de embarque

2.2.2 AVL

Los procedimientos detallados en esta sección tienen como objetivo caracterizar el movimiento de los vehículos con un único registro para cada parada de cada servicio.

2.2.2.1 Eliminar filas duplicadas e inválidas

En primer lugar, se identifican y filtran las entradas duplicadas. Además, se supone que las entradas con un identificador de parada que no se corresponda con uno de los definidos en los datos de entrada (tabla 1-a), están causadas por eventos excepcionales que no corresponden a una llegada a una parada del sistema.

2.2.2.2 Identificar trayectorias

El siguiente paso es utilizar las columnas de los datos AVL para diferenciar las trayectorias que constituyen la oferta de transporte público. Para ello, en este trabajo se define una '*trayectoria*' como una serie de registros AVL consecutivos que comparten los mismos valores de *vehículo, línea* y *grupo*.(tabla 6a)

2.2.2.3 Determinar grupos de visitas

La tabla 4 muestra cómo se examina cada trayectoria para distinguir las ocasiones en las que se añade más de una fila al conjunto de datos para la misma escala en una parada (por ejemplo, cuando se vuelven a abrir las puertas para dejar entrar a un pasajero retrasado en el autobús). El procedimiento para identificar estos '*grupos de visitas'* (calcular los rangos de cada entrada sobre su trayectoria, y entre aquellos registros con los mismos valores de trayectoria y parada; y luego evaluar la variable de clasificación de cada elemento como su resta) es similar al que ya se ha descrito e implementado en 2.2.1.1 para encontrar *grupos de paradas* en los datos AFC.

Parada	*Rango cronológico en trajectoria*	-	*Rango cronológico en (traject., parada)*	=	*Número del grupo de visita*	*Parada*
A	1	-	1	=	0	A
B	2	-	1	=	1	B
C	3	-	1	=	2	C
C	4	-	2	=	2	
D	5	-	1	=	4	D
E	6	-	1	=	5	E
C	7	-	3	=	4	C
F	8	-	1	=	7	F
...						

Tabla 4: Cómo se identifican los eventos de AVL vinculados a una única visita

2.2.2.4 Combinar los eventos de cada grupo de visitas

La información correspondiente a cada grupo de visita se resume en la tabla avl sintetizado (tabla 5), que incluye el instante más temprano y más tardío en el que según el AVL el bus estuvo en la parada.

instante	*duración*	*parada*
...		
12:50:29	0	151
12:51:11	19	135
12:51:18	198	135
12:51:47	<null>	135
12:55:07	14	134
...		

(a) *avl*

llegada	*salida*	*parada*
...		
12:50:29	12:50:29	151
12:51:11	12:54:36	135
12:55:07	12:55:21	134
...		

(b) *avl_sintetizado*

Tabla 5: Combinación de múltiples eventos AVL en una visita a la parada

2.2.2.5 Identificar y descartar desplazamientos entre paradas no plausibles

Considerando cada trayectoria como una serie de tramos de viaje entre sus grupos de visitas, no son posibles aquellos más cortos que el tiempo de viaje en flujo libre entre las paradas implicadas. Se dan dos situaciones posibles:

- Al retrasar la hora de salida en la parada anterior, aumentando así la longitud del tramo, se resuelve el problema. Esto equivale a suponer que la información sobre el tiempo que el autobús permaneció en la parada inicial del tramo no es fiable.
- Ni siquiera poniendo a cero el tiempo de permanencia en la primera parada hay tiempo suficiente para viajar a la segunda. En este caso, ambos grupos de visitas se considerarán poco fiables y se eliminarán.

Además, los tramos de viaje más largos que el límite superior establecido para su ruta (tabla 1f) se utilizarán para dividir sus trayectorias. Así, las entradas de AVL que presenten el mismo vehículo, ruta y grupo, pero separadas por un tramo de viaje demasiado largo para haber ocurrido durante un único servicio, se considerarán por separado.

2.2.2.6 Resultado

La tabla 6 muestra cómo se almacena el resultado del preprocesamiento AVL en las tablas *trayectorias* y *avl_sintetizado*.

Columna	*Tipo*	*Descripción*
id	entero	Id de la visita.
línea	entero	Id de línea.
vehículo	entero	Id vehículo.
group	entero	UID del grupo (AVL).

(b) *avl_sintetizado*

Tabla 6: Resultado del preprocesado de AVL

2.2.3 Planificación

En primer lugar, los eventos registrados en el subsistema de programación deben ser corregidos por el valor apropiado de ini_srv_crrct (tabla 1f, representado por *s* en la formulación de esta sección), si está definido para la ruta correspondiente.

A continuación, se crea un intervalo de tiempo *n* para cada servicio planificado, que engloba las horas de llegada y salida que pueden deducirse de las columnas más específicas disponibles, siempre que proporcionen una información coherente (por ejemplo: las salidas no pueden producirse antes que las llegadas). También se crea otro buffer de tiempo *q* en torno a su hora de inicio prevista t_p, con un semi-ancho igual al a la separación máxima entre servicios (tabla 1f, *s* en esta sección). Este intervalo se utilizará en la sección 3.7 para vincular cada entrada del horario con el servicio que lo materializa. Las ecuaciones (1) y (2) enuncian respectivamente el parámetro y las variables, y detallan las condiciones que se acaban de describir; mientras que la tabla 7 muestra la estructura de la información de planificación tras el preprocesamiento.

$$n = \left[[t_a, t_d]\ if\ t_a \leq t_d\right], \left[[t_p, t_d]\ if\ (t_a > t_d \vee \nexists t_a) \wedge t_p \leq t_d\right], \left[[t_d, t_d]\ if\ (t_a > t_d \vee \nexists t_a) \wedge t_p > t_d\right], [< null > en\ otro\ caso]] \quad (1)$$

$$q = [t_d - s, t_d + s] \quad (2)$$

donde:

- tp: t. salida programado instante
- td: t. salida registrado instante
- ta: t. llegada bus registrado instante
- n: rango t. del subsist. De planif. [t. llegada, t. salida]
- q: búfer de búsqueda [cota t. inf., cota t. sup.]

Columna	*Tipo*	*Descripción*
id	entero	Id inicio serv.
parada	entero	Id parada.
vehicle	entero	Vehicle id.

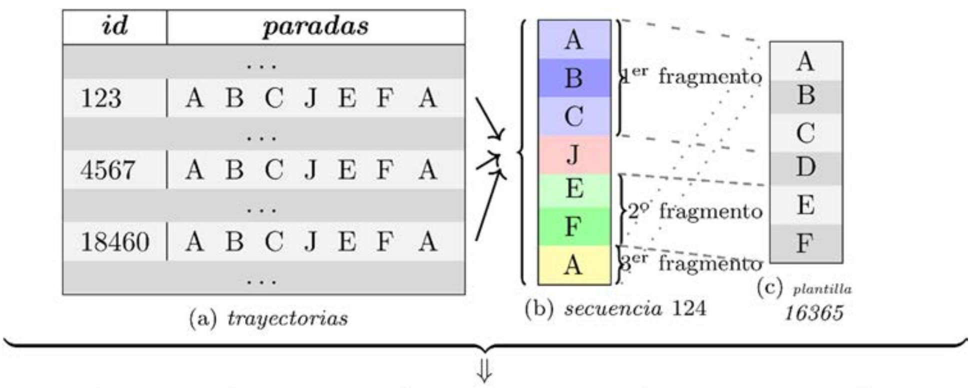
rango_planif	rango t.	[llegada, salida] de subs. planif.

Tabla 7: Resultado del preproceso de la planificación en bruto´

2.3 Analizar las trayectorias de la AVL como secuencias y fragmentos de rutas

Las trayectorias de AVL se analizan como secuencias ordenadas de paradas, que serán los bloques de construcción para ensamblar los servicios completos que se han producido, definidos por aquellas secuencias elegidas como ‘plantillas’.



Ordin. en sec.	*Ordin. en plantilla (núm. parada)*	*Longitud*	*Id sub-secuenc.*	*Id secuenc.*	*Plantilla*
...					
1	1	3	1	124	16365
5	4	2	2	124	16365
7	1	1	3	124	16365
...

plantilla	entero	Id plantilla.

(c) *fragmentos*

Tabla 9: Resultado del análisis de las secuencias de AVL

La tabla 8 ilustra este proceso, y la 9 recoge los resultados de sus tres pasos.

2.3.1 Identificar distintas secuencias de trayectorias de la AVL

Se asigna un identificador a cada secuencia de paradas única extraída de las trayectorias de cada ruta, como se muestra en las tablas 8a, 8b y 9a. Esta relación se almacena en campo ‘*secuencia de paradas*’ de la tabla de trayectorias.

2.3.2 Encontrar las secuencias a utilizar como plantillas

Esta metodología parte de la base de que cada línea puede dividirse en una serie de ‘sublíneas’ que representan los servicios que la componen (por ejemplo, los viajes de ida y vuelta entre los terminales; o un único viaje de ida y vuelta en el caso de las rutas circulares). Cada sublínea se caracteriza por su ‘plantilla’ de secuencia de paradas (tabla 8c) que debe seguir un recorrido típico, completo y perfectamente registrado de esa sublínea. Estas plantillas pueden conocerse de antemano, o averiguarse mediante el examen de las secuencias de paradas encontradas durante su paso anterior, y sus frecuencias relativas, ya que las plantillas estarán muy probablemente entre las que se encuentran más a menudo. Se almacenan como se ilustra en la tabla 9b.

2.3.3 Descomponer las secuencias en fragmentos de plantilla

Como se muestra en las tablas 8b a 8d, las secuencias seguidas por las trayectorias pueden dividirse en:

- Fragmentos continuos de las plantillas de su ruta (es decir, no faltan elementos entre sus extremos), que representan partes de servicios que el sistema AVL logró registrar correctamente. Permiten ver cada trayectoria encontrada en los datos AVL como una serie de segmentos que se ajustan a su plantilla. El cuadro 9c muestra cómo se almacenan.

- Porciones incompatibles (causadas por entradas erróneas en el subsistema AVL; el vehículo que realiza otra ruta secundaria; u operaciones incorrectas, por ejemplo, no actualizar el ordenador de a bordo para reflejar que el autobús sigue una ruta diferente).

2.4 Elegir los modelos de distribución de los tiempos de recorrido y de parada

Estos modelos se utilizan como parte de los criterios para identificar los fragmentos de AVL o los grupos de embarque que forman parte del mismo servicio; para inferir la información de las paradas que faltan; y para filtrar los tiempos de inicio de servicio registrados erróneamente. Para cada ruta, se necesitarán los tiempos de viaje de los enlaces entre las paradas consecutivas y los tiempos de permanencia de todas ellas menos la última.

Deben tener en cuenta los factores conocidos que modifican los tiempos de desplazamiento y permanencia en la zona de estudio, como la hora, si es un día laborable o no, o los cambios de movilidad estacionales.

2.5 Ensamblar los servicios

Los servicios se construyen partiendo de una 'semilla' que se completa hacia atrás y hacia delante en el tiempo, buscando segmentos de AVL y eventos de grupos de embarque que formen parte de la misma sublínea y con el mismo identificador de vehículo que la semilla que, según el instante del punto de datos conocido más lejano en la dirección de crecimiento actual y las distribuciones de probabilidad de la duración de los tramos intermedios desconocidos del viaje y las llamadas en las paradas, caen dentro del intervalo de predicción de amplitud mínima de probabilidad $\boldsymbol{g}$.

'$\boldsymbol{g}$' es un parámetro de esta metodología (ecuación 3). Cuanto más se acerque a uno, más exhaustiva será la búsqueda, y aumenta el riesgo de considerar eventos no válidos o no relacionados como parte de los servicios actuales. Sin embargo, si se fija demasiado bajo, pueden ignorarse eventos que realmente formaban parte del servicio que se está caracterizando.

$$g: probabilidad\ del\ intervalo\ de\ predicción \quad g \in [0,1] \tag{3}$$

Para cada sublínea y dirección (hacia atrás o hacia delante en el tiempo), las semillas se seleccionan siguiendo dos procesos iterativos consecutivos. En primer lugar, haciendo un bucle sobre los fragmentos de AVL con una longitud mínima $\boldsymbol{c}$, de mayor a menor. '$\boldsymbol{c}$' es el parámetro "**longitud mínima de las semillas AVL**" (ecuación 4). Esta decisión parte de la hipótesis de que los fragmentos de trayectoria AVL más largos tienen más probabilidades de ser fiables, mientras que los más cortos pueden deberse a errores de reloj, GPS o de funcionamiento. A continuación, los grupos de embarque no filtrados se utilizarán también como semillas. El algoritmo omitirá aquellas semillas contenidas en la tabla de eventos a ignorar (explicada en el último párrafo de esta sección).

$$c: Long.\,mín.\,de\ la\ semilla\ AVL \quad c \in \mathbb{N} - \{0\} \tag{4}$$

Una vez que se ha establecido una semilla, ésta "crece" tanto hacia atrás como hacia adelante, siguiendo un procedimiento que se asemeja al de la navegación por estima: partiendo del punto más lejano conocido en una dirección (el punto fijo inicial), se calculan intervalos de predicción de amplitud mínima de probabilidad ***g*** para las salidas o llegadas (si se recorre hacia atrás o hacia adelante, respectivamente) de las escalas en paradas consecutivamente más lejanas, como la suma de los tiempos de viaje y de parada de las paradas intermedias implicadas, hasta que se alcanza una de las siguientes condiciones (comprobadas en este orden) y se selecciona un nuevo punto fijo:

- El intervalo de predicción interseca el *rango_avl* de al menos un registro de la tabla *avl_sintetizado*. En este caso, se escoge el rango de horas de llegada y salida más cercano al más probable, y se identifica una porción del fragmento que lo engloba, para añadirlo al nuevo servicio en crecimiento, desde este registro hasta lo que se encuentre primero entre:

    - La penúltima o segunda parada de la ruta, mientras crece hacia adelante o hacia atrás, respectivamente.
    - El final de su fragmento en la dirección de crecimiento actual.

  Esta distinción tiene como objetivo, por un lado, ahorrar tiempo de computación, al sumar en un solo paso varias escalas del vehículo; y por otro, asegurar que siempre se calcule un rango de viabilidad en los terminales. Estos rangos, además de utilizarse como parte del proceso actual, para filtrar las entradas irreales del IPTS en esas paradas, se emplearán para decidir la mejor manera de incluir la información disponible de planificación.
- El intervalo de predicción se solapa con el rango de embarque de al menos un grupo de embarque compatible. Se elige el intervalo más cercano a las horas de llegada y salida más probables.
- Si la parada analizada es una terminal, se elige la llegada (o la salida, si se hace crecer el servicio hacia atrás) y el tiempo de permanencia más probables.

En la primera o en la segunda condición, "compatible" significa que se refiere a la misma ruta y al mismo vehículo que la semilla; y que no está en la tabla de eventos a ignorar (explicada en el último párrafo de esta sección). Si aparece más de una posibilidad, se selecciona la más probable según las distribuciones de tiempo de viaje y tiempo de parada.

En los tres casos, una vez seleccionado el nuevo punto fijo, el conjunto de valores más probables para los tiempos de viaje y los tiempos de permanencia del enlace se utilizará para inferir los tiempos de llegada y salida en las paradas intermedias que falten.

Después de llegar a una terminal, el crecimiento en la dirección actual termina. Para aquellas rutas en las que los datos en éstas se han considerado especialmente poco fiables (*term_dudos* = verdadero en la tabla 1f), si la llamada en la parada más cercana está respaldada por los datos de AVL o AFC, siempre se inferirán las horas de llegada y salida.

Una vez que una semilla ha crecido hasta abarcar un servicio completo, tal y como se describe en su plantilla; se crea un buffer que la engloba, extendiéndose hacia atrás y hacia delante en el tiempo desde la respectiva llegada y salida de cada llamada, añadiendo el límite inferior de tiempo de ida y vuelta para la ruta correspondiente (*t_vuelt_min*, tabla 1f). Los segmentos de AVL y los grupos de embarque con los que se superponga se añaden a las tablas de elementos a ignorar durante el resto del proceso de ensamblaje del servicio. Esto sirve para dos propósitos: hacer que ningún evento sea utilizado como parte de más de un servicio; y que los vehículos sigan itinerarios factibles (que pase suficiente tiempo antes de que vuelvan a la misma parada, como parte de otro servicio).

La figura 4 muestra un diagrama de flujo de la primera parte de este proceso, que utiliza segmentos de datos AVL como semillas. La segunda parte es completamente análoga, pero sólo se utiliza la información restante del AFC. La figura 3 ilustra un ejemplo completo, en el que los principales pasos son:

- (1): La semilla inicial es un segmento AVL que va desde la llegada a las :20:13 a AB, hasta la salida a las :22:41 de AE.
- (2): Ésta crece hacia atrás, utilizando el intervalo de búsqueda [:18:51, :19:53] en el punto final AA. Se ha definido fijando la llegada a AB como punto fijo, y calculando el intervalo de predicción con probabilidad ***g*** para la presencia del vehículo en AA.
- (3): Se encuentra un único evento AVL compatible y superpuesto (3a), con horas de llegada y salida :18:31 y :18:55, respectivamente:

    - Si las lecturas en los terminales de esta ruta se han considerado tan fiables como en otras paradas (y = falso), se aceptará (3a) como la llamada del autobús en el terminal inicial.
    - En caso contrario, dado que el punto fijo del que parte la búsqueda se encuentra en la parada próxima al terminal (3c), se preferirá la visita inferida 3b, de :19:15 a :19:46.

Al ser uno de los extremos de la ruta, el crecimiento hacia atrás termina.

- (4): A medida que se avanza, se calcula el intervalo de búsqueda que se utilizará en AF, utilizando como referencia fija la hora de salida de AE (:22:41). El resultado es el intervalo de predicción de probabilidad g de la presencia del autobús en AF: [:23:04, :24:05], que no cruza ninguna entrada compatible de los subsistemas AVL o AFC.
- (5): Se sigue buscando hacia adelante. En AG, se crea otro intervalo de predicción con probabilidad ***g*** para la llegada del autobús. Esta vez, se necesitará la suma de las distribuciones individuales de los tiempos de viaje de AE a AF, y de AF a AG; y del tiempo de parada en AF. El rango resultante ([:23:17, :24:57]) se solapa con un grupo de embarque ([:23:55, :23:59]). Sus eventos de embarque más tempranos y más tardíos se utilizarán como aproximación a la llegada y salida en AG.
- (6): Considerando ahora el intervalo de 1m14s entre la salida del autobús de AE a las :22:41, y la llegada a AG a las :23:55; la combinación más probable de los tiempos de viaje de AE a AF y de AF a AG; y del tiempo de parada en AF es, según sus respectivas distribuciones probabilísticas, 45s, 26s y 3s; respectivamente. Así, los tiempos de llegada y salida en AF se fijan en [:23:26, :23:29].
- (7): De nuevo, la búsqueda se realiza en la parada H. Esta vez, se encuentra una entrada AVL compatible. Ésta y otras tres del mismo fragmento se añaden al servicio.
- (8): Hubo que deducir varias paradas intermedias entre la salida de AK y la llegada y AR. Las horas de llegada y salida que faltan se fijarán en sus valores más probables, de acuerdo con las 7 distribuciones de tiempo de viaje y 6 de tiempo de permanencia implicadas.
- (9): Por último, se llega al otro extremo de la ruta. Dado que no se encuentra ningún AVL o AFC compatible, la llegada a esta parada; así como las llegadas y salidas a otras posteriores a la última salida conocida, si la hay; se fijan en sus valores medios.

El resultado después de utilizar todos los datos de AVL y AFC (tabla 10) es el resultado de esta metodología, y consiste en tres tablas:

- *servicios*, que sintetiza cada uno de los servicios que han sido detectados por esta metodología.
- *visitas_a_paradas*, que caracteriza a cada servicio.
- *rangos_búsqueda*, donde se guardan los intervalos de predicción utilizados durante la creación de los servicios.

Columna	*Tipo*	*Descripción*
vehículo	entero	Id vehículo.
id	entero	Id servicio.
serv_comb	entero	Id del serv. que lo engloba (si es aplic.).
plantilla	entero	Id. plantilla
comienz_prog	entero	Id del inicio planeado (si es aplic.).

Figura 4: Proceso de inferencia de un servicio a partir de una semilla AVL

2.6 (Opcional) detectar y fusionar los casos en los que un vehículo ha cambiado su id a mitad de servicio

Algunos de los servicios del caso presentado en la siguiente sección de este trabajo varían su identificación de vehículo a mitad de servicio una vez. Pueden detectarse en esta metodología como dos servicios, uno 'anterior' y otro 'posterior', extremadamente cercanos en el tiempo; en los que un único vehículo podría haber proporcionado todas las visitas no inferidas a las paradas. Esta sección sigue la nomenclatura descrita en (5).

[$\emptyset, \lambda$:ids de servs. ant. y post. con $\emptyset, \lambda \in \mathbb{Z}$], [$C$:relación deben combinarse con $C = \{(\emptyset, \lambda) / \emptyset, \lambda$ son el mismo serv.$\}$], [T:instantes. son los posibles instantes],
[R:rangos t. con $R = \{(\rho[0], \rho[1]) \in T^2, \rho[0] \leq \rho[1]\}$],
[&&:relación "se superponen" con $\&\& = \{\rho_i, \rho_j\}, \rho_j[0] \leq \rho_i[1] \leq \rho_j[1] \vee \rho_j[0] \leq \rho_i[0] \leq \rho_j[1] \vee \rho_i[0] < \rho_j[0] \wedge \rho_i[1] > \rho_j[1]$], [$\sigma_i$:rango del serv. i-ésimo con $\sigma =$ (comienzo, fin) $\in R$], [$\upsilon_{i,j}$: visit range for service i at stop j con $\upsilon =$ (llegada, salida) $\in R$], [$\in_{i,j}$: rango de búsqueda del servicio i en parada j con $\in =$ (cota inf., cota sup.) $\in R$], [τ: núm. parada con $\tau \in \mathbb{N}$], [$\sigma\mu_i$:cota inf. del t. viaje entre paradas i e $i+1$] (5)

Para corregir este problema, los autores proponen el siguiente procedimiento que se debe llevar a cabo para cada secuencia utilizada como plantilla de servicios

2.6.1 Identificar los pares de servicios que deben combinarse

- Para ahorrar tiempo de cálculo, sólo se considerarán aquellos servicios que presenten solapamiento entre sus correspondientes rangos de servicio:

$$\emptyset C \lambda \Longrightarrow \sigma_{\emptyset} \&\& \sigma_{\lambda} \quad (6)$$

- Además, para cada escala de cada servicio en una parada, se crea un buffer de tiempo, como el más pequeño que incluye su rango de visita y, si existe, su rango de búsqueda. Se considera que dos servicios se suceden lo suficientemente cerca como para ser candidatos viables cuando sus buffers de tiempo se solapan.

$$\emptyset C \lambda \Longrightarrow \exists \tau, \upsilon_{\emptyset,\tau} \&\& \upsilon_{\lambda,\tau} \vee \in_{\emptyset,\tau} \&\& \in_{\lambda,\tau} \vee \upsilon_{\emptyset,\tau} \&\& \in_{\lambda,\tau} \vee \in_{\emptyset,\tau} \&\& \in_{\lambda,\tau} \quad (7)$$

- Por último, debe ser posible, teniendo en cuenta los límites inferiores de los tiempos de viaje entre paradas, que un solo autobús realice todas las entradas de visitas a paradas de ambos servicios que se desprenden de los datos del IPTS. El cumplimiento de esta condición depende del número de parada más alto para el que el servicio 'anterior' presenta una entrada de visitas a paradas no inferida (τ_{φ}); y, correspondientemente, del más bajo del 'posterior' (τ_{λ}):

- Si $\tau_\varphi = \tau_\lambda = \tau$, ambos representan la misma parada, en la que el IPTS tiene registros con los identificadores de los vehículos antiguos y nuevos. En dicha parada se calculan los siguientes rangos de tiempo:

  - Un "intervalo de viabilidad" $\zeta_{\varphi,\lambda}$ que delimita el lapso de tiempo en el que es posible que el autobús haya llegado tras salir de la $(\tau\text{-}1)^{\text{ésima}}$ parada, como se describe en el servicio ‘anterior’ φ, y aun así llegue a la $(\tau +1)^{\text{ésima}}$ del ‘posterior’ λ, teniendo en cuenta los límites mínimos de las duraciones de los tramos de viaje implicados:

$$\xi_{\emptyset,\lambda} \in R;\ \xi_{\emptyset,\lambda} = (\upsilon_{\emptyset,(\tau-1)}[1] + \mu_{(\tau-1)}, \upsilon_{\lambda,(\tau+1)}[0] - \mu_\tau) \tag{8}$$

  - Un "rango de presencia de bus" $\eta_{\varphi,\lambda}$, que es el rango de mínimo-ancho que engloba a los de los servicios ‘anterior’ y ‘posterior’:

$$\eta_{\emptyset,\lambda} \in R;\ \eta_{\emptyset,\lambda} = (min(\upsilon_{\emptyset,\tau}[0], \upsilon_{\lambda,\tau}[0]), max(\upsilon_{\emptyset,\tau}[01], \upsilon_{\lambda,\tau}[1]) \tag{9}$$

  La condición se cumple si estos dos rangos se superponen:

$$\emptyset C\lambda \wedge \tau_\emptyset = \tau_\lambda \Longrightarrow \xi_{\emptyset,\lambda} \&\& \eta_{\emptyset,\lambda} \tag{10}$$

- Si $\tau_\varphi < \tau_\lambda$, el lapso entre la salida registrada del primer servicio desde la parada τ_φ y la llegada registrada del segundo a τ_λ debe ser mayor o igual que el límite inferior del tiempo total de viaje entre ellos.
- Si $\tau_\varphi > \tau_\lambda$, los dos servicios candidatos no proceden de uno solo que haya cambiado su id.

La ecuación (11) resume estos criterios:

$$\emptyset C\lambda \Leftrightarrow \{[\xi_{\emptyset,\lambda} \&\& \eta_{\emptyset,\lambda}\ if\ \tau_\emptyset = \tau_\lambda], [\upsilon_{\lambda,\tau_\lambda}[0] - \upsilon_{\emptyset,\tau_\emptyset}[1] \leq \sum_{\tau=\tau_\lambda}^{\tau_\emptyset - 1} \mu_i\ \ if\ \tau_\emptyset < \tau_\lambda\} \tag{11}$$

2.6.2 Actualizar las tablas de caracterización de los servicios

Los servicios que cumplen las ecuaciones. (6), (7) y (11) se fusionan en uno nuevo. Las horas de llegada y salida de cualquier parada entre τ_φ y τ_λ se elegirán como las más probables, según las distribuciones de tiempo de permanencia y de viaje; y la información para relacionarlos se almacena en las columnas serv_comb y servs_comb. de la tabla 10a.

La figura 5 ilustra un ejemplo, en el que la metodología detecta que las entradas que en una primera aproximación se utilizaron para afirmar que dos servicios diferentes de una ruta entre las paradas AR y BJ tuvieron lugar (azul y naranja) son en realidad parte de uno solo, y entonces reevaluar las llamadas desconocidas en las que este hecho puede ser utilizado para mejorar las estimaciones de llegada y salida:

- El estado de los dos servicios propuestos por el apartado 2.5 de esta metodología cumple con las condiciones que los identifican como uno solo, con un cambio de id de vehículo intermedio:

    - Sus buffers temporales se solapan en al menos una parada, como puede verse observando las partes coloreadas en azul y naranja.
    - Considerando sólo las escalas respaldadas por datos del IPTS, la más tardía de uno de los servicios (visita del servicio anterior en AY, 17:11:50, marcado 1a) ocurre en una parada anterior a la más temprana del posterior (visita a BE, 17:22:05, marcada 1b). El intervalo entre la salida del primero y la llegada al segundo es de 10m15s, mientras que la suma de los límites inferiores de los tramos de viaje implicados es de 2m23s, lo que significa que un solo vehículo podría ser responsable de ambos.

- Se recalculan los tiempos intermedios de llegada y salida entre AY y BE. En lugar de sus valores medios según sus respectivas distribuciones y la salida de AY o la llegada a BE; adoptarán la combinación más probable de valores que satisfagan ambas condiciones al mismo tiempo.

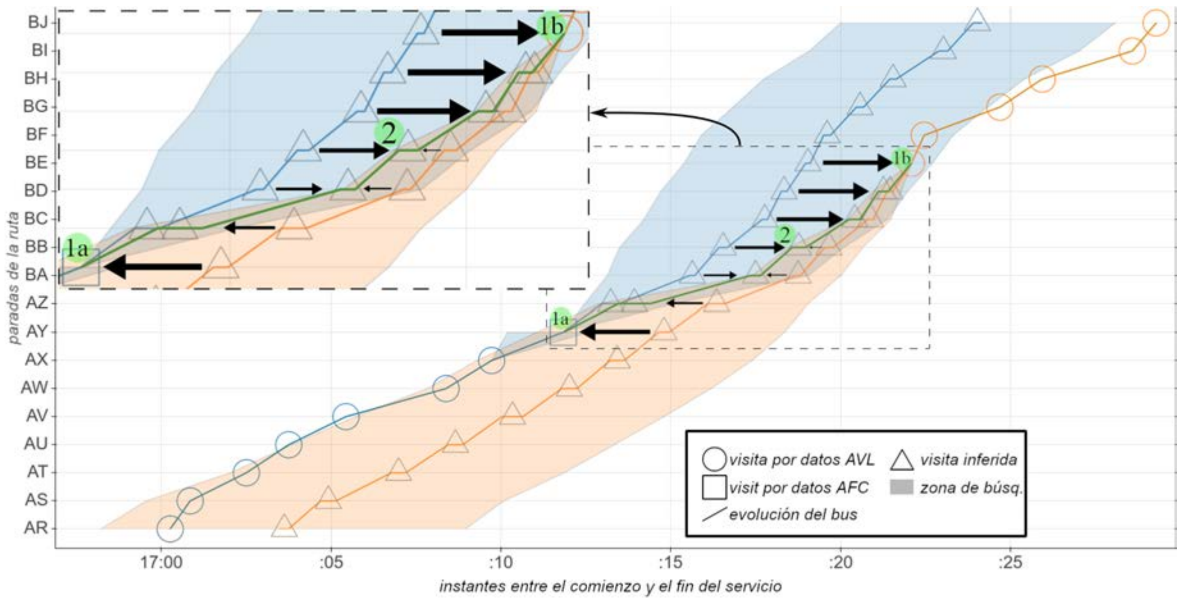

Figura 5: Fusión de 2 servicios (‘anterior’ azul, ‘posterior’ naranja, visitas modificadas: línea verde)

2.7 Asignación de servicios a los recorridos programados y actualización de los intervalos de tiempo de las visitas

Esta parte de la metodología tiene varios objetivos: en primer lugar, diferenciar entre los servicios previstos que se materializaron o no; identificar los recorridos extra no programados; y eliminar las visitas inferidas a paradas que no se produjeron realmente, para aquellos servicios que se identifican con éxito como que comienzan ‘aguas abajo’ de la terminal inicial.

Una vez que se ha vinculado un servicio con su inicio programado, la información adicional de la tabla de horarios puede utilizarse para afinar aún más las horas de llegada y salida. Estos son los pasos propuestos, que también se muestran en forma de diagrama de flujo en la fig. 6:

- Se realiza un bucle sobre todos los pares (inicio programado, servicio) en los que la salida de este último de la parada prevista cae dentro del buffer *q* (eq. 2) del primero, dando prioridad a los pares que que comparten la mismo *id de vehículo*, y luego ordenados por el valor absoluto del lapso entre la salida del servicio y el inicio programado, de forma ascendente. A menos que alguno de ellos ya haya sido vinculado, pasan a serlo entre sí.
- Si se encuentra un emparejamiento, a partir del terminal inicial de toda la ruta, se eliminan consecutivamente las visitas inferidas a las paradas, hasta llegar a una que esté respaldada por registros AFC o AVL.
- Si el subsistema de planificación registró el inicio del servicio, se evaluará la verosimilitud de su correspondiente rango de tiempo *n* (eq. 2), utilizando el rango de viabilidad apropiado almacenado en la tabla de rangos de búsqueda (tabla 10c, si no está disponible, se crea uno utilizando la llamada más cercana del servicio con soporte de datos). Si *n* se considera creíble, pueden darse dos situaciones:

    - Si la escala del servicio se había deducido previamente (sección 2.5) a partir de otros datos del IPTS, la información disponible se combinará para obtener las presencias más temprana y más tardía del autobús en esa parada.
    - En caso contrario, se utilizará n como rango [llegada, salida] al inicio del servicio.

- Las visitas inferidas aguas abajo, hasta la primera sustentada por datos del IPTS, se mejoran hasta sus nuevos valores más probables, considerando el tiempo total de viaje entre el inicio del servicio programado y ese primer punto de datos conocido, y las distribuciones de tiempo de viaje y de parada.

La figura 7 muestra las primeras paradas de un servicio de ejemplo:

- Su estimación inicial se ha vinculado a una salida prevista en la parada AF, con una diferencia entre sus tiempos de salida inferidos y los previstos de 51s.
- Las paradas anteriores al inicio previsto no están respaldadas por ningún registro IPTS, y se borran.
- En este caso, la llegada y la salida fueron registradas por el subsistema de planificación a las 07:25:39 y 07:26:01, respectivamente. Como estas horas están dentro del rango de búsqueda de ese servicio en la parada AF ([07:23:39, 07:26:13]), se aceptan como lo que realmente ocurrió.
- Las visitas a AG, AH, AI y AJ también se recalculan teniendo en cuenta la nueva información.

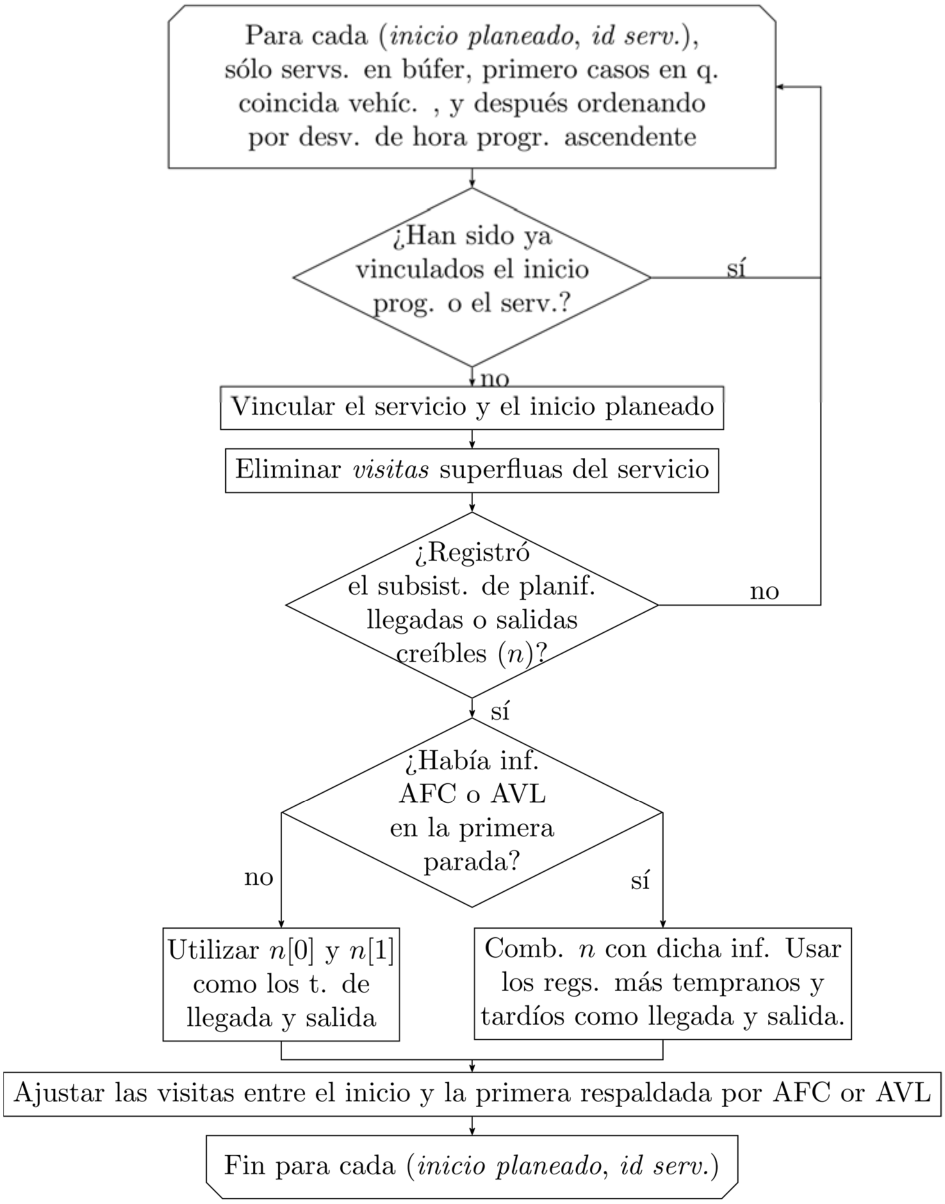

Figura 6: Asociación de servicios programados e inferidos

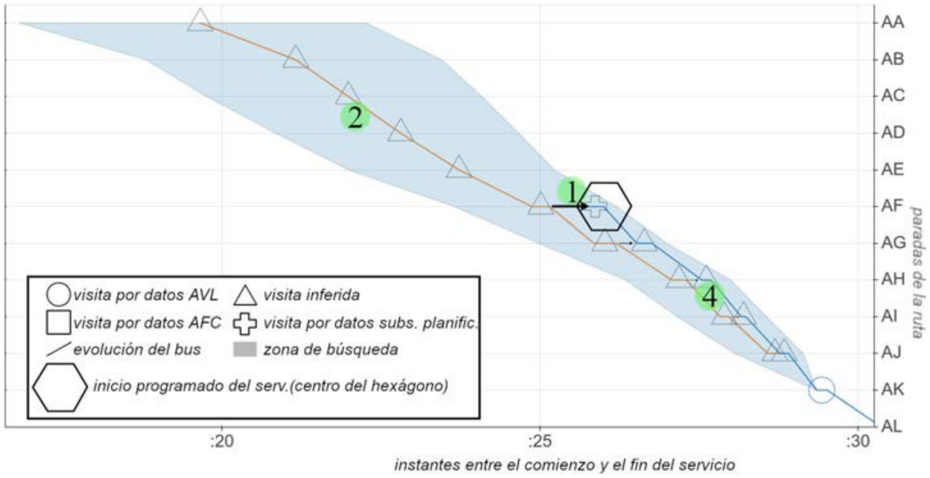

Figura 7: Mejora de la llegada y salida de un servicio una vez identificado su probable inicio programado. Caracterización final en azul, entradas modificadas en naranja

2.8 Imputación de grupos de embarque

Una vez definidas y refinadas las escalas de todos los servicios posibles, los grupos de embarque se asignarán primero a un servicio y luego a la parada en la que se produjeron.

Para la primera tarea, un rango de imputación (ligeramente resaltado con un patrón diagonal para el segundo caso de la fig. 8) se crea para cada servicio desde el momento en que el vehículo llegó a su parada inicial, menos el límite superior del tiempo entre servicios (‘*s*’ *en la fig. 7*, *sep_max* en la tabla 1f) para asegurarse de que se identifican todos los eventos AFC pertinentes en el terminal inicial, marcado como 6a); hasta el momento en que dejó su penúltima parada (ya que no se deben asignar eventos AFC a la última parada de un servicio), más el parámetro ‘***o***’ (), que permite cierto margen entre los eventos AVL y AFC, para cubrir casos como validaciones después de que el vehículo abandone la parada o desincronizaciones menores del reloj, marcado como 6b.

$$\boldsymbol{o}: \text{holgura AFC} \quad \text{tiempo} \qquad (12)$$

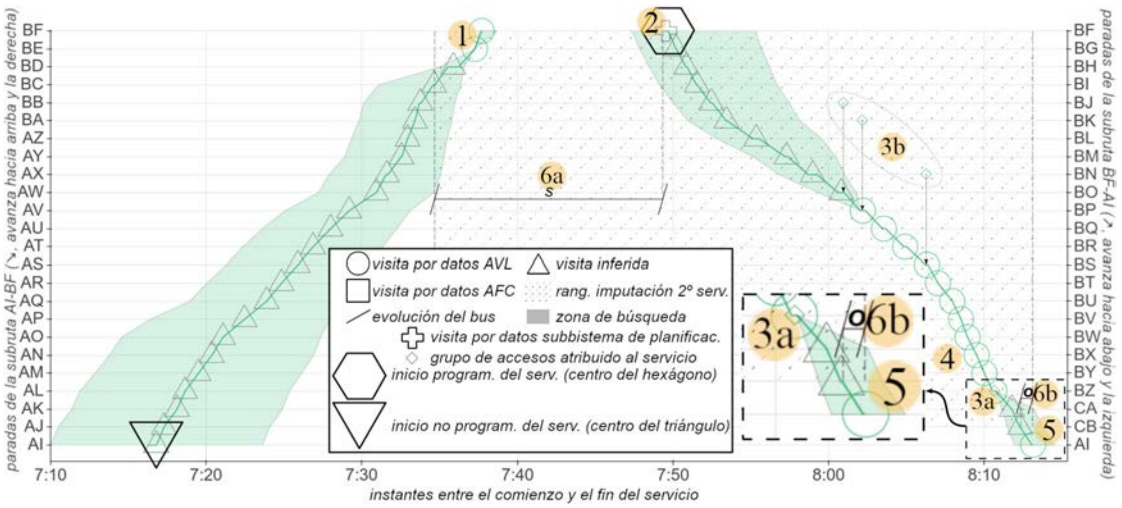

Figura 8: **Imputación de los grupos de embarque y análisis de los datos del IPTS**

Cada *grupo de embarque* se trata en un proceso de dos pasos:

- En primer lugar, se asigna al servicio cuya franja horaria solapa, y que se refiere al mismo vehículo y ruta. Si no se encuentra ningún servicio, se ignora el requisito de coincidencia de ruta, para tratar aquellos casos en los que el estado del subsistema de expedición de billetes no reflejaba la ruta que seguía realmente el vehículo. Cualquier grupo de embarque que quede no estará vinculado a un servicio.
- A continuación, se identifica la parada adecuada dentro del servicio, considerando todas sus escalas menos la última:
    - Si la diferencia entre el *rango_embarque* (tabla 3) y el *rango de visita* (tabla 10a) en la parada especificada por el grupo de embarque es menor o igual a la holgura ***o***, esa parada será aceptada como aquella en la que los viajeros subieron al autobús (por ejemplo, 3a en la fig. 8).
    - En caso contrario, se asumirá que el AFC no identificó correctamente la identificación de la parada. En su lugar, se elegirá el de la llamada más cercana del vehículo (por ejemplo, 3b en la fig. 8, donde los 3 grupos de embarque que se registraron como ocurridos en las paradas BJ, BK y BN se asignan respectivamente a BO, BP y BS).

2.9 Seleccionar servicios respaldados por suficiente información

El último paso es establecer y aplicar un criterio para aceptar o rechazar cada uno de los posibles servicios que han sido identificados por esta metodología. Se sugiere establecer límites que consideren estas características (ecuación 13):

- Si se asignó o no una salida planificada al servicio (*w*). En este último caso, también hay que tener en cuenta si la identificación del vehículo es la misma en ambas bases de datos (*p*), y si el subsistema de programación registró una hora de salida compatible (*v*).
- El número total *h* de grupos de embarque atribuidos al servicio, como se ha descrito en la sección 2.8.
- Cuántas visitas de ese servicio provienen de la información de AVL (*f*).
- El número de paradas entre la primera y la última visita apoyada por los datos del IPTS (*l*).

$[w$: el servicio esta planeado (lógico)$]$, $[p$: se empleó el vehículo previsto (lógico)$]$,
$[v$: Subs. de planif. resgistró un t. salida válido (lógico)$]$,
$[h$: Núm. de grupos de acceso $(h \in \mathbb{N})]$, $[f$: Visitas respaldadas por AVL $(f \in \mathbb{N})]$,
[l: separación máx. entre visitas respaldadas por IPTS $(l \in \mathbb{N})]$ (13)

La figura 8 ofrece un ejemplo, analizando dos posibles servicios consecutivos de un vehículo, que cubren sub-líneas complementarias entre los terminales AI y BF, ambos compuestos por 23 tramos de viaje. Sólo 2 entradas consecutivas de la tabla *avl_sintetizado* apuntan a la existencia del primero (1); mientras que el segundo se apoya en un servicio planificado de ese vehículo para el que el subsistema de programación registró la primera escala (2), 4 grupos de embarque (mostrados en 3a y 3b), 12 filas de *avl_sintetizado* (4), y por el hecho de que el intervalo entre la primera (2) y la última (5) escala, obtenidas a partir de observaciones registradas en el IPTS cubre toda la ruta. Es casi seguro que el primer servicio no ocurrió, mientras que el segundo es muy probable que sí.

3. APLICACIÓN A UN CASO REAL

Los resultados de esta metodología se ilustran utilizando los eventos AVL y AFC, y los inicios de servicio programados de los vehículos que, durante 1 año, recorren la línea 1 en Santander, una ciudad de la costa norte de España (fig. 9).

Figura 9: Ciudad de Santander [mapa, Wikimedia] [foto, SPIEGEL]

Funciona aproximadamente desde las 07:00 hasta las 23:00, con intervalos entre servicios de como máximo s = 20min. En aproximadamente la mitad de las ocasiones, el subsistema de programación registra, con una desviación de alrededor de z = 20s, la llegada y salida del vehículo de la primera parada del servicio. Un viaje completo de ida y vuelta requiere al menos d = 1h, mientras que un tramo de viaje único, incluso en las circunstancias más desfavorables, no debería durar más de e = 15min. Aunque el IPTS es extremadamente útil durante las operaciones diarias, la explotación de sus datos tiene que superar varios problemas:

- Baja fiabilidad de AVL y AFC en la mayoría de los extremos de los servicios (y = verdadero), debido a la forma en que a veces se manejan los ordenadores de abordo y al hecho de que cuando un autobús está vacío al acercarse al final de la ruta, los conductores a menudo encuentran más conveniente esperar hasta su próximo recorrido en una parada anterior a la final.
- Diariamente, cada viaje que cubre una de las 2 sub-líneas a veces no puede ser identificado de forma fiable con un *id* dentro de los conjuntos de datos AVL y AFC: este campo puede mostrar varios valores dentro de un mismo viaje, o el mismo valor puede ser utilizado para recorridos consecutivos que cubren ambas sub-líneas.

Además, este identificador no es coherente entre las informaciones de AVL, AFC y planificación.

- Falta de entradas AVL.
- Eventos AVL y AFC erróneos que se derivan de las limitaciones del IPTS, como la pérdida de la señal GPS, los fallos de comunicación o los errores del ordenador de a bordo; o de operaciones atípicas o incorrectas (por ejemplo, el establecimiento de parámetros de estado del vehículo que identifican erróneamente la tarea que se está realizando).
- La información relativa a si un viaje planificado finalmente ocurrió y cuándo comenzó es la mayoría de las veces precisa, pero a veces el inicio de un servicio normalmente realizado no se registra, o lo hace con marcas de tiempo muy inexactas.
- En ocasiones, al cambiar el conductor de un bus en mitad de un servicio, el identificador del vehículo cambia, por lo que presentarán 2 valores diferentes.

Esta implementación utiliza el lenguaje procedimental PL/pgSQL dentro de una base de datos PostgresSQL 13.2 para sus tareas principales; y Python 3.8 y Bokeh 2.2 para mostrar una representación interactiva de los resultados.

3.1 Aplicación de la metodología

3.1.1 Datos de entrada

3.1.1.1 Paradas y sub-líneas

Santander cuenta con aproximadamente 460 paradas de autobús. La ubicación de las 75 que conforman la ruta 1, que se divide en dos sub-lineas con una parada intermedia ("Consuelo Berges 16") y ambas terminales en común, se muestra en la fig. 10. Estas sub-líneas proporcionan las plantillas que se utilizarán para desglosar las secuencias de paradas encontradas durante el tratamiento de los datos de la AVL.

Figura 10: Paradas de la línea 1

Este itinerario comienza en el parque científico PCTCAN, en el oeste, y atraviesa la ciudad hacia el este a través de las principales arterias, pasando por muchos de sus centros comerciales, residenciales, turísticos y administrativos hasta llegar al Parque de la Península de La Magdalena (uno de sus principales lugares de ocio). A continuación, gira hacia el noroeste y sigue el litoral, dando acceso a las playas más populares de Santander. Finalmente desemboca en Valdenoja, un barrio que aunque presenta algún uso comercial limitado se puede caracterizar como un suburbio dormitorio.

Durante los días no laborables la actividad en el PCTCAN disminuye considerablemente, por lo que los autobuses no visitan las 3 paradas más orientales. Además, especialmente durante los días laborables, varios servicios de refuerzo planificados pero no anunciados comienzan “aguas abajo” por la primera parada, para aprovechar espacios libres breves que tengan los conductores entre otras asignaciones.

3.1.1.2 AFC

El conjunto de datos incluye 2586600 eventos AFC en bruto. Casi todos (99,99%) corresponden a paradas reales dentro de la ciudad, mientras que el resto tiene ids que no se refieren a una parada física.

3.1.1.3 AVL

Hay 1569417 eventos AVL en bruto. Todos representan llamadas en paradas reales de la ciudad.

3.1.1.4 Información del subsistema de planificación

Mientras que el horario diario que los viajeros tienen en cuenta a la hora de planificar sus viajes en la ruta 1 especifica, dependiendo de si es un día laborable o no, alrededor de 100 u 80 lugares y horas en los que comienza un servicio, la autoridad de transporte planifica algunos recorridos extra de vehículos reales, ofreciendo servicios adicionales menos conocidos de la ruta, como varios que comienzan en el hospital Valdecilla para el personal que acaba de terminar sus turnos, o reforzando la oferta durante los períodos conocidos de máxima demanda cuando la distribución de los recursos disponibles lo permite. Los recorridos adicionales de los vehículos que no están presentes en la información de programación pueden producirse debido a decisiones tácticas durante las operaciones diarias.

3.1.2 Preprocesamiento

3.1.2.1 AFC

Siguiendo la metodología expuesta en el apartado 2.2.1, se han encontrado 719971 grupos de paradas., divididos en 724550 grupos de embarque (un 0,6% más de eventos). De ellos, 108 (0,01%) duran más de *s* y no se tendrán en cuenta.

Hay, en promedio, 1 grupo de embarque por cada 4 eventos de billetaje en bruto. Estos grupos de embarque proporcionan además una primera estimación de reserva de las horas de llegada y salida en las paradas, que se utilizará si no se dispone otros registros.

3.1.2.2 AVL

Como se explica en el apartado 2.2.2, los eventos AVL consecutivos que representan la misma visita a una parada se fusionan, dejando 1532299 entradas (un 2% menos). De ellas, 78520 (5%) se consideran poco fiables porque forman parte de tramos de viaje imposiblemente cortos. Las 1453779 entradas restantes, reunidas en la tabla *avl_sintetizado*, se clasifican en 45840 trayectorias.

3.1.3 Analizar las trayectorias de la AVL como secuencias

Las 45840 trayectorias presentan 5800 secuencias de paradas diferentes. Las dos más frecuentes coinciden con los itinerarios ya conocidos de las sub-líneas estudiadas (fig. 10), y representan alrededor del 30% de los trayectos. Las demás contienen en la mayoría de los casos uno o varios fragmentos compatibles con una de las sub-líneas (como se describe en la tabla 8d), aunque a veces (2% de las trayectorias) el estado de un vehículo no cambió entre las sub-líneas, por lo que una misma trayectoria contiene información relativa a más de un servicio.

3.1.4 Especificar los modelos de distribución de tiempos de viaje y de parada

Debido a sus ventajas computacionales, se han elegido dos familias de distribuciones normales (ecuación 14) para modelar los tiempos de viaje y de parada. Teniendo en cuenta los ciclos de movilidad de la ciudad, cada una de estas familias proporciona una función diferente para cada línea, parada, tipo de día (laborable, sábados, o domingos y festivos), periodo del año (verano o no), y clase temporal (con un lapso de 30min, y aproximadamente 16 horas diarias de servicio, hay 32 clases posibles: De 07:00 a 07:30, de 07:30 a 08:30, etc.).

$[p_{a,\tau,\gamma,\delta,\xi,\eta}$: t. viaje entre paradas con $p \in T; p \sim \mathcal{N}((\mu_p)_{a,\tau,\gamma,\delta,\xi}, (\sigma_p)_{a,\tau,\gamma,\delta,\xi}{}^2)]$,
$[u_{a,\tau,\gamma,\delta,\xi,\eta}$: t. parada con $u \in T;\ u \sim \mathcal{N}((\mu_u)_{a,\tau,\gamma,\delta,\xi}, (\sigma_u)_{a,\tau,\gamma,\delta,\xi}{}^2)]$, [$a$: id de la línea],
[τ: núm. de parada (para t. viaje, el de la parada inic.)], [γ: época del año, $\gamma \in$
{verano, resto del año}], [δ: tipo de día, $\delta \in$
{laboral, sábado, domingo o festivo}], [ξ: clase de h. del día, $\xi \in$
$\{1 \ldots \eta\}$], [η: núm. de clases de h. $\eta \in \mathbb{N}$ (14)

Los tiempos de viaje y los tiempos de permanencia de los tramos de la ruta 1 se han caracterizado en cada parada por 192 distribuciones cada uno, según el periodo del año, el tipo de día, y la franja horaria aplicables. Sus medias y desviaciones estándar se han calculado utilizando las entradas pertinentes de la tabla avl_sintetizado.

3.1.5 Ensamblar los servicios

Tras aplicar el proceso descrito en el apartado 3.5, se encontraron 42319 posibles servicios.

3.1.6 Fusionar los casos en los que un vehículo ha cambiado su id a mitad de servicio

Este refinamiento permite detectar alrededor de 2 incidencias diarias de este problema, reduciendo el número de servicios candidatos a 41641.

3.1.7 Asignación de servicios a los viajes programados y actualización de los intervalos de tiempo de las visitas

40352 servicios han sido asignados a un inicio de servicio programado (111 utilizando un vehículo diferente al previsto); mientras que los otros 1289 no lo fueron.

3.1.8 Imputación de grupos de embarque

La aplicación de los criterios descritos en el apartado 2.8 proporciona los siguientes resultados:

- Se ha considerado que el 94,7% de los grupos de embarque informan correctamente de su ruta y parada de autobús.
- El 5% han sido asignados a otra parada que la registrada automáticamente.
- El 0,3% no estaba vinculado a ningún servicio. Es probable que representen casos en los que el estado del vehículo erróneamente reflejaba que viajaba por la línea 1.

3.1.9 Seleccionar los servicios respaldados por suficiente información

Tras considerar los resultados de los apartados 3.1.7 y 3.1.8, se han elegido los siguientes criterios de aceptación, utilizando la nomenclatura de la ecuación (13):

- Para los servicios asignados a un inicio programado (w = True):
    - Aceptar siempre si se ha utilizado el vehículo previsto (p = True).
    - Si se ha utilizado un autobús distinto al programado (p = Falso), exigir al menos 3 grupos de embarque vinculados al servicio ($h \geq 3$).
- Los servicios no programados requerirán más pruebas: al menos tres grupos de embarque y no menos de 12 entradas totales (un tercio del número de paradas de una sub-línea) que avalen su existencia ($h \geq 3 \land h + f \geq 12$).

Aplicando estos umbrales, la metodología reporta una media de 120 y 97 servicios diarios, según se analice un día laborable o no. En el primer caso, el 96,5% de los servicios habían sido previamente planificados, y se materializaron con el vehículo previsto; mientras que el 3% fueron planificados, pero ejecutados con un vehículo diferente; y el 0,5% fueron servicios no planificados. Durante los días no laborables, las ratios correspondientes son del 99,2%, 0,5% y 0,3%; lo que es coherente con el hecho de que los fines de semana y los días festivos suelen ser menos exigentes para el transporte público de la ciudad, lo que se traduce en menos desviaciones del horario para reaccionar a la evolución del sistema de tráfico.

3.2 Análisis de los resultados

3.2.1 Caracterización de los servicios

Esta sección recoge varios ejemplos para ilustrar cómo esta metodología ha mejorado con éxito la caracterización de los servicios que estaban registrados en el IPTS de una manera que dificultaba su consideración.

3.2.1.1 Reconstrucción de un servicio a partir de información fragmentada y errónea

La figura 11 muestra el caso elegido para este análisis. El eje horizontal temporal se ha dividido en tres regiones con un desplazamiento entre ellas para facilitar su visualización:

- El central, donde se representa el servicio real detectado por la metodología y la salida prevista (5). Su eje temporal se ha colocado en la parte inferior del gráfico.
- La zona más a la izquierda, con su eje temporal situado en la parte superior de la figura. Incluye los datos brutos pertinentes de AVL y AFC, con un desplazamiento de -20min:
    - 4 identificadores de viaje AVL
        - (1): Desde “Arsenio Odriozola 16” hasta “San Fernando 66”, con un espacio de casi 1h entre “Plaza de Italia” y “Luis Martínez”.
        - (2): Desde “San Martín” hasta “Pctcan”, solapando con (1) a lo largo de sus primeras 9 paradas, faltando datos en “Avenida de Valdecilla” y “Torres Quevedo 22”.
        - (3): Un único evento, en la “Plaza de Italia”.
        - (4): Un único evento, en 'Pctcan', la última parada del servicio. Ocurre alrededor de medio minuto antes de que termine (2).
    - 19 eventos de AFC, que se producen entre la “Plaza de Italia” y “José Mª Cossío 24”.
- La zona de la derecha sólo contiene las horas de llegada y salida claramente no relacionadas registradas por el subsistema de planificación (6), con un desplazamiento de -40min.

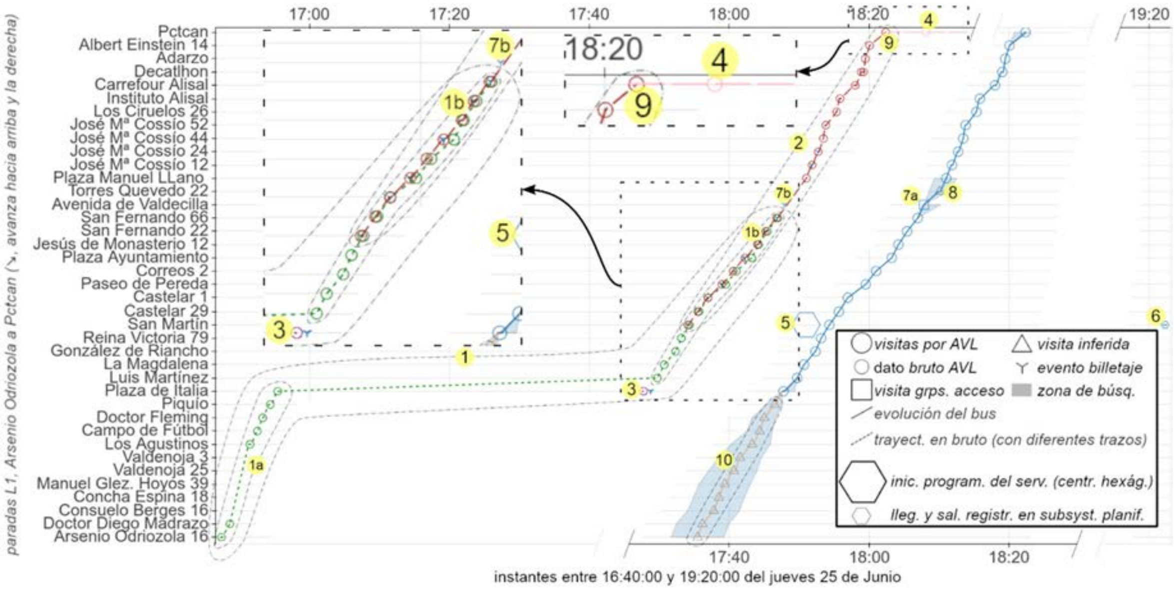

Figura 11: Caracterización de un servicio con información fragmentada y errónea

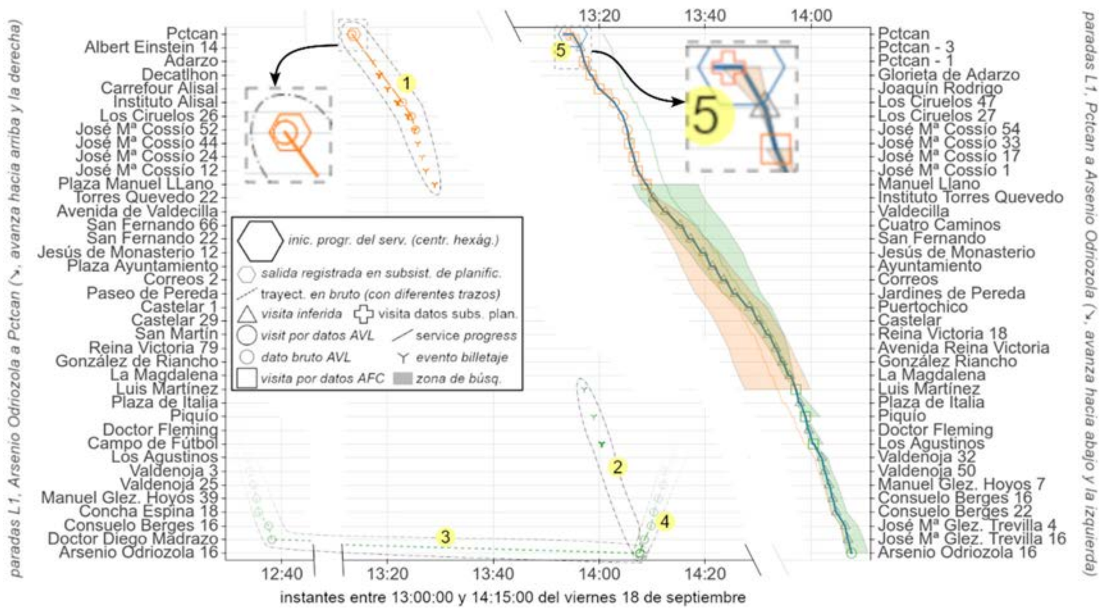

Figura 12: Caracterización de un servicio cuya id de vehículo cambia mientras sucede

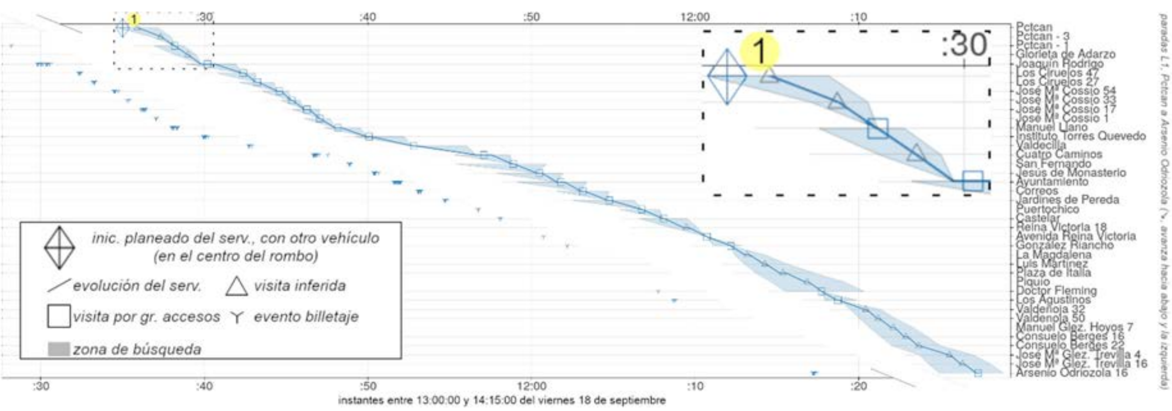

Figura 13: Servicio con sólo datos AFC. El vehículo utilizado no fue el previsto

El servicio propuesto se ha construido haciendo uso de la información disponible. La primera parte del viaje 1 se ha considerado como 2 fragmentos diferentes, descartando el primero (1a, que probablemente se debe a un estado incorrecto del vehículo) y utilizando el segundo (1b). Después de la última entrada de 1, la escala en “Avenida Valdecilla” (7a) se aproxima a partir de un evento de billetaje (7b); y la de “Torres Quevedo 22” (8) se infiere considerando las horas de salida y llegada de la parada anterior y siguiente, respectivamente. De las dos posibles llegadas a la terminal final (9), la del viaje 4, que ocurre 30s antes, es más probable según la hora de salida de “Albert Einstein 14” y la distribución de tiempos de viaje entre estas paradas durante el periodo de tiempo [17:30-18:00] en un día laboral.

Cabe destacar que, aunque el servicio estaba programado para comenzar en “San Martín”, la metodología ha detectado con éxito que en realidad comenzaba unas paradas más arriba (en “Plaza de Italia”, a partir del viaje 3). La búsqueda de eventos anteriores (10) no devolvió ninguna coincidencia.

3.2.1.2 Cambio de id de vehículo a mitad de servicio

La figura 12 muestra cómo aparece la información relativa a un servicio de la sub-línea de Pctcan a Arsenio Odriozola en el IPTS, y su caracterización por esta metodología. De nuevo, el eje temporal horizontal se ha dividido en tres zonas:

- La zona de la derecha, que contiene, con el eje temporal en la parte superior, los dos servicios detectados inicialmente, cómo se han combinado y el inicio previsto vinculado a ellos.
- Las regiones del centro y de la izquierda muestran, con desplazamientos de -40min y -20min y sus ejes temporales en la parte inferior, los registros brutos pertinentes.

Inicialmente, el paso 2.5 de la metodología había encontrado dos servicios:

- Uno para el vehículo 14 (naranja), respaldado por una trayectoria de 4 paradas, y varios eventos de billetaje (1), siendo el último en "Manuel Llano".
- Otro para el vehículo 224 (verde), deducido de 4 eventos de billetaje en 3 paradas (2 , el más temprano en “Luis Martínez”), y cualquiera de los dos eventos en bruto de AVL con la misma marca temporal en la terminal “Arsenio Odriozola 16”, que forman parte de trayectorias opuestas que terminan (3) o comienzan (4) en ese lugar.

Se ha detectado, como se describe en el apartado 2.6, que estos servicios están formados con información parcial de uno que los engloba (se muestra con una línea azul más gruesa). Su correspondiente entrada en el subsistema de programación (5) sólo ha detectado la salida del vehículo, un poco más tarde que los datos de AVL disponibles en esa parada. Como está dentro del rango de viabilidad de “Pctcan – 1”, se acepta y se utiliza para actualizar la hora de salida en “Pctcan”, y para mejorar la llamada inferida en la parada intermedia “Pctcan – 3”.

3.2.1.3 No hay datos de AVL y la identificación del vehículo es incorrecta

La figura 13 muestra un caso que ilustra dos situaciones que se dan en el caso de uso: que el subsistema AVL no registre ninguna entrada y que un vehículo diferente al previsto realice el servicio.

Hay un desplazamiento de 10 minutos entre el lugar donde se dibuja el servicio y la salida programada (parte derecha, eje temporal en la parte superior), y donde se encuentran los datos brutos del AFC (a la izquierda, eje temporal en la parte inferior). Se puede observar (1) que, como el subsistema de planificación no registró el inicio del servicio, las escalas en "Pctcan" y "Pctcan - 3" tuvieron que inferirse utilizando la llegada a "Pctcan - 1" como punto fijo.

3.2.2 Tratamiento de las terminales donde se inician los servicios

El objetivo de esta sección es estudiar el beneficio de la forma en que esta metodología maneja los datos disponibles en los terminales especialmente problemáticos, como ocurre en esta ruta. Para ello, los 25466 servicios que presentan tiempos de salida registrados del subsistema de planificación que, como se describe en el apartado 2.7, han sido aceptados para su caracterización, se utilizarán como verdad de base para compararlos con los resultados obtenidos en tres escenarios en los que no se tendrá en cuenta esa información:

(A): Sigue el comportamiento de la metodología por defecto para una ruta cuando el subsistema de programación no registró el inicio de un servicio.

(B): Si los datos de la primera parada se consideran creíbles, utilícelos de la misma manera que en cualquier otra parada.

(C): Si el inicio planificado de un servicio cae dentro de su rango de búsqueda (tabla 10c) correspondiente (ya almacenado, o calculado utilizando la escala más cercana del servicio sustentada en datos reales), se utilizará como salida, si ocurre más tarde que cualquier entrada AFC o AVL disponible. Esto equivale a suponer que el cumplimiento del horario es lo suficientemente estricto como para confiar en las horas de salida previstas, a menos que sean imposibles o muy improbables.

La figura 14 muestra las distribuciones del error absoluto de la hora de salida del servicio comunicada en los escenarios A y C. Los servicios se han clasificado en función de su “espacio vacante”: a qué distancia (medida en tramos de viaje) se encuentran sus primeras visitas basadas en los datos de AVL o AFC respecto a sus inicios programados. Como puede observarse, la decisión de basarse en la hora de inicio inferida en lugar de la prevista proporciona aproximaciones con menor dispersión (desviaciones estándar de 13s y 17s, respectivamente) y un menor error medio absoluto (MAE), aunque a medida que aumenta la incertidumbre (más llamadas desconocidas entre el inicio del servicio y el primer punto de datos) esta ventaja disminuye.

Los escenarios A y B sólo difieren para aquellos servicios en los que se pueden encontrar datos AVL o AFC compatibles en la primera parada programada (espacio vacante cero). La figura 15 muestra sus distribuciones de errores absolutos en este caso. De nuevo, el escenario A infiere los datos que faltan con menos dispersión (desvíos estándar de 15s y 17s, respectivamente) y MAE (11s frente a 13s).

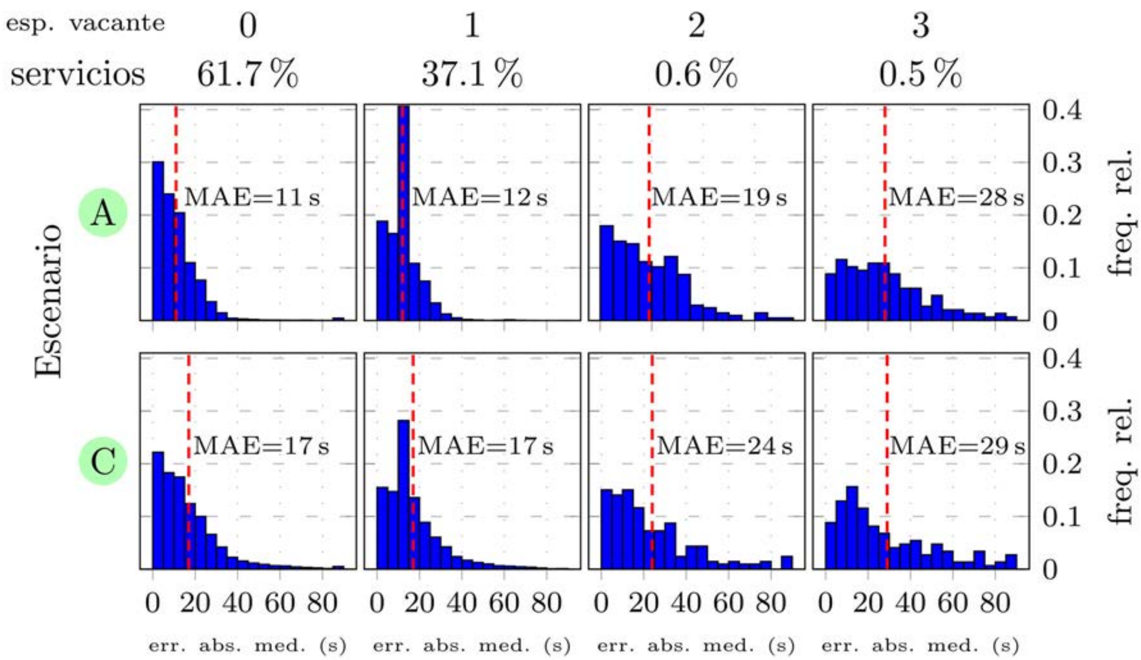

Figura 14: Distr. de errores abs. de hora de salida para los escenarios A y C

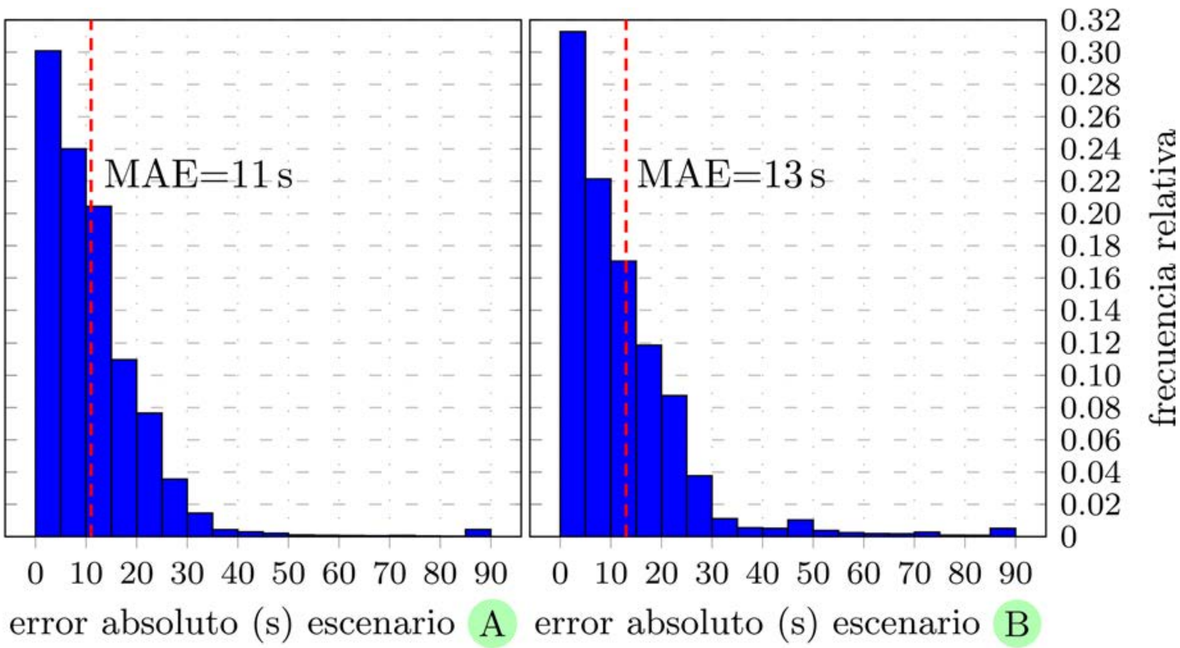

Figura 15: Distr. de los errores abs. de la hora de salida en los escenarios A y B

3.2.3 Solidez frente a los datos ausentes y erróneos

En esta sección se analiza cómo afecta a la metodología información de AVL y de detección del inicio del servicio incompleta y errónea (los eventos de emisión de billetes están totalmente disponibles en todos los escenarios). Los 16863 servicios en los que los subsistemas de planificación y AVL registraron todas las escalas (el 49% del total) se utilizarán como datos reales; y se compararán con los resultados de ejecutar esta metodología utilizando sólo una parte de los datos AVL brutos registrados y de las detecciones del subsistema de planificación, elegidos mediante un muestreo Bernoulli; añadiendo también diferentes cantidades de lecturas erróneas AVL sintéticas, que se han generado aleatoriamente siguiendo estas reglas:

- La *parada*, el *vehículo* y la *UID de grupo* se eligen entre todos sus valores presentes.
- *Instante* ocurre entre las 07:00 y las 23:00 de cualquier día del año.
- El muestreo de la distribución de duraciones se simula utilizando sus percentiles y la Distribución Uniforme.

En la fig. 16, los porcentajes son relativos a las lecturas de AVL en bruto y a los servicios planificados disponibles en el conjunto de datos. Por ejemplo, un escenario con un 25% de datos reales y un 75% de errores simulados sólo lee la llegada y la salida de los vehículos en la parada inicial registrada por el subsistema de programación en el 25% de los servicios programados; mientras que sus registros de AVL en bruto se crea combinando un muestreo de Bernoulli de la información real con una probabilidad del 25% y una cantidad tres veces superior de entradas falsas.

A medida que se dispone de más datos reales en un escenario, los servicios se caracterizan con mayor precisión. Por ejemplo, con una muestra relativamente pequeña (25%), si bien el percentil 99 no difiere significativamente de no utilizar AVL o de detectar el inicio del servicio en absoluto (algo menos de 7min), ya se puede apreciar que el MAE es bastante más probable que sea menor: el cuartil inferior, la mediana y el cuartil superior se reducen de 4s, 9s y 24s a 0s, 4s y 13s, respectivamente (A y B).

También es notable la resistencia de la metodología contra las entradas incorrectas artificiales, que crece a medida que se dispone de más lecturas verdaderas en el escenario. Dos ejemplos son:

- Con sólo el 25% de los datos reales, añadir cuatro veces más entradas erróneas sólo aumenta el cuartil superior de 6m50s a 7m7s (B y C).
- Si toda la información real está disponible, la metodología identifica con éxito los valores correctos como semillas, y es capaz de ignorar por completo muchos eventos falsos (D y E).

4. CONCLUSIÓN

La metodología descrita en este trabajo es capaz de combinar la información del AFC, del AVL y del subsistema de programación para proporcionar una mejor caracterización de los servicios de las rutas ofrecidas en un Sistema de Transporte Público; mejorando los problemas que comúnmente ocurren cuando se trabaja con datos del IPTS. Los eventos cuyos atributos los clasifican erróneamente como parte de diferentes servicios son identificados y tratados adecuadamente, así como aquellos que probablemente no hayan ocurrido realmente. Las escalas en cada parada de cada servicio se delimitan combinando las múltiples fuentes de datos disponibles en ese caso concreto, proporcionando las horas de llegada y salida más probables si no las hay. Asimismo, se formula una forma de detectar y tratar aquellos casos en los que un vehículo cambia su identificación a mitad de servicio, lo que llevaría a una tergiversación de su perfil de carga.

Se ha presentado un estudio de caso, en el que varios ejemplos ilustran algunos de los problemas que resuelve esta metodología (información fragmentada y errónea, cambio de identificación del vehículo a mitad de servicio y caracterización de un servicio no planificado utilizando únicamente datos AFC). También se utiliza para analizar la repercusión de la forma en que se tratan los datos de los terminales y cómo se comporta la metodología con diferentes proporciones de información buena y errónea.

Como próximo objetivo, los autores están trabajando actualmente en la aplicación de la metodología de cadenas de viaje con los eventos de billetaje y los servicios caracterizados por esta metodología, para proporcionar perfiles de carga de vehículos y matrices OD más precisos. Otras posibles líneas de investigación son la utilización de otras distribuciones para modelar los tiempos de permanencia y de viaje, o la aplicación de modelos más detallados para estimar a partir de los eventos de billetaje la llegada y la salida en una parada cuando no se dispone de registros AVL.

RESUMEN

La reducción del tiempo de viaje en transporte público y la mejora de su fiabilidad constituyen elementos fundamentales para la captación de usuarios no cautivos. Para alcanzar estos objetivos en sistemas de transporte público en superficie, especialmente en situaciones de frecuente congestión, una estrategia adecuada es la reserva de plataforma. Sin embargo, estas reservas se encuentran en ocasiones con una fuerte contestación por parte de la opinión pública, especialmente por los perjuicios inmediatos que se provocan a algunos ciudadanos, debido fundamentalmente a la reducción de espacio para la circulación y estacionamiento del vehículo privado. Por ello, los técnicos deben aportar cuantificaciones lo más precisas posible de los beneficios de la plataforma reservada para el sistema de transporte público y sus usuarios.

El objetivo del trabajo que se expondrá en esta ponencia es avanzar en la cuantificación de la influencia de la existencia de un carril bus en algunas variables de operación del sistema. Se analizan las variaciones en los tiempos de viaje o en la propia variabilidad del tiempo de recorrido entre situaciones con carril bus y situaciones de referencia en plataforma compartida.

Como caso de estudio se presenta el carril bus en la ciudad de A Coruña, que se implantó en el año 2008 y se retiró finalizando el año 2011, siendo sustituido por una vía prioritaria vigilada con priorización semafórica y control del aparcamiento indebido. A partir del análisis estadístico de la información recogida en la base de datos del Sistema de Ayuda a la Explotación, se analizan los tiempos de viaje y su variabilidad en tres años de comparación. Se realiza un estudio desde una perspectiva temporal, durante y después del periodo en el que funcionó la reserva de plataforma, y desde una perspectiva transversal, comparando con la situación en otras líneas o tramos que no empleaban el carril bus. Se ha obtenido que el tiempo medio de recorrido tras retirar el carril bus aumentó en un 14% y el coeficiente de variación aumentó en un 46%. Para el caso de estudio, los viajes con una duración mayor de 6 minutos pasaron del 3,57% al 18,67%. La influencia de la reserva se cuantifica tanto para días hábiles como no hábiles. Los tramos de contraste no han mostrado variaciones relevantes en las variables analizadas en el mismo periodo.

1. INTRODUCCIÓN

Uno de los pilares para alcanzar una movilidad sostenible en las áreas urbanas y metropolitanas es el fomento de la utilización del transporte público. En conjunción con otras medidas, esta utilización es uno de los instrumentos relevantes para alcanzar los objetivos establecidos en el acuerdo de París. Dentro del transporte público, el autobús convencional juega un papel fundamental en la movilidad de las ciudades pequeñas y medianas, así como en ciertas relaciones de baja demanda en grandes áreas metropolitanas. Los sistemas BRT y BHLS pueden prestar servicios de capacidad alta o media en estos contextos mediante la implantación de medidas específicas de reserva de plataforma y explotación. Aumentar el atractivo del autobús, especialmente para captar a los viajeros no cautivos, constituye por tanto una medida deseable dentro de la política de transporte.

Los sistemas de autobuses en plataforma compartida tienen el inconveniente de que sufren los efectos de la congestión del tráfico, lo que repercute en los tiempos de viaje en esas situaciones y en la fiabilidad del cumplimiento de horarios. Esta incertidumbre supone un inconveniente añadido para el viajero, especialmente en los viajes pendulares al trabajo o estudios, dado que tiene que adelantar su salida para aumentar la probabilidad de llegar puntualmente a su destino.

Con el fin de promover el uso de los sistemas de autobuses, mejorando sus tiempos de viaje, comodidad de uso, visibilidad y fiabilidad, la reserva de plataforma es una de las medidas fundamentales. Estas reservas abarcan desde simples carriles de uso reservado señalizados con pintura, con potenciales problemas de respeto, hasta separaciones físicas de una parte de la calzada reservada al transporte público, en ocasiones compartida con otros usuarios como taxis o bicicletas.

Estas reservas de plataforma suponen en general la disminución de espacios para el aparcamiento y para la circulación del tráfico general. Por este motivo, es frecuente que sufran una contestación importante por parte de algunos colectivos. Se considera relevante disponer de medidas empíricas que permitan cuantificar los beneficios para la operación de los autobuses que supone una reserva de plataforma. Una herramienta adecuada para este fin es el empleo de datos de funcionamiento de las operaciones en presencia y en ausencia de una reserva de plataforma.

En la presente ponencia se analiza la influencia en los tiempos de viaje del autobús y en su variabilidad de un caso de estudio singular, dado que se refiere a la retirada de una plataforma reservada existente en la ciudad de A Coruña. En el segundo apartado se revisa el estado del conocimiento, en el apartado 3 se presenta el caso de estudio, en el apartado 4 se expone la metodología empleada y se analizan los resultados obtenidos. Se finaliza con unas conclusiones y unas líneas abiertas de trabajo.

2. EFECTOS DE LAS PLATAFORMAS RESERVADAS EN LAS OPERACIONES

Diversos estudios han puesto de manifiesto que la fiabilidad del servicio, el tiempo de viaje en el vehículo y el tiempo de espera (condicionado por la frecuencia del servicio y también por el cumplimiento de los horarios programados) están entre los factores que los usuarios valoran en el momento de elegir un sistema de transporte público frente al vehículo privado. Para una revisión de la literatura acerca de los atributos de calidad que atraen a los usuarios del coche puede consultarse Redman et al. (2013).

En lo relativo a la influencia de la plataforma reservada en el tiempo de recorrido y en la fiabilidad, existen diversos análisis estadísticos de esta influencia. Tanaboriboon y Toonim (1983) analizaron el impacto de diferentes carriles para autobús en Bangkok, con longitudes entre 1,2 y 6,3 km y tiempos de recorrido entre 5 y 15 minutos. Los análisis se llevaron a cabo con medidas manuales en las horas punta de mañana y tarde. Sus resultados muestran un rango de variación amplio, con reducciones del tiempo medio de viaje entre 0,7% y 23% según corredor, sentido y horario.

Arasan y Vedagiri (2010) analizaron mediante microsimulación un carril reservado de 10 km, sin interferencia del tráfico general en las intersecciones ni prioridad semafórica. Obtuvieron como resultado una reducción del tiempo de recorrido de los autobuses de alrededor de un 15% en condiciones de nivel de servicio C, lo que es equivalente en ese caso a un aumento del 17,8% sin plataforma reservada. Para el nivel de tráfico correspondiente a la capacidad de la infraestructura, la reducción obtenida fue del entorno del 70%. Es evidente que la plataforma reservada no va a tener efecto en ausencia de tráfico.

Surprenant-Legault y El-Geneidy (2011) estudiaron el impacto de añadir un carril reservado para autobuses en dos rutas paralelas en Montreal. Analizando un tramo de 6,82 km con carril bus obtuvieron que la inclusión de la reserva de plataforma supuso un ahorro entre el 1,3% y el 2,2% en el tiempo de recorrido total según la dirección. Llamativamente, los coeficientes de variación del tiempo de recorrido total aumentaron en una de las direcciones de viaje para las dos rutas tras la implementación de la reserva de plataforma, mientras que disminuyeron en dirección contraria, lo que atribuyen a las circunstancias del caso. Como señalan estos autores, un coeficiente de variación bajo facilita la programación de horarios e incrementa la fiabilidad y el cumplimiento de horarios. El estudio posterior de Diab y El-Geneidy (2013) incide en modelizar la influencia de los diferentes factores y medidas tanto en los tiempos de viaje como en su variabilidad. Este nuevo estudio obtiene que el carril exclusivo supone un 2,7% de ahorro en el tiempo de viaje y una reducción del 4,3% en la desviación respecto a la programación, pero un 0,5% más de varianza del tiempo de viaje, que atribuyen a las colas de vehículos delante del autobús en los giros.

3. CASO DE ESTUDIO

El caso de estudio corresponde a la red de autobuses de la ciudad de A Coruña. La red está explotada por la Compañía de Tranvías de La Coruña (CTC), operador privado histórico constituido en 1901 que opera el transporte urbano de la ciudad desde 1903 (Martínez y Piñeiro, 1997). La red está constituida por 23 líneas diurnas y una nocturna. En el año 2019 transportó 23.003.516 viajeros, con un incremento de 5,08% respecto a 2018 (Compañía de Tranvías de La Coruña, 2020). En 2020, como consecuencia de la pandemia, la cifra de viajeros descendió un 40,8% hasta los 13.623.457 (Compañía de Tranvías de La Coruña, 2021). Puede encontrarse un análisis del efecto de la pandemia en esta red en Orro et al. (2020).

Es habitual que la implantación de una reserva de plataforma venga acompañada de cierta reordenación de las líneas, así como de medidas complementarias de apoyo a la circulación de los autobuses. El objeto de este análisis es el carril bus que se implantó en la ciudad en el año 2008. Tras decidirse su eliminación, los separadores físicos se retiraron a mediados de diciembre del año 2011, lo que constituye una circunstancia poco frecuente en los últimos años. Esta retirada permite estudiar el funcionamiento de las líneas durante la existencia de la reserva de plataforma y en el periodo posterior a su retirada, en el que durante cierto tiempo se mantuvo la misma configuración de las líneas.

Debe señalarse que una vez retirado el carril bus se estableció en el tramo afectado lo que se denominó una “Vía prioritaria vigilada” (VPV), en la que se estableció un especial control de los estacionamientos indebidos, así como un sistema de priorización semafórica del transporte público (Villas, 2012). Este sistema de priorización semafórica se activaba para aquellos autobuses que estuviesen retrasados. Sin embargo, la reducida distancia entre intersecciones y el número de paradas no permiten esperar una gran eficiencia de este sistema, especialmente en situaciones de tráfico congestionado. El proceso de implantación se realiza desde diciembre de 2011 hasta mediados de marzo de 2012 en que entran en funcionamiento las cámaras de vigilancia.

La comparación se va a establecer por tanto entre una reserva de plataforma y una situación posterior de calle con especial atención a la fluidez del tráfico. Se van a tomar como referencias temporales tres años. El primero es el año 2010, con el carril bus en pleno funcionamiento, como valor correspondiente a la reserva de plataforma. El segundo es el año 2012, una vez culminada la retirada del carril bus y año en el que se implanta la VPV. Como tercera referencia temporal se incluirán datos del año 2014, donde es previsible una cierta relajación en la supervisión de la VPV.

El carril bus constaba de varios tramos. Se ha seleccionado como tramo objeto de estudio el comprendido entre las paradas 194 y 197 de la red, correspondiente al trayecto por la calle Federico Tapia y posteriores, en el centro de la ciudad, en el que posteriormente se implantó la VPV incluyendo la priorización semafórica. Las líneas que transcurrieron por el tramo en algún momento del periodo de estudio fueron 4, 6, 6A, 11, 21, 23, 24 y UDC (línea especial a la Universidad de elevada frecuencia y utilización en periodo lectivo). La longitud del tramo es de 945 m con distancias entre paradas de 351 m, 300 m y 294 m. Existen 6 intersecciones semaforizadas en el tramo.

La calle es de dirección única, el carril bus estaba ubicado a la derecha de la sección y separado del carril de circulación mediante un separador físico de tipo “aletas de tiburón”. En la mayor parte del tramo la sección con carril bus incluía un carril de circulación y una línea de aparcamiento en la margen izquierda de la calzada. El carril bus podía ser empleado por los taxis, las motocicletas y las bicicletas. En la situación con VPV se disponía de dos carriles de circulación y aparcamiento a ambos lados de la calzada. Ambas situaciones pueden observarse en la Figura 1, en la que se pueden observar las marcas viales de color naranja que denotan la VPV.

Figura 1: Sección de la calle Federico Tapia con carril bus (2010) y con la VPV (2012)

Con el fin de aislar en lo posible la influencia de la eliminación de la reserva de plataforma de otros efectos provocados por las variaciones de demanda a lo largo del tiempo, se han seleccionado dos tramos de contraste en otras ubicaciones de la ciudad. Los criterios de selección para estos tramos de contraste fueron que tuviesen una configuración viaria, una longitud, una demanda de los servicios de autobús y una distancia entre paradas similar al tramo de Federico Tapia. El primero de los tramos de contraste corresponde a la Avenida Salvador de Madariaga (paradas 380 a 383) y el segundo a la Avenida de Oza (paradas 29 a 32). En la Figura 2 se puede observar la ubicación de los tramos dentro de la ciudad, así como las paradas y la distancia entre ellas en el tramo de Federico Tapia.

Figura 2: Ubicación de los tramos de estudio y detalle del tramo de Federico Tapia

4. METODOLOGÍA Y RESULTADOS

4.1 Metodología

La fuente fundamental de información para el desarrollo del análisis es la base de datos del Sistema de Ayuda a la Explotación de la CTC. Se han realizado las consultas correspondientes para obtener los instantes de paso por cada una de las paradas de los tramos objeto de estudio de todas las expediciones que realizaron esos trayectos en los periodos estudiados. Se ha recopilado también la información del número de viajeros que subieron en cada parada, que serán empleados en desarrollos posteriores. Se ha realizado el proceso de curación de los datos para eliminar registros erróneos y un preproceso de la información para estructurarla adecuadamente poder realizar los análisis de tiempo de recorrido.

Tras los análisis de consistencia de los datos se ha decidido eliminar el periodo comprendido entre octubre y diciembre de 2012 en todos los tramos, debido a que en la Avenida Salvador de Madariaga se realizaron obras que mantuvieron las paradas sin servicio.

Una vez depurados los datos se dispone de una muestra total para el tramo de estudio de 47.863 expediciones en 2010, 46.591 expediciones en 2012 y 45.611 expediciones en 2014. A efectos de análisis se emplearán tanto los datos generales como separados por días hábiles y no hábiles.

4.2 Tiempo de recorrido en el tramo con plataforma reservada

En la Tabla 1 se muestra la estadística descriptiva de la distribución de los tiempos de recorrido en el tramo en el que estuvo funcionando el carril bus. Los datos de 2010 corresponden a la situación con plataforma reservada, mientras que los datos de 2012 y 2014 corresponden a la situación sin reserva de plataforma y con VPV.

Como se ha señalado, la finalidad habitual de establecer una reserva de plataforma es evitar el efecto de la congestión en el transporte público. A lo largo de la semana, lo habitual es que las horas con congestión significativa se concentren en determinados horarios, generalmente en días hábiles. Por este motivo, la presencia de una reserva de plataforma va a reducir principalmente los viajes con tiempos de recorrido elevados. Es fundamental para el análisis representar la distribución de los tiempos de viaje. Para ello, en la Figura 3 se muestran los histogramas de los tiempos de recorrido y las estimaciones de densidad *kernel*, además de la media y la mediana en cada uno de los años.

	General			**Días hábiles**			**Días no hábiles**		
Año	**2010**	**2012**	**2014**	**2010**	**2012**	**2014**	**2010**	**2012**	**2014**

Tabla 1: Parámetros de centralidad y dispersión de la variable tiempo de recorrido en el tramo de la calle Federico Tapia (paradas 194 a 197)

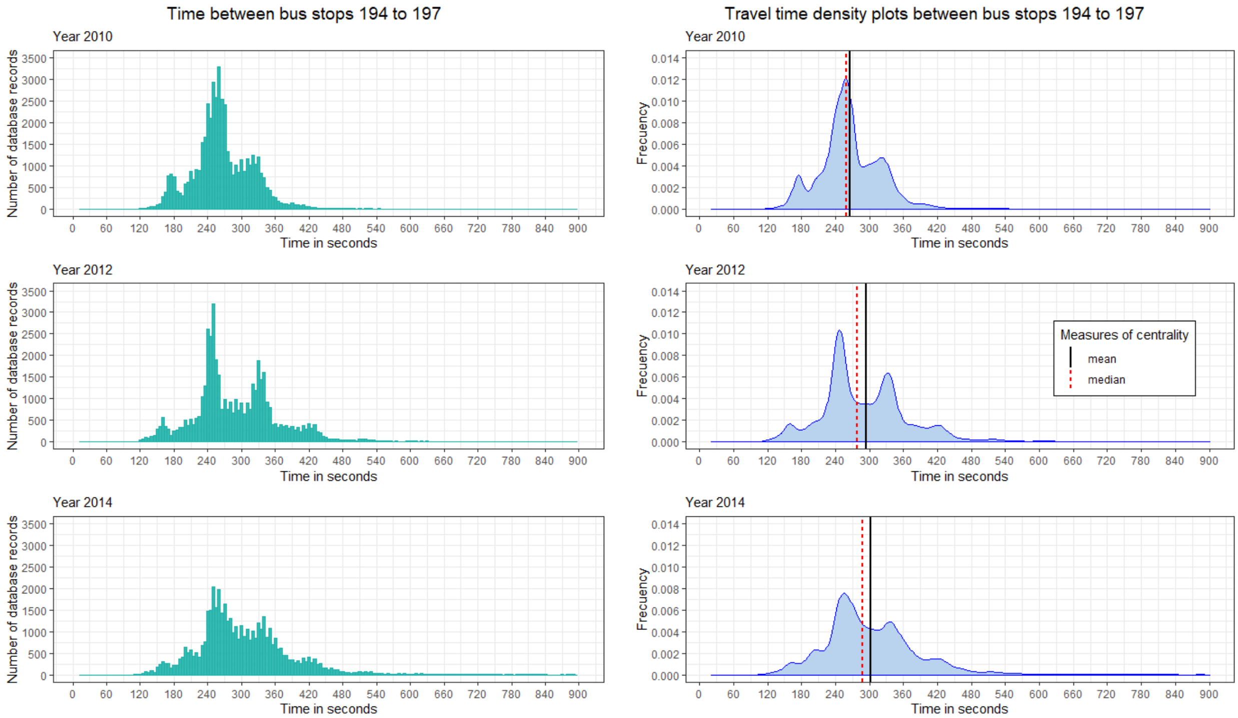

Figura 3: Histograma y estimador de densidad *kernel* del tiempo de recorrido en todos los días de la semana en el tramo de la calle Federico Tapia (paradas 194 a 197)

Como se puede observar, mientras funcionó la plataforma reservada, la media y la mediana de la distribución de los tiempos de recorrido son inferiores a la situación una vez que se elimina el carril bus. Los 945 m del tramo se recorren en las condiciones más rápidas en 93 segundos, pero los tiempos medios en el año estudiado con funcionamiento del carril bus fueron de 265,54 segundos.

El tiempo medio de recorrido del tramo aumentó entre 2010 (con carril bus) y 2012 (con la VPV recién implantada) en 28,08 segundos, con notables variaciones entre los días hábiles (35,3 segundos) y los días no hábiles (6,73), lo que es un resultado esperable al existir menor congestión en esos días. Si se compara la situación con carril bus en 2010 con la situación en 2014, donde es posible que el grado de supervisión de la VPV se haya reducido, el incremento medio del tiempo de viaje en el tramo es de 37,13 segundos (43,08 s en días hábiles y 17 s en días no hábiles). Si se evalúa en términos porcentuales, el tiempo medio de recorrido en general aumentó un 14,0% entre 2010 y 2014, valor que sube a 15,8% en días hábiles frente a un 7,0% en días no hábiles. En estas variaciones pueden influir otros factores, como podría ser una variación global del tráfico o de la demanda del autobús. El estudio de tramos de contraste presentado en el apartado 4.3 permite descartar cambios importantes debidos a la evolución temporal.

Como puede comprobarse, los valores obtenidos están en consonancia con los presentados en la revisión de la literatura por Tanaboriboon y Toonim (1983) y por Arasan y Vedagiri (2010), mencionados anteriormente, mientras que el efecto del carril bus es mucho más relevante que en el caso estudiado en Surprenant-Legault y El-Geneidy (2011) y Diab y El-Geneidy (2013).

Cuantificando la variabilidad involucrada, se observa cómo el coeficiente de variación general aumenta desde 0,205 en 2010 a valores de 0,298 y 0,284 en 2012 y 2014 respectivamente, lo que permite cuantificar el aumento de la variabilidad del tiempo de recorrido entre un 39% y un 46% de su valor, con porcentajes de incremento similares en días hábiles y no hábiles. Resulta de interés el análisis detallado de las distribuciones de los tiempos de viaje. Como puede observarse, la distribución es multimodal, observándose con claridad en algunos de los periodos dos modas y con otras de menor magnitud. La separación entre estas modas sugiere que pueden estar asociadas a los ciclos semafóricos. Debe tenerse en cuenta que, en situaciones de congestión sin reserva de plataforma, las colas en los semáforos y su tiempo de disipación pueden provocar que todos los autobuses tengan que sufrir un retraso aun cuando en flujo libre hubiesen encontrado el semáforo abierto. En ocasiones puede ser insuficiente la capacidad de la fase verde del semáforo para eliminar toda la cola y debe esperar un ciclo adicional. Como se ha mencionado, existen dudas sobre la efectividad de la priorización semafórica con la configuración de la zona.

En la situación con plataforma reservada, la mayor parte de los viajes se concentran en el entorno del tiempo medio y de la mediana en 260 – 265 segundos. Sin embargo, cuando se elimina el carril bus, además de subir el tiempo medio al entorno de los 300 segundos, los viajes se dispersan hacia la derecha de la distribución, apareciendo un primer pico relevante en torno a 240 s, un segundo pico en torno a 340 s e incluso se aprecia un tercer pico en torno a los 420 segundos. Existe un número relevante de valores que presentan tiempos de recorrido elevados, lo que no ocurría en el caso de existencia de un carril reservado para autobuses.

La distribución acumulada de los tiempos de viaje puede observarse en la Figura 4. En la situación de 2010, con la plataforma reservada, el 99,33% de los autobuses realizaban el recorrido en menos de 7 minutos. Una vez retirada esta plataforma, el tiempo de recorrido que no es superado por ese porcentaje de autobuses ha subido por encima de los 10 minutos. Con el carril bus, solo el 3,57% de los viajes superaban los 6 minutos, en 2014 el 18,67% de los viajes superaban esa cifra. Mientras que en 2010 el 75,28% de los viajes tenía una duración de menos de 5 minutos, en 2014 solo el 55,09% de los viajes se completaban en ese tiempo. Debe señalarse que lo esperable es que esos viajes de mayor duración se concentren en las franjas de mayor demanda y con mayor uso por parte de viajeros pendulares, ya que se tratarán de las horas punta de los días laborables. Por un lado, esto va a suponer que el número de viajeros perjudicados por estos incrementos de tiempo sea más elevado. Por otro lado, se trata de un tipo de viajero que requiere una mayor fiabilidad en su tiempo de viaje ya que puede no tener flexibilidad en su hora de llegada a destino, por lo que esta variabilidad va a ir en detrimento de su captación por el transporte público.

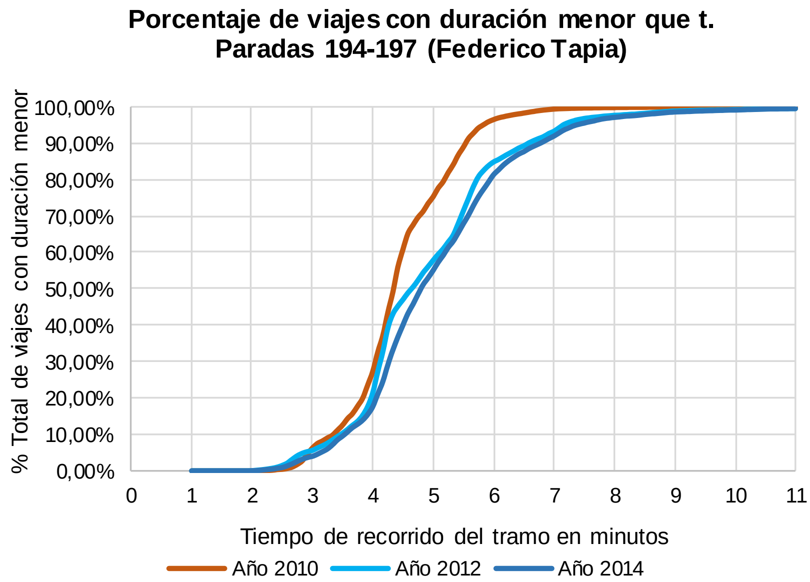

Figura 4: Distribución acumulada de los tiempos de recorrido en el tramo de la calle Federico Tapia (paradas 194 a 197)

4.3 Comparación con los tramos de contraste

Con el fin de verificar si esta evolución de los tiempos de viaje y de su variabilidad en el periodo 2010 – 2014 se puede atribuir principalmente a la retirada del carril bus, se han repetido los cálculos en otros dos tramos de la ciudad, previamente presentados.

En la Figura 5 se puede observar la evolución del tiempo medio de recorrido y del coeficiente de variación en los tres tramos analizados. Puede observarse cómo el notable incremento de la variabilidad en el tramo de la calle Federico Tapia tras la retirada del carril bus no se reproduce en los otros dos tramos, donde permanece aproximadamente estable. Como ya se ha señalado, la influencia de la reserva de plataforma en los tiempos medios es menos notable, pero igualmente se verifica que la tendencia observada en el tramo de la calle Federico Tapia no se observa en otros tramos de la ciudad, por lo es razonable atribuirlo a la influencia de la retirada del carril bus y su sustitución por una VPV.

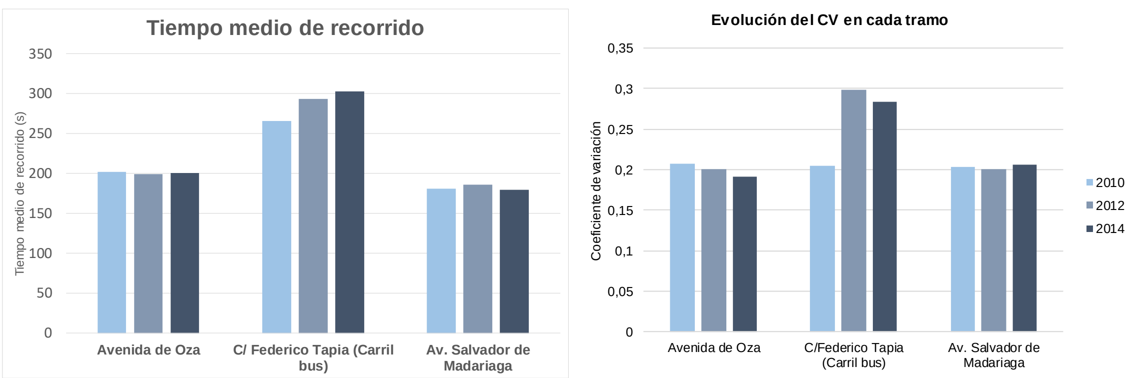

Figura 5: Comparación de tiempos de recorrido y variabilidad con tramos de contraste

Se ha realizado también la comparación de las distribuciones acumuladas, que se muestran en la Figura 6. De nuevo puede observarse que la diferencia que se apreciaba en la Figura 3 no se produce en estos tramos. Puede observarse también cómo estos tramos no están afectados por una congestión acusada, como sí existe en la zona de Federico Tapia, por lo que las gráficas son sensiblemente más verticales, con menores diferencias entre los recorridos más rápidos y los más lentos. Por lo tanto, un carril bus en estas vías tendría poca capacidad de mejorar la situación actual en cuanto a variabilidad del tiempo de recorrido y en cuanto a disminución de tiempos de recorrido. Esto está en consonancia con valores del efecto de la reserva de plataforma muy bajos reportados en otros estudios mencionados en la revisión de la literatura. Este tipo de análisis resulta de utilidad para decidir en qué tramos establecer reservas de plataforma.

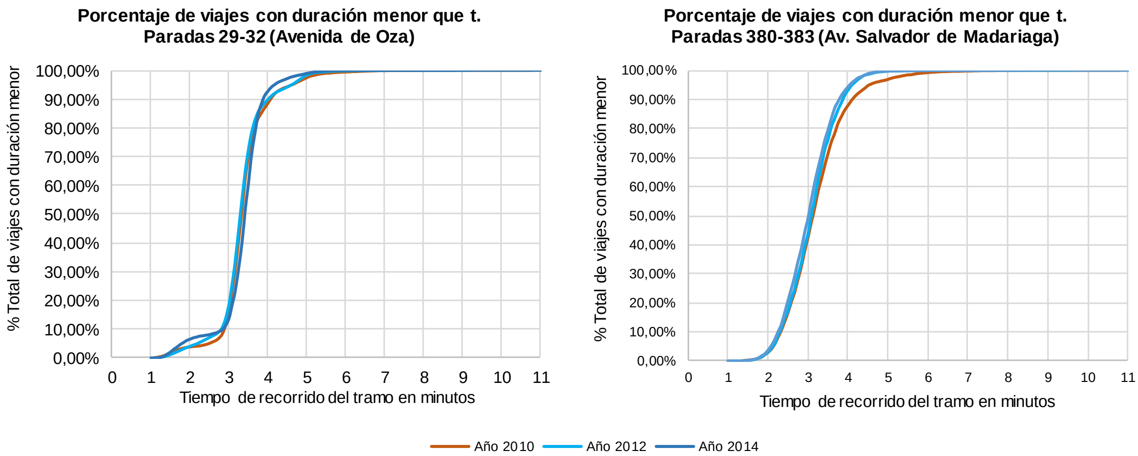

Figura 6: Comparación de distribuciones acumuladas con tramos de contraste

4. CONCLUSIONES

Las plataformas reservadas para el transporte público permiten evitar los efectos de la congestión del tráfico en las operaciones de estos sistemas. Sus ventajas se ponen de manifiesto en aquellas circunstancias en las que existe congestión en el tramo. En viales en que la congestión se produce solo en las horas punta de los días laborables, las plataformas reservadas van a ser más efectivas en eliminar los viajes de mayor duración y en reducir la variabilidad de los tiempos de recorrido que en reducir globalmente los tiempos de viaje promedio. Sin embargo, esos viajes de mayor duración van a producirse en general en los momentos de mayor demanda, lo que es relevante a efectos de evaluar los beneficios obtenidos con esta medida. Adicionalmente, la mayor variabilidad se va a producir en días hábiles y en horas punta, momento en el que es del mayor interés captar a los viajeros pendulares. Estos viajeros suelen tener además un horario fijo de entrada, por lo que el efecto atractor hacia el transporte público de una baja incertidumbre en el tiempo de recorrido puede ser más relevante para el cambio modal.

En el caso de estudio analizado de la ciudad de A Coruña se ha comparado la situación con un carril reservado para autobuses y taxis y un carril de circulación general frente a dos carriles para circulación general con priorización semafórica para los autobuses con retraso y especial vigilancia de los aparcamientos indebidos. La retirada del carril bus ha supuesto un incremento del tiempo medio de recorrido al finalizar el periodo analizado del 14,0% en general y del 15,8% en días hábiles. Desde el punto de vista de la variabilidad, el coeficiente de variación se ha incrementado un 46% en ese periodo. Se han analizado las distribuciones acumuladas, cuantificando la reducción de los viajes de mayor duración. En el caso de estudio los viajes que superan los 6 minutos de duración aumentaron del 3,57% al 18,67%, mientas que los viajes de más de 5 minutos han pasado del 24,72% al 44,91%. Se ha contrastado la variación de parámetros observada en el tramo en el que se ha retirado la plataforma reservada con otros tramos similares de la ciudad, donde se observa que no se han producido modificaciones relevantes en el periodo. El estudio de los histogramas de densidad y las distribuciones acumuladas del tiempo de recorrido pueden ser un instrumento útil para valorar la oportunidad de implantar plataformas reservadas, dado que estas actuarán fundamentalmente sobre los valores más elevados de la distribución.

Entre las líneas de investigación abiertas está el estudio de la distribución horaria de los viajes en los que se producen los mayores ahorros y la evaluación de los pasajeros que se benefician. También resulta de interés analizar la influencia de las operaciones en las paradas según la demanda de subidas y bajadas, el cumplimiento de intervalos, la modelización de los diferentes efectos, la comparación con los valores que se extraen de metodologías de cálculo existentes y la extensión de estos análisis a otros tramos de estudio.

AGRADECIMIENTOS

Los autores agradecen la financiación recibida en el proyecto “Paradas, transbordos y reserva de plataforma. Análisis experimental y modelización de su influencia en sistemas de autobús (IMPROVEBUS)”, de referencia RTI2018-097924-B-I00 MCI/AEI/FEDER, UE.

Los autores agradecen a la Compañía de Tranvías de La Coruña el acceso a los datos de su Sistema de Ayuda a la Explotación.

THE UNDELAYABLE LEGAL REFORM OF PUBLIC PROCUREMENT RULES IN THE MANAGEMENT MODELS FOR THE URBAN TRANSPORT PUBLIC SERVICE IN THE AUTONOMOUS COMMUNITY OF CASTILLA Y LEÓN

José Manuel Cantera
Professor of Administrative Law, University of Burgos, Spain

ABSTRACT

The purpose of this paper is, on the one hand, to analyze the management models that Law 7/1985, of April 2, 1985, regulating the Local Regime Bases, offers to the Provincial Capital Cities of the Autonomous Community of Castilla y León in Spain, a Member State of the European Union, for the provision of public urban transport services. And on the other hand, in line with and in relation to the previous premise, to study how it influences and determines, depending on the form of management of the public service of urban transport chosen by each town council, which articles of Law 9/2017, of November 8, on Public Sector Contracts, should be applied.

From the study of these issues, it will be concluded that the level of application of the contractual legislation will not be the same, it will be disruptive and unequal, which requires a necessary legislative modification that equates the application of the contractual regulations, regardless of the model of management of the urban transport public service that the Municipalities decide to adopt.

1. INTRODUCTION

The aim of this research is to analyze the service management models of urban public transport in the provincial capital cities of the autonomous community of Castilla y León in Spain and their relationship with public procurement. We will corroborate that the system for contracting the urban public transport service within these municipalities is different and discriminatory. This treatment shows the violation of the principle of equality in the application of the rule (Carmona, 1994).

2. MODALITIES OF PUBLIC MANAGEMENT OF LOCAL ENTITIES

Spanish local legislation distinguishes two modes of management for local public services (Guayo, 2004): direct management and indirect management.

2.1 Modes of direct management of public services

The forms of direct management of a public service can adopt the following models: Provision of a public service by a local entity, in which the municipality, with its own resources, provides the service; provision of a public service by a local autonomous agency, in which an entity with legal personality (Quintana, 1992), dependent on the municipality, provides the public service; Public service's provision by a local Public Business Entity, according to which it is a separate and distinct entity from the municipality to which the service provider depends and is financed mainly by market income; and public service provision by a local Mercantile Society, according to which it is a private legal entity that provides the service and its assets must be public, either completely owned by e municipality, participated by it or owned by other public entities (Melania, 2011).

A recent legislative amendment established direct management as a preference over indirect management (Fernández, 2016). If the municipality opts for indirect management, it must be approved by the Plenary of the Local Government (Huergo, 2019).

2.2 Modes of indirect management of public services

The choice of municipalities for the forms of management is a prerogative of their local autonomy, constitutionally guaranteed (Fernandez-Miranda, 2008). When the municipality decides on the indirect management of a public service, the choice of the private or commercial entity that will provide it will follow the procedures of Law 9/2017, of November 8, on Public Sector Contracts.

The previous public procurement legislation included four types of public service management contracts or indirect management modes: the concession, the interested management (Nieves, 1958), the concert (Domínguez, 2011) and the provision of public services through a mixed economy company (Iglesias, 2010). The current public procurement regulations no longer include public service management contracts (López, 2017). However, it has maintained the administrative concession, although under the name of service contract in favor of citizenry, a notion that is highly criticized because it rethinks the classic concepts of public service contract and service contract (Fortes, 2019).

3. THE FORMS OF MANAGEMENT OF THE COLLECTIVE URBAN TRANSPORT PUBLIC SERVICE IN THE CITY COUNCILS OF CASTILLA Y LEÓN

In this section we will analyze the forms of public service provision of urban collective transport in the nine provincial capitals of the autonomous community of Castilla y León in Spain, which are: Ávila, Burgos, León, Palencia, Salamanca, Segovia, Soria, Valladolid and Zamora. It is a compulsory public service in accordance with local legislation. The population in Ávila is of 57,744 inhabitants, in Burgos of175,821, in León of 124,303, in Palencia of 78,412, in Salamanca of144,228, in Segovia of 51,674, in Soria of 39,398, in Valladolid of 298,412, in Zamora of 61,406.

3.1 Municipalities that provide urban public transport services under a service concession scheme

The municipalities that provide public urban transport services under a service concession are: Ávila, Palencia, Salamanca, Segovia, Soria and Zamora. All these municipalities opt for a form of indirect management. The municipalities selected this form of management because they only have to wait a the successful bidder to comply with the obligations of the service concession contract.

3.2 Municipalities which provide urban public transport services under direct management by the City Council itself

The Municipalities that provide the urban collective transport service under direct management by the City Council itself are Burgos and León. Both municipalities opted for this model to be implemented directly by the Local Council itself. These municipalities understood that the management of the service should be held by their City Councils, with their own means and with the aim of protecting the public interest at stake.

3.3 Municipalities that provide the urban collective transport service as a public company with entirely public capital

The only municipality that provides the urban public transport service as a public company is Valladolid, through a municipal company. One of the reasons for using this method of management was to reduce the application of public procurement rules.

4. PUBLIC PROCUREMENT REGULATIONS FOR URBAN COLLECTIVE TRANSPORT

The normative systems of public procurement that the state legal system includes (Moreno & Pintos, 2015) are going to be developed below.

4.1 Public procurement laws that affect, directly and indirectly, the management of urban collective public transport

The entrance of the Kingdom of Spain into the European Economic Community in 1986 meant that it was obliged to submit to its regulations, its institutions and the judicial resolutions of the courts that make up the Community. It also affected the matter of public procuring (Allain, 2006). The Community Directives on public procurement (Verdeaux, 2003), which have followed one another throughout the life of the European Union, amount to ten. One of them is Directive 2014/24/EU of the European Parliament and the Council, dated February 26, 2014, which has been transposed into the Spanish legal framework by Law 9/2017, dated November 8, on Public Sector Contracts.

A second rule that regulates public procurement is the one relating to special economic sectors. The European law currently in force in this area is Directive 2014/25/EU of the European Parliament and the Council, dated February 26, 2014. This rule has been transposed into Spanish law by means of Book I of Royal Decree-Law 3/2020, of February 4, on urgent measures.

And the third European law on public procurement is the one on concession contracts, known as Directive 2014/23/EU of the European Parliament and the Council of February 26, 2014, on the award of concession contracts (Graells, 2015), which has also been transposed in Spain through Law 9/2017, of November 8, on Public Sector Contracts.

4.2 Subjective scope of public sector contracts, in general

Article 3 of Law 9/2017, dated November 8, on Public Sector Contracts, lists three types or classes of public entities for the purposes of public procurement: Public Sector entities from a broad or generic point of view (it refers to the entire Spanish public sector), Procurement Authorities (this concept has been drawn up by the state legislator to cover the notion of a public company in the European Union) and Public Administrations (the Spanish public entities, bodies or agencies that fall into this group are the territorial or similar administrations, including the local Autonomous Bodies).

4.3 Subjective area in the special sectors of water, energy, transport and postal services

The subjective scope of Book I of Royal Decree-Law 3/2020, of 4 February, on urgent measures, is made up of three concepts which, according to its article 5.2, are Contracting Entity, Adjudicating Power and Public Company.

The public entities to which the contracting procedures provided for in the law on the special sectors of water, energy, transport and postal services are applied, are different from and more flexible than those established in the public sector contracting legislation that are considered to be Public Administrations.

4.4 Subjective scope of the contracts for the concession of works and the concession of services

The subjective scope of contracts for the concession of works and the concession of services (Bovis, 2005) is the same as that set forth in Law 9/2017, of November 8, on Public Sector Contracts, distinguishing, for the purposes of contracting, between Public Administration, the Awarding Authority and the Public Sector.

5. THE PUBLIC CONTRACTING REGIME WILL DEPEND ON THE PUBLIC SERVICE MANAGEMENT MODE CHOSEN BY EACH CASTILLA Y LEÓN CITY COUNCIL

From all the above, we can highlight the disparity in the mechanisms for public contracting in the Spanish legal system. The public procurement system will depend on the public sector entity that contracts, and in urban public transport, the model chosen by each municipality of Castilla y León. The list of the entire public procurement system of the state legal system that we have set forth, together with the management methods of the existing urban collective public transport services in the municipality, leads to the following perspective.

The City Councils of Ávila, Palencia, Salamanca, Segovia, Soria and Zamora, which manage urban public transport through service concessions, make the management model subject to the provisions for an administrative contract in Law 9/2017, of November 8, on Public Sector Contracts.

The City Councils of Burgos and León, as they are public administrations, will follow the procedures set forth in Law 9/2017, of November 8, on Public Sector Contracts for any type of work, service or supply required by the public collective transport service. There will be as many administrative contracts tendered as requirements to be satisfied by the service.

Finally, in the City Council of Valladolid, the urban public transport service is managed by a municipal public company. It has the legal nature of a Bidding Power and, therefore, it will have to be in accordance with the Law 9/2017, of November 8, of Contracts of the Public Sector for the Bidding Powers. It will have a much lower level of application of contractual rules than the ones the above-mentioned City Councils are subject to. In this case, moreover, when the object of the contract consists of the activities of making available or operating networks that provide a service to the public in the field of bus transport (Bermejo, 2008), they will be governed by the provisions of Book I of Royal Decree-Law 3/2020, of February 4, on urgent measures.

From what has been explained, we can affirm that there is a disparity of rules and procedures of public contracting in the provision of the service of collective urban transport. Their application will depend on the type of direct or indirect management - public or private

(Hansson, 2010) - chosen by each one of the nine provincial capital cities of Castilla y León, leading to dysfunctional public procurement regulations (Santamaria, 2016).

6. CONCLUSIONS

Firstly, the legal regime of Local Entities includes the possibility that Town Councils may, in the exercise of their constitutionally and legally granted local and organizational autonomy, opt for different modes of management of public services in general and of the public urban transport service in particular.

Secondly, the municipalities which are provincial capital cities in the autonomous community of Castilla y León in the Kingdom of Spain have different models for managing public transport services: indirect management (the municipalities of Ávila, Palencia, Salamanca, Segovia, Soria and Zamora), direct management by the Coruncil itself (the municipalities of Burgos and León) and direct management by means of a local commercial company with entirely public capital (the municipality of Valladolid).

Thirdly, the legislation on public procurement in the European (Community Directives) and Spanish (Spanish public procurement laws) legal systems is detailed and not homogeneous: its application will depend on the purpose of the contract, the area in which it conducts its activity and the public sector entity it contracts.

Fourthly, the public procurement rules applicable to the management of the public service of urban public transport are as varied as the forms of organization of the urban public transport’s public service that each capital city of Castilla y León follows.

Fifthly, the disparity between the contractual and public service regulations to be applied, which depend on many factors, leads to a regulatory dysfunction that should be modified so that no one is left out of the same public contracting procedures, which guarantee the efficient management of public resources managed through the public urban collective transport service.

Sixthly, the solution we propose would be a legislative modification in which it would be clear that, regardless of the method of management of the public service of collective urban transport chosen by each municipality - when the satisfaction of a need, expressed in a work, a service or a supply, is foreseen - the same rule would be applied, in all its virtuality. This will generate a great deal of legal security for those applying the Law and for the contracting bodies of all the public sector entities affected.

ABSTRACT

This paper analyzes the effect of the limited range of battery electric bus on the operation of the bus services charged at the bus garage. A model has been built to calculate the performance of the routes according to the type of charging scheme. It evaluates the total cost of the bus service, considering the necessary resources due to range limitations and electric constraints. Based on the analysis of the real data of a bus line in the city of Barcelona, diesel or hybrid vehicles are still found to be more competitive than electric vehicles because of the acquisition costs of electrical technology. The study shows that the charging operation at the bus garage, without being the most profitable option a priori, is adequate when the design and operation parameters of the bus route fall below certain values.

1. INTRODUCTION

Most of the largest bus fleets in our cities are made up of traditional vehicles that present internal combustion engines (ICE). A large part of the pollutants present in urban areas can be attributed to these vehicles, which contribute to the global warming problem and affect the health of citizens in metropolitan areas. Changing this type of vehicle to fully electric fleets would contribute to reducing carbon dioxide (CO2) emissions, reducing the consumption of fossil fuels, and improving energy efficiency, as can be seen in Jang et al. (2016), Corazza et al. (2016), Miles and Potter (2014) and Zhou et al. (2016).

Fully electric fleets involve the use of battery electric buses (BEB), whose only source of energy is a battery pack equipped on board. Charging these batteries can be done in various ways, but the most common are opportunity charging during the service and overnight charging (Miles and Potter, 2014). Opportunity charging is performed on the street using fast chargers, which take 5-10 minutes to restore full power. Overnight charging is performed in the bus garage, using slow or fast chargers, while the vehicles are not in service. In the case of overnight charging the battery size is significantly larger than in the opportunity charge to provide large travel ranges between two consecutive charging operations. This means long charging times (up to 5 hours).

To guarantee a wide deployment of BEB in cities, it is necessary to consider new operations and the limitations that their use implies in bus fleets, as explained in Mahmoudzadeh et al. (2017). In Li (2014) the operational limitations of these vehicles and the effect of different factors (driving, air conditioning, etc.) on energy consumption are explained. Likewise, Xylia and Silveira (2018) show the results of experimental implementations of electric buses in Europe.

A basic point in the implementation of BEB is its implementation cost. As shown in Teoh et al. (2017) and Feng et al. (2013) the cost of capital and charging stations are significantly high. On the contrary, this type of bus can reduce operating costs by up to 80% compared to ICE vehicles. In this way, it turns out that the total cost of ownership (TCO) and the life cycle cost of BEB are essential to evaluate the profitability of their implementation. In this sense, Lajunen (2014) presents an in-depth analysis of the TCO of electric buses, the conclusions of which show that there is a lot of uncertainty in its estimation.

In Lajunen and Lipman (2016) we can find a broad life cycle analysis for different bus technologies, considering capital, maintenance, energy consumption and emission costs. Here it is shown that diesel hybrid buses are still competitive in terms of life cycle cost with respect to other powertrains, but it is suggested that improved BEB will be able to compete with diesel and natural gas in the future. Another important point indicated in this work is that a significant public investment is necessary to create efficient fast charging infrastructures.

Regarding the influence of energy demand on the provision of bus services, we can highlight the work of Vepsäläinen et al. (2018), where the effect of a wide list of factors and characteristics of the route is analyzed, validating a predictive model of electricity demand. Bi et al. (2017) analyze the life cycle cost of charging infrastructure, comparing conductive and inductive systems. And, for their part, Chen et al (2018) compare the profitability of charging lane technologies, charging stations and battery exchange stations.

In this paper, the effect of the new requirements of battery electric vehicles on the operation of the bus services charged at the garage is analyzed. To do this, a model has been developed, that analyzes the most suitable charging operation and performance. They are evaluated based on the total cost of the system on a given bus route, and the calculation of the resources required due to electrical limitations. The model considers two different charging strategies or schemes: garage charging (day or night) and opportunity charging at bus terminal stations on the given route. The modeling of the charge at the garage is based on the proper scheduling of the vehicle deadheading movements to the garage, to satisfy the electrical limitations and the attributes of the service.

An improvement procedure has also been incorporated to optimize the total cost of the system, based on advancing the charging operations before the moment when the vehicles begin to run out of battery, similar to Gao et al. (2017). This minimizes the additional vehicles required, compared to the usual procedure where charging operations are performed just when the vehicles are running out of power.

Finally, the calculation of the performance and the resources required in the opportunity charging is based on the queue theory at the charging facilities, taking into account the irregular arrivals of buses to the on-route chargers and the available loading time. This severely limits the viability of electrical systems on routes with busy headways.

2. MODELING FRAMEWORK

2.1 Problem formulation

We consider a linear bus route of length *2L*, where the buses travel in two directions and the stops are evenly spaced at a distance s. Buses can enter and exit service only at the terminal stop furthest from the garage, located l_G units away.

We assume that the bus service is performed in a period of time hday on a typical day, with N stationary periods or time windows of size hi $(i = 1\ldots N)$, in which the external variables of the system, such as hourly demand Λ_i and the cruising speed vi, remain constant. It is assumed that the duration of the stationary periods is greater than the dead times of traveling to the garage, that is $(2l_G/v_i) \ll$ hi. Furthermore, a constant time headway H_i is assumed for each time window. The number of necessary vehicles $M^0(i)$ and the commercial speed $v_c{}^0(i)$ in time window i when no charging operation is required, are defined in Equation (1). From now on, the superscript *0* represents the value of the corresponding variable when the electric charge operation does not affect it, and the superscript *1* the opposite case. We also assume that at the end of the last stationary period an additional period of time of length h_{night} begins in which there is no bus service. All vehicles are sent to the garage for maintenance until the next day.

$$M^0(i) = (2L)/(H_i v_c^0(i)) \quad (1)$$

Using this notation, the fleet size required for bus route operation on a typical day would be $M_T^0 = max\, M^0(i)$. Said fleet size will not be constant, but we will have a fleet size variation $\Delta M^0(i)$ defined in Equation (2) and for which $M^0(0) = 0$ veh. This assumes that in each period there will be a number of vehicles introduced on route $M_{in}^0(i)$ and a number of vehicles removed from route $M_{out}^0(i)$ at the beginning of period i. These variables will be equal to zero if there are no restrictions that affect the autonomy of the vehicles, but they will present a positive value when the electric vehicles run out of batteries and must be charged.

$$\Delta M^0(i) = M^0(i) - M^0(i-1) = M^0_{in}(i) - M^0_{out}(i) \quad (2)$$

The energy consumption of a vehicle is calculated by the product of the distance traveled by the energy consumption factor associated with the vehicle technology in service f_C *(kWh/veh-km)*. The effective capacity of the batteries is calculated by $E = E'(1\text{-}SOC_{min})$, where we subtract from the nominal capacity of the battery E' the minimum energy value ($E' * SOC_{min}$) that the buses need at any time of service in emergency case. This minimum value depends on the minimum threshold for the state of charge of the batteries (SOC_{min}) defined by the manufacturer.

If in a time period *k* vehicles are introduced into the system ($M_{in}(k) > 0$), it will be necessary to check whether these vehicles can provide service throughout the day or should be recharged in an intermediate period $j>k$. We define the energy consumed by the vehicle until the beginning of period *i* as *C(i)* (determined by Equation 3) and the energy remaining in the battery at the beginning of period *i* by *B(i)*. For the vehicle to be able to provide service up to a period of time *i*, Equation (4) must be fulfilled, where *B(k)* represents the energy available when the vehicle was introduced in the period of time *k*. We generally assume $B(k) = E'$.

$$C(i) = f_c \sum_{j=k}^{i-1} h_j v_c(j) \quad (3)$$

$$B(i) = B(k) - C(i) \geq 0 \qquad k < i \quad (4)$$

We will define $T_{end}(i) = T_R(i) + \sum_{j=1}^{i-1} h_j$ as the absolute time in which the vehicles entered into the service at the beginning of time window *i* will remain without batteries, where $T_R(i)$ is the maximum operating time of the vehicles that start in the period of time *i*. To calculate this value, we need to know how many full-time windows and how long in the next time window (t_{k^*}) the vehicle will be able to travel until the batteries are exhausted, which results from solving Equation (5). In this way we can rewrite $T_R(i)$ as $T_R(i) = \sum_{j=i}^{k^*-1} h_j + t_{k^*}$.

$$t_{k^*} | \quad E = f_C\left(\sum_{j=i}^{k^*-1} h_j v_c^0(j) + t_{k^*} v_c^0(k^*)\right) y \quad 0 \leq t_{k^*} < h_{k^*} \quad (5)$$

A vehicle entered in time window *i* will run out of batteries in time window $N_{end}(i)$, the calculation of which involves complying with Equation (6). With the values of $T_{end}(i)$ and $N_{end}(i)$ we can define exactly the moment when a vehicle entered in the time window *i* needs a charging operation. We will consider that if a vehicle entered in time window *i* has enough charge to complete the service until the end of the day, then $N_{end}(i) = N + 1$.

$$\sum_{j=1}^{N_{end}(i)-1} h_j \leq T_{end}(i) < \sum_{j=1}^{N_{end}(i)} h_j \quad (6)$$

In this way, it will not be necessary to carry out charging operations during the h_{day} service period when T_{end} *(1) > hday* and N_{end} *(1) = N + 1*. In this case, the transport company can only carry out the night charging scheme in the garage (G-Scheme) if the hnight period is long enough to fully charge the battery pack. Under these conditions, the stored energy $B^0(i)$ will always be positive.

2.2 Overnight charging operations at the bus garage

In this case, we are going to consider that the buses are charged in the garage with slow chargers (with speed S_N) in the period of non-provision of the transport service, this being a complementary charging operation of the daily load in the garage (with speed $S_D > S_N$). In this way, the vehicles charged in this period can be used the next day according to service needs.

We will call T_{el} the moment at which the night charge scheme (G-Scheme) begins with respect to the initial service time, and N_{el} the time window after which the night charge begins ($T_{el} = \sum_{i=1}^{N_{el}} h_i$). The vehicles recharged at night must be those that belong to the subset $M_{inv,N}$ *(i)* in each period of time $i \leq N$.

To simplify the problem, we will assume that all daily services present the same stationary periods, demand, speeds and, therefore, vehicle needs in each time window *i = 1… N*. However, if the services corresponding to different days have different temporal patterns, this methodology can be easily adapted.

With these premises, Equation (7) shows the condition to be fulfilled in order to fully charge the batteries at the beginning of the period of time *k*, when the vehicle has arrived at the garage in period *i* of the previous day. If this condition is not met, it is not possible to recharge the batteries between time periods *i* and *k*.

$$E' < \left\{\left(h_{day} + h_{night} + \sum_{m=1}^{k-1} h_m\right) - \sum_{n=1}^{i-1} h_n\right\} \cdot 1/S_N \qquad (7)$$

3. COST ANALYSIS

The total cost of a day of service for the transport company will be calculated by $Z = Z_M + Z_B + Z_V + Z_C$, where ($Z_M$) represents the sum of the depreciation of the vehicle plus labor costs, (Z_B) is the cost of batteries, (Z_V) is the cost of the distance and (Z_C) is the cost of the charging infrastructure.

We will consider here a series of operational parameters that directly affect the variable costs of transport companies. The first of these is the total distance traveled by the bus fleet during the entire day of service, calculated as vehicles-kilometer traveled in one day, VKT (veh-km/day). The second in importance is the total time that the vehicle-driver pair is providing service throughout the day, either on the corresponding route or in the dead movement to the garage, defined as the vehicle-hours traveled in service, VHT (veh-h/day). Finally, the vehicle-hours depreciated throughout the day, VHD (veh-h/day), will be calculated, representing the total number of vehicles needed throughout the day, either on the road or in the garage.

Equation (8) shows the calculation of ZM. In this equation, the cost ratio c_{t1} represents expenses related to drivers, and cost ratio c_{t2} represents vehicle depreciation, insurance, and other fixed costs of the vehicle throughout the day.

$$Z_M = c_{t1}VHT + c_{t2}VHD \tag{8}$$

Equation (9) calculates the cost of the battery, considering the energy capacity of the batteries equipped in each vehicle (E') and the unit cost of the battery per kWh acquired c_b.

$$Z_B = E' \cdot c_b \cdot VHD \tag{9}$$

In Equation (10) the cost of the distance traveled is calculated, where c_d is the unit cost of the distance, which considers the cost of energy to operate the vehicles and other expenses related to the kilometers traveled.

$$Z_V = c_d VKT \tag{10}$$

Finally, Equation (11) calculates the cost of the charging infrastructure. Here, the c_{cg} parameter considers the cost of capital and the daily operating cost.

$$Z_C = c_{cg}\left(N_{ch,N}\right) \tag{11}$$

4. RESULTS

To verify the goodness of the generated model, an analysis of a real case of a bus line in the city of Barcelona has been carried out. Within the city's urban bus network, route V13 has been selected, on which the model has been applied to calculate the costs of the bus company when implementing a fully electric bus service with its auxiliary charging facilities.

In the short-term scenario, the values obtained in pilot tests in Barcelona for the operational parameters of the service and the average cost of capital in developed countries have been considered for the analysis. On the other hand, other scenarios have been considered and sensitivity analysis have been carried out to estimate the influence of the cost of electrical technology on long-term efficiency.

The reference values for the analysis of the performance of the battery, the charger and the electric vehicle, as well as those necessary to compare with the diesel and diesel-hybrid engines, have been obtained from the operational data monitored by the TMB bus operator in 2018 (TMB, 2018).

4.1 Discussion

Table 1 shows the values obtained for the most significant variables of the model carried out. With these values, it is possible to analyze the operational performance of the route, the amount of resources required, and the operational costs for the different types of engine and bus loading schemes on route V13 in the city of Barcelona.

	Diesel	**Hybrid**	**Electric**		
			G-Charge Opt.	**O-Charge Reg.**	**O-Charge Skip**
VHT (Veh-h/day)	281.5	281.5	281.5	291.9	281.5
VHD (Veh-h/day)	456.0	456.0	456.0	480.0	456.0
VKT (Veh-km/day)	2974.2	2974.2	2974.2	3010.6	2974.2
Charging/Fuel stations	1	1	0	0	0
Opportunity chargers	0	0	0	2	2
Overnight chargers	0	0	10	2	9
Fleet size (veh)	19	19	19	20	19
Z_M (Euros/day)	17,215.1 €	17,639.2 €	18,122.6 €	18,911.6 €	18,122.6 €
Z_V (Euros/day)	4,491.0 €	3,212.1 €	2,260.4 €	2,288.1 €	2,260.4 €
Z_C (Euros/day)	109.7 €	109.7 €	283.8 €	214.8 €	352.0 €
Z_B(Euros/day)	0.0 €	0.0 €	1,191.2 €	1,253.9 €	1,191.2 €
Z (Euros/day)	21,815.8 €	20,961.0 €	21,857.9 €	22,668.3 €	21,926.0 €

Table 1: Modelling results for different vehicle technologies and charging schemes in route V13

As we can see, the operating cost of fully electric vehicles is slightly higher than the cost corresponding to diesel or hybrid vehicles. This is because BEB technologies are more expensive than diesel and hybrid vehicles. In this way, the cost savings that can be obtained in the operation do not compensate for the higher cost of electric vehicles and batteries. However, the variation in operating cost between the different alternatives analyzed stands at 4%, so it is to be expected that a reduction in the prices of batteries and electric vehicles in the near future due to the maturity of these technologies will favor a competitive advantage of BEB systems.

Regarding the distribution of system costs, the time component of the cost (depreciation of the vehicle plus labor costs) is the most important in all cases (83% in BEB systems, 80% in ICE and 85% in hybrids), followed by the distance-based component (10% in BEB systems, 20% in ICE and 15% in hybrids), with the cost of batteries being 6% and the cost of installing charging systems 1% in the BEB systems. With these values, the G-Charge charging scheme can equalize the costs of diesel and hybrid systems if the price of vehicles and batteries decreases by 28% and 2%, respectively.

For the route that has been analyzed in this case, the most suitable BEB alternative is night charging in the garage (G-Charge). This is due to the fact that the buses have large battery packs to ensure their operation throughout the working day, which makes the size of the fleet in this case equal to that required in ICE and hybrid technologies. On the other hand, if the opportunity charge is used in the regular option (O-Charge Regular), it would be necessary to increase the size of the fleet in a vehicle with respect to the G-Charge scheme or the diesel system. This increase is justified by the time spent on the chargers installed on the street after completing each round trip on the route. To equalize the total cost of the G-Charge scheme, the company should skip the charge operation in predefined time windows throughout the day (O-Charge Skip).

4.2 Sensitivity analysis

The sensitivity analysis carried out aims to analyze the influence of the variation in battery capacity. For this, the same type of BEB analyzed in the real route V13 of Barcelona has been maintained, but allowing to modify the size of the battery pack installed in it. A variable energy consumption factor that depends on the weight of the batteries has been considered, as described in Gao et al. (2017). With the values of the analyzed route, a consumption factor - battery capacity relationship equivalent to $f_c = 0.0005E' + 1.2243$ *(kWh/km)* has been obtained for standard buses.

For the route analyzed, the most profitable charging scheme is the one of opportunity that allows to skip charging operations in certain periods of time (O-Charge Skip), provided that the capacity of the batteries is E'≤275 kWh, as you can see at Figure (1). On the other hand, if the omission of charge is not allowed in the opportunity charge (O-Charge Regular), it turns out that it is much more expensive than the optimal charge in the garage (G-Charge Optimum) for a capacity E '> 250 kWh.

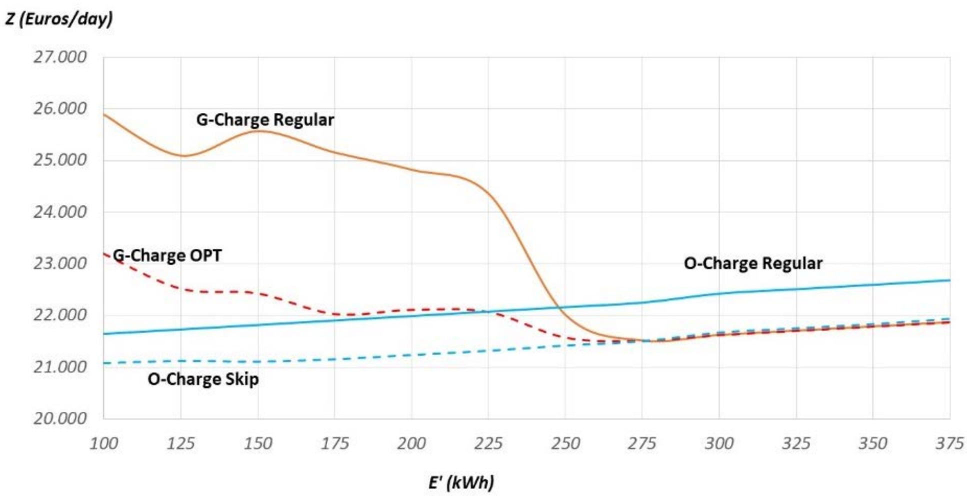

Figure 1: Total cost in the different charging schemes versus battery capacity

If we increase the capacity of the installed batteries, the cost of the O-Charge system increases linearly, thus approaching the cost of the G-Charge system. In this way, if the capacity of the batteries increases (E'> 275 kWh), the charge in the garage (G-Charge Optimum and G-Charge Regular) presents the same performance as the O-Charge scheme. In fact, the threshold E'= 275 kWh defines the minimum battery pack to provide all-day service on G-Charge.

With a capacity E'<275 kWh, the smaller the battery pack, the more vehicles are required in G-Charge Optimum. This means that G-Charge Optimum presents a monotonous decreasing fleet size with respect to the battery capacity until reaching the value E'= 275 kWh, which does not happen in the G-Charge Regular scheme.

An interesting fact is that in the G-Charge scheme the size of night charging facilities is minimal when the size of the fleet is maximum. This is because a charger can serve more vehicles in the night period the smaller the battery pack is and because there are idle vehicles that can be charged at time $t > T_{el}$.

5. CONCLUSION

After the analysis carried out, we can conclude that the costs of current BEB technologies are even higher than conventional ICE or hybrid technologies. However, this cost difference is at a fairly low level, located in a range of 4 to 8%, thus a reduction in the acquisition costs of electrical technology, combined with the greater awareness of reducing polluting emissions makes electric buses a more attractive option for companies. With the results of the line analyzed in Barcelona, a battery cost of less than € 300 / kWh and a reduction in the purchase cost of vehicles of 12% - 30% are needed, so that BEB systems will be more efficient than the ICE and hybrids, respectively.

It is important to note that operation with BEB implies a personalized design of the vehicle in terms of batteries and charging system, depending on the characteristics of the route to be served. This makes BEB vehicles, unlike ICE or hybrids, only interchangeable on routes with similar characteristics. If this premise is not met, it is very possible that the transport company needs to increase the size of its fleet to guarantee the correct provision of the service. Therefore, we can conclude that BEB technology does not allow flexible fleet management.

From the sensitivity analysis carried out, we can infer that the O-Charge opportunity charging system is always more profitable than the G-Charge garage charging if the service shows good regularity and the chargers are at the terminal stops along the route. As a condition it is necessary that the minimum capacity of the batteries is 100-125 kWh to guarantee a complete circuit. This charging system can be enhanced by allowing vehicles to skip charging during peak periods. This reduces vehicle travel times and equates the necessary fleet to that of ICE technology. In this sense, it is shown that it is more appropriate to carry out a configuration of several chargers in a single terminal stop of the route (scheme N-0) than to have chargers in both terminal stops (scheme N-N), which is only profitable on very long routes where the capacity of the batteries could not guarantee a complete round trip route. Therefore, if the loading operation can be skipped in the time windows of higher demand, the cost of the company can be reduced by 3 - 4%.

When the urban structure hinders or prevents the implementation of opportunity chargers at the terminal stops of the routes, the increase in the distance to travel to carry out the loading operation penalizes the opportunity load, favoring the use of the load in the garage. In this case, the garage charge equals the fleet size of the opportunity charge as long as the batteries have a capacity greater than 300-375 kWh, although it increases the cost of the batteries and requires long charging intervals.

On the other hand, if we analyze routes with low service regularity or routes with short distances, we obtain that the time spent charging is critical to guarantee the correct provision of the service. For this reason, the location of various tandem charging areas is required, which is difficult to implement in consolidated urban areas with a shortage of available public space and penalizes the opportunity charging system.

In this way, if we cannot implement the proper design of the opportunity charging facilities, we favor the use of garage charging. In this case, the buses must incorporate large capacity batteries to avoid having to go to the garage to charge during the service. If this is not fulfilled and the capacity of the batteries does not guarantee the complete provision of the service, it is necessary to increase the fleet to replace the vehicles that have to go to the garage to charge during the day.

In the analyzes carried out, a much higher performance of the G-Scheme Optimum algorithm has been demonstrated over the G-Scheme Regular algorithm, which tells us that we should not wait until the vehicles are about to exhaust the capacity of the batteries to perform the charge, but it is more appropriate to have a small additional fleet that begins to replace the buses from the start of the service.

RESUMEN

El Bus Lost Time (BLT) o tiempo perdido por el autobús se define como el tiempo transcurrido desde que el autobús abre las puertas hasta que embarca la primera persona. Este concepto se incluye en la tercera edición del Transit Capacity and Quality of Service Manual para estaciones de autobús semirrápido (Bus Rapid Transit, BRT) con tres zonas de detención, pero no se considera para paradas de autobús regular en ningún caso.

En esta ponencia se presentan valores de BLT para paradas de autobús convencional, mostrando la influencia que la lluvia tiene en este parámetro. En concreto, se mostrará que los aumentos de BLT por efecto de la lluvia son mayores que los que se producen para tiempo seco cuando se utiliza la segunda posición de detención en una parada doble.

Los datos utilizados se han tomado mediante medidas realizadas por una persona in situ, distinguiendo diferentes niveles de intensidad de lluvia fácilmente identificables a través del comportamiento de los viandantes. Se ha realizado un tratamiento estadístico de los datos para determinar el ajuste a distribuciones estadísticas estándar (normal y lognormal) así como para confirmar que las diferencias obtenidas en los valores de BLT son significativas.

1. INTRODUCCIÓN Y REVISIÓN BIBLIOGRÁFICA

El conocimiento de los tiempos de operación de autobuses urbanos es una herramienta necesaria para el operador y el planificador. Este conocimiento es preciso para la organización de los horarios tratando de garantizar el cumplimiento de los intervalos en las diferentes condiciones, así como para el estudio de nuevas líneas o modificaciones en las existentes. Uno de los aspectos que va a influir en el funcionamiento del sistema son las condiciones meteorológicas y, en concreto, la existencia de lluvia.

Uno de los componentes del tiempo de operación es la demora en la parada (Dwell Time, DT). En este estudio se pretende determinar la influencia de la lluvia en la demora en parada de los autobuses urbanos convencionales.

El estudio de la demora de los autobuses en las paradas puede remontarse a Muzyka (1974), quien utilizó su distribución con el objeto de realizar simulaciones. Posteriormente, en 1980, se realizó una campaña de medidas de demoras en parada en EE. UU. (Levinson, 1983). Para una revisión de las primeras medidas de la demora en parada se puede consultar Dueker (2004).

El concepto de tiempo de demora se define en la segunda edición del Transit Capacity and Quality of Service Manual (Transportation Research Board, 2003) como: “el tiempo necesario para servir a los pasajeros en la puerta más cargada, más el tiempo necesario para la apertura y cierre de puertas”, de acuerdo con la Ecuación 1:

$$t_d = P_a t_a + P_b t_b + t_{oc} \quad (1)$$

donde:

- t_d=tiempo de demora medio (s);
- P_a = número de pasajeros desembarcando del autobús por la puerta más cargada (s);
- t_a=tiempo de servicio de los pasajeros que desembarcan (s/p);
- P_b = número de pasajeros embarcando al autobús por la puerta más cargada (s);
- t_b=tiempo de servicio de los pasajeros que embarcan (s/p); y
- t_{oc} = tiempo de apertura y cierre de puertas (s);

A los tiempos reflejados en la ecuación anterior se les puede añadir un tiempo adicional, que es el tiempo de espera del autobús entre el momento en que el autobús se detiene en su punto de parada y el momento en que la primera persona embarca. Este tiempo fue definido por Jaiswal (2010) y Jaiswal et al. (2010) como “tiempo perdido por el autobús” (Bus Lost Time, BLT). Los valores medios de BLT que obtuvieron, para una estación de un sistema de autobús semirrápido (Bus Rapid Transit, BRT) con tres zonas de detención, fueron de 4.3, 3.1 y 5.2 s para las zonas de detención 1, 2 y 3 respectivamente, mientras que los valores del percentil 85 fueron 7.2, 4.5 y 8.7 s.

Estos estudios condujeron a una modificación en la formulación de la demora en parada (DT) en la tercera edición del Transit Capacity and Quality of Service Manual (Transportation Research Board, 2013), pero únicamente para estaciones de sistemas de autobús semirrápido (BRT), objeto de los citados estudios. En este caso se consideró el término “Boarding Lost Time” (tiempo perdido en el embarque), definiéndolo como el tiempo transcurrido mientras los pasajeros caminan hasta la(s) puerta(s) del autobús desde sus posiciones de espera en la parada. La formulación de DT cambió a:

$$t_d = t_{pf,max} + t_{oc} + t_{bl} \quad (2)$$

donde:

- t_d = tiempo de demora medio (s);
- $t_{pf,max}$ = máximo tiempo de flujo de pasajeros de todos los canales de puerta (s);
- t_{oc} = tiempo de apertura y cierre de puertas (s), con valores típicos de 2-5 s; y
- t_{bl} = tiempo perdido en el embarque (s);

El valor de BLT se establece como 0 s en el caso de paradas con una única zona de detención. Para tres zonas de detención se propone un valor que varía entre 4.0 y 4.5 s para condiciones de mayor o menor congestión en la zona de espera de la parada. Finalmente, para estaciones de BRT con dos zonas de detención, el analista debe evaluar la frecuencia de utilización de la segunda zona de detención para determinar un valor entre 0 y 4 s (Transportation Research Board, 2013).

Finalmente, Kathuria et al. (2016a y 2016b) hacen hincapié en el hecho de que el BLT solo se debe considerar cuando no se solapa con la fase de desembarque, produciendo por tanto un aumento en el DT. En sus investigaciones determinaron los escenarios de embarque y desembarque en los que se debe considerar el BLT. Estudiaron el BLT para una estación de BRT con dos zonas de detención, obteniendo valores medios de 1.8 y 2.4 s para la primera y segunda zona de detención, con percentiles 85 de 2.1 y 2.7 s respectivamente (Kathuria et al., 2016a). La lluvia no era una variable relevante ni en estos estudios ni en los de Jaiswal (2010) y Jaiswal et al. (2010), por tratarse de estaciones cerradas o cubiertas completamente con marquesinas.

En Novales et al. (2021), se ha analizado el incremento del BLT debido a la lluvia en un caso de estudio de autobús convencional en A Coruña, considerando únicamente el valor del BLT. En esta ponencia se presenta un análisis análogo de ese caso de estudio, pero empleando como variable de análisis conjuntamente el BLT y el tiempo de apertura y cierre de puertas, tratando así de establecer qué medida es más adecuada de cara a su medición en campo y su incorporación a los cálculos de demora en parada.

En esta ponencia se analizan por tanto los valores de BLT, incluyendo apertura y cierre de puerta, para una parada de autobús regular en bahía con dos zonas de detención. Se considera de forma explícita el efecto de la lluvia, ya que se ha observado que afecta notablemente al comportamiento de los viajeros que esperan en la parada. En ausencia de precipitación los viajeros pueden esperar fuera de la marquesina y se empiezan a mover hacia el punto esperado de detención cuando observan que el autobús se acerca. En situaciones de lluvia, especialmente si es intensa, tienden a esperar bajo la marquesina hasta conocer el punto exacto de detención. Esto va a suponer una modificación del tiempo desde la detención del autobús hasta la subida del primer viajero, objeto de esta ponencia.

Para una revisión de la influencia de la lluvia en el comportamiento del viajero se puede consultar Liu (2017). El Transit Capacity and Quality of Service Manual (Transportation Research Board, 2013) señala que el porcentaje de circulación puntual puede caer por debajo del 80% durante condiciones de mal tiempo y que la meteorología influye en la velocidad de los peatones.

Esta ponencia está organizada como sigue: el apartado 2 presenta el caso de estudio y procedimiento de toma de datos; en el apartado 3 se realiza el análisis de la influencia de la lluvia en el parámetro analizado, en el apartado 4 se realiza un análisis de ajuste a distribuciones estadísticas estándar; finalmente, en el apartado 5 se presentan las conclusiones del estudio.

2. CASO DE ESTUDIO Y RECOGIDA DE DATOS

Tras un análisis de las condiciones requeridas, se seleccionó para la toma de datos una parada situada en frente a la iglesia de San Pedro de Mezonzo en la ciudad de A Coruña. Su configuración general se presenta en las figuras 1 y 2. Se trata de una parada en bahía situada tras una intersección en una calle de sentido único, con prioridad en la siguiente intersección. Los autobuses circulan en tráfico mixto sin ningún tipo de preferencia. Existe espacio para la detención de dos autobuses, siendo la longitud total de la zona de detención de 25 m. En esta parada la marquesina está situada a 3 m del borde del bordillo y adyacente a la primera zona de parada de los autobuses, hecho que va a tener influencia en el BLT, ya que se debe recorrer cierta distancia hasta la puerta del autobús bajo la lluvia.

Figura 1: Parada de San Pedro de Mezonzo. Fotografía de la configuración general

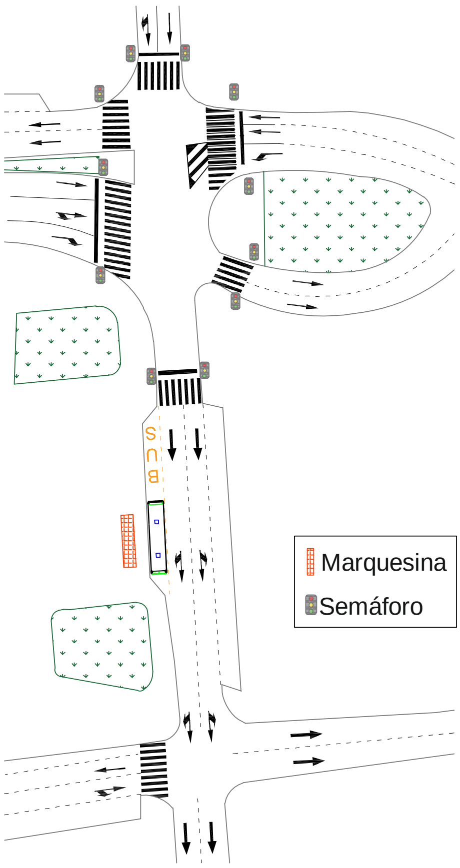

Figura 2: Parada de San Pedro de Mezonzo. Plano de la configuración general

La parada es servida por 6 de las líneas de la red, incluyendo la línea que presta el servicio específico a la Universidad (UDC), esta última con importantes variaciones en el servicio fuera de los días lectivos y según el horario. En la Tabla 1 se muestran los intervalos habituales programados y las consiguientes frecuencias de las líneas durante la campaña de toma de datos. En conjunto pasan por la parada en hora punta 27.8 autobuses/hora con un intervalo medio de 2.2 minutos, lo que supone que sea frecuente la utilización de la segunda posición de detención. En hora punta hay un refuerzo de la línea UDC que parte de esta parada. El número total de autobuses que emplearon la parada en 2019 fue de 126573.

Línea	Intervalo en día lectivo (min)	Frecuencia (autobuses/hora)
4	12	5
5	18	3.3
12	24	2.5
20	20	3
24	30	2
UDC (hora punta)	5	12
UDC (hora valle)	10	6
TOTAL (hora punta)	2.2	27.8
TOTAL (hora valle)	3.6	16.8

Tabla 1: Líneas, intervalos y frecuencias en la parada de San Pedro de Mezonzo

Para este trabajo fue necesario realizar una toma de datos manual, dado que los datos registrados por el Sistema de Ayuda a la Explotación no recogen los movimientos de los viajeros antes de subirse al autobús, por lo que no permiten el análisis del BLT. Aunque se tomaron datos adicionales, en esta ponencia se presentarán los relativos a lo que los autores han llamado T3 (s), que es el tiempo transcurrido entre la detención del vehículo y el embarque del primer pasajero, considerándolo embarcado cuando sus dos pies están dentro del autobús. En contraste con el artículo citado previamente, no se ha distinguido el tiempo de apertura de puertas, ya que hay ocasiones en que el pasajero empieza a embarcar antes de que la puerta haya completado su apertura y las diferentes tecnologías de los modelos de autobuses dificultan el establecimiento unívoco de los tiempos totales de apertura de puertas.

Se tomaron los datos de un total de 734 autobuses en días laborables de junio de 2019, en diferentes horarios (en Novales et al., 2021 se pueden consultar más detalles sobre la toma de datos). Se ha verificado que no se producen disparidades en los valores de la media de T3 para los datos sin lluvia en función del día de la semana.

Se realizó una limpieza de los datos para eliminar los registros correspondientes a situaciones inusuales que no son consistentes con el fenómeno que se pretende estudiar, tales como detenciones del autobús previas a la posición de parada definitiva sin abrir puerta, aparcamiento ilegal en parada, incidencias inusuales que demoran el embarque, etc. Sin embargo, se mantuvieron registros correspondientes a otras circunstancias que aumentan la demora pero que se consideran parte del uso regular del sistema. Es el caso, por ejemplo, de pasajeros embarcando al autobús con un carrito de la compra o un objeto similar. Tras este proceso de depuración de datos se mantuvieron los registros correspondientes a 718 autobuses, que constituyen la muestra estudiada.

Para el registro de información sobre la intensidad de lluvia se optó también por la observación directa. Se estudiaron los datos de precipitación recogidos en las tres estaciones meteorológicas autonómicas de la ciudad, pero se descartó su utilización por estar situadas a más de 2 km de distancia de la parada de estudio. Los registros cada diez minutos de lluvia recogida no permiten estudiar el fenómeno de interés por dos motivos: en primer lugar, la lluvia es un fenómeno muy local, por lo que los registros de estaciones a 2 km de distancia no son representativos de la situación en la parada (se verificó que, en varias ocasiones, pese a estar lloviendo en la parada, las tres estaciones registraban niveles diezminutales nulos de precipitación); en segundo lugar, para este estudio, el intervalo en el que interesa conocer si existe o no precipitación dura solamente unos segundos, los que transcurren desde que el autobús se está aproximando a la parada hasta el embarque del primer viajero. Por tanto, si se pretendiese realizar un registro automatizado de lluvia, serían precisos equipos de medición locales capaces de registrar intensidades de precipitación en periodos extraordinariamente breves.

Para permitir esta recogida manual de datos de precipitación se optó por establecer una clasificación cualitativa, pero con una definición precisa basada en comportamientos de los viandantes que la hiciese extrapolable. En todo caso, la totalidad de la toma de datos se realizó por el mismo observador para evitar sesgos en esta recogida. Las categorías de lluvia definidas (Novales et al., 2021) fueron:

- 0 – sin lluvia;
- 1 – llovizna: es difícil determinar si llueve o no. La mayoría de las personas ni siquiera se molesta en abrir el paraguas;
- 2 – lluvia ligera: es indudable que llueve, pero los viandantes no se empapan. Algunas personas no se molestan en abrir el paraguas, aunque la mayoría sí lo hace.
- 3 – lluvia moderada: el nivel de lluvia es molesto, y las personas que no están a cubierto se empapan tras un corto período de tiempo. Las personas que tienen un paraguas disponible lo abren, y todas las que pueden ponerse a cubierto lo hacen.
- 4 – lluvia intensa: el nivel de lluvia es intenso, y las personas que no están a cubierto se empapan totalmente. La mayoría de los viandantes detienen su movimiento temporalmente para ponerse a cubierto y esperar a que la precipitación remita.

3. ANÁLISIS DE LA INFLUENCIA DE LA LLUVIA EN T3

La estadística descriptiva de la muestra se presenta en la Tabla 2. El número de datos registrados para cada zona de detención fue de 576 para la primera y 142 para la segunda. El valor medio de la demora conjunta por apertura de puertas y BLT (T3) es de 3.84 s para la zona de detención 1 y 4.29 s para la 2. El valor máximo de T3 para la zona de detención 1 es de 8.68 s, pero los 5 valores por encima de 6.8 s para esta zona de detención corresponden a situaciones en las que el primer pasajero que embarcó portaba un carrito de la compra (u objeto similar). Para la segunda zona de detención, el valor máximo de T3 es de 7.97 s, con solo 3 registros mayores de 6.8 s, cada uno de ellos correspondiente a situación de lluvia ligera, moderada o fuerte.

	T3 (s)	
	Zona de detención 1	**Zona de detención 2**
count	576	142
mean	3.84	4.29
std	0.93	1.09
min	1.59	2.11
25%	3.20	3.54
50%	3.72	4.18
75%	4.35	5.09
max	8.68	7.97

Tabla 2: Estadística descriptiva de la muestra

Para realizar un análisis de mayor detalle se ha optado por realizar distintas agrupaciones de datos. En la Tabla 3 se presenta la estadística descriptiva de T3 agrupando los datos por zona de detención e intensidad de lluvia. En la primera parte de la tabla se presentan todos los niveles de lluvia por separado, mientras que en la segunda parte se han creado diferentes agregaciones para ambas zonas de detención al objeto de preparar los datos para el análisis estadístico posterior. En la Figura 2 se presenta el box plot para T3 con los datos agrupados en función de la zona de detención y la intensidad de lluvia.

La muestra puede considerarse pequeña para el caso de la primera zona de detención en los niveles de lluvia 3 y 4, así como para la segunda posición con lluvia. En algunos de los análisis se emplean estos datos con propósito ilustrativo, mientras que en otras ocasiones se agrupan para tener muestras de mayor tamaño en cada una de las categorías analizadas.

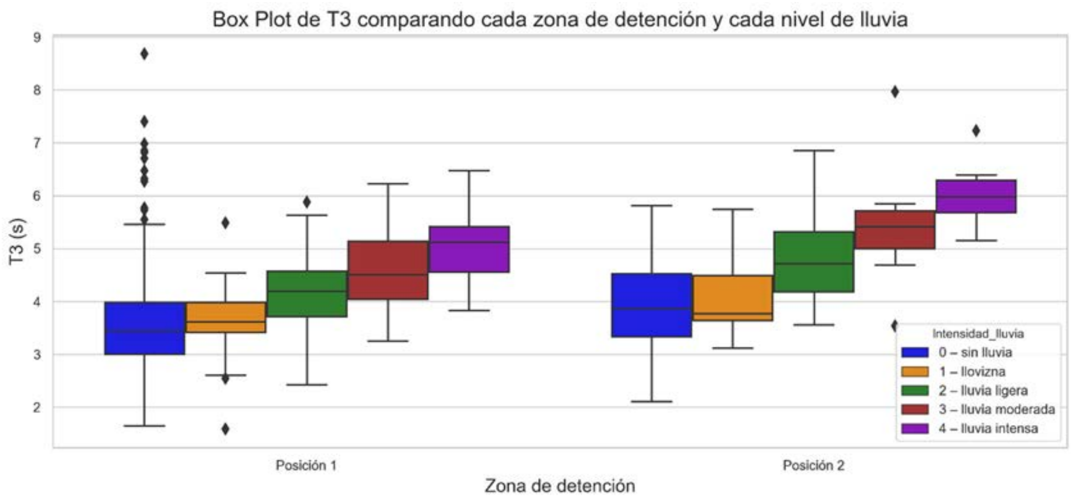

Figura 2: Box plot según zona de detención e intensidad de lluvia.

Zona de detención	Intensidad de lluvia	count	mean	std	cv	min	25%	50%	75%	max
1	0 – sin lluvia	358	3.57	0.89	0.25	1.65	3.00	3.45	3.99	8.68
	1 – llovizna	50	3.65	0.58	0.16	1.59	3.43	3.62	3.99	5.49
	2 – lluvia ligera	90	4.14	0.69	0.17	2.43	3.72	4.20	4.57	5.88
	3 – lluvia moderada	43	4.59	0.70	0.15	3.26	4.04	4.51	5.15	6.23
	4 – lluvia intensa	35	5.09	0.69	0.14	3.83	4.56	5.12	5.42	6.48
2	0 – sin lluvia	93	3.90	0.88	0.22	2.11	3.33	3.86	4.53	5.81
	1 – llovizna	10	4.10	0.88	0.22	3.12	3.64	3.77	4.49	5.74
	2 – lluvia ligera	19	4.77	0.87	0.18	3.56	4.19	4.72	5.32	6.85
	3 – lluvia moderada	10	5.43	1.12	0.21	3.54	5.00	5.42	5.72	7.97
	4 – lluvia intensa	10	5.99	0.60	0.10	5.16	5.69	5.98	6.29	7.23
1	0 + 1 + 2 + 3 + 4 – cualquier situación	576	3.84	0.93	0.24	1.59	3.20	3.72	4.35	8.68
2	0 + 1 + 2 + 3 + 4 – cualquier situación	142	4.29	1.09	0.25	2.11	3.54	4.18	5.09	7.97
1	0 + 1 – sin lluvia (o imperceptible)	408	3.58	0.86	0.24	1.59	3.06	3.50	3.99	8.68
1	1 + 2 + 3 + 4 – cualquier lluvia	218	4.27	0.81	0.19	1.59	3.71	4.24	4.73	6.48
1	2 + 3 + 4 – lluvia perceptible	168	4.45	0.78	0.18	2.43	3.96	4.43	4.97	6.48
2	1 + 2 + 3 + 4 – cualquier lluvia	49	5.02	1.08	0.22	3.12	4.13	5.16	5.73	7.97

Tabla 3: Estadística descriptiva de la muestra con datos agrupados por zona de detención e intensidad de lluvia

Del análisis de la tabla y la figura se pueden extraer algunas conclusiones. Cada aumento en el nivel de lluvia produce un aumento de la media de T3 de alrededor de 0.5 s para la primera zona de detención, excepto para el caso “1 – llovizna”. El incremento del valor medio de T3 debido a una lluvia intensa, en relación a la situación sin lluvia (1.52 s), es apreciablemente mayor que el que se produce por el uso de la segunda zona de detención en relación con la primera en situación sin lluvia (0.33 s).

En la segunda parte de la tabla puede observarse que los valores medios de T3 aumentan en alrededor de 0.9 s para el caso de “lluvia perceptible” en relación al caso de “sin lluvia o imperceptible”, para la primera zona de parada. Los datos de desviaciones típicas y coeficientes de variación muestran que los registros de cada categoría no tienen una dispersión acusada.

La figura muestra con mayor claridad cómo aumenta T3 con la intensidad de lluvia para cada una de las zonas de detención, excepto para el caso de llovizna en la segunda zona de detención. Se observa que los valores de T3 son mayores para la segunda posición de detención respecto a la primera. Para comprobar si estas diferencias son significativas se han realizado contrastes estadísticos formales, que se muestran en la Tabla 4. Los test empleados suponen normalidad de los estimadores de la media y tienen en cuenta el test de igualdad de varianzas. Se comprueba que todas las diferencias de medias son significativas a excepción de las diferencias entre los niveles “0 – sin lluvia” y “1 – llovizna” para la primera posición de detención.

Comparación $\mu_1 > \mu_2$				Test igualdad varianzas 95% dos colas H0: $\sigma_1^2 = \sigma_2^2$	Test igualdad medias 95% una cola H0: $\mu_1 = \mu_2$
Variable 1		Variable 2			
Posición	Intensidad de lluvia	Posición	Intensidad de lluvia		
2	0 – sin lluvia	1	0 – sin lluvia	Aceptar H0	Rechazar H0
1	1 – llovizna	1	0 – sin lluvia	Rechazar H0	Aceptar H0
	2 – lluvia ligera		1 – llovizna	Aceptar H0	Rechazar H0
	3 – lluvia moderada		2 – lluvia ligera	Aceptar H0	Rechazar H0
	4 – lluvia intensa		3 – lluvia moderada	Aceptar H0	Rechazar H0
1	1 + 2 + 3 + 4 – cualquier lluvia	1	0 – sin lluvia	Aceptar H0	Rechazar H0
1	2 – lluvia ligera	1	0 + 1 – sin lluvia (o imperceptible)	Rechazar H0	Rechazar H0
1	2 + 3 + 4 – lluvia perceptible	1	0 + 1 – sin lluvia (o imperceptible)	Aceptar H0	Rechazar H0
2	0 + 1 + 2 + 3 + 4 – cualquier situación	1	0 + 1 + 2 + 3 + 4 – cualquier situación	Rechazar H0	Rechazar H0
2	1 + 2 + 3 + 4 – cualquier lluvia	1	1 + 2 + 3 + 4 – cualquier lluvia	Rechazar H0	Rechazar H0

Tabla 4: Diferencias de medias de T3 para diferentes niveles de lluvia y posición de detención

Estos resultados respaldan la necesidad de considerar la influencia de la lluvia en T3, y por tanto en la demora en paradas, para calcular adecuadamente la capacidad de las paradas o para simular el funcionamiento del sistema de transporte público en estas situaciones. La diferencia de medias de T3 para cada uno de los niveles de lluvia perceptible es de alrededor de 0.5 s, dando lugar a una diferencia de alrededor de 1.5 s para el caso de lluvia intensa en comparación con la situación sin lluvia. Para un análisis binario de lluvia perceptible (2-4) frente a sin lluvia o imperceptible (0-1), la diferencia es de casi 0.9 s (0.87 s) para la posición de parada 1.

El valor medio de T3 para posición de parada 1 sin lluvia es de 3.57 s, lo que considerando un tiempo de apertura de puertas de alrededor de 1.66 s (valor obtenido en un número limitado de medidas con desviación típica 0.5 s) daría lugar a un valor medio de BLT de 1.91 s, muy similar al obtenido por Kathuria et al. (2016a) para su configuración (1.8 s). El uso de la segunda posición de detención da lugar a un aumento del valor medio de T3 (y por tanto de BLT) de 0.33 s con respecto a la primera posición para la situación sin lluvia, mientras que dicha diferencia era de 0.6 s en Kathuria et al. (2016a). Esta diferencia debida a la posición de detención es inferior a la influencia del aumento de un nivel de intensidad de lluvia.

De acuerdo con el análisis realizado, se puede proponer un incremento de BLT de 0.5 s para cada uno de los saltos entre niveles sin lluvia – lluvia ligera – lluvia moderada – lluvia intensa para la posición de detención 1, y de 1 s si solamente se considera la diferenciación entre lluvia perceptible y situación sin lluvia o imperceptible. El uso de la segunda posición de detención (en lugar de la primera) para la situación sin lluvia puede dar lugar a un incremento de 0.3 s, mientras que el incremento para cualquier situación de lluvia (niveles 1 a 4 combinados) es de 0.7 s. Estos valores son válidos para configuraciones de parada similares a la estudiada en este trabajo.

4. ANÁLISIS DE LA DISTRIBUCIÓN DE VALORES DE T3

En este apartado se realizará un análisis del ajuste de los datos de la muestra a distribuciones estadísticas estándar, y se presentarán conclusiones previas de otros autores.

La dispersión de los valores para cada nivel de precipitación y cada zona de detención se estudia mediante histogramas de frecuencias y estimación de densidades kernel (KDE). En la Figura 3 se muestra la frecuencia de observaciones para zona de detención 1 con cada nivel de lluvia y para zona de detención 2 sin lluvia. En la Figura 4 se presentan los histogramas con estimación de densidad kernel superpuestos para esos mismos casos.

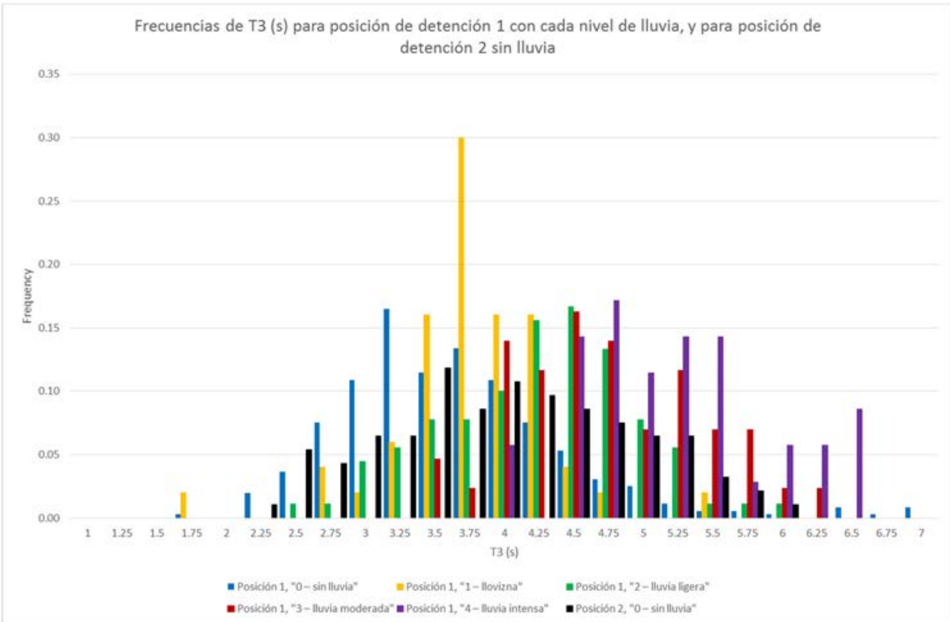

Figura 3: Frecuencia de observaciones para posición 1 con cada nivel de lluvia y para posición 2 sin Lluvia

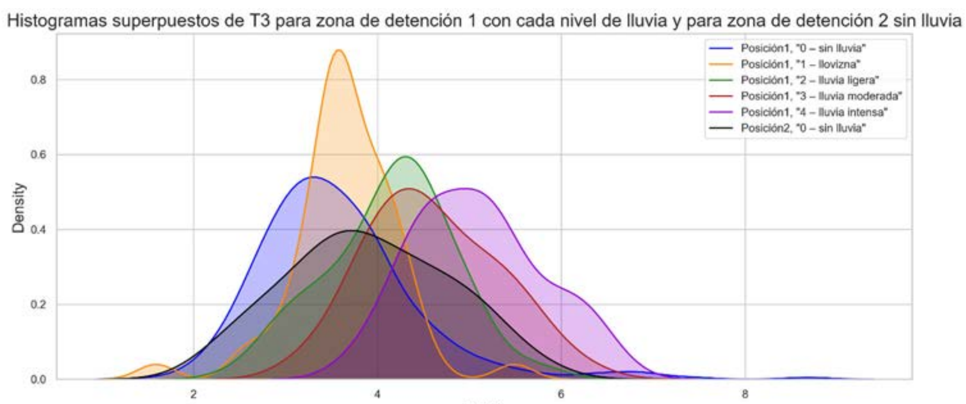

Figura 4: Estimación de densidad kernel para posición 1 con cada nivel de lluvia y para posición 2 sin lluvia.

Jaiswal et al. (2010) determinaron, mediante la utilización de gráficos de probabilidad, que el BLT sigue una distribución lognormal para cada una de las posiciones de detención analizadas. Widanapathiranage et al. (2015) determinaron que el tiempo de demora total en las estaciones de BRT sigue también una distribución lognormal, aunque no presentan contrastes formales. Kathuria et al. (2016) analizaron la distribución de BLT para cuatro períodos del día utilizando tests Kolmogorov – Smirnov y Chi-Square, concluyendo que el BLT parece seguir una distribución lognormal para dichos períodos. Estos estudios de BLT no consideran la influencia de la lluvia, como se indicó en el apartado 1, por lo que cabe esperar que el BLT en condiciones de no lluvia siga también una distribución lognormal.

Los datos recogidos en esta investigación se han analizado para diferentes agregaciones de niveles de lluvia, como se muestra en la Tabla 5. Las muestras se comparan con distribuciones teóricas normales y lognormales. Estos análisis son útiles para determinar las características de las variables, y se han empleado para seleccionar los contrastes realizados en el apartado anterior para analizar la influencia de la lluvia en T3. En general, desde un punto de vista de análisis estadístico, la normalidad es una propiedad deseable porque simplifica la aplicación de ciertas técnicas de análisis. Sin embargo, la distribución normal da lugar a ciertos inconvenientes en los procesos de simulación, debido a la presencia de valores negativos de T3 que no se pueden dar en la vida real. En este sentido, las distribuciones lognormales son más adecuadas para simulación, ya que no producen valores negativos, y pueden dar lugar a más valores en la cola derecha, lo que parece más acorde con lo que puede suceder en la realidad.

Posición	Intensidad de lluvia	Count	Mean estimation		Confidence interval 95%		Lognormal Fitting				Normal fitting			
			Value	s.e.	min	max	Test		p-value	95%	Test		p-value	95%
1	0 – sin lluvia	358	3.57	0.05	3.48	3.66	0.05	L	0.02	No	0.09	L	0.00	No
	1 – llovizna	50	3.65	0.08	3.49	3.81	0.16	L	0.00	No	0.12	L	0.08	Yes
	2 – lluvia ligera	90	4.14	0.07	4.00	4.28	0.11	L	0.02	No	0.07	L	0.3289 *	Yes
	3 – lluvia moderada	43	4.59	0.11	4.39	4.80	0.98	S-W	0.83	Yes	0.98	S-W	0.66	Yes
	4 – lluvia intensa	35	5.09	0.11	4.86	5.31	0.98	S-W	0.63	Yes	0.97	S-W	0.37	Yes
2	0 – sin lluvia	93	3.90	0.09	3.72	4.08	0.06	L	0.5776 *	Yes	0.05	L	0.8171 *	Yes
1	0 + 1 + 2 + 3 + 4 – cualquier situación	576	3.84	0.04	3.76	3.91	0.02	L	0.816 *	Yes	0.06	L	0.00	No
2	0 + 1 + 2 + 3 + 4 – cualquier situación	142	4.29	0.09	4.11	4.47	0.06	L	0.2755 *	Yes	0.07	L	0.08	Yes
1	0 + 1 – sin lluvia (o imperceptible)	408	3.58	0.04	3.50	3.66	0.05	L	0.01	No	0.09	L	0.00	No
1	1 + 2 + 3 + 4 – cualquier lluvia	218	4.27	0.06	4.16	4.38	0.05	L	0.2008 *	Yes	0.05	L	0.2049 *	Yes

2	1 + 2 + 3 + 4 – cualquier lluvia	49	5.02	0.15	4.72	5.32	0.97	S-W	0.16	Yes	0.10	S-W	0.30	Yes

* Para p-value > 0.1 el test estadístico se compara con el valor asintótico en la tabla de Lilliefors

Tabla 5: Estimación de intervalos de confianza de la media de T3 (s) y ajuste a distribución normal y lognormal

Razali y Wah (2011) realizaron un análisis de la potencia de los principales contrastes estadísticos de normalidad, concluyendo que el contraste de Shapiro – Wilk es el más potente, aunque necesita modificaciones para muestras con n > 50. También establecieron que Lilliefoers siempre supera al contraste original de Kolmogorov – Smirnov en su análisis. Además, recomiendan que no se utilicen solamente técnicas gráficas en este tipo de comprobaciones, sino que se combinen con contrastes formales de normalidad y parámetros de inspección de la forma tales como los coeficientes de curtosis y asimetría estadística (skewness).

En este trabajo se usa el test de Shapiro – Wilk (S-W) para muestras de tamaño menor que 50 y el test de Lilliefors para los otros casos. Según Razali y Wah (2011) estos contrastes no dan resultados adecuados para muestras con n≤ 30, por lo que no se pueden aplicar a ciertos niveles de intensidad de lluvia para la posición de detención 2. Se han realizado también comparaciones gráficas mediante Q-Q plots así como análisis de parámetros de forma con Jarque – Bera que no se presentan en esta ponencia.

Los resultados muestran que la hipótesis de ajuste a la distribución lognormal no se puede rechazar al 95% para ninguna de las posiciones de detención cuando se consideran los datos agregados para cualquier intensidad de lluvia (niveles 0 a 4) o para situación de lluvia (niveles 1 a 4). Tampoco se puede rechazar con ese nivel de confianza para los casos de lluvia perceptible (niveles 2 a 4 agregados), lluvia moderada (nivel 3) y lluvia intensa (4) en posición de detención 1. Esto se da también para la situación sin lluvia en la posición de detención 2.

Por otra parte, la hipótesis de ajuste a la distribución normal solo se puede rechazar al 95% para los casos de posición de detención 1 sin lluvia (nivel 0), en cualquier situación (niveles 0 a 4 agregados) y en situación sin lluvia o imperceptible (niveles 0 y 1).

Para los casos de posición de detención 1 sin lluvia (0) o con lluvia imperceptible (0+1) se rechazan tanto la hipótesis de normalidad como de lognormalidad.

4. CONCLUSIONES

Esta ponencia muestra la influencia de la lluvia en los valores de T3 (y por tanto en el tiempo perdido por el autobús en la parada, BLT – Bus Lost Time –) para una parada de autobús convencional con dos posiciones de detención, considerando 5 niveles de intensidad de lluvia (de “0 – sin lluvia” a “4 – lluvia intensa”). Los valores y distribuciones obtenidas no serían directamente extrapolables a paradas con configuraciones diferentes de la presentada.

La conclusión principal es que se produce un aumento de BLT de alrededor de 0.5 s para cada aumento de nivel de intensidad de lluvia (obviando el nivel “1 – llovizna”) para la posición de parada 1. Este valor es mayor que la diferencia de BLT entre las dos posiciones de parada para tiempo seco, que con las hipótesis presentadas sería de 0.3 s. Si se considera solamente una situación binaria de “lluvia perceptible” frente a “sin lluvia o imperceptible” para la posición de parada 1, se debe considerar un aumento de BLT de 0.9 s.

Los datos recopilados, con diferentes niveles de agregación, se han comparado con las distribuciones teóricas normal y lognormal. Al objeto de realizar simulaciones, se puede suponer distribución lognormal para ambas posiciones de detención para el caso de no distinguir niveles de lluvia, así como para el caso de lluvia de cualquier intensidad. También para los casos de posición de detención 1 con lluvia moderada o intensa y para posición 2 sin lluvia. Para posición de detención 1 con llovizna o lluvia ligera se debe considerar distribución normal, en cuyo caso se pueden utilizar normales truncadas para evitar la obtención de valores negativos de T3.

Estos resultados son coherentes con valores previos obtenidos por otros autores y citados a lo largo de la ponencia. Por otra parte, en este estudio se presentan resultados de tiempo adicional de demora agregando el tiempo de apertura de puertas y el BLT, en contraposición con publicaciones previas de los autores en que se consideraban estos valores por separado. Las conclusiones obtenidas realizando esta agregación son similares a los resultados previos, pero la toma de datos puede resultar más sencilla teniendo en cuenta que la identificación visual del momento exacto en que las puertas han terminado de abrirse puede resultar compleja en algunas situaciones.

AGRADECIMIENTOS

Esta ponencia forma parte del proyecto “Paradas, transbordos y reserva de plataforma. Análisis experimental y modelización de su influencia en sistemas de autobús (IMPROVEBUS)”, de referencia RTI2018-097924-B-I00, cofinanciado por el Ministerio de Ciencia, Innovación y Universidades de España y por la Unión Europea a través del Fondo Europeo de Desarrollo Regional (ERDF).

Los autores agradecen a la Compañía de Tranvías de La Coruña (operador del sistema de autobuses urbanos de la ciudad) el acceso a los datos de su Sistema de Ayuda a la Explotación.

ABSTRACT

One of the main complaints about the performance of the bus systems is the time lost at recurrent stops along the route, that results in a low bus speed service. Among the potential measures to speed up the bus service, the introduction of the Autonomous Driving Modular Bus, able to adjust the transport unit by coupling or decoupled pods, will represent a new paradigm in the provision of service. This concept is able to maintain high stable cruising speeds to the transport unit, decoupling only one pod with passengers that may alight at the next stop. This paper analyze the potentialities of this concept in terms of user travel times and operationg cost. This work also features the formulation and analytical models to calculate the performance and oeprational variables, implementing them into two existing bus lines in Barcelona.

1. INTRODUCTION

The current commercial speed of buses in crowded areas (8-15 km/h, Vuchic, 2013) is significantly lower than other public transportation modes in competition (15-40 km/h in tramways, 24-55 km/h in subways). There are several strategies to speed up buses along the routes based on segregated lanes, double lanes, multiple boarding platforms at stops, traffic light synchronization, etc (see Kittelson and associates, 2013). Nevertheless, the travel time savings obtained are still marginal and require huge investments to deploy right of way measures or technological devices. In fact, these measures do not dramatically change the operation of buses: every transit vehicle, with passing passenger onboard, is still obliged to loose cruising speeds before and after a stop location, and is held at the stop facility during dwell time. The major challenge for bus operation would be whether the time lost performing these processes at intermediate stops can be removed from the bus motion. It means that bus services may resemble taxi systems, offering a direct door-to-door service from origins to destinations without intermediate stops. However, one of the innovation concepts that is gaining momentum and could meet this goal is the Autonomous Driving Modular Bus. With this new concept, travel times could be reduced considerably while the service quality could be upgraded. This paper is aimed at analyzing the potentialities of this concept by means of an analytical model. This model consists of several compact formulas to estimate both the user performance (travel time) and operational cost of the service. The model developed is applied to low and high demanded routes in the current Barcelona Bus Network, so the implementation of this new system will be analyzed. The less demanded line corresponds to the V5 (Zona Franca-Avinguda Pearson), while the crowded one to the H10 (Plaça de Sants-Olímpic de Badalona).

2. CONCEPT OF AUTONOMOUS DRIVING MODULAR BUS

Buses are still conceived as a classical configuration of one driver leading the bus and slowing at every stop that passengers request. In order to understand the meaning of this new technology, we must see beyond the concept of bus that we own. This new system is developed with the idea of not stopping at traffic lights neither at bus stops, with totally electric vehicles and, as its name suggest, driverless.

First, no-stopping at traffic lights is not anything new. Many on-streets public transport, like the Barcelona, Zaragoza, or Granada's tramways, rarely stop at them since activated traffic light priority measures are deployed (Estrada et al., 2009). This idea should be tested in buses with the aim to ease bus circulation in detriment of the private vehicle. Of course, this requests a complete restructuration of the current traffic lights configuration.

Second, this technology changes drastically our conception of buses. Nowadays, the word "bus" makes us thing about a large and indivisible vehicle to convey people. But the "modular" bus suggests something different; the current bus will be transformed into a convoy made of n-pods that will be able to couple and uncouple freely, like a train with its wagons. The key idea in this conception is that pods will be detached from the convoy to give service at the bus stop, while the other part of the convoy continues its journey. A brief scheme of the concept is shown in Figure 1.

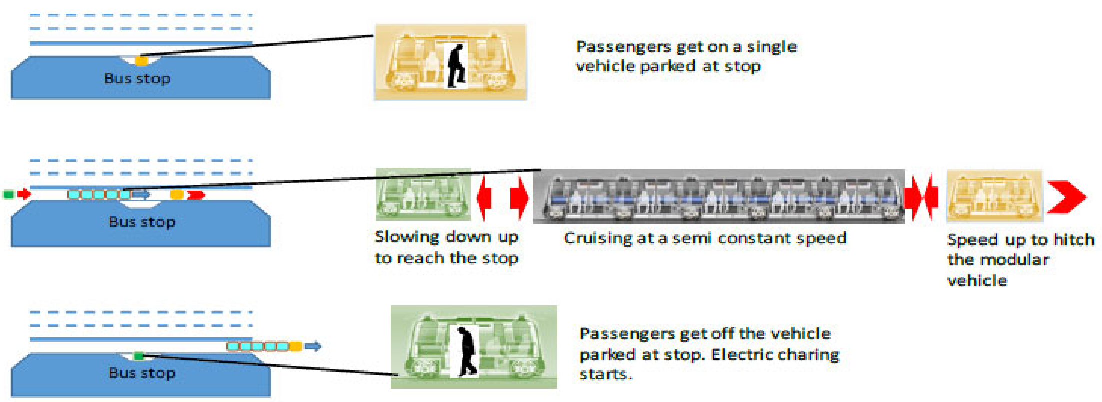

Figure 1: Operational scheme.

On the other side, there will always be a pod ready at the bus stop to depart when it detects that the convoy is approaching.This new pod will be attached to the front of the set, and the procedure will be repeated at the next bus stop. This ability of coupling and uncoupling gives passengers the chance of not stopping at every bus stop, as they will be able to move freely between pods when the convoy is running. In addition, it will be possible to couple and uncouple n-pods per stop depending on the demand that needs to be satisfied, and this ability will also ease the job when it comes to deploy more pods when the service requires it. Finally, these pods will be driverless and their traction will be based in electric batteries.

3. METHODOLOGY

The model proposed has some simplifications to make the estimation of performance variable easier to reproduce and understand. Despite this, the results obtained are not far from the real ones (Daganzo, 2009), and can therefore be taken as valid. These simplifications are to assume a uniform demand through all the line, and an equidistance spacing between stops. The model presented aims to reduce the total cost of the system (Z_T), as the sum of the agency's (Z_A) and users' (Z_U) costs (Eq. 1).

$$Z_T = Z_A + Z_U \tag{1}$$

3.1 Agency's Costs

The formula to determine all the cost incurred by the agency (Equation 2) is a combination of different factors that are introduced along the following subsections.

$$Z_A = €_L \cdot L_T + €_V \cdot V + €_M \cdot M + €_{ER} \cdot M + €_B \cdot C \cdot M \tag{2}$$

3.1.1 Infrastructure Cost (€L) and Route Length (LT)

These firsts terms of the equation do not vary regardless of the bus type: diesel, hybrid or electrical. The proxy $€_L$ represents de infrastructure deterioration, expressed in [€/km-h], and the variable L_T is the route length expressed in [km].

2.1.2 Unit Vehicle Distance Cost (€V) and Distance Covered by the Fleet (V)

The unit vehicle distance cost represents the energy cost per kilometer to run each pod plus its maintenance cost. It is expressed in [€/veh-km] and its values are (Estrada et al, 2021).

Concept	Value
Energy Cost	0,036
Pod Maintenance	0,66
$€_V$ Total	**0,696**

Table 1: Estimation of the unit distance cost, €V [EUR/veh-km].

It has been estimated that the pod's energy consumption will fall between the consumption of an electric car and bus. Considering a Tesla Model S (5 meters long) with an average consumption of 0,20 kWh/km (Motorpasion, 2019), and a 1,00-1,40 kWh/km as an average current standard bus (12 meters) consumption (Estrada et al, 2021), a pod energy consumption of 0,30 kWh/km will be considered. Then, multiplying this number by the electricity price (0,1199 €/kWh Spain average in April 2020) the energy cost is obtained. Regarding the maintenance cost, the value has been taken directly from Estrada et al (2021). On the other side, the distance covered by the fleet per hour (*V*) [veh-km/h] is calculated with the following equation.

$$V = L_T/H \cdot \#_{pods/convoy} \quad (3)$$

where H represents the headway [hours].

3.1.3 Unit Vehicle Temporal Cost (€M) and Number Vehicles (M)

The third term of the sum corresponds to the agency expenses related to temporal units, expressed in [€/veh-h], and the number of pods serving the line (*M*). These temporal expenses are determined in the following table.

Concept	Value
Driver Salary	0,00
Vehicle Amortization	1,587
Insurances, Technicians and Engineers	11,83
$€_M$ Total	**13,417**

Table 2: Estimation of the unit temporal cost, €M [EUR/veh-h].

The driver salary disappears because of the autonomous vehicles. Regarding the vehicle amortization, easymile (pod manufacturer) builds 4 meters long pods. So, considering the average acquisition price per meter of electric, hybrid and diesels buses according to Estrada et al (2021), an acquisition price of 100.000 €/vehicle will be approximated. If each pod runs for 15 years, 300 days/year and 14 hours/day, the value is obtained. The insurances and other salaries are also taken directly from Estrada et al (2021). On the other side, the number of pods needed per line are found with Eq. (4).

$$M = [V/v_{Net} + n \cdot L_T/s] \quad (4)$$

where n represents the number of pods stopped at each bus stop, v_{Net} stands for the commercial speed [km/h], and s is the separation between two bus stops [km]. Through all this model, "n" will be considered 1. Please, note that the second quotient represents the total number of stops thanks to the simplification of equidistance spacing between stops.

3.1.4 Unit Vehicle Charging Facility Cost (€ER)

The charging of pods will be performed during the 10 hours per day that they do not run. Because obtaining a reference value is quite complex, it has been taken the one from Estrada et al (2021) for electric buses with a slight modification. Now, it will be considered that each charger can supply energy to two pods simultaneously, and its lifespan should be 30 years, 300 days/year and 10 hours/day. This parameter is expressed in [€/veh-h].

Concept	Value
Facility Amortization (€/day)	9,60
Facility Maintenance (€/day)	10,00
Pods per Charger	2
$€_{ER}$ Total (€/veh-h)	**0,98**

Table 3: Cost of the Charging Facility, €ER.

3.1.5 Unit Temporal Battery Cost (€B) and Battery Capacity (C)

This new technology must satisfy that the battery endures for all day run without charging. Of course, a different charging scheme must be implemented with charging points along the road, but to simplify the model, it will be considered that pods can only be recharged at depots.

First, the term $€_B$ represents the battery cost expressed in [€/kWh-h] considering a battery lifespan of 4 years (Estrada et al, 2021). What is more, Estrada et al (2021) also suggests recommends using a battery price of 400$/kWh. So, if the pod runs 300 days/year and 14 hours/day, "€B" stands for a value of 0,021 €/kWh-h. The Battery Capacity, expressed in [kWh], is something to be determined with the results shown at the end, as it is totally related to the headway (H), stop spacing (s) and the number of pods per convoy. However, the pod's energy consumption per day is found in Eq. (5), and it satisfy the Battery Capacity (C) requirement.

$$Consump. = v_{Net}[\text{km/h}] \cdot f_{consump}[\text{kWh/km}] \cdot 14[h/day] \cdot (1 + S_{Factor}) < C \qquad (5)$$

The consumption factor is 0,30 kWh/km, the pod runs 14 hours/day, and a 20% safety factor has been taken, which is enough to cover extra consumptions like accelerations, air cooling and slopes. Finally, the commercial speed (or net speed) is approximated with the following equation.

$$v_{Net} \approx L_T/((L_T/v_{Cr}) + (H + \tau) \cdot (L_T/s \cdot \#_{pods/convoy} + 1)) \qquad (6)$$

where v_{Cr} represents de cruising speed of the pod [km/h], and "τ" the time lost by each pod for breaking and accelerating at a bus stop in comparison with a non-stopping one [hours].

3.2 Users' Costs

When users travel, they spend time and money. The money side is fully covered with the ticket price, but one way to transform this time into monetary units is using the so-called Value of Time, which takes into account the user salary. The formula used to determine the user's cost is the following one, where Λ represents the hourly demand expressed in [pax/h], β the value of time and the term into brackets is the expected door-to-door travel time of a single passenger.

$$Z_U = \Lambda \cdot \beta \cdot (A + W + IVTT) \tag{7}$$

3.2.1 Value of Time (β)

This first parameter of the equation is crucial because it translates the time spend on public transport into monetary terms. It is estimated to be 12,50 €/pax-h. This average value comes from considering a salary of 2.000 €/month and working 40 hours per week.

3.2.2 Access and Exit Time (A)

The first and last part of every journey by public transport corresponds to the walking time to the bus stop and to our destination once we get off the transport. Because one of the simplifications is to consider an evenly distributed demand, the expected access and exit time are the same, so the term "A", [hours], represents the sum of both.

$$A = ((s/4)/v_w + (s/4)/v_w = s/(2 \cdot v_w \tag{8}$$

where v_w is the walking speed of the pedestrian [km/h].

3.2.3 Waiting Time (W)

The waiting time includes factors like service regularity, traffic jams, and even smart-phones applications that tells the remaining time for the vehicle to come. Nevertheless, to simplify the calculous, considering a perfect regularity and no use of mobile phones, and with the aid of the same simplification used in 3.2.2., the expected waiting time is half the headway.

$$W = H/2 \tag{9}$$

3.2.4 In-Vehicle Travel Time (IVTT)

This is usually the bigger time when travelling by public transport. So, if an improvement of the service offered needs to be done, it is imperative to reduce the time spend by the user inside the bus. In this particular case of the autonomous and modular bus, the user will only perceive an acceleration, travelling at constant speed, and breaking time. So, the equation used is shown hereunder.

$$IVTT = (l/v_{Cr}) + \tau) \quad (10)$$

where l represents the length travelled by the user inside the pod (which has been considered as $L_T/4$ to be conservative) in [km], and "τ" the time lost by a pod to accelerate and brake in comparison with a non-stopping one.

4. RESULTS AND DISCUSSION

The Autonomous Driving Modular Bus has not been implemented yet in any city as a conventional mode of transport. Thus, these chapter will not study any real configuration but to give the optimal parameters to obtain the best configuration and minimize the total cost of the system (Z_T). These "key" parameters are the headway (*H*), the stop spacing (*s*), and number of pods per convoy. In addition, it will be also possible to determine the battery capacity (*C*).

Besides the battery capacity requirement, any public transport service must also satisfy the occupancy (O) one. It means that the service provided must be enough to cover the whole demand, otherwise there would be users that will not be able to go aboard. The occupancy is found with Eq. (11).

$$O = l/L_T \cdot \Lambda \cdot H \ \leq C_p \quad (11)$$

where Cp represents de pod capacity [pax/veh], with a value of 15 pax/pod according to Easymile. Finally, and before getting into detail with the results, it must be stated that a minimum and maximum threshold on those key parameters have been adopted to simulate a real solution, and not letting the optimization fall into an unfeasible one.

Concept	V5 Line	H10 Line
Headway (minutes)	5-15	1-7
Stop spacing (km)	0,30-0,75	0,30-0,75
Minimum pods/convoy	2	3

Table 4: Optimization thresholds.

4.1 Input parameters

The set of parameters (Guida et al., 2018; Estrada et al., 2021) used are presented below.

Parameter		V5 Line	H10 Line
Line Length (L_{Total})	km	15,20	23,70
Demand (Λ)	pax/h	396	6.247
Length covered by Users (l)	km	3,80	5,93
Free Speed (v_{Cr})	km/h	40,00	
Maximum Speed (v_{Max})	km/h	50,00	
Acceleration (a)	m/s^2	1,30	
Value of Time (β)	€/h	12,50	
Pedestrian Walking Speed (v_{walk})	km/h	4,00	
Infrastructure Cost ($€_L$)	€/km-h	7,61	
Unit Vehicle Distance Cost ($€_V$)	€/veh-km	0,696	
Unit Vehicle Temporal Cost ($€_M$)	€/veh-h	13,417	
Unit Vehicle Charging Facility Cost ($€_{ER}$)	€/veh-h	0,98	
Unit Temporal Battery Cost ($€_B$)	€/kWh-h	0,021	

Table 5: Input parameters.

4.2 Results

After combining all the equations and numbers seen up to now, and doing an optimization process with the main aim to reduce the total cost of the system (Eq. 1), the following optimal variables are found.

Parameter		V5	H10
Headway (H)	min	8,00	1,50
Stop spacing (s)	km	0,73	0,30
Battery Capacity (C)	kWh	63,96	118,03
Pods/Convoy	-	2	4
Total Pods (M)	veh	39	243
Occupancy (O)	pax/veh	13,20	39,04
Agency's Costs (Z_A)	€/h	888,40	6.922,44
Users' Costs (Z_U)	€/h	1.266,63	15.702,83
Travel Time per Trip	min	15,35	12,07

Table 6: Optimization results.

It can be clearly seen that the occupancy is always below the convoy capacity. What is more, all convoys have one extra pod in case any user wants to get off at the next bus stop.

4.3 Comparison with Current Configuration

If the optimal results obtained are compared with the current bus configuration in those lines (run by diesel, hybrid, and electric buses), the user's and total costs suffers a huge downfall. It must be clarified that the V5 is served with standard buses (12 meters), while H10 with articulated ones (18 meters).

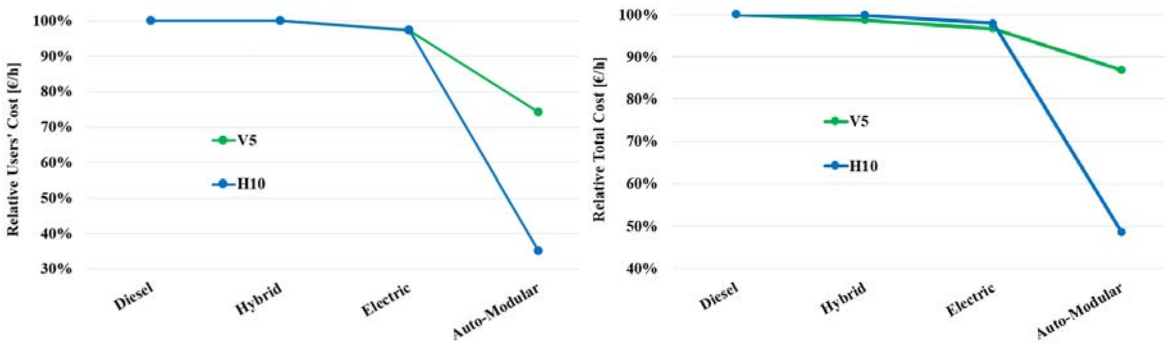

Figure 3: a) Relative Users' Cost to Diesel vehicles, b) Relative Total Cost to Diesel vehicles

As reflected in both figures, user and total costs are reduced when technology evolves to greener vehicles. In addition, one must notice the tremendous reduction the Autonomous Driving Modular Bus could bring to the system if it is implemented. However, it has been seen that the agency cost would increase considerably. In this sense, the current configuration for the H10 line run by electric buses, produces expenses up to 2.228 €/h, while the optimal one for the autonomous driving modular bus provides an agency cost of 6.922 €/h. This occurs due to the large number of pods needed in comparison with the number of buses deployed today.

5. CONCLUSION

It is inevitable to express the necessity for developing a more efficient and sustainable public transport. The results express it themself; as technology upgrades, the reduction in users' and total costs is significant. And not only that, but in environmental and health terms too.

The results also demonstrate that low-demanded lines do not perceive that change in the technology as much as the high-demanded ones. This means that for the low ones, the improvement in technology is not a key factor when it comes to determine the optimal type of bus (diesel, hybrid…). Nevertheless, the high-demanded lines experience a contrary effect; the need for a better and sustainable bus type rises in effigy while the total costs are more than halved. Thus, a first conclusion is the good behavior this new technology would have in high-demanded lines.

Although the results displayed demonstrate the high efficiency it presents, the model has been applied to a very particular case. So, it needs further study in other environments and situations, as well as an exhaust research in different operational schemes and charging itineraries within the lines, which will come in handy to reduce costs even more.

Finally, this further study also needs to focus on the elongation of these lines through the suburbs, which will improve the territorial cohesion with the peripherical neighborhoods and will connect them in a fast and efficient way.

MULTIMODAL SHORTEST HYPERPATHS CONSIDERING CROWDING IN TRANSIT VEHICLES

David López

ABSTRACT

In rush hours, the onboard crowd level within transit vehicles is a problem of any large city. At the expense of time savings, some users will avoid riding crowded lines if they consider that transit vehicles do not have enough personal space. This paper presents a hypergraph model and an algorithm to find multimodal shortest hyperpaths considering the user constraints on the sequence of boarded modes and their preferences of onboard crowding levels. It is assumed that transit inter-arrivals are random. A penalty for riding transit vehicles is defined to model how the users perceive the onboard crowd levels. This penalty depends on the onboard crowd levels and the seating capacity of the vehicles. A state-automaton is used to model the user constraints on the sequence of boarded modes. To find the shortest hyperpaths, the user selects their origin, destination, the maximum number of modal transfers, and the onboard crowd level threshold. A use case on a sample multimodal network is presented.

1. INTRODUCTION

Saturated transit networks are a common issue in any large city. Whenever possible, some users will avoid large crowds or wait at stops for less crowded vehicles. Transit users not only want to reduce their travel time, other factors like cost, transfers, and occupancy also affect their route choice (Raveau et al., 2014). Haywood et al. (2017) pointed out that traveling in crowded vehicles affects users' sanity by decreasing their perception of security and increasing their anxiety and stress.

Expanding the fleet or transit routes may mitigate the effects of crowded vehicles, but these solutions are expensive or may take several years to carry out. An affordable solution to the onboard crowd problem is to display at the stops the crowd information of the incoming vehicles. This information leads to a shift in the passenger distribution among consecutive vehicles, thus reducing the onboard crowd levels (Zhang et al., 2017). Preston et al. (2017) found that it is unlikely that advanced information on onboard crowding will reduce crowd levels during peak hours; however, crowding information will reduce the users' stress and improves the passenger experience while traveling.

Since the onboard crowd information within transit vehicles is an important point to consider for some users, this paper presents a label-correcting algorithm to find multimodal shortest hyperpaths in a multimodal transport system where:

- The user restrict the sequence of boarded modes
- Selects the maximum onboard crowd levels they would like to face during their trip

To find the shortest paths and extension of the algorithm by Lozano & Storchi (2002) is developed. Since transit users experience the onboard crowd levels differently (Whelan & Crockett ,2009), a penalty is defined to model the user perception of the onboard crowd levels. It is considered that the transit modes have random-arrivals, i.e., the arrival-rate at stops is random and the waiting times can only be estimated based on particular distribution.

The subsequent sections are organized as follows. In Section 0, the related work is presented. Section 0 presents a brief introduction to hypergraph notation. Section 0 shows a hypergraph model of a multimodal transport system where: (1) the transit has random-arrivals, (2) the sequence of modes is restricted, and (3) the onboard crowd levels are considered. Section 0 presents the algorithm for finding the shortest hyperpaths bound by modal transfers and onboard crowd levels. An example of usage is shown in Section 0, and in Section 0, the conclusions are highlighted.

2. RELATED WORK

Assessing how users perceive the onboard crowding levels has been studied by conducting surveys. In 2009, Whelan & Crockett (2009) conducted a study in the UK trains to know how passengers perceive time while traveling in crowded vehicles. The authors conclude that standing passengers perceive longer travel times than seated passengers. The authors also found out that the perceived travel time of standing passenger is equal to the travel time multiplied by a scalar which depends on the onboard crowding. Let call this scalar the *riding penalty*. Qin (2014) uses the results of Whelan & Crockett (2009) and proposes three non-linear functions to estimate the *riding penalties*. Other authors like Batarce et al. (2016), Haywood et al. (2017), Tirachini et al. (2017), Bansal et al. (2019), and Márquez et al. (2019) also conducted surveys to estimate the *riding penalty*. As expected, few similarities are found in the mentioned studies as the *riding penalty* estimation depends on the network geometry, the infrastructure, and the idiosyncrasy of passengers. In the presented research, a non-linear function proposed by Qin (2014) is adapted to estimate the *riding penalty*.

Finding shortest paths in transit networks considering onboard crowd levels helps users find routes that accommodate to their personal preferences. Nuzzolo et al. (2015) and Comi & Nuzzolo (2016) developed tailored utility functions to model travel costs in scheduled transit systems. By using surveys and individual preference learning processes, the utility functions are defined and calibrated to model the user preferences on arrival times, onboard crowding levels, and total transfers. Rajapaksha et al. (2017) leverage the use of ubiquitous data sources to propose a framework that could be used to find the shortest paths with low onboard crowding levels. Katona et al. (2017) propose an ant-colony algorithm to find multimodal shortest paths where onboard crowd levels are considered. Unlike other works where the transit is schedule-based, the presented work aims to develop a routing algorithm and hypergraph model for a multimodal transport network where the transit has random-arrivals, such that the hyperpath algorithm considers:

- The user preferences on onboard crowd levels
- The user constraints on the sequence on board modes
- The user bounds of modal transfers.

In the presented paper, the crowd levels are modeled with a penalty that grows as more people get on the vehicles, and according to the reviewed research, this is how people perceive the crowd as the vehicle fills up. The penalty can be calibrated for a particular user or situation (commuting vs. leisure trip), but the calibration procedure is out of the paper's scope. Although the works mentioned in the last paragraph consider the onboard crowding levels for the path computation, the authors fail to present a model of how they estimate the crowding levels.

3. PRELIMINARIES

A directed hypergraph is a pair $H = (V, E)$, where V is the set of nodes and E is the set of arcs and hyperarcs. An arc $a \in E$ is defined as a pair of nodes $a = (i, j)$ where $\{i, j\} \subset V$. A hyperarc $e \in E$ is defined as the pair $e = \big(t(e), h(e)\big)$ where $t(e) \subset V$ is the set of *tail* nodes and $h(e) \subset V$ is the set of *head* nodes (Voloshin, 2009). A hyperarc $e = \big(i, h(e)\big)$ is a *support* hyperarc and a hyperarc $e' = \big(i, h'(e)\big) : h'(e) \subseteq h(e)$ is a *contained* hyperarc (Lozano & Storchi, 2002). Fig shows a directed hypergraph where $e_1' = (1,7)$ is a *contained* hyperarc of the *support* hyperarc $e_1 = (1, \{1,7\})$.

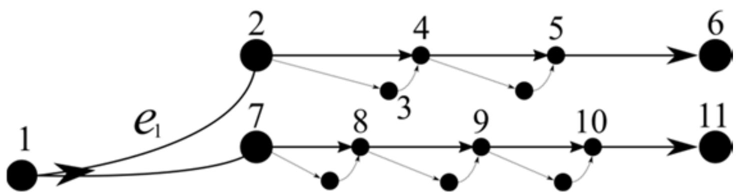

Figure 1: Representation of a directed hypergraph

Let $B(j)$ be a set of arcs $a \in E$ and *contained* hyperarcs $e' \in E : |h'(e)| = 1$ entering to the node j, i.e., $B(j) = \{a = (i,j) \in E$ and $e' = (i',j) \in E : \{i,i',j\} \subset V\}$ (López & Lozano, 2020). For example, in the hypergraph shown in figure 1 $B(4) = \{a = (2,4), e' = (3,4)\}$.
A path r_{id}, that connects an origin o and a destination d is a sequence of nodes, arcs and hyperarcs. A hyperpath p_{id} is the minimum set of acyclic paths r_{id}, such that the destination d is connected to any node that belongs to r_{id} (Nguyen & Pallottino, 1989). A sub-hyperpath $p_{id}(l)$ from the node i to the node d associated to the line l is compose by a *contained* hyperarc $e' = (i,j)$ and a set of consecutive arcs $\{(j,j_1),(j_1,j_2) \dots (j_{n-1},d)\}$, such that the *contained* hyperarc and all the arcs are associated to a unique transit line. In figure 1 the sub-hyperpath $p_{1,6}(l) = \{(1,2),(2,4),(4,5),(5,6)\}$.

4. HYPERGRAPH MODEL

Let H be a hypergraph that models a multimodal transportation system, such all transit modes have random-arrivals. The hypergraph $H = (V,E,M)$ where, V is the set of nodes, E is the set of arcs and hyperarcs and $M = \{M1, M2, M3, M4\}$ is the set of modes such that:

- $M1 \coloneqq$ Pedestrian mode
- $M2 \coloneqq$ Bicycle mode
- $M3 \coloneqq$ Non-rail transit modes
- $M4 \coloneqq$ Rail transit modes
- $M5 \coloneqq$ Modal transfers

The arcs $(i,j) \in E$ model the pedestrian, bicycle and modal transfers networks. The travel time of an arc $(i,j) \in E$ is defined as τ_{ij}. Two consecutive stops of the same transit line are modeled with one *contained* hyperarc $e' = (i,j)$ and two arcs (j,k) and (j,m), where e' represents boarding a transit vehicle at stop i, (j,k) represents riding the vehicle from stop i to stop k and descending at stop k and (j,m) represents riding the vehicle from stop i to stop k and not descending at the stop k.

Since the inter-arrival of transit vehicles is random, the waiting time at stops depends on the transit lines the user is willing to board to get to the destination. Let $e = \big(i,h(e)\big)$ be a *support* hyperarc representing the set of lines stopping at i. Each *contained* hyperarc of e is associated with one of the lines stopping at i. Let L_i be the set of transit lines stopping at i associated with the *support* hyperarc $e = \big(i,h(e)\big)$. Given an origin and a destination, it is defined the *attractive set* of lines, $L_i^{e^b} \subseteq L_i$, such that at stop i, the user is willing to board the first arriving line in $L_i^{e^b}$ to reach the destination. The *attractive set* defines the concept of *boarding* hyperarc $e^b = \left(i,h(e^b)\right) : h(e^b) \subseteq h(e)$ where each *contained* hyperarc of e^b is associated with one line in the *attractive set* (Lozano & Storchi, 2002).

Next are defined four concepts for the lines contained in the *attractive set* (Spiess & Florian, 1989):

- φ_{ij}^{l} is the arrival-rate of the line l associated with the *contained* hyperarc $e' = (i, j)$
- ϕ_{e^b} is the arrival-rate of the lines contained in the *attractive set*. It is defined as $\phi_{e^b} = \sum_{j \in h^b(e)} \varphi_{ij}^{l}$ such that, $l \in L_i^{e^b}$ and $e'_l = (i, j)$ is a *contained* hyperarc of the *boarding* hyperarc e^b
- $\omega_{e^b} = 1/\phi_{e^b}$ is the waiting time of the lines in the *attractive set*
- $\pi_{e^b, l} = \varphi_{ij}^{l}/\phi_{e^b}$ is the probability of boarding the line l in the *attractive set*

The user constraints on the sequence of transport modes are modeled with a state automaton and are described as follows. Lozano & Storchi (2002) defined the *viability* of a hyperpath for knowing which combinations of modes are admissible according to the constraints on the sequence of boarded modes. A hyperpath is *viable* if all the sub-hyperpaths satisfy the constraints on the sequence of boarded modes.

The combination of boarded modes in a hyperpath is indicated with the *state* of the hyperpath. In this paper, it is assumed that the bicycle and rail modes are constrained, i.e., if one of these modes is taken and then left, then the mode cannot be retaken in any other part of the trip. Since the hypergraph H has two constrained modes, eight combinations of modes are *viable*, and eight *states* can be associated with the hyperpaths.

The *deterministic finite state automaton* (DFA) shown in figure 2 defines the sequence of *viable states* and is used to know which hyperpaths are *viable*. The DFA is defined by the graph $A = (S, M, \gamma, 0, F)$ where: $S = \{0,1,2,3, \dots 8\}$ is the set of *states*, $M = \{M1, M2, M3, M4, M5\}$ is the set of modes, 0 is the initial *state*, and $F = \{1,4,6,8\}$ is the set of *states* for finishing trips. All trips end by foot so all *states* in F include the pedestrian mode (see figure 2). Finally, the function $\gamma(m, m', s) = s' : \gamma: M \times M \times S \rightarrow s$, models the arcs of the DFA, i.e., the tuple (s, s') is an arc in the DFA if it is possible to transfer from the mode m to the mode m' while maintaining the constraints on the sequence of boarded modes.

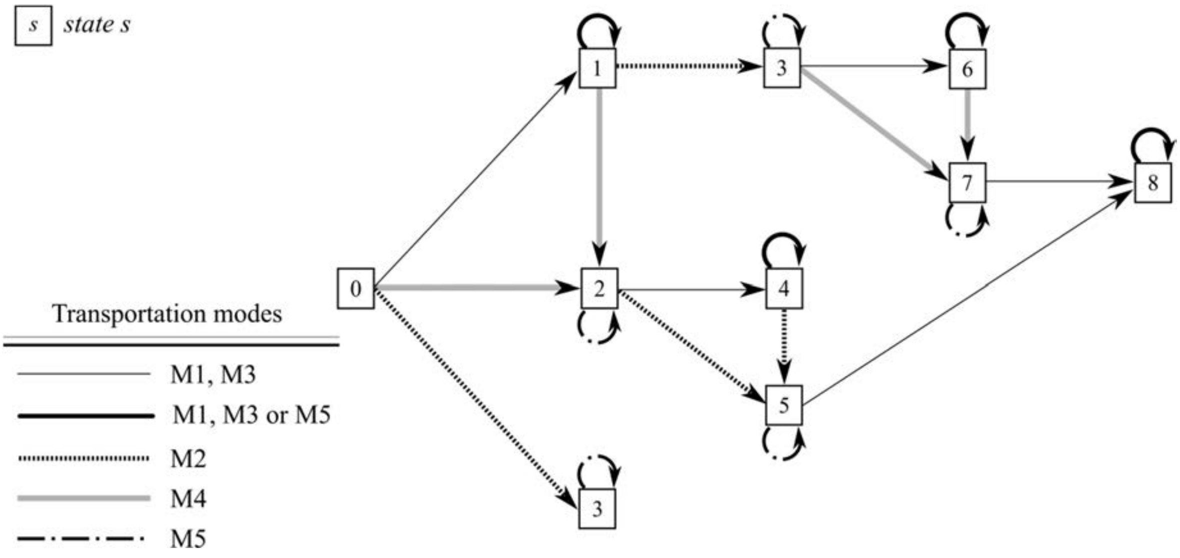

Figure 2: DFA graph with bicycle and rail transit mode restrictions

For each pair of *states* s and s', such that the modes accepted in s are also accepted in s', it is possible to define a relationship to know which *state dominates* the other. This relationship defines an order between any pair of hyperpaths for knowing which hyperpath has a better chance to grow. Artigues et al. (2013) defines the *dominance* between *states* as follows:

Definition 1. *Let s and s' be two states such that all modes accepted in s are also accepted in s'. Define $s \ll s'$, s' dominates s, if for any modes $m \in M$ and $m' \in M$, such that m is a feasible mode for s, one of the following conditions holds:*

- $\delta(m, m', s') = \emptyset$,
- $\delta(m, m', s') = \delta(m, m', s)$
- $\delta(m, m', s) = s$ and $\delta(m, m', s') = s'$.

With the Definition 1 the set of *states* dominating s, $PS_s = \{s' \in S : s \ll s'\}$, is obtained. The *hyper transition* of *states* is defined to get the resulting *state* when a boarding hyperarc e concatenates two hyperpaths. For example, if $e = (i, h(e) = \{j, k\})$ concatenates the hyperpaths $p_{jd}^{s_x}$ and $p_{kd}^{s_y}$, then *hyper transition* of the *states* is $s_x \circ s_y = s_e$, such that s_e indicates the combination of modes used in $p_{jd}^{s_x}$ and $p_{kd}^{s_y}$ (Lozano & Storchi, 2002).

Let p_{id}^{s} be a hyperpath from i to d with *state* s. The *expected travel time* of p_{id}^{s} (Lozano & Storchi, 2002) is recursively defined in Equation 1.

$$\lambda_{id}^{s} = \Big\{ \big[\tau_{ij} + \lambda_{jd}^{s'} \text{ if } (i,j) \text{ is an arc}\big] \; or \; [\omega_{e^b} + \textstyle\sum_{j \in h(e^b)} \pi_{e^b,l} \cdot \lambda_{jd}^{s'} \text{ if } e^b \text{ is a } boarding \text{ hyperarc}] \Big\} \tag{1}$$

The *penalty for riding* a transit vehicle models the user perception of the onboard crowding levels. It is assumed that:

- No penalty is given if the user travels seated or there is enough personal space in the vehicle.
- A penalty is given if the personal space in the vehicle is limited.
- The user will not board vehicles at full capacity.

The *penalty for riding* a transit vehicle is an exponential function that depends on the seating capacity and the people on board, this penalty is described as follows. Let $e' = (i, j)$ be a *contained* hyperarc and let (j, k) and (j, m) two arcs. The *contained* hyperarc e' represents boarding a transit vehicle at stop i. The arc (j, k) represents riding the vehicle from stop i to stop k and descending at stop k. The arc (j, m) represents riding the vehicle from stop i to stop k and continuing the trip.

Let $\theta_{jk}(l) = f_{jk}(l)/s(l)$ be the *seat load factor* of the arc (j, k) associated to the line l, such that $f_{jk}(l)$ is the average passenger flow of the arc (j, k) associated to the line l and $s(l)$ is the number of seats of a line l vehicle. Note that $\theta_{jk}(l) = \theta_{jm}(l)$ since both arcs (j, k) and (j, m) represent riding a transit vehicle of the line l from stop i to stop k.

The *seat load factor* may change from one stop to another. For example, consider the sub-hyperpath $p_{id}(l) = \big(e = (i, j), (j, j_1), (j_1, j_2), (j_2, j_3), (j_3, d)\big)$, such that $\{i, k_1, k_2, k_3, d\}$ are consecutive stops of l, see figure 3. A user boarding at stop i and going to stop d, will experience different levels of crowd during the trip, hence the *seat load factor* might change for consecutive arcs, i.e., $\theta_{jj_1}(l) \neq \theta_{j_1j_2}(l) \neq \theta_{j_2j_3}(l) \neq \theta_{j_3d}(l)$. An example of such phenomenon is represented in figure 3 where the passengers getting on and off the vehicle are represented with the red and green pawns, respectively, and the user going from i to d is the black pawn. For instance in figure 3 $\theta_{j_1j_2}(l) \neq \theta_{j_2j_3}(l)$, because from stop j_1 to stop j_2 there are three passengers in the vehicle while from stop j_2 to stop j_3 there are two.

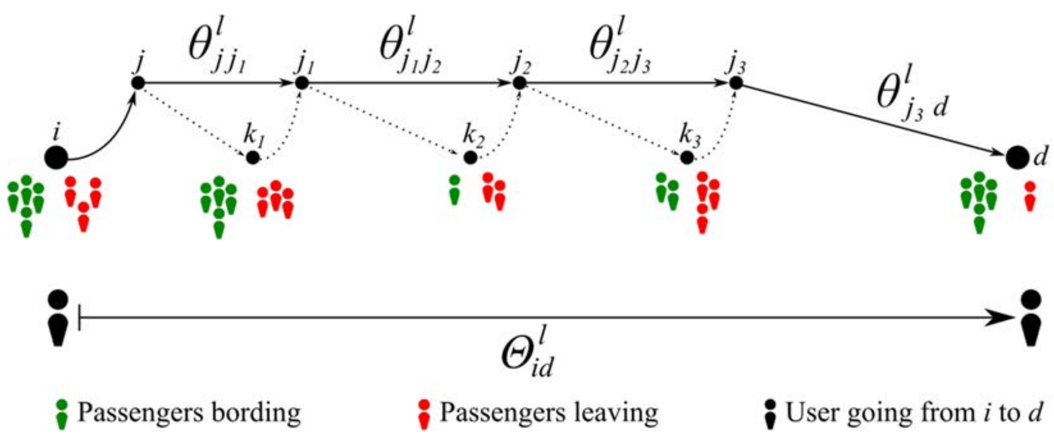

Figure 3: Seat load factor of the line l from the stop i to the stop d

To estimate the *seat load factor* variations of the sub-hyperpath $p_{id}(l)$, in Equation 2 is recursively defined the line *seat load factor* $\Theta_{id}(l)$ of the sub-hyperpath $p_{id}(l)$ as the incremental weighted average of the arc *seat load factors*.

$$\Theta_{id}(l) = \left\{\left[(\tau_{ij}\left(\theta_{ij}(l) - \Theta_{jd}(l)\right))/T_{id}(l) + \Theta_{jd}(l) \text{ if } (i,j) \text{ is an arc}\right] \; or \; [\Theta_{jd}(l) \text{ if } (i,j) \text{ is a } contained \text{ hyperarc}]\right\} \quad (2)$$

such that, $T_{id}(l)$ is the in-vehicle travel time of the sub-hyperpath $p_{id}(l)$.

To capture the dispersion of the arc *seat load factors* of $p_{id}(l)$, in Equation 3 is recursively defined the standard deviation of the arc *seat load factor*, $\sigma_{id}(l)$, of the sub-hyperpath $p_{id}(l)$.

$$\sigma_{id}(l) = \left\{\left[\sqrt{((\left(\sigma_{jd}(l)\right)^2 + \tau_{ij}\left(\theta_{ij}(l) - \Theta_{jd}(l)\right)\left(\theta_{ij}(l) - \Theta_{jd}(l)\right))/T_{id}(l))} \text{ if } (i,j) \text{ is an arc}\right], \; or \; [\sigma_{id}(l) \text{ if } (i,j) \text{ is a } contained \text{ hyperarc}]\right\} \quad (3)$$

Users are penalized for riding transit vehicles according to their preferences on onboard crowding levels. For example, some users might like to travel seated all the time, so they are penalized if $\Theta_{id}(l) > 1$. Two bounds are set; one is for know when a user is not penalized for riding transit vehicles, and the other is for know when a user will not board a transit vehicle. Let $\underline{\delta}$ be the *lower seat load factor*, such that if $\Theta_{id}(l) < \underline{\delta}$ the user is not penalized for riding the line l from the stop i to d. Let $\overline{\delta}$ be the *upper seat load factor*, such that if $\Theta_{id}(l) > \overline{\delta}$ the user will not ride the line l from the stop i to d. In Equation 4 is defined the *penalty for riding* the sub-hyperpath $p_{id}(l)$ (Qin, 2014).

$$r_{id}(l) = \{[0 \text{ if } \Theta_{id}^{l} < \underline{\delta}], \; [T_{id}(l)/(1 + e^{1000(1-\Theta_{id}(l))}) + \; \beta T_{id}(l) e^{4(\Theta_{id}(l)-\underline{\delta})} \text{ if } \underline{\delta} \leq \Theta_{id}^{l} \leq \overline{\delta}], \; [\infty \text{ if } \Theta_{id}^{l} > \overline{\delta}]\} \quad (4)$$

such that, $\beta \in [0, \infty\}$ is a parameter that models the user haste, bigger β's means the penalties are more considerable for ridding crowded buses. In contrast, with smaller β's, the user is less penalized. For $\Theta_{id}(l) > \overline{\delta}$ the penalty for riding the sub-hyperpath $p_{id}(l)$ is infinity, meaning that users will not ride the line l from node i to node d.

Figure 4 shows the plot of $r_{id}(l)$ over $\Theta_{id}(l)$ such that $T_{id}(l) = 1$, $\underline{\delta} = 1.4$, $\overline{\delta} = 2.5$ and $\beta \in \{0, 0.25, 0.5, 0.75, 1\}$.

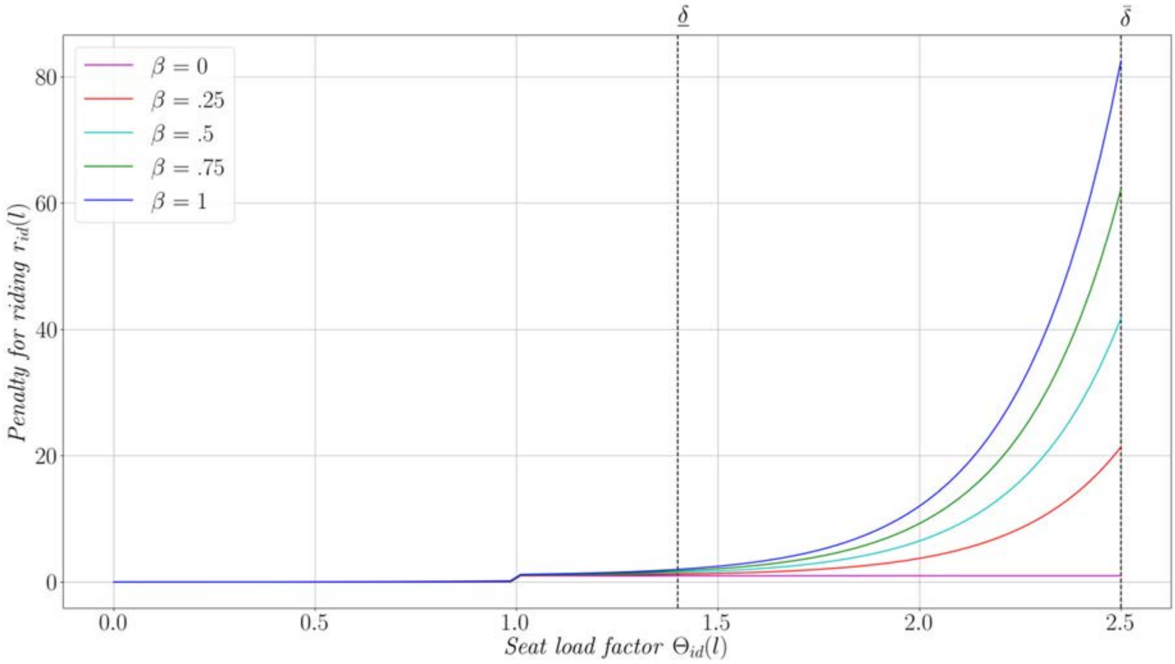

Figure 4: Penalty for riding with different β parameters

As shown in figure 4, $r_{id}(l)$ is close to zero when $\beta = 0$ (see magenta line), i.e., impatient or hasty users are not penalized for riding crowded transit since they value more their time and will ride any line that takes them fast to their destination. While with bigger β's, the penalty for riding transit grows exponentially, in this case, users are highly penalized, and therefore less crowded lines are preferred.

To compute the *penalty for riding* the hyperpath p_{id}^{s}, the *expected seat load* factor of p_{id}^{s} is recursively defined in Equation 5.

$$\Theta_{id}^{s} = \left\{\left[(\mathrm{T}_{id}(l)\left(\theta_{id}(l) - \Theta_{jd}^{s'}(-l)\right))/\mathrm{T}_{id}^{s} + \Theta_{jd}^{s'}(-l) \text{ if } (i,j) \text{ is an arc}\right],\ \left[\sum_{j\in h(e^b)} \pi_{e^b,l} \cdot \Theta_{jd}^{s} \text{ if } e^b \text{ is an hyperarc}\right]\right\} \quad (5)$$

such that, T_{id}^{s} is the in-vehicle travel time of p_{id}^{s}, $\Theta_{jd}^{s'}(-l)$ is *expected seat load factor* of the hyperpath $p_{jd}^{s'} \setminus p_{jd}(l)$, i.e., the sub-hyperpath $p_{jd}(l)$ is not included in the computation of $\Theta_{jd}^{s'}(-l)$.

The standard deviation of the *expected seat load factor* of $p_{id}(t)$ is recursively defined in Equation 6.

$$\Theta_{id}^{s} = \left\{\left[\sqrt{(((\sigma_{jd}^{s'}(-l))^{2} + \mathrm{T}_{id}(l)\left(\Theta_{id}(l) - \Theta_{jd}^{s'}(-l)\right)(\Theta_{id}(l) - \Theta_{id}^{s}))/\mathrm{T}_{id}^{s})} \text{ if } (i,j) \text{ is an arc}\right],\ \left[\sum_{j\in h(e^b)} \pi_{e^b,l} \cdot \sigma_{jd}^{s'} \text{ if } e^b \text{ is an hyperarc}\right]\right\} \quad (6)$$

such that, $\sigma_{jd}^{s'}(-l)$ is *expected seat load factor* of the hyperpath $p_{jd}^{s'} \setminus p_{jd}(l)$.

Finally, the *penalty for riding* the hyperpath p_{id}^{s} is defined in Equation 7.

$$r_{id}^{s} = \{[0 \text{ if } \Theta_{id}^{s} < \underline{\delta}],\ [\mathrm{T}_{id}^{s}/(1 + e^{1000(1-\Theta_{id}^{s})}) +\ \beta \mathrm{T}_{id}^{s} e^{4(\Theta_{id}^{s} - \underline{\delta})} \text{ if } \underline{\delta} < \Theta_{id}^{s} \leq \overline{\delta}], \\ [\infty \text{ if } \Theta_{id}^{s} > \overline{\delta}]\} \quad (7)$$

5. SHORTEST HYPERPATH ALGORITHM

A label-correcting algorithm is presented for finding the shortest hyperpaths. The algorithm finds a set of hyperpaths with minimum *expected travel time*, bounded by modal transfers and *seat load factors*. The pseudo-code of the algorithm is shown in Section 5.1. Before starting the shortest hyperpath computation, users select their origin $o \in V$, destination $d \in V$, maximum modal transfers w_{max}, and *seat load factors* bounds ($\underline{\delta}$ and $\overline{\delta}$). The interval from $\underline{\delta}$ to $\overline{\delta}$ is divided into two equal parts by δ' to obtain the *load factor levels* $\delta_1 = \underline{\delta}$, $\delta_2 = \delta'$ and $\delta_3 = \overline{\delta}$. The set P_i is created for storing all *viable* hyperpaths starting at node i.

The sets of node-*state* pairs P_{now}, P_{next}, and Q are created for looping through the arcs in $B(j)$. On the first iteration $P_{now} = \{[d, 0]\}$ and $P_{next} = \emptyset$ and $Q = \emptyset$. Storing elements in P_{now}, P_{next} and Q are for finding the shortest hyperpaths in incremental order with respect to *load factor levels* and modal transfers. The shortest hyperpaths with no modal transfers and *load factor level* below δ_1 are found in the first round. Then, the algorithm finds the shortest hyperpaths with no modal transfers and *load factor level* below δ_2. The hyperpaths with no modal transfers and *load factor level* below δ_3 are found on the next round. After all the *load factor levels* are scanned, the number of modal transfers w is incremented by one unit, and the algorithm finds the shortest hyperpaths with one modal transfer and *load factor level* below δ_1; the process is repeated for δ_2 and δ_3. The algorithm ends when $w > w_{max}$ or when all *load factor levels* are scanned for each modal transfer, i.e., $P_{now} = \emptyset$.

All labels of the algorithm are initialized as follows:

- $\lambda_{id}^{s} = \infty, w_{id}^{s} = 0 \ \forall\ i \in V$ and $s \in S$
- $C_{e^b}^{*} = \infty, \Phi_{e^b}^{*} = \infty, h_{e^b}^{*} = \emptyset \ \ \forall\ e^b \in E$
- $\lambda_{dd}^{0} = 0; w = 0; \delta = \delta_1\ ; P_{now} = \{[d, 0]\}; P_{next} = \emptyset; \mathrm{Q} = \emptyset$
- $P_i = \emptyset\ \forall\ i \in V \setminus \{d\}; P_d = \{p_{dd}^{0}\}$

If $P_{now} \neq \emptyset$, $\delta \leq \overline{\delta}$ and $w \leq w_{max}$, get $(i, j) \in B(j)$ and check if the last *expected travel time* of p_{jd}^{s} $(last(p_{jd}^{s}))$ is greater than the actual *expected travel time* of p_{jd}^{s}. This condition eliminates *dominated* hyperpaths by checking if in previous loops a fastest hyperpath was found.

The sub-procedures *getLambda* and *getHyperLambda* concatenates arcs and *contained* hyperarcs, respectively. The procedure *getLambda* concatenates (i,j) to hyperpath p_{jd}^{s} as follows:

- If $\Theta_{jd}^{s} > \overline{\delta}$ or $\theta_{ij}(l) > \overline{\delta}$ the concatenation is canceled because of the user restriction on *seat load factors*.
- With the function *getStateAndTransfers*, get the *state* s' that results from concatenating (i,j) with the hyperpath p_{jd}^{s} (see the DFA shown infigure 2). If the concatenation produces more than w_{max} modal transfers, the hyperpath is not *viable* and the procedure terminates
- Check if $\tau_{ij} + \lambda_{jd}^{s}$ is lower than $\lambda_{id}^{s'} : p_{id}^{s'} \in P_i$. If the condition does not hold, the new hyperpath is no generated because it is *dominated* by $p_{id}^{s'}$. Otherwise, continue to the next step
- Check if $\tau_{ij} + \lambda_{jd}^{s}$ is lower than $\lambda_{id}^{s''} : p_{id}^{s''} \in P_i$ for at least one $s'' \in PS_s$. If the condition does not hold, the new hyperpath is no generated because it is *dominated* by at least one $p_{id}^{s''} \in P_i : s'' \in PS_s$. Otherwise, continue to the next step.
- Concatenate (i,j) with the hyperpath p_{jd}^{s} to generate a *viable* hyperpath $p_{id}^{s'}$ and add $p_{id}^{s'}$ to P_i
- If the mode of (i,j) is $M2$ or $M3$. Compute $\Theta_{id}(l)$, $\sigma_{id}(l)$, $r_{id}(l)$, $\Theta_{id}^{s'}$, $\sigma_{id}^{s'}$, and $r_{id}^{s'}$ with Equations (2-7). If the mode of (i,j) is different from $M2$ or $M3$, then $\theta_{id}(l) = \theta_{jd}(l)$, $\sigma_{id}(l) = \sigma_{jd}(l)$, $r_{id}(l) = r_{jd}(l)$, $\Theta_{id}^{s'} = \Theta_{jd}^{s}$, $\sigma_{id}^{s'} = \sigma_{jd}^{s}$, and $r_{id}^{s'} = r_{jd}^{s}$
- If the mode of (i,j) is a modal transfer, add the pair $[i,s']$ to Q, unless it is already in there. If the mode of (i,j) is not a modal transfer consider the following cases:

    - If $\theta_{ij}^{l} \leq \delta$ add $[i,s']$ to P_{now}, unless it is already in there
    - If $\theta_{ij}^{l} > \delta$ add $[i,s']$ to P_{next}, unless it is already in there

The procedure *getHyperLambda* concatenates the *contained* hyperarc $e' = (i,j)$ to hyperpath p_{jd}^{s} as follows:

1. If $\Theta_{jd}^{s} > \overline{\delta}$, the concatenation is canceled because the restrictions on *seat load factors*
2. Check if $p_{id}^{\hat{s}} \in P_i$, such that $e^b = \{i, h^b(e)\}$ is the last hyperarc of $p_{id}^{\hat{s}}$. If $p_{id}^{\hat{s}} \neq \emptyset$ then $s_e = s \circ \hat{s}$, otherwise $s_e = s$
3. If $\lambda_{jd}^{s} \geq \lambda_{id}^{\hat{s}}$ the hyperpath p_{jd}^{s} is *dominated* by $p_{id}^{\hat{s}}$ and the concatenation does not proceed. Otherwise, continue to the next step

4. Let $e^b = (i, h^b(e) \cup \{j\})$, compute $\Phi^*_{e^b}$ as the sum of the average arrival-rates of all the lines associated to e^b. If $\Phi^*_{e^b} = \varphi_{ij}$ continue to step 4.1, otherwise continue to step 4.2
   4.1. Add the estimated waiting time of the *contained* hyperarc (i,j) to the *expected travel time* of the hyperpath p^s_{jd}, $C^*_{e^b} = \frac{1}{\varphi^l_{ij}} + \lambda^s_{jd}$. Since (i,j) is a *contained* hyperarc and p^s_{jd} is a hyperpath starting at i, then the *expected seat load factor* and the *penalty for riding* are exported inherited from the hyperpath p^s_{jd}, i.e., $\Theta^*_{id} = \Theta^s_{jd}$ and $r^*_{id} = r^s_{jd}$.
   4.2. Compute $C^*_{e^b}$ as the incremental weighted average of $C^*_{e^b}$ and λ^s_{jd}. In this case, the algorithm is concatenating the hyperpaths p^s_{jd} and $p^{\hat{s}}_{id}$ with the *contained* hyperarc (i,j). Hence is necessary to compute (in Section 5.1, see the sub-procedure *getIncHPenalty*):
      4.2.1. $\Theta^*_{e^b}$ as the incremental weighted average of $\Theta^*_{e^b}$ and Θ^s_{jd}
      4.2.2. $\sigma^*_{e^b}$ as the incremental weighted average of $\sigma^*_{e^b}$ and σ^s_{jd}
      4.2.3. $r^*_{e^b}$ with the Equation 7
5. If $C^*_{e^b} \leq \lambda^{s_e}_{id} : \lambda^{s_e}_{id} \in P_i, s_e = s \circ \hat{s}$, and $\Theta^*_{e^b} \leq \overline{\delta}$, get the set PS_{s_e} and continue to the next step, otherwise the new hyperpath is dominated by $p^{s_e}_{id}$ or the new hyperpath is restricted by the user *upper load factor*.
6. If $C^*_{e^b} \leq \lambda^{s''}_{id}$ for at least one $s'' \in PS_{s_e}$, continue to the next step. Otherwise, the new hyperpath is not generated because it is *dominated* by $p^{s''}_{id}$
7. Concatenate $e' = (i,j)$ with the hyperpath p^s_{jd} (and with the hyperpath $p^{\hat{s}}_{id}$, if exists) to produce a new *viable* hyperpath $p^{s_e}_{id}$
8. Make $r^*_{e^b} = r^{s_e}_{id}$, $\Theta^*_{e^b} = \Theta^{s_e}_{id}$, $r_{jd}(l) = r_{id}(l)$ and $\Theta_{jd}(l) = \Theta_{id}(l)$. Note that the penalty for riding the sub-hyperpath $p_{id}(l)$ and the *seat load factor* of $p_{id}(l)$ are inherited from the sub-hyperpath $p_{jd}(l)$ because (i,j) is a *contained* hyperarc.
9. Add $[i, s_e]$ to P_{now}, unless it is already in there.

When the algorithm ends, it generates a solution set, P_i, of *viable* hyperpaths. To obtain the *Pareto-Optimal* set of solutions, select from P_i the non-dominated hyperpaths regarding the *expected travel time*, the modal transfers, and the *penalty for riding*. From the *Pareto-Optimal* set, the users choose the hyperpath they prefer according to their personal views, such as the number of transfers or onboard crowding conditions of the ride. The *expected seat load factor* standard deviation, σ^s_{id}, can be used for comparing two hyperpaths in terms of the passengers onboard. For instance, if two hyperpaths have similar penalties but one of them has a smaller σ, a user may prefer the hyperpath with the small σ since the onboard crowd will be more stable during the trip.

5.1. Shortest hyperpaths algorithm pseudo-code

Procedure. *Combined Real-Time Shortest Hyperpaths*

$\lambda_{id}^{s} = \infty, w_{id}^{s} = 0 \; \forall \; i \in V$ and $s \in S$

6. EXAMPLE

Figure 5 shows a multimodal hypergraph composed of three modes; pedestrian ($M1$), buses ($M2$), and private bicycles ($M3$). The mode $M5$ is the modal transfer arcs. The pairs $\left(\tau_{ij}, \theta_{ij}(l)\right)$ on top of the arcs are the arc's travel time and *seat load factor*. On the top of the *contained* hyperarcs is the associated average arrival-rate of the bus line.

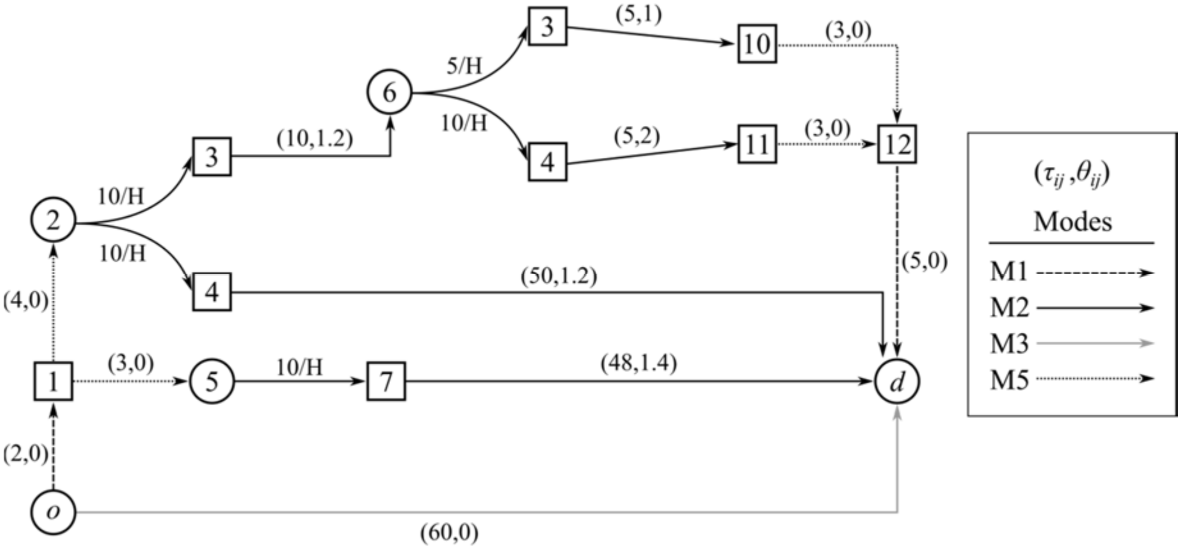

Figure 5: Example hypergraph with three modes and viable hyperpaths

Figure 6 shows the results of computing the shortest hyperpaths from the node o to the node d with a maximum of three modal transfers such that, $\underline{\delta} = 1$, $\overline{\delta} = 1.4$, and $\beta = 1$. The vector $(\lambda_{id}^s, w_{id}^s, s, r_{id}^s)$ near the nodes indicates the *expected travel time*, the maximum modal transfers, the *state*, and the *penalty for riding* of the *viable* hyperpath p_{id}^s. For example, the vector $(25,1,1,7.5)$ on top of node 6 is associated with the *viable* hyperpath p_{6d}^1, such that $\lambda_{6d}^1 = 25$, $w_{6d}^1 = 1$, $s = 1$ and $r_{6d}^1 = 7.5$. The *viable* hyperpath p_{6d}^1 is composed of the *contained* hyperarc $(6,3)$ and the arcs $(3,10)$, $(10,12)$, and $(12, d)$. Since $\theta_{4,11} = 2$ and $\overline{\delta} = 1.4$, the *contained* hyperarc $(6,4)$ and its consecutive arcs are not in p_{6d}^1 as the user prefers not to board vehicles with such onboard crowd levels. The *Pareto-Optimal* set of solutions are the starred vectors on top of node o.

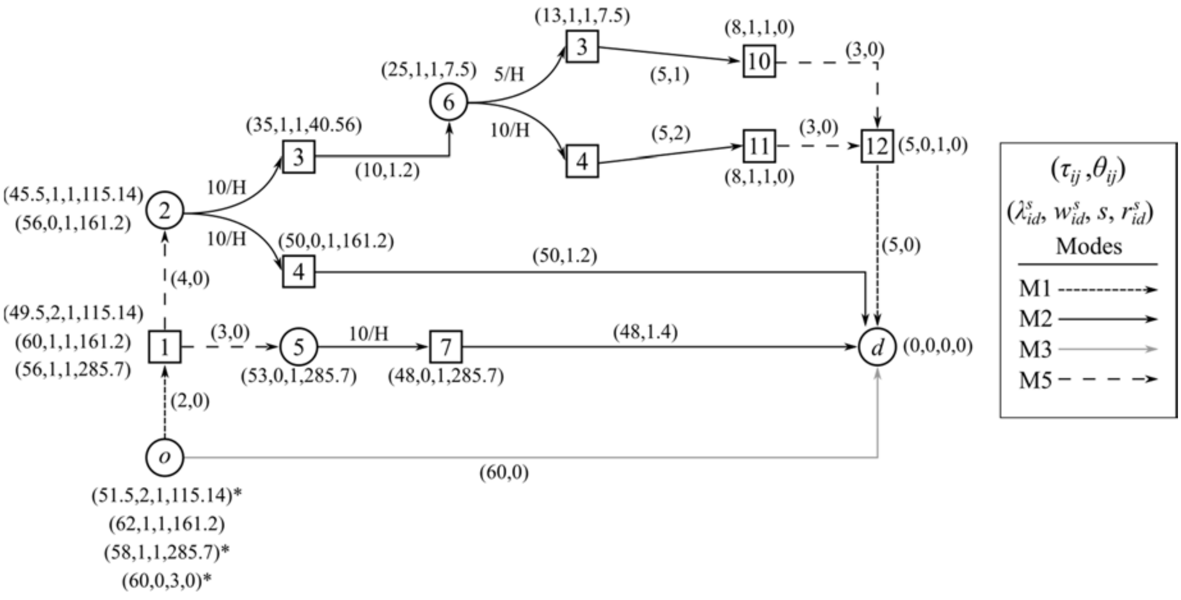

Figure 6: Solution set of viable hyperpaths

Figure 7 shows the three shortest hyperpaths in the Pareto-Optimal set. In the first solution, the user rides a bicycle for 60min to get to the destination. Solution 2 is 58 minutes long; to reach the destination, the user walks to location 1 and then goes to stop 5 for boarding a bus with high onboard crowd levels. Solution 3 is the fastest solution with the lowest onboard crowd levels. However, this solution has the most modal transfers. In solution 3, the user walks to location 1 and then at stops 2 boards the first arriving bus to reach the destination. The decision on selecting the path depends on the user inclinations. Take a long trip by bike to avoid buses (solution 1). Ride a single bus with high onboard crowd levels (solution 2). Alternatively, make many modal transfers to ride buses with low onboard crowd levels (solution 3).

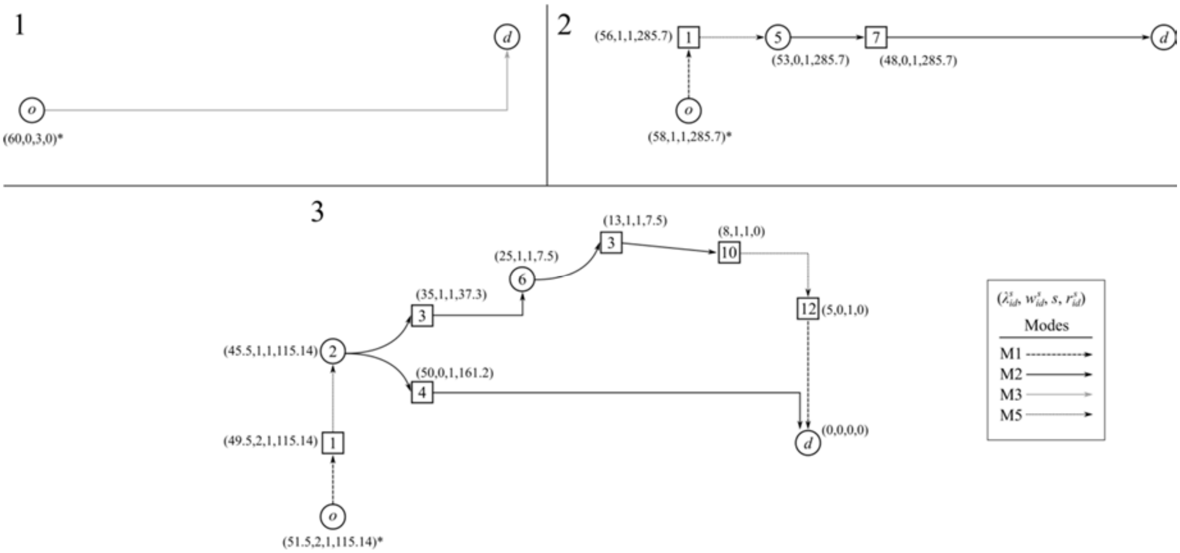

Figure 7: Shortest hyperpath in the Pareto-Optimal set

7. CONCLUSIONS

The presented paper describes a hypergraph model and routing algorithm to find the shortest hyperpaths in a multimodal network where the transit has random-arrivals and are considered the user constraints on the sequence of boarded modes and onboard crowd levels. The *states* and *seat load factors* transform the 'traditional' route planners (that only consider generic factors such as time, cost, or transfers) into personal trip assistants with tailored routes. Nowadays, the enormous amounts of accessible transportation-data set an ideal ground for developing tailored routing algorithms to user habits or idiosyncrasies. In light of the COVID19 pandemic, the presented model and algorithm could be used to find the paths with the lowest levels of onboard crowd and thus reduce the risk of contagion. However, for this tool to be valuable and accurate for COIVD19 applications, real-time information on onboard crowd levels is required.

RESUMEN

Desde hace unos años, los análisis mediante datos georreferenciados por telefonía se han convertido en una alternativa económica a las encuestas tradicionales. Si bien proporcionan datos más fiables, los móviles no permiten el análisis de la toma de decisiones que, en muchas ocasiones, ni el propio usuario es verdaderamente consciente de los factores que le condicionan.

En este contexto, el análisis factorial de variables latentes se convierte en una herramienta indispensable. Estas son aleatorias y no observadas directamente, siendo modeladas a través del estudio de la variabilidad en otras variables sí observables. En términos prácticos, a partir de las respuestas de los encuestados a preguntas sencillas, éstas se pueden agrupar en diferentes variables latentes. Estas preguntas por sí mismas no tienen valor alguno, sino que es la variable que obtenemos de manera indirecta la que nos va a resultar de utilidad.

En el presente artículo, se muestran los principales resultados del análisis factorial de las encuestas realizadas en el Puerto de Málaga dentro del proyecto AUTOMOST: Automated driving for dual-Mode System Transport, para el estudio de la aceptabilidad de la implantación de una línea de autobús autónomo que conectara la terminal de cruceros y el centro urbano. A partir de cinco temáticas que la bibliografía y la experiencia nos decían que podrían ser influyentes (Tecnofilia, Seguridad Vial, Valores Medioambientales y Seguridad Física), se ha podido identificar que la más determinante para el rechazo es la tecnofobia. Esta variable está determinada por la edad y el nivel de formación, por lo que el perfil que presentará mayor aversión es de una persona de avanzada edad con bajo nivel de estudios.

Aunque en líneas generales el modelo muestra gran aceptabilidad al vehículo autónomo para el transporte colectivo, será necesaria la realización de campañas específicas para reducir el rechazo de este tipo de usuarios.

1. ANTECEDENTES

La automatización del transporte es una de las principales metas del sector, pues implica una optimización de recursos, tanto en la amortización del material móvil como en la mejora de la capacidad de la red, en muchos casos ya saturada. Además, se estima un aumento en la seguridad, una mejora en la eficiencia energética y, por tanto, una reducción de las emisiones de gases contaminantes. En otras palabras, cambiará de manera significativa la movilidad y la relación del usuario con el transporte.

Ante este nuevo paradigma en la movilidad, surge la necesidad de comprender la aceptabilidad que pueda tener el vehículo autónomo y, sobre todo, si puede afectar a la elección modal o su rechazo si se trata del transporte público. Es en este contexto donde nace y se desarrolla el proyecto AUTOMOST (*Guiado Automatizado para Sistema de transporte dual*), cuyo objetivo declarado es *desarrollar tecnologías que permitan la automatización de vehículos en aplicaciones de transporte urbano e industriales, de cara a incrementar significativamente la eficiencia, seguridad y sostenibilidad*. En concreto, AUTOMOST permitirá la implementación de sistemas de control compartido (Dual-Mode) para futuros vehículos automatizados que permitan la operación de servicios de manera más eficiente y flexible, en un contexto de infraestructuras inteligentes y conectadas.

Automost es un proyecto del programa CIEN, convocatoria 2016, adjudicado a un Consorcio formado por Corporación Española de Transporte, S.L.U., AVANZA Spain S.A.U., IRIZAR S.Coop, DATIK Información Inteligente S.L., ETRALUX, S.A., Ingeniería INSITU, S.L., Novadays, S.L., Microelectrónica MASER, S.L., TECNALIA, Universidad Politécnica de Madrid (INSIA y TRANS*y*T), CEIT-IK4 y la Universidad de Vigo.

Dentro de las tareas asignadas al Centro de Investigación del Transporte de la Universidad Politécnica de Madrid (TRANSyT-UPM) en el marco del proyecto, se ha realizado un profundo análisis de la aceptabilidad y satisfacción de los potenciales usuarios de la futura línea de autobuses autónomos entre el puerto de Málaga y el centro urbano. En el presente artículo, se recogen los resultados obtenidos de las encuestas realizadas en el puerto a los usuarios de los autobuses que cubren el servicio de la actual línea. Con ayuda de las preguntas de caracterización y de variables latentes, ha sido posible realizar un modelo logístico multinomial con el objetivo de establecer las razones que motivan a un determinado participante a querer subirse o no a bordo de un autobús autónomo.

2. INTRODUCCIÓN Y OBJETIVOS

El vehículo autónomo se define como aquel que desplaza, pasajeros o mercancías, con determinado nivel de automatización, con el principal objetivo de asistir o sustituir el control humano (Stocker & Shaheen, 2017). Los fabricantes especializados en esta industria estimaban que para 2020 ya habría vehículos en el mercado con un alto nivel de automatización (European Commission, 2017).

AUTOMATIZACIÓN- ASPECTOS GENERALES	
Aspectos positivos	**Aspectos negativos**
• Reduce el coste de personal dedicado a la conducción • Se reducen los riesgos de accidente más comunes en la conducción (falta de atención, distancias de seguridad o adelantamientos inseguros) • Optimización de los recursos, como el combustible, y una reducción en las emisiones de gases contaminantes por medio de una conducción mucho más eficiente. • "Devaluar" el coste del tiempo de viaje (no se pierde tiempo en conducir, aprovechando ese tiempo para otras cosas) • Mejorará la equidad (mayores y niños tendrán mayor accesibilidad), y se reduce la cautividad (menos limitante para personas sin carné de conducir)	• Necesidad de importantes inversiones: equipos y material móvil específicos, rediseño de la infraestructura, necesidad de hiperconexión y un mantenimiento especializado. • Introduce nuevos riesgos: puede ser menos seguro en situaciones especiales o no previstas en la programación (fallos del sistema, terrorismo, decisiones que requieran razonamiento humano) • La automatización puede reducir la oferta de empleo, y puede afectar las barreras tecnológicas. • Aspectos territoriales (si disminuye el coste del transporte, y puede hacer que la gente viva más lejos)
AUTOBUSES AUTÓNOMOS- ASPECTOS ESPECÍFICOS	
Aspectos positivos	**Aspectos negativos**
• Potencial para aumentar la fiabilidad y la puntualidad • Posible reducción de costes fijos por la disminución de personal de conducción • Necesidad de un aumento en la inversión, tanto en la infraestructura como en el material móvil.	• Dificultad para controlar impagos • Dificultad en la gestión de incidencias (compra de billetes, requerimientos específicos de información, necesidades específicas de los pasajeros) • Posible disminución de la sensación de seguridad (al no existir una persona física que represente a la autoridad en el autobús). • Despersonalización de la imagen de la empresa.

Tabla 1: Aspectos importantes relativos a los vehículos autónomos. Fuente: López-Lambas & Alonso (2019).

No obstante, pese a existir distintos proyectos de automatización en el transporte público rodado, se siguen identificando barreras importantes: la aceptación de los usuarios, las políticas junto la regulación vigente (para facilitar e incentivar el desarrollo y las pruebas en terreno), la adaptación de la infraestructura y el desarrollo de la tecnología (ERTRAC Working Group, 2019) (Canis, 2019) (Litman, 2017; Fagnant & Kockelman, 2015; Buehler et al., 2009). En la tabla 1 se muestra un resumen de los principales condicionantes encontrados en los estudios sobre vehículos autónomos, destacando los relacionados con los autobuses, de los cuales, por cierto, existen pocos análisis científicos (Bösch et al., 2018).

En este artículo, se presentan los resultados de las encuestas que se llevaron a cabo en el marco del proyecto AUTOMOST para el servicio de autobuses que conectan el puerto de Málaga con el centro urbano. El objetivo es desarrollar un modelo que mida la aceptabilidad de los usuarios a la hora de introducir autobuses autónomos en la red de transporte público, así como identificar los perfiles de usuarios potenciales o reacios a los vehículos autónomos en general. La identificación de variables latentes ha sido fundamental para poder analizar la toma de decisiones en un área tan innovadora del transporte. Se ha considerado apropiada para el estudio, ya que ni el propio usuario es verdaderamente consciente de los factores que le pueden condicionar.

En el siguiente punto, se explica en mayor detalle la metodología de la encuesta presencial, al tiempo que se profundiza en el concepto de las variables latentes y los modelos factoriales realizados. En la sección cuatro, se detallará el proceso lógico llevado a cabo durante el análisis factorial, al igual que los pasos seguidos para la obtención del modelo. Finalmente, se mostrarán las principales conclusiones obtenidas y las futuras líneas de investigación que abre el presente artículo.

3. METODOLOGÍA

Al objeto de comprender la aceptabilidad del vehículo y su conducción, se han desarrollado un gran número de estudios a través de encuestas online (Payre et al., 2014; Zmud et al., 2016), encuestas presenciales (Eden et al., 2017; Nickkar et al., 2021; Payre et al., 2014) y Focus Group o grupos de discusión (López-Lambas & Alonso 2019). Aunque, en líneas generales, la aceptación del vehículo autónomo es extensa y hay un amplio conocimiento en la materia por parte de la ciudadanía, no hay suficientes evidencias para trasladar estas afirmaciones al transporte público colectivo. En este caso, es ventajosa la realización de un modelo de identificación a través de variables latentes, dada la peculiaridad de los autobuses autónomos.

Las variables latentes son una serie de características del individuo que no pueden ser preguntadas directamente, ya que el propio participante no tendría la capacidad de responder al ser constructos psicológicos que no se pueden inferir de forma directa. En otras palabras, no se pueden observar directamente: solo pueden ser medidas a través de otras variables o indicadores directamente observables.

Para la construcción de este modelo, el primer paso consiste en el estudio de todos aquellos factores que puedan influir en el uso del autobús autónomo. Para ello, es necesario comprender el ámbito del estudio, al igual que una revisión de la literatura y los distintos enfoques en la materia. A partir de los Focus Group, o grupos de discusión, realizados en el marco del proyecto AUTOMOST y tras el análisis del estado del arte en profundidad, se seleccionaron las siguientes variables:

- Tecnofilia: afición hacia la tecnología o dispositivos relacionados, generalmente con ordenadores, móviles, tabletas o el resto de los dispositivos informáticos y programables.
- Seguridad vial: prevención del riesgo de accidente en el tránsito de un vehículo.
- Valores medioambientales: conjunto de impactos sobre el medio ambiente y reducción de emisiones de gases contaminantes.
- Pertenencia a una comunidad: influencia o "presión social" sobre nuestras decisiones a partir de la opinión de amigos, conocidos, prensa o redes sociales.
- Seguridad física: miedo a sufrir agresiones, robos, atracos o caídas durante la conducción.

Una vez definidas las variables, el siguiente paso es el conocimiento de la estructura que subyace tras cada una de ellas. Esta puede ser ya conocida por el modelizador, o bien, debe ser descubierta. En ambos casos, es necesaria la utilización de técnicas de modelización con estructuras de covarianza, en particular el Análisis Factorial Exploratorio (AFE), el cual nos permite identificar esas posibles asociaciones entre los datos. La finalidad de los AFE es la determinación de las variables observables que pueden ayudar a evaluar y medir cada una de las variables latentes incluidas en el modelo. De este modo, se pueden obtener cuantas variables latentes estén relacionadas con las observables y que indicadores pueden asociarse a su valoración. A lo largo del proceso, se pueden suprimir del modelo aquellas variables observables que sean innecesarias en la estimación de las latentes, manteniendo aquellas que mejor ajuste proporcionen.

En nuestro caso de estudio, las variables observables son las respuestas de los participantes de la encuesta. Por este motivo, es necesario realizar varias preguntas para cada variable relacionadas con ella, a las que el encuestado puede responder de forma directa. En este tipo de estudios, las respuestas directas a las preguntas no son verdaderamente importantes al objeto de la investigación, sino las variables obtenidas a partir de dichas respuestas tras su análisis factorial. Por ejemplo, la variable latente Tecnofilia se obtuvo a través de la valoración de afirmaciones como "Me gusta probar nuevos dispositivos tecnológicos" o "Necesito herramientas tecnológicas en mi vida diaria". Siguiendo las recomendaciones de la bibliografía y experiencias previas, se combinaron en el cuestionario la escala de Likert (Likert, 1932) y el diferencial semántico (Osgood, et al 1957). En estos casos, es contraproducente preguntar directamente al usuario su grado de tecnofobia, ya que no es verdaderamente consciente de su influencia en las decisiones que toma en su día a día, pudiendo exagerar sus respuestas y distorsionar la muestra.

Para poder confirmar las hipótesis del análisis previo, es conveniente la realización de un Análisis Factorial Confirmatorio (AFC) a continuación. De este modo, se obtiene un modelo óptimo y significativo donde podemos valorar realmente las variables latentes a partir de indicadores medidos en las encuestas y confirmar las relaciones propuestas en las estructuras de datos. Además, en estos modelos ya están introducidas las variables latentes, estudiando la influencia de unas sobre otras. Sin embargo, debido a la complejidad de este análisis y el alcance del presente estudio, se descartó su realización.

Una vez estudiadas las variables latentes, y gracias a la recopilación y caracterización de los participantes, se pudo desarrollar un modelo logit multinomial que definiera el grado de aceptabilidad de los usuarios a una línea de autobús autónomo. En el siguiente apartado, se resumen los datos recogidos en la encuesta, la identificación de las variables latentes, al igual que las principales conclusiones de las preguntas de preferencias declaradas.

4. PROCEDIMIENTO Y ANÁLISIS DE LOS RESULTADOS BÁSICOS DE LA ENCUESTA

La encuesta se realizó en el puerto de Málaga durante el verano del 2019 de forma presencial, por lo que no se ha podido ver alterada por la crisis sanitaria sars-covid19 y sus restricciones sobre la movilidad. La muestra total es de 300 participantes. Teniendo en cuenta que durante ese mismo año hubo 16.051 cruceristas, se estima un margen de error muestral en torno al 5% (nivel de confianza del 95%)asumible para la realización del modelo.

La encuesta constaba de tres partes diferenciables: por un lado, una caracterización del individuo, por otro, una serie de preguntas relacionadas con las variables latentes, y finalmente, preguntas sobre la conducción autónoma y las preferencias declaradas del encuestado a la hora de abordarse en un autobús autónomo. A pesar de la elevada tasa de participación que presentan las encuestas online y de su menor coste, se seleccionaron las encuestas presenciales para una mejor definición de los perfiles de los usuarios afectados por la modificación del servicio y una mejor recogida de su nivel de aceptación (Berrada et al., 2020).

La muestra que participó en la encuesta presenta como perfil mayoritario a un hombre europeo entre los 46-60 años con formación universitaria. Sin embargo, hay una proporción razonable tanto en la distribución de género como de edad. De este modo, se estableció como representativa la muestra recogida.

Cabe destacar que la mayoría de los encuestados son extranjeros y que el ámbito de estudio es muy particular. Los españoles no representan ni el 1% del total de la muestra y los usuarios de la línea, una vez inaugurada, serán cruceristas mayoritariamente, usuarios esporádicos del servicio de transporte público al llegar a Málaga.

4.1 Caracterización de la muestra

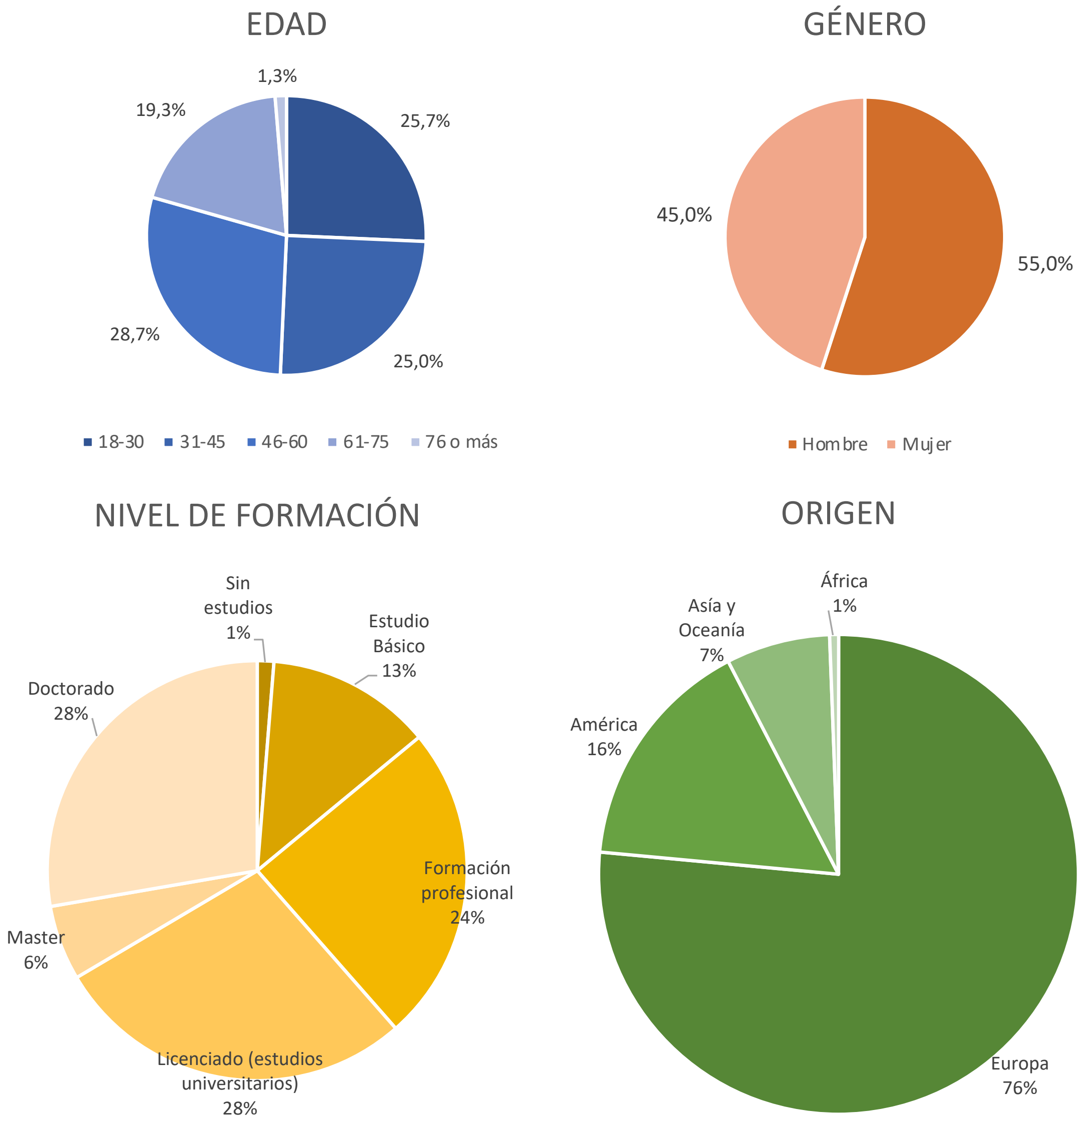

Figura 1: Caracterización de los participantes de la encuesta.

4.2 Análisis factorial y caracterización de variables latentes

Como se ha mencionado anteriormente, las variables latentes no se pueden obtener de forma directa, sino a través de otras variables observables. Para alcanzarlas, se hace una transformación de los resultados de las preguntas básicas, obteniendo unos nuevos resultados con media 0 y desviación estándar 1. En la siguiente figura se muestran los histogramas asociados a cada una de las variables latentes estudiadas a través del software estadístico SPSS.

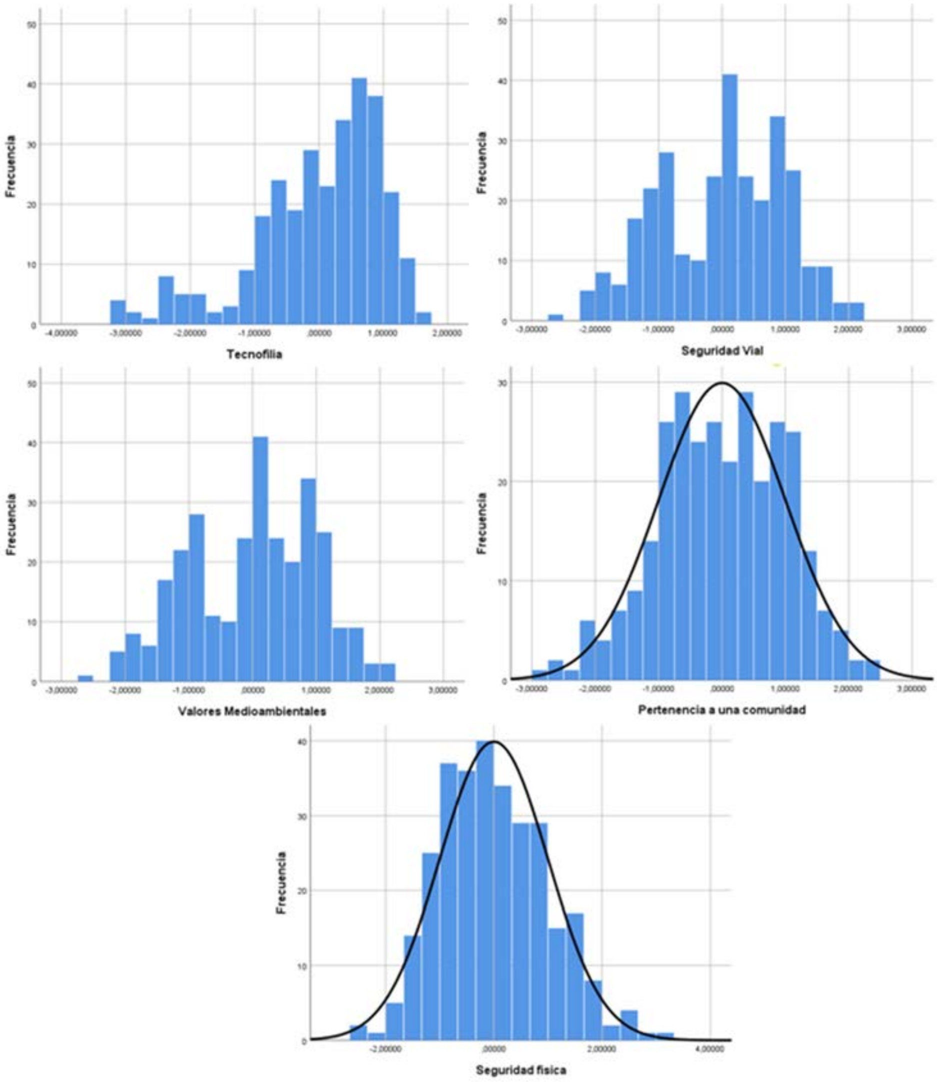

Figura 2: Histogramas de las variables latentes

- Tecnofilia: La mayor parte de las respuestas se concentran en torno al valor nulo. De manera general, la tendencia es hacia la indiferencia a la aparición de nuevas tecnologías. Sin embargo, hay valores extremos en la parte negativa, lo que indica que pueden existir perfiles de usuarios con alto rechazo hacia nuevas tecnologías, llegando a presentar tecnofobia.
- Seguridad vial: La distribución de las respuestas es mucho más repartida, sin casos significativamente extremos. Se identifican niveles similares entre las personas que tienen miedo a sufrir un accidente como aquellas a las que no les influye.
- Valores medioambientales: Los valores para este supuesto son también bastante neutrales. Sin embargo, existe cierta tendencia más visible hacia la no necesidad de tener en cuenta el cuidado del medio ambiente. En otras palabras, una parte de los encuestados no tienen interés en realizar acciones para mejorar el medioambiente en las ciudades y luchar contra el cambio climático.
- Pertenencia a una comunidad: A diferencia de las variables anteriores, se aprecia una tendencia a seguir la función normal. Sin embargo, hay valores y frecuencias más

altas en las cercanías del valor central que en el propio valor central. Esto indica una pequeña polarización en los dos posibles sentidos. No se le otorga una importancia suficientemente alta como para que se produzca un cambio significativo de la función normal.

- Seguridad física: También se aprecia una tendencia a seguir una distribución normal, aunque ligeramente descentrada hacia el lado negativo.

A la hora de planificar una estrategia de acción sobre la base de los resultados de la encuesta, es imprescindible comprender a que público objetivo hay que dirigirse, siendo necesario el estudio de las variables latentes a partir de los datos recopilados en la encuesta y la identificación muestral. Para realizar esta caracterización, se ha calculado una regresión lineal entre las variables latentes y los resultados con la primera parte de la encueta. A continuación, se muestran y explican los principales resultados del análisis.

	Coef. no estandarizados	**Desv.**	**Coef. estandarizados**	**t**	**Sig.**
	B	**Error**	**Beta**		
Tecnofilia					
(Constante)	0,305	0,17		1,793	0,074
Edad	-0,561	0,038	-0,623	-14,683	0
Nivel de formación	0,313	0,041	0,322	7,596	0
Seguridad Vial					
(Constante)	-0,441	0,191		-2,313	0,021
Edad	-0,287	0,045	-0,318	-6,385	0
Género	0,79	0,1	0,394	7,899	0
Valores medioambientales					
(Constante)	0,025	0,228		0,111	0,912
Edad	-0,172	0,051	-0,191	-3,367	0,001
Nivel de formación	0,116	0,055	0,119	2,104	0,036
Pertenencia a una Comunidad					
(Constante)	-0,748	0,228		-3,276	0,001
Edad	0,143	0,051	0,159	2,791	0,006
Nivel de formación	0,115	0,055	0,119	2,092	0,037
Seguridad Física					
(Constante)	0,223	0,255		0,875	0,382
Edad	0,146	0,082	0,105	1,78	0,076
Tipo de ciudad de residencia	-0,124	0,057	-0,128	-2,183	0,03

Tabla 2: Resultados de las regresiones lineales para la caracterización de las variables latentes.

- Tecnofilia: Esta variable viene determinada por la edad, principalmente, y por el nivel de formación, como se puede apreciar en la anterior tabla. Conforme aumenta la edad del individuo, mayor aversión hacía las nuevas tecnologías. Por el contrario, a mayor nivel educativo, mayor predisposición a las nuevas tecnologías.
- Seguridad vial: En este caso, la variable viene determinada por la edad (A medida que aumenta hay una menor preocupación por la seguridad vial) y el género, siendo está última la más influyente.
- La peculiaridad de la variable género es que no se trata de una variable ordenada, por lo que los resultados varían en función del orden en el que se han introducido las respuestas. En el presente estudio, se introdujeron primero las respuestas de género masculino (al ser mayoritarias) y después las de género femenino. Una tendencia positiva, como es el resultado obtenido, indica que el último grupo de variables tiene una mayor influencia sobre la variable latente. En otras palabras, las mujeres presentan mayor preocupación por la seguridad vial.
- Valores medioambientales: Las variables edad y nivel de formación son las de mayor influencia, aunque sus valores B son pequeños. En lo que respecta a las tendencias, mientras conforme aumenta la edad la preocupación por el Medio Ambiente disminuye, en el caso del nivel de formación se aprecia una mayor preocupación medioambiental conforme aumenta el nivel de estudios.
- Pertenencia a una comunidad: En este caso, vuelven a aparecer la edad y el nivel de formación como las variables que caracterizan a las variables latentes. Sin embargo, ambas muestran tendencias positivas: a mayor edad y nivel de formación, mayor sentimiento de pertenencia a una comunidad.
- Seguridad física: En el caso de la seguridad física, además de la edad, entra en juego la variable ciudad de residencia. Los resultados muestran que, cuanto mayor sea el tamaño de la ciudad y más la edad del individuo, existe una mayor preocupación por la integridad física individual.

4.3 Conocimiento sobre la conducción autónoma y preferencias declaradas

Una vez se ha caracterizado la muestra de la encuesta, e identificado y estudiado las variables latentes, hay que entender el nivel de conocimiento sobre el vehículo y autobús autónomo de los participantes, al igual que su comportamiento en situaciones hipotéticas relacionadas con su conducción autónoma.

En primer lugar, se preguntó a los participantes sobre su conocimiento y experiencia en vehículos autónomos, así como sus preferencias declaradas sobre su uso. En líneas generales, el conocimiento sobre esta tecnología es bastante alto, si bien apenas ha sido experimentada.

Respecto a la preferencia declarada, apenas un 9% de los participantes afirmó que bajo ningún concepto se subirían a un vehículo autónomo. Por otro lado, hay un porcentaje nada desdeñable (un 28,3%) que precisaría de más información o conocimiento de determinadas características para decidirse.

	Sí	No	Quizás
¿Ha oído hablar del vehículo autónomo?	90,3%	9,7%	n/a
¿Ha montado alguna vez en un vehículo autónomo?	5,3%	91,3%	n/a
¿Se montaría en un vehículo autónomo?	62,7%	9,0%	28,3%

Tabla 3: Resultados sobre las preguntas sobre el conocimiento del vehículo autónomo.

Una vez caracterizado el conocimiento sobre conducción autónoma, se contextualizó en el caso particular del autobús autónomo. Por un lado, se preguntó sobre las preferencias declaradas respecto a la conducción autónoma del autobús, así como la influencia que tendría mantener un componente humano, en el caso de las personas que presentaran dudas.

	Sí	No	Quizás
Si este autobús no llevara conductor, ¿se habría montado?	62,30%	9,30%	28,30%
Si el autobús sin conductor llevara a bordo una persona para ayudar a los pasajeros, ¿se montaría?	82,40%	17,60%	n/a
Si esta persona pudiera tomar el control del autobús en caso de que fuera necesario, ¿se montaría?	100,00%	0,00%	n/a

Tabla 4: Resultados sobre las preguntas de preferencias declaradas sobre el autobús autónoma.

Los resultados sobre las preferencias declaradas relacionadas con la conducción autónoma son muy similares con los obtenidos para el caso del autobús. Además, el porcentaje de personas que se subirían al autobús va incrementándose a medida que se aumenta el factor humano en su conducción autónoma. Más del 80% de las personas que presentaban dudas a abordar en un autobús autónomo, lo harían si existiera la figura de un ayudante para los pasajeros. Todos afirman que se subirían al autobús con la figura de un conductor que tomara el control del vehículo en caso de que fuera necesario.

Después se preguntó por la importancia que dan los participantes a la figura del conductor en una serie de tareas. De este modo, se puede comprender el papel que representa el conductor del autobús para los usuarios y su posible futuro desempeño en la conducción autónoma.

Los resultados muestran que la principal función está relacionada con la seguridad operacional. En otras palabras, los usuarios valoran muy positivamente sus labores durante la conducción. Sin embargo, la figura del conductor no proporciona mayor seguridad frente agresiones (físicas o verbales), intimidaciones, robos o hurtos. Además, cabe destacar que la experiencia como usuario se valora muy negativamente por los participantes de la encuesta.

	Media	Mediana	Moda	Desviación
Seguridad (física: temor a una agresión, intimidación, hurto/robo),	2,93	3	3	1,261
Seguridad (operacional: fallos del vehículo que comportan accidentes)	4,24	5	5	1,036
Experiencia como usuario (Subir a bordo, bajar, compra del billete, información a bordo o antes de subir sobre rutas, paradas, tiempo de viaje y espera del próximo bus, etc.)	2,12	1	1	1,364

Tabla 5: Resultados sobre el vehículo autónomo.

5. MODELO DE DECISIÓN

Una vez analizados los resultados directos de la encuesta y las variables latentes, se genera un modelo logit multinomial para estimar la aceptabilidad del autobús autónomo. Se ha elegido este modelo porque la variable dependiente que se quiere analizar es categórica, y tiene más de dos opciones de respuesta: Sí, No o Quizás. Con este modelo se identificarán las variables socioeconómicas y latentes que sean más influyentes en la toma de decisiones de los usuarios potenciales de un servicio de transporte público con autobuses autónomos.

En un primer momento, se consideraron todas las variables, tanto de caracterización como las variables latentes obtenidas, así como las posibles interacciones que existieran entre ambas. Sin embargo, para que un modelo sea útil, ha de ser capaz de pronosticar correctamente el mayor número de casos con el menor número de variables. Con esta idea, se han eliminado aquellas que no eran estadísticamente significativas o que no aportasen valor significativo. En otras palabras, con coeficientes de significación superiores al 0,05.

Siguiendo estas recomendaciones, dos variables latentes finalmente no se emplearon en el modelo – Seguridad física y Pertenencia a una comunidad- al tener valores de significancia muy elevados (0,269 y 0,139, respectivamente), así como bajos valores de chi-cuadrado (2,6 y 3,9 frente a 270,77, 12,24 y 27,76 del resto de variables latentes). Por tanto, se han utilizado en un primer momento Tecnofilia, Protección del Medio Ambiente y Seguridad Física, con las variables de caracterización del usuario.

En un modelo multinomial se compara una opción definida como base con todas las demás opciones posibles. En este caso, se ha definido como base la opción positiva (“Sí”). La estimación obtenida del modelo es la siguiente:

		B	Desv. Error	Wald	Sig.	OR (Exp(B))	OR para cambio de ½ unidad	95% de intervalo de confianza para Exp(B)	
								Límite inferior	Límite superior
NO	(Intersección)	-6,544	1,137	33,131	0,000				
	Tecnofilia	-6,714	0,827	65,925	0,000	0,001	0,03	0,000	0,006
	Protección Medioambiental	-0,975	0,402	5,892	0,015	0,377	0,61	0,172	0,829
	Seguridad física	1,068	0,407	6,900	0,009	2,911	1,71	1,312	6,460
QUIZÁS	(Intersección)	-0,532	0,182	8,557	0,003		0,77		
	Tecnofilia	-2,949	0,364	65,609	0,000	0,052	0,23	0,026	0,107
	Protección Medioambiental	-0,617	0,192	10,334	0,001	0,540	0,73	0,370	0,786
	Seguridad física	1,012	0,213	22,572	0,000	2,750	1,66	1,812	4,174

Tabla 6: Resultados del modelo multinomial logit aplicado con tres variables latentes: tecnofilia, protección al medio ambiente y seguridad física.

Durante el análisis de la importancia de cada término en el modelo, hay que fijarse en el Exponente B. (Odds Ratio)Este indicador nos proporciona el incremento de las posibilidades de éxito de una de las opciones de resultado respecto a la otra cuando se incrementa una unidad en el término estudiado. Debido a que el rango de las variables latentes es pequeño, se ha calculado también para un incremento de media unidad, de manera que se hace más comprensible el significado e influencia de este valor.

Como se puede apreciar en la anterior tabla, existe una variable que destaca sobre el resto de las empleadas: la tecnofilia. La tecnofilia es especialmente influyente en la comparación entre Sí vs No, si bien también destaca en la comparación entre Sí vs Quizás, aunque en menor medida. Para comprender la importancia de esta variable, valga el siguiente análisis para su visualización: es 33 veces más probable (1/0,03) que una persona con una puntuación de 2 esté dispuesta a subirse a un autobús de conducción autónoma que una persona de 1,5, comparando Si vs No. En el caso de Sí vs Quizás, este valor se reduce a 4,4 veces. El resto de las variables presentan valores muy similares y mucho más bajos, todos ellos entre 1 y 2. En otras palabras, mientras que los valores de protección medioambiental y seguridad física, e incluso el de Tecnofilia para Sí vs Quizás, se encuentran en los rangos de lo que se suele obtener en modelos logarítimicos, el resultado de Tecnofilia en Sí vs No es muy superior al habitual.

Esto indica que, si bien existen más factores, el tratamiento de la aceptación de las nuevas tecnologías ha de ser un elemento clave en la implementación del autobús autónomo. De este modo, para lograr el éxito de este modelo de conducción en el transporte público sin afectar gravemente a la demanda, se ha de conseguir que el mayor número de usuarios, independientemente de sus habilidades con las tecnologías y los dispositivos, no solo puedan utilizar el servicio, sino que se sientan cómodas haciéndolo.

Finalmente, se ha analizado qué valores son más influyentes en los indecisos (que hayan contestado quizás) a la hora de subirse un autobús autónomo si hubiese un asistente a bordo. En este caso, se ha optado por una regresión logarítmica binomial. Las variables estadísticamente significativas son Seguridad Vial y Física.

	B	**Error estándar**	**Wald**	**Sig.**	**Exp(B)**	**95% C.I. para EXP(B)**	
						Inferior	**Superior**
Seguridad Vial	0,702	0,346	4,114	0,043	2,018	1,024	3,977
Seguridad Física	0,744	0,305	5,975	0,015	2,105	1,159	3,824
(Constante)	-2,084	0,427	23,801	0,000	0,124		

Tabla 7: Resultados del modelo binomial logit aplicado con las variables latentes de Seguridad Vial y Seguridad Física.

6. LÍNEAS DE INVESTIGACIÓN FUTURAS

El presente estudio abre nuevas líneas de investigación sobre la conducción autónoma en el transporte público rodado. Aunque, en líneas generales, se muestra un gran conocimiento sobre el vehículo autónomo y aceptación de este modelo de conducción cuando se trata de un autobús, los resultados no son completamente extrapolables al servicio completo de la red de transporte público.

Los participantes de la encuesta, en su totalidad, eran cruceristas y extranjeros. En otras palabras, usuarios esporádicos de una red de transporte público desconocida y con alto porcentaje de cautividad. Además, gran parte del itinerario que realizaría el autobús sería dentro del puerto, una situación de tráfico acotada y limitada con influencia mínima de las externalidades típicas de la conducción del día a día en una gran ciudad.

Con el objeto de validar el actual modelo desarrollado, por medio de la diversificación y ampliación de la muestra, es recomendable extender este análisis a usuarios fidelizados en el transporte público de la ciudad. De este modo, se podría comprender la aceptabilidad de este modelo de conducción en ámbitos mucho más urbanos. Al mismo tiempo, sería interesante estudiar su influencia sobre la elección modal, su capacidad de atracción de usuarios del vehículo privado al transporte público.

7. CONCLUSIONES

En muchos casos, se puede explicar la toma de decisiones de un individuo sen función de sus características socioeconómicas, relativamente fáciles de obtener. Sin embargo, cuando se trata de decisiones en las que no se necesita meditar mucho, o que incluso no se es verdaderamente consciente de las motivaciones, esta caracterización se torna más compleja.

En el presente artículo se demuestra la necesidad de considerar las variables latentes en el estudio de la aceptabilidad del autobús autónomo, ya que su estudio ha sido fundamental para el desarrollo del modelo. Mediante una serie de sencillas preguntas, ha sido posible caracterizar a los participantes en aspectos no accesibles de manera directa. Aunque lo ideal es obtener un modelo con las variables básicas de caracterización, no se han conseguido resultados adecuados hasta introducir las variables latentes validadas: Tecnofilia, Protección del Medio Ambiente y Seguridad Física. Con ello, se ha logrado un modelo válido y fiable, con el que se pueden explicar las razones que motivan la decisión de abordar un autobús autónomo.

Al mismo tiempo, con este análisis se ha podido demostrar cómo el vehículo autónomo en general, y el autobús autónomo en particular, tiene un nivel de aceptación bastante alto, si bien existen aún potenciales usuarios que muestran dudas a la hora de abordar un vehículo de estas características. A medida que se incremente el factor humano, se reduce el número de usuarios indecisos hasta desaparecer. Esta situación es muy similar a la conducción autónoma: a medida que aumenta su nivel de autonomía, aumenta el estrés y su rechazo (Hewit, et al., 2019¸ Rödel et al., 2014). De este modo, se aprecia una estrecha relación entre la conducción autónoma, tanto en transporte individual como en el transporte colectivo.

Finalmente, el factor más influyente en la toma de decisiones a la hora de abordar un autobús de conducción autónoma es la tecnofilia. Esta variable está determinada por la edad y el nivel de formación, por lo que el perfil de persona en el que más hay que centrarse es el de personas de avanzada edad con bajo nivel de estudios.

AGRADECIMIENTOS

De parte de los autores, nos gustaría aprovechar para agradecer la oportunidad de participar en el ambicioso proyecto de AUTOMOST - GUIADO AUTOMATIZADO PARA SISTEMA DE TRANSPORTE DUAL, y haber podido colaborar con el Grupo Avanza en el objetivo de alcanzar un transporte público urbano más competitivo y sostenible.

Al mismo tiempo, nos gustaría agradecer el papel del Congreso de Ingenieros de Transporte en la divulgación y la colaboración científica entre universidades y empresas, permitiéndonos presentar las principales conclusiones de este modelo de aceptabilidad de la conducción autónoma en el transporte público.

RESUMEN

Las encuestas son un método comúnmente utilizado para establecer los niveles de satisfacción de los usuarios con un sistema de transporte público. Independientemente del tipo de encuesta realizada y de la metodología empleada, los estudios presentan habitualmente una imagen puntual y concreta del servicio mostrando los resultados de forma agregada o diferenciando por líneas y características socioeconómicas de los usuarios. Sin embargo, no se analiza la satisfacción como una variable con variación temporal o espacial. En este artículo se presenta un caso práctico aplicado a la ciudad de Santander donde se realiza un análisis de la evolución de la satisfacción con el servicio a lo largo de un día en varias líneas que conforman el sistema de transporte público de la ciudad. A su vez, se analiza cómo cambia esta percepción en los distintos puntos de la ciudad. Los resultados muestran que la satisfacción general de los usuarios con respecto al servicio disminuye en las horas punta del día, al igual que se detecta una variación con respecto a los distintos puntos de la ciudad analizados. Además, algunos atributos fueron más relevantes que otros, mostrando diferencias significativas en su importancia en diferentes franjas horarias y líneas de autobús. Estos resultados pueden ayudar a mejorar los servicios de transporte de forma más precisa, mostrando las diferencias espacio-temporales que existen en las evaluaciones realizadas por los usuarios.

1. INTRODUCCIÓN

La mejora de la calidad del servicio ofertado y de la satisfacción del usuario permite potenciar el uso del transporte público y la fidelización del cliente. A su vez el fomento del uso del transporte público es uno de los pilares de la promoción de la movilidad sostenible, dada su capacidad para transportar personas de forma más eficiente que el transporte privado motorizado, reduciendo la congestión (Nguyen-Phuoc, Young, Currie y De Gruyter, 2020), la emisión de contaminantes (Beaudoin, Farzin y Lin Lawell, 2015; Borck, 2019; Gendron-Carrier, Gonzalez-Navarro, Polloni y Turner, 2018) y ofreciendo una mayor equidad social (Cuthill, Cao, Liu, Gao y Zhang, 2019; Foth, Manaugh y El-Geneidy, 2013; Manaugh y El-Geneidy, 2012).

Entre las herramientas que se han utilizado para promover una mejora de la satisfacción de los usuarios con el servicio de transporte público se encuentran los Customer Satisfaction Surveys (CSS) (J. de Oña y de Oña, 2015). Este tipo de encuestas intentan medir cual es el grado de satisfacción de los usuarios con el servicio, dado que una satisfacción más elevada puede identificarse como el factor más determinante de una intención comportamental favorable al uso del transporte público (Lai y Chen, 2011). Además de la satisfacción general, los CSS también miden la percepción de la calidad de los atributos particulares del servicio, con el objetivo de detectar aquellos aspectos que podrían mejorarse obteniendo el mayor impacto en términos de satisfacción y por lo tanto de uso del transporte público. Estos atributos pueden ser muy variados por lo que suelen clasificarse en distintos grupos, como los propuestos por la norma UNE-EN 13186 (2003), siendo estos la oferta de transporte público (servicio ofertado, accesibilidad), la realización del servicio (información, tiempo, atención al cliente, confort, seguridad) y el impacto medioambiental. Otros autores han señalado la existencia de atributos de tipo básico (ocupación, cobertura del servicio, fiabilidad) en los que, si la percepción de la calidad es baja, la demanda del servicio puede verse seriamente comprometida, mientras que otros son de tipo no básico y contribuyen a la satisfacción, pero no son determinantes para la elección del servicio (características de las paradas, limpieza de los vehículos, amabilidad de los empleados) (Eboli y Mazzulla, 2008).

Sin embargo, la satisfacción del usuario no es un fenómeno estático, sino que puede variar tanto en términos espaciales como temporales. En términos espaciales entre distintas zonas de prestación del servicio dentro del mismo área urbana (Cordera, Nogués, González-González y dell’Olio, 2019), entre distintas ciudades o incluso entre distintos segmentos de las líneas de transporte. En términos temporales la satisfacción puede ser variable entre distintas partes del día (hora punta/hora valle) o entre distintos intervalos temporales. Conocer esta variabilidad en la satisfacción de los usuarios puede ser importante para diagnosticar cuando y donde el servicio presenta problemas. Este estudio plantea profundizar en esta línea de investigación mediante el análisis y la modelización de la satisfacción de los usuarios obtenidas a través de un CSS realizado en Santander (Cantabria, España) considerando las variaciones espacio-temporales de las respuestas. El CSS tuvo en cuenta tanto la satisfacción de los usuarios con el servicio a nivel general como la percepción da la calidad del mismo en 28 aspectos específicos.

En la literatura técnica sobre la medición de la calidad del servicio y sobre la satisfacción de los clientes del transporte público la atención prestada a estos fenómenos de diversidad espacial y temporal ha sido limitada. Un ejemplo es el trabajo de Allen, Muñoz y de Dios

Ortúzar (2020), los cuales combinaron datos de encuestas sobre la satisfacción de los usuarios del Metro de Santiago de Chile con datos sobre la operación del servicio como los niveles de ocupación, las frecuencias, la velocidad comercial y la ocurrencia de accidentes críticos. Además, los autores desagregaron el análisis en las distintas líneas del sistema, periodos del día, días de la semana, estaciones y años, siendo por lo tanto el ejemplo más notable encontrado de consideración de la variabilidad espacial y temporal de la satisfacción. Sin embargo, este estudio no consideró la variabilidad de la satisfacción y la percepción de la calidad a nivel de distintos segmentos de la misma línea, lo cual puede dar más detalles sobre los factores que influyen en las elecciones de los usuarios.

Tanto Cats, Abenoza, Liu y Susilo (2015) como Börjesson y Rubensson (2019), J. de Oña, de Oña, Eboli y Mazzulla (2016) y Kawabata et al. (2020) han utilizado datos de serie temporal que les permitió analizar la evolución de la satisfacción de los usuarios en el tiempo. Cats et al. (2015) examinaron cómo la satisfacción de los usuarios cambió en Suecia entre los años 2001 y 2013, mostrando un declive de ésta generado por la peor interface con el cliente y el aumento del tiempo de viaje. Börjesson y Rubensson (2019) utilizaron también datos sobre la satisfacción de los usuarios en Suecia, en este caso entre los años 2008 y 2016, encontrando una relación importante entre satisfacción y el nivel de aglomeración y fiabilidad del servicio. J. de Oña et al. (2016) realizó una investigación sobre la evolución de la satisfacción y la percepción de la calidad del servicio mediante el uso de index numbers y datos obtenidos de una CSS realizada entre 2007 y 2013. Esto permitió detectar un ascenso en la satisfacción con el servicio en los primeros años de la serie (2008-2010) junto con una caída en los años posteriores (2010-2012) y una ligera recuperación al final (2013). Sin embargo, este estudio no tuvo en cuenta diferencias espaciales en la satisfacción con el servicio ni los factores explicativos de estos cambios. Kawabata et al. (2020) utilizaron datos del Benchmarking in European Service of Public Transport para los años 2001-2015 con el objetivo de apoyar la hipótesis de que la mejora en la calidad del servicio influye positivamente tanto en la satisfacción del usuario como en la frecuencia de uso del servicio. Aunque los autores demostraron la existencia de esta relación, también detectaron la existencia de un retardo temporal desde que se produce la mejora en la calidad hasta que ésta se traduce en una mayor frecuencia de uso por parte de los usuarios. Otras investigaciones han tenido en cuenta además el efecto de la crisis financiera de 2008 en la satisfacción de los usuarios, como las realizadas por de R. de Oña, de Abreu e Silva, Muñoz-Monge y de Oña (2018) y Efthymiou y Antoniou (2017) para los casos español y griego respectivamente.

Entre los estudios que se han centrado más bien en diferencias espaciales, J. de Oña (2020) utilizó los datos de cinco ciudades europeas: Madrid, Roma, Berlín, Lisboa y Londres, para examinar cual era el rol de la involucración en el transporte público, demostrando su papel mediador entre la satisfacción del usuario y la intención comportamental de usarlo. Esta línea de investigación fue ampliada por el mismo autor en J. de Oña (2021), considerando si la satisfacción era un factor mediador parcial o completo entre la calidad del servicio y las intenciones comportamentales, utilizando datos recogidos en las mismas cinco ciudades.

Esta comparación espacial permitió establecer que el modelo de ecuaciones estructurales (SEM) que consideró la satisfacción como un factor mediador completo se ajustó mejor en todas las ciudades con la excepción de Londres. Además, en las cinco ciudades factores como la frecuencia, la puntualidad, la velocidad y la intermodalidad fueron los más relevantes.

Como puede verse de la revisión de los estudios anteriores, la mayor parte de las investigaciones que han tenido en cuenta la diversidad de la satisfacción de los usuarios, lo han hecho más en términos temporales que espaciales y más a escala de diferentes áreas de estudio (ciudades) que dentro del mismo sistema de transporte. Esta investigación se centrará más bien en la diversidad espacial y temporal de la satisfacción de los usuarios a escala intraurbana, un enfoque que ha sido menos explorado y puede ser interesante para la detección de los factores que expliquen esta diversidad.

En el apartado siguiente se repasan los datos disponibles mediante la CSS que han sido básicos para la realización de este estudio. En el apartado 3 se describe la metodología empleada, tanto para estimar la contribución de los diferentes factores específicos a la satisfacción global como para la diferenciación de las valoraciones a nivel espacial y temporal. En el apartado 4 se presentan los resultados obtenidos, prestando especial relevancia a las variaciones temporales y espaciales en la satisfacción. Por último, se ofrecen una serie de conclusiones y recomendaciones de política obtenidas a partir de estos resultados.

2. DATOS

2.1 Encuesta

La recogida de datos se basó en una CSS dividida en 2 grandes partes. En la primera parte de la encuesta se preguntaba al usuario un total de 7 cuestiones relacionadas con sus características socioeconómicas y las del viaje. Las preguntas fueron: edad, género, situación laboral, nivel de ingresos mensual, nivel de uso del autobús, motivo del viaje (origen y destino) y si disponían de algún modo de transporte alternativo para realizar ese mismo trayecto que estaban realizando en autobús. La segunda parte de la encuesta se centraba en obtener la información referente a la satisfacción y percepción de los usuarios de la calidad del servicio. En total, los usuarios establecieron su percepción sobre la calidad de 24 atributos relacionados con el sistema de transporte, al igual que evaluaron la satisfacción general del servicio en su conjunto.

Para definir la percepción sobre la calidad de los atributos, los encuestados debían realizar dos actividades. Para facilitar la realización de dichas actividades, los atributos se agruparon en grupos de 4 atributos escogidos aleatoriamente. Cada encuestado solo evaluaba 3 grupos de atributos, evaluando de esta forma solo 12 de los 24 atributos definidos para el conjunto de la encuesta. Se optó por este diseño para facilitar que las encuestas pudieran realizarse dentro de unos márgenes de tiempo aceptables. El primer ejercicio a realizar, dentro del grupo de atributos, se basaba en una evaluación del nivel de calidad convencional basada en ítems de Likert de 5 puntos (de Muy Mal a Muy Bien). Una vez evaluados los atributos, a los encuestados se les pedía que escogieran de entre los cuatro atributos mostrados aquel que consideraban más importante y aquel que consideraban menos importante, realizando de esta forma un ejercicio de tipo Best-Worst Caso 1. Para acabar la encuesta los encuestados evaluaban la satisfacción general utilizando los mismos niveles definidos anteriormente.

2.2 Muestra

La CSS se realizó entre los meses de octubre y noviembre de 2017 en la ciudad de Santander. Las encuestas se completaron mediante entrevistas presenciales en 4 líneas de la ciudad operadas por la empresa pública de transportes. Se consiguieron un total de 808 encuestas válidas comprendidas en una franja horaria entre las 8 de la mañana y las 8 de la tarde. El número de encuestas realizadas se muestra en la Tabla 1.

Hora del día	Encuestas completadas				
	Línea 1	Línea 2	Línea 3	Línea 13	Total
<= 9:00	24	28	30	16	98
9:01 - 10:00	35	36	31	34	136
10:01 - 11:00	21	28	8	11	68
11:01 - 12:00	15	12	9	4	40
12:01 - 13:00	18	9	13	20	60
13:01 - 14:00	28	10	50	16	104
14:01 - 15:00	10	8	12	4	34
15:01 - 16:00	14	28	5	8	55
16:01 - 17:00	10	33	15	18	76
17:01 - 18:00	14	17	19	19	69
18:01 - 19:00	21	13	3	17	54
19:01+	4	4	3	3	14
Total	214	226	198	170	808

Tabla 1: Tamaño de la muestra

En la Tabla 2 se muestran las variables socioeconómicas de la muestra para cada una de las líneas de transporte analizadas y para el total de encuestas. Referente al género, se puede observar que las mujeres están sobrerrepresentadas en todos los casos. La edad de los encuestados se reparte de forma más uniforme, si bien existen más observaciones de personas de menos de 25 años y un menor número de las personas de más de 75. Otro aspecto a destacar en cuanto a la edad es la variación entre las líneas 1, 2 y 3 frente a la línea 13. Las tres primeras muestran un mayor número de usuarios jóvenes, mientras que la línea 13 muestra un número muy superior de usuarios de más de 65 años. En lo que respecta a la situación laboral, la mayoría de los encuestados son trabajadores, seguidos de estudiantes y jubilados. En la línea 13, en relación a la diferencia de edad, el número de jubilados es mayor que en el resto de las líneas. Prácticamente la mitad de los encuestados podría realizar el mismo viaje en coche ya que lo tienen disponible. El potencial uso de la bicicleta es muy bajo, al igual que el de la moto. El motivo de viaje principal es aquel relacionado con el hogar, siendo el segundo motivo principal el trabajo. El motivo del viaje por líneas es a grandes rasgos similar, sin embargo, en la línea 3 se observa un número de viajes menor relacionados con el ocio, mientras que en la línea 13 existe un número mayor de viajes por motivo compras. Más de la mitad de los usuarios encuestados pueden considerarse viajeros recurrentes, ya que la mayoría de los encuestados realiza entre 5 y 15 viajes semanales. En cuanto a nivel de ingresos de la muestra, el reparto es similar en todas las líneas, sin embargo, cerca del 40% de los encuestados prefirió no responder a esta pregunta al tratarse de un aspecto sensible.

Atributo	**Nivel**	**Lín. 1**	**Lín. 2**	**Lín. 3**	**Lín. 13**	**Total**

	Sin respuesta	41%	48%	42%	35%	42%

Tabla 2: Variables socioeconómicas consideradas en la encuesta

La Tabla 3 muestra el nivel de calidad percibida de los atributos ordenados de mayor a menor valor.

El atributo mejor valorado es el uso de vehículos con combustibles alternativos (vehículos híbridos en la fecha de realización de la encuesta).

En segundo lugar, están los tiempos de acceso y egreso de las paradas, lo cual demuestra una buena densidad de paradas a lo largo de la red.

Por otro lado, en la parte inferior de la tabla se encuentran atributos característicos del servicio de transporte público como son las frecuencias de los servicios o el precio.

Por último, las variables ambientales como los sistemas de aire acondicionado y el ruido también muestran una baja calificación.

Orden	Atributo	Acrónimo	Media	Desv. Est.
1	Uso de autobuses híbridos	HY	8,10	1,91
2	Tiempo de acceso a la parada	AT	7,34	2,24
3	Tiempo de egreso desde la parada al destino final	DT	7,29	2,22
4	Limpieza del vehículo	CL	7,04	1,75
5	Facilidad de transbordo	TR	6,96	2,24
6	Información en las paradas	IS	6,90	2,43
7	Información a bordo	IB	6,83	2,24
8	Confort de los buses	CM	6,77	1,86
9	Fiabilidad / puntualidad	SR	6,75	2,16
10	Amabilidad del conductor	DK	6,57	2,12
11	Calidad de las paradas	ST	6,56	2,03
12	Información en la aplicación móvil	IM	6,53	3,19
13	Cobertura de las líneas	LC	6,50	2,07
14	Información en la página web	IW	6,46	2,39
15	Espacio para las personas con movilidad reducida	RM	6,27	2,22
16	Tiempo de espera	WT	6,26	2,27
17	Nivel de ocupación	OC	6,25	2,17
18	Facilidad de entendimiento del mapa de líneas	MD	6,21	2,46
19	Tiempo de viaje	TT	6,18	2,14
20	Servicio ofertado (frecuencias y horarios)	SE	6,10	2,42
21	Forma de conducción	DS	5,98	2,15
22	Precio	PR	5,83	2,35
23	Calefacción / aire acondicionado	CA	5,77	2,49
24	Ruido	NO	5,71	2,06
	Satisfacción general	OS	6,73	2,01

Tabla 3: Niveles de calidad percibida de los atributos

3. METODOLOGÍA

3.1 Obtención de la satisfacción general

Disponer de varias observaciones en diferentes momentos del día requiere varios métodos de agregación para poder comparar los resultados de las diferentes líneas de transporte público y los grupos horarios en diferentes tramos de las líneas.

El proceso que se ha seguido comienza con la división de las líneas de transporte público en tramos que coinciden con las paradas de subida y bajada de pasajeros de cada una de las líneas. Dividiendo la línea en tramos, se procesan los datos de las encuestas recogidas a los viajeros de forma que se ha asignado la satisfacción global del viaje (OS) a los tramos que discurren entre el punto de subida y bajada de los viajeros. De este modo, para establecer la puntuación del viaje, se agregan los datos de cada uno de los trayectos entre las paradas (Figura 1). Para ello, se recopilan las puntuaciones individuales de cada usuario y se asignan a cada uno de los tramos de línea que el usuario utiliza en su trayecto entre la parada de subida y la de bajada. La puntuación media de los usuarios que han utilizado cada tramo se emplea para obtener la puntuación de ese tramo. Para poder visualizar correctamente los datos, la puntuación de cada usuario se ha extrapolado a una escala entre 1 y 10, respecto a la escala inicial que valoraba entre 0 y 4 los viajes.

Finalmente, para obtener las puntuaciones registradas en las líneas en distintos segmentos temporales, el procedimiento seguido consiste en agrupar las observaciones por franjas horarias y aplicar una división como la realizada en el agregado de todas las líneas, dividiendo las puntuaciones por el número de franjas de las líneas en función del número de viajeros que suben y bajan del autobús.

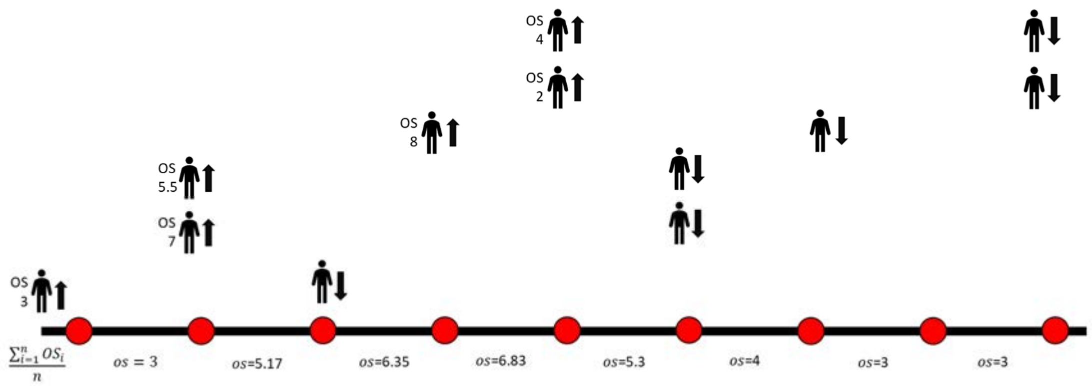

Figura 1: Estimación de la satisfacción general por segmentos

3.2 Modelización Best-Worst

La encuesta realizada se basó en ejercicios Best-Worst (BW) caso 1 (Louviere, Flynn y Marley, 2015). Los modelos basados en BW se han realizado considerando una especificación tipo Logit Multinomial (MNL), donde se asume que la parte no observable de la utilidad se distribuye de acuerdo a una distribución generalizada de valor extremo tipo

1 (distribución Gumbel) con las variables aleatorias independientes e idénticamente distribuidas.

Se han definido un total de K atributos en la encuesta. En cada ejercicio se mostraba un subconjunto Y de 4 atributos diferentes. La probabilidad de escoger una alternativa b como mejor opción (*best)* y una alternativa $w \neq b$ como peor opción (*worst)* se define como $P_{BW}(bw \mid Y)$. La encuesta no permitía escoger una misma opción como opción best y opción worst.

La probabilidad de elección calculada mediante una especificación Logit se define como un modelo Maxdiff (Marley y Louviere, 2005). La expresión del modelo es:

$$P_{BW}(\, b_w|Y) = \exp[v(b) - v(w)] / \sum_{l,k \in Y} \exp[v(l) - v(k)] \;\; \text{con } l \neq k \qquad (1)$$

Donde $v(.)$ es la utilidad observable calculada como una función de los atributos $v(k) = \delta_k y_k$ donde y_k es un vector indicador de 0 y 1 que presenta el valor 1 cuando un atributo k se muestra en la pregunta y 0 en caso contrario. De esta forma, el parámetro δ_k representa la importancia relativa de un atributo frente al atributo base, al cual se le asigna $\delta_0 = 0$. Para incluir la variabilidad temporal en el modelo es necesario considerar cierta heterogeneidad de la muestra. Se define el parámetro del modelo como $\delta_i = \boldsymbol{\delta} + \boldsymbol{\Lambda t_i}$, donde $\boldsymbol{\delta}$ continúa siendo un parámetro constante dependiente del atributo k, mientras que $\boldsymbol{\Lambda}$ representa la variación sobre el valor del parámetro para cada franja temporal $\boldsymbol{t_i}$ al que pertenece cada individuo i.

4. RESULTADOS

4.1 Variación espacial de la satisfacción

En la Figura 2 se muestra el análisis espacial de las 4 líneas encuestadas diferenciando los distintos tramos entre paradas. La satisfacción media de cada tramo se ha calculado de acuerdo con lo establecido en el apartado 3.1. De forma general se puede observar que la variación en la satisfacción a lo largo de una línea no es muy grande. De la misma forma, la satisfacción es muy similar a lo largo de las cuatro líneas de la red, siendo este un nivel de satisfacción medio.

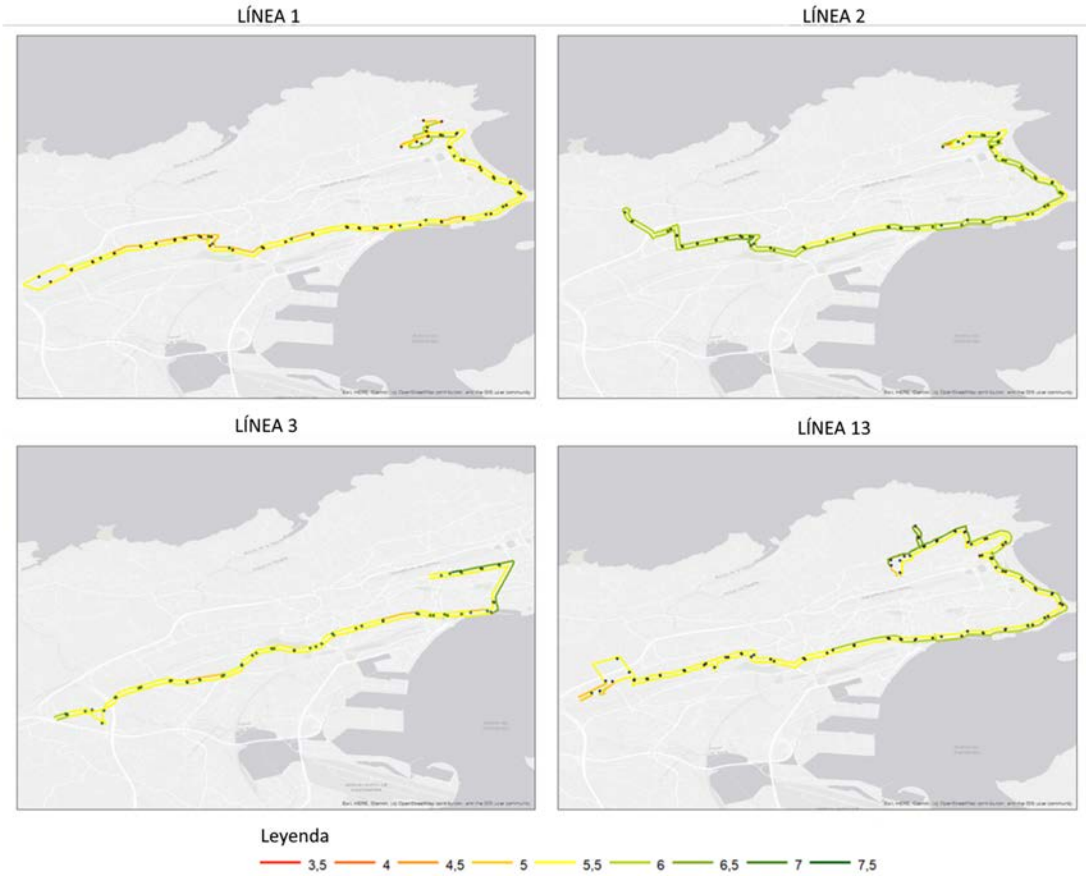

Figura 2: Variación espacial de la satisfacción general

Analizando la línea 1, se puede observar que existe mayor variación en los extremos de la línea, correspondiendo estas zonas a las áreas de la ciudad con una menor densidad de líneas. En la zona noreste se observan niveles de satisfacción contrapuestos, donde algunos usuarios muestran una satisfacción positiva con la línea, mientras que otros usuarios se muestran menos satisfechos con el servicio. En el extremo oeste también se observa una menor satisfacción con la línea.

La línea 2 muestra un nivel de satisfacción mayor que el resto de las líneas, aunque la satisfacción es algo menor en la zona central de la línea y en la zona oeste. La satisfacción en la zona oeste refleja un carácter direccional, mostrando los usuarios una satisfacción mayor al utilizar el servicio en dirección sur.

La línea 3 muestra una satisfacción media en prácticamente la totalidad de la línea, a excepción de varios tramos de satisfacción baja y un tramo en la zona oeste con satisfacción mayor. Esta última parte corresponde a un tramo de la línea que solo se realiza en horas concretas del día y sirve para conectar el centro de la ciudad con la zona universitaria. Se observa además que la satisfacción en este tramo es direccional siendo mayor en dirección a la universidad. La razón de esto puede deberse a que la alternativa en transporte público para acceder a la zona universitaria desde el centro de la ciudad requiere de un trayecto más largo y por lo tanto esta línea supone la mejor alternativa disponible.

Por último, la línea 13 muestra una mayor satisfacción en la zona noreste de la misma, en especial cuando se utiliza el servicio en dirección norte. El resto de la línea muestra un nivel de satisfacción medio, a excepción del extremo oeste, donde la satisfacción de los usuarios es menor. Esta última zona corresponde también a un área de la ciudad con una densidad de transporte público muy bajo.

4.2 Variación temporal de la satisfacción

Con los datos obtenidos en las encuestas se ha realizado un análisis sobre cómo varía la satisfacción a lo largo de un día. Para ello, se han agrupado las respuestas obtenidas en franjas de 1 hora, para un periodo comprendido entre las 8 de la mañana y las 8 de la tarde. En la Figura 3 se puede observar la variación del promedio de la satisfacción general a lo largo del día. Los momentos de menor satisfacción corresponden con los periodos punta de utilización del sistema de transporte, obteniendo la menor puntuación en la hora punta del mediodía. En las horas valle del día la satisfacción general es superior a la media siendo el momento de mayor satisfacción la hora valle de la tarde.

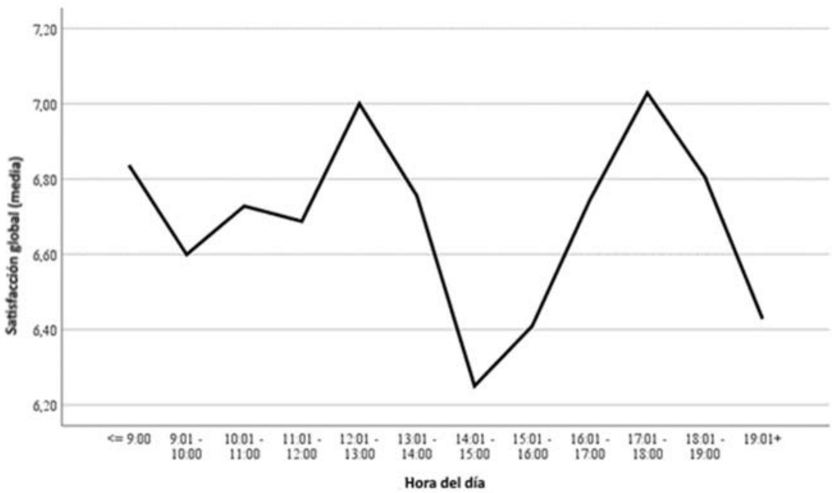

Figura 3: Variación temporal de la satisfacción general

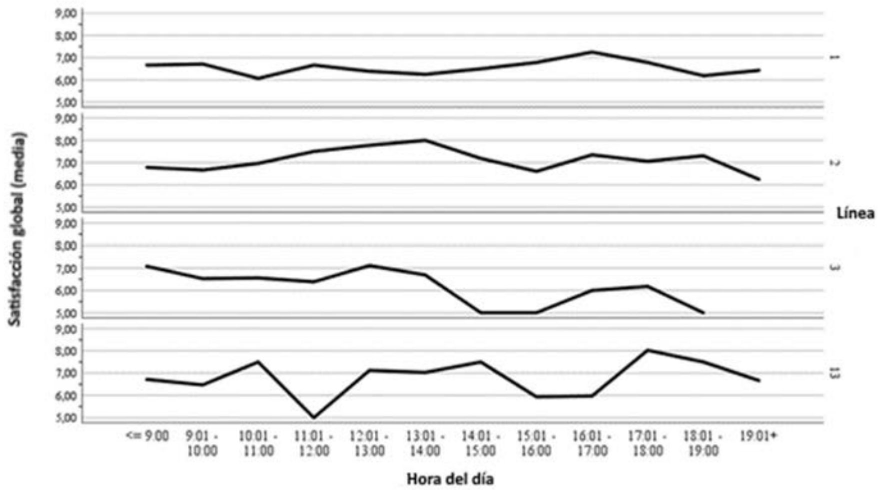

Figura 4: Variación temporal de la satisfacción general por líneas

Se ha realizado un análisis similar segregando los resultados por líneas (Figura 4). Los resultados muestran que la variación de la satisfacción general a lo largo del día es distinta dependiendo de la línea. Las líneas de mayor frecuencia y mayor número de usuarios (líneas 1 y 2) muestran una variación diaria de la satisfacción menor. Sin embargo, las líneas de menor frecuencia muestran una variación en la satisfacción mucho mayor. La línea 13 muestra un perfil de satisfacción distinta a las demás, observándose el menor nivel de satisfacción en la hora valle teórica de la mañana. Este fenómeno puede darse debido a que los usuarios principales de esta línea son personas de avanzada edad que tienden a tener horarios de movilidad distintos al resto de usuarios.

Para comprobar si la variabilidad de la satisfacción es significativa a lo largo del día, se ha realizado un test ANOVA para la satisfacción general y todos los atributos evaluados. Igualmente, el test ANOVA se ha realizado considerando 3 tipos de condicionantes: en primer lugar, se ha analizado la variación por hora del día, en segundo lugar, por periodo del día (hora punta mañana, hora valle mañana, hora punta mediodía, hora valle tarde y hora punta tarde) y, por último, se ha realizado el mismo test considerando las diferentes líneas analizadas. Los resultados de los tres test se muestran en la Tabla 4. Aquellas variables cuyas variaciones han resultado ser significantes se han resaltado en negrita.

Observando los resultados del test ANOVA, se puede concluir que la variabilidad de la mayoría de los atributos no depende ni del momento del día ni de la línea. Sin embargo, algunos atributos sí que se perciben distintos. La variación por cada hora es por lo general menor que si se consideran franjas horarias. El precio (PR), la cobertura de las líneas (LC), la ocupación (OC) y el ruido (NO) son atributos que se han evaluado de forma distinta dependiendo de la hora del día. En el caso de las franjas horarias, los atributos con mayor variación a lo largo de los distintos periodos del día son el precio, la cobertura de las líneas, la ocupación, la calefacción / aire acondicionado (CA), el confort de los autobuses (CM) y la amabilidad del conductor (DK). En menor medida, el tiempo de viaje (TT), la información en el móvil (IM) y la facilidad de entendimiento del mapa (MD) también varían en los distintos periodos del día. A diferencia de la variación temporal, la satisfacción general del servicio sí que varía dependiendo de la línea analizada. Muy relacionado con lo anterior, tanto la percepción de la frecuencia (SE) como la fiabilidad del servicio (SR) cambian también dependiendo de la línea. Otros aspectos relacionados con las líneas y que varían por línea son la información en el bus (IB), el nivel de ocupación, el sistema de calefacción / aire acondicionado, el ruido y la información en dispositivos móviles.

ANOVA test	Por hora		Por franja horaria		Por línea	
	Valor F	Sig.	Valor F	Sig.	Valor F	Sig.

Tabla 4: Test ANOVA considerando diferencias temporales y por línea

4.2.1 Resultados de la modelización

En la Tabla 5 se muestra el modelo MNL estimado considerando la variación temporal de los distintos atributos recogidos en la CSS. Para incluir la variable tiempo se han utilizado las franjas horarias de hora pico mañana (7:00 – 9:00), hora valle de mañana (9:00 – 13:00), la hora pico de mediodía (13:00-15:00), hora valle de tarde (15:00 – 17:00 y 19:00 en adelante) y hora punta tarde (17:00 – 19:00). Se han considerado estas franjas horarias para disponer de observaciones suficientes para estimar el modelo. Los valores de los parámetros muestran el nivel de importancia de cada atributo, es decir, a mayor valor mayor es la importancia de ese aspecto. Las variables que consideran interacción aportan una variación debido a la franja horaria con la que interactúan.

Por lo tanto, si una interacción muestra un parámetro negativo, ese atributo tiene una menor importancia en esa franja horaria, mientras que, si muestra un valor positivo, la importancia aumenta. En el modelo definitivo solo se han considerado aquellas interacciones que han resultado ser estadísticamente significativas.

Tabla 5: Modelo MNL basado en Best-Worst considerando variación temporal

Con los modelos estimados es posible establecer el nivel de importancia de cada atributo para cada franja horaria analizada. En la Tabla 6 se muestran los valores normalizados de la importancia y el promedio de la calidad percibida para cada atributo en cada franja horaria. Al atributo más importante de cada franja horaria se le ha asignado el valor 10 mientras que al menos importante se le ha asignado el valor 0 y el resto de valores se han ponderado de forma lineal entre estos dos valores de acuerdo a los resultados del modelo.

Las variables más importantes para los usuarios han resultado ser aquellas más relacionadas con las características operativas de las líneas, siendo estas la cobertura de las líneas, la fiabilidad del servicio y el servicio ofertado (horarios y frecuencias). Estas tres variables han resultado ser importantes, dejando claro que la variación de la importancia de los atributos a lo largo del día no es muy notable.

Los atributos menos importantes para los usuarios han resultado ser aquellos relacionados con servicios adicionales o secundarios, como son la información en la página web, la información dentro del bus, el sistema de calefacción o el ruido. En el caso de estas variables menos importantes, la variabilidad a lo largo del día es mayor que en el caso de los atributos importantes, y aunque su importancia crezca no llegan a alcanzar niveles de importancia altos.

Los atributos cuya importancia cambia de forma significativa son la facilidad de realizar transbordos (TR), que es mucho más importante en la hora punta de la tarde en comparación al resto del día, y la información en las paradas (IS) y la amabilidad del conductor, que son más importantes en las horas punta de todo el día frente a las horas valle.

Tabla 6: Importancia y calidad percibida de los atributos por franjas horarias

4.3 Variación espacial y temporal de la satisfacción

Por último, es posible combinar el análisis temporal con el espacial para estudiar la evolución de la satisfacción de los usuarios a lo largo del día en los distintos puntos de la red. En la Figura 5 se muestran los resultados para la satisfacción general de la línea 1 en los 6 periodos analizados. El mismo proceso podría realizarse para todas las líneas y todos los atributos, sin embargo, dicha información no se ha añadido en el artículo por mantener una extensión razonable.

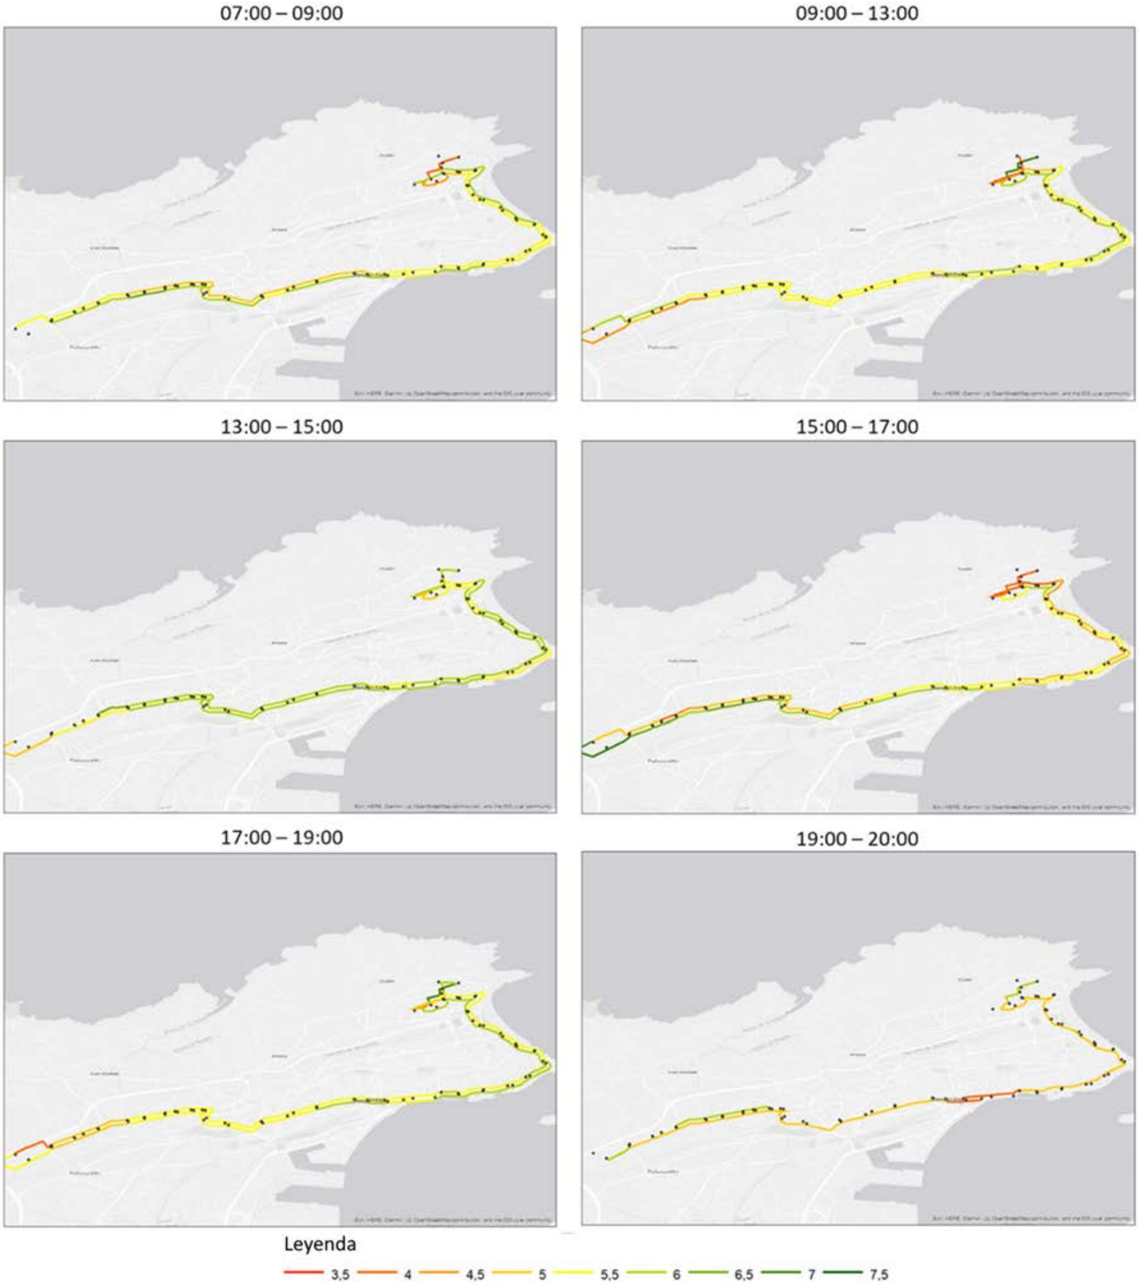

Figura 5: Variación espacial y temporal de la satisfacción general en la línea 1

Analizando las imágenes en su conjunto, se puede observar que la satisfacción cambia tanto espacialmente como temporalmente de forma simultánea, esto es, que en distintas horas del día la satisfacción es diferente en distintos puntos de la red.

Observando la hora punta de la mañana (7:00-9:00) se detecta que la satisfacción tiene un carácter claramente direccional. Los usuarios que cogen el bus para ir de la zona norte (principalmente residencial) a la zona oeste (residencial y laboral) muestran una satisfacción más negativa del servicio, mientras que en sentido contrario la satisfacción es mayor. En la hora valle de la mañana (9:00 – 13:00) el efecto es el contrario, la satisfacción es peor en dirección este, mientras que aumenta en dirección oeste. En la hora punta del mediodía la tendencia vuelve a cambiar, en este caso la direccionalidad es más homogénea, mientras que la distinción es entre la zona central de la línea y las zonas periféricas, donde se observa una menor satisfacción en estas últimas. Al comienzo de la tarde (15:00 – 17:00) la tendencia es similar a la hora punta de la mañana, observándose unas satisfacciones generales menores. El menor nivel de satisfacción se ha observado a las 15:00, al finalizar la hora punta del mediodía y empezar la hora valle de la tarde. En la hora punta de la tarde (17:00 – 19:00) la tendencia es similar a la del mediodía, donde las peores opiniones de los usuarios se perciben en los extremos de la línea. A partir de las 19:00 la satisfacción es baja de forma generalizada.

Por lo tanto, observando las variaciones diarias de la satisfacción de los usuarios, se puede decir que esta está inversamente relacionada con la direccionalidad de los viajes realizados por obligación (trabajo, estudios) en las horas punta, mientras que en las horas valle la tendencia es la contraria.

5. CONCLUSIONES

El artículo presentado desarrolla una metodología de análisis que complementa el estado del arte actual. La variación de la satisfacción entre distintas líneas de un mismo servicio ha sido analizada en diversos estudios, tal y como se ha mencionado en la introducción de este artículo. Sin embargo, la variación espacial y temporal en la satisfacción de cada línea no se ha tenido en cuenta anteriormente, habiéndose demostrado en este estudio que dicha variación existe y puede ser significativa.

El análisis espacial de las líneas ha demostrado que existe una clara distinción entre varios puntos de la red en lo referente a la percepción de la calidad. Por lo general, las zonas con una densidad de líneas de transporte público menor tienden a valorar el servicio de forma diferente que las zonas donde hay una mayor elección de líneas. Esta variación puede ser positiva o negativa dependiendo de cada zona y de cada línea, estableciéndose la necesidad de estudiar de forma específica cada caso.

Por otro lado, el análisis temporal de la satisfacción ha demostrado que la calidad percibida por los usuarios cambia a lo largo del día. Considerando al usuario medio, puede decirse que los niveles de satisfacciones menores se dan en las horas punta del día. En el caso concreto de este artículo, el peor nivel de satisfacción se ha observado en la hora punta del mediodía. Analizando la variación temporal por líneas, se ha observado que la variación es menos marcada en las líneas de mayor frecuencia y demanda (mejores prestaciones), en comparación con las líneas menos utilizadas y de menor frecuencia (peores prestaciones). Otro aspecto importante es que el tipo de usuario afecta a la localización horaria del punto de menor satisfacción, siendo este el caso de la línea 13 analizada. En esta línea el número de usuarios de edad avanzada es alto, por lo que las horas de más uso se encuentran desplazadas del resto de líneas, siendo este un factor que afecta a la variación de la satisfacción, puesto que en esta línea el peor nivel se ha observado en la hora valle de la mañana.

Los modelos BW estimados han permitido estudiar la variación de la importancia de los atributos a lo largo del día. En este aspecto, aunque sí existe una variación de los niveles de importancia entre los distintos atributos, la variabilidad a lo largo del día no es significativa en la mayoría de los casos. Algunas excepciones son la facilidad de hacer trasbordos, que gana mayor importancia para los usuarios en la hora punta de la tarde, la información en las paradas que es más importante en las horas punta del día y la amabilidad del conductor, que también es más importante en las horas punta.

Por último, el análisis en conjunto de la variación espacial y temporal ha demostrado que la satisfacción de los usuarios cambia con la hora del día y el lugar, siendo la direccionalidad del flujo un aspecto importante a considerar. Además, la satisfacción del usuario es generalmente menor en los extremos de la línea.

En resumen, el estudio presentado en este artículo ha demostrado que la satisfacción de los usuarios cambia dependiendo de la zona de la ciudad y la hora del día donde se analice. Este resultado puede servir a las empresas operadoras para mejorar los servicios de forma más específica, actuando en aquellos lugares y aquellos momentos donde la satisfacción es más baja.

AGRADECIMIENTOS

Este trabajo se ha basado en el proyecto de investigación REALTIMEQUALITY-Modelización y control de la calidad percibida y de la calidad del servicio en tiempo real como herramienta para incentivar la demanda de transporte público, (TRA2015-69903-R), financiado por el Ministerio de Economía, Industria y Competitividad (MINECO) y el Fondo Europeo de Desarrollo Regional (FEDER-UE) en el marco del Plan Nacional de Investigación Científica y Técnica y de Innovación 2013-2016.

ABSTRACT

The pandemic made the transport system administration switch the way decisions were made in topics such as the response speed, resilience to shifts in the demand, and the new policy needs. Therefore, public transport requires monitoring tools, such as dashboards, and an emphasis in user characterization, in addition to traditional modeling and supply-demand indicators historically used by TransMilenio in order to command the operation of the public transport system of Bogotá D.C.

This study employed descriptive spatial and statistical analysis to comprehend the relations among the registers of contagion waves, user polls and the boarding information on SITP. Complementarily, the article shows the shifts in the demand towards the regulatory milestones for the pandemic, and how short-term changes in bus supply were made due to these set of regulations.

The paper also provides a recap of the international discussion about the occupation, efficiency, and biosecurity of massive public transport systems. The main results for TransMilenio were some supply changes, among others.

1. INTRODUCTION

The entity in charge of planning and coordinating the public transport system of Bogotá D.C, Empresa de Transporte del Tercer Milenio – TRANSMILENIO S.A., has three different services. The first one is the worldwide known as BRT, with a fully dedicated lane, central stations, high floor buses, and payment outside the bus. The second one is a conventional bus service with validation on board that covers the demand of the zones where there are not BRT lanes, carrying people from their neighborhoods to the BRT stations, making last mile solutions or trips to remote places in Bogotá's rural zone. The third one is TransMiCable, which is a cable system included statistically in the demand of the BRT and serves the locality of Ciudad Bolívar. The TRANSMILENIO system comprises 761 articulated buses, 1,323 bi-articulated buses and 273 dual standard buses for the BRT, as well as 7,105 bus services with validation on board and 160 cabins for the cable. Fig. 1 illustrates its geographical distribution through Bogotá.

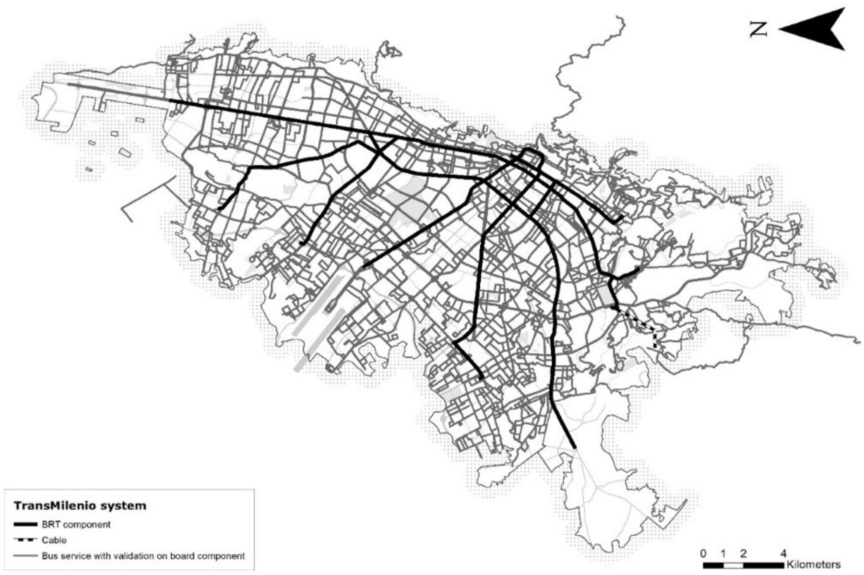

Figure 1: TRANSMILENIO: BRT system and on board validation bus service

Trying to predict the dynamism of a contagious disease is not an easy task, however, getting as close to reality as possible through models and analyses, such as those shown in this study, is an effort that can save human lives (Gomez, Prieto, Leon, & Rodríguez, 2021). For the purposes of this paper, people decide in the way described before. For a university council, it can be rational to order scaled schedules for on-campus lessons, because they want to prevent desertion and maximize learning, restricted by the capacity controls imposed due to the pandemic and the probability that an outbreak starts in the campus. For a student, the choice related to the self-care measures works in the same way. If the student considers that going to the campus is too risky for their life or for the life of people who live with them, the student will choose not to go, even if the place is open. On the other hand, if the student thinks that only by wearing mask, they will be able to protect themselves from COVID-19, they will more probably go to the campus, given the choice of the university council. In the student's example, the information and the context play a role on how they make their decisions. This mechanism of decision is similar to the one described by Przybylowski, Stelmak, & Suchanek (2021). In that way, each individual's decision plays a key role that has to be taken into account when modeling demand.

2. LITERATURE REVIEW

This chapter included three focuses: The first about de pandemic and public transport, the second on geographic information systems and their use with infectious diseases and finally, the third on changes the individual preferences and behavior.

2.1 Literature about the pandemic and public transport

The reviews and recommendations about COVID-19 and the challenges of public transportation indicate a general context about the service and the risk for users (Gutiérrez, Miravet, & Domènech, 2020). Likewise, changes in the demand for transport modes were evident, as well as the decrease in public transport systems (Le , Sheng, & Sharp, 2021) (Komla Junior Dzis, Obeng-Atuah, Ackaah, Yaw Tuffour, & Eric Aidoo, 2021) and research needs (Gkiotsalitis & Cats, 2020).

The case studies during COVID-19 about the effects on public transport show a global problem that includes analysis of supply, demand and biosecurity, in countries like Turkey (Devecí, Aydin, & Kusakci, 2021), Finland (Tiikkaja & Viri, 2021), Poland (Przybylowski, Stelmak, & Suchanek, 2021) and United Kingdom, regarding the future of public transport (Vickerman, 2021).

2.2 Literature on geographic information systems and their use with infectious diseases

In 1854, an English doctor named John Snow, through the spatial location of cholera cases in London, managed to realize a pattern that until then no one had noticed, thus discovering the source of the outbreak of the disease in a water pump of the place (Fradelos, Tsaras, Papathanasiou, & Kleisiaris, 2014). Although geographic information systems did not exist in 1854, this example makes it clear that having information on a map allows us to ask ourselves questions and solve problems, as we do with current tools.

Another investigation on the spread of hepatitis C was carried out in Connecticut (Navarro, Trooskin, & Hadler, 2005) through cluster analysis. This study was able to identify clusters in the most densely populated urban areas, which had previously been identified as areas of substantial injection drug use. Although local demographic characteristics alone do not follow a particular phenomenon, crossing them with other geographic variables helps to prevent disease transmission.

Currently, with the COVID-19 pandemic that can affect a population very quickly, it is necessary to have a solid support of spatial information for decision-making, formulation of measures and evaluation of the effectiveness of prevention and control of COVID-19 (Zhou, y otros, 2020). Considering the above, the cities with updated information day after day on dashboards, and maps on the location of infections and availability of care in medical centers for decision-making are those that have the least consequences to regret.

2.3 Changes in the individual preferences and behavior

A preference is a comparative evaluation of a set of objects and works as a cognitive marker that reminds people how to interact with the environment. The objects of preferences are not given for being organized but are those that can be perceived by a human being, whose experience allows to differentiate, and those which a human being's cognitive capacity can remember (Druckman & Lupia, 2000). In the case of the preferences for a contagious disease, as COVID-19, the preference for staying home or going out to work depends on factors such as the education received by the person related to viruses, their risk tolerance, among others. Thus, two people who receive the same information about a first case detected can react in two different ways.

The rational choice theory is an approach founded on methodological individualism (MI), from which human behavior is explained. The MI starts its analysis with the principle that social behavior reflects the choices everyone makes. For that reason, the individual behavior determines the social outcomes. In this paper, we suppose that choices made by everyone, such as deciding to work or not, or by each person with agency, e.g. a university headmaster, can impact the results in activities related to occupancy of public transport. Back into the ration choice theory, Elster (1996) says that the social behavior responds mainly to the decisions made individually, which are the consequence of a rational thought. This is an instrumental rationality, which means that people use reason to obtain something they want. In this sense, a choice is rational if it maximizes o minimizes certain objective people trace for themselves, with a given context, rules, as well as other types of restrictions, e.g. the income level or the education you received.

For example, in the case of COVID-19, your rational choice can be guided by the principle of minimizing the probability of being infected, while having to do an essential job (e.g., a nurse), or maximizing your personal income, given some restrictions to your individual behavior. Once the person identifies the rule of decision, the decisions of public health are linked with people's personality (Blagov, 2020) or a consequence of the current political discourse with which people identify (Hatcher, 2020). A rational choice explains each one's behavior as the decisions made to accomplish that rule. Therefore, the rationality, in this case, is guided by the results an individual plans to obtain.

3. SUMMARY OF THE INTERNATIONAL BENCHMARKING

This chapter is divided into two parts, the first on benchmarking of the policies of the pandemic and the second, benchmarking of the occupancy.

3.1 Benchmarking of the policies adopted in the early stages of the pandemic

The benchmarking is presented in Table 1, this includes cities of the five continents about transport system and strategies used in pandemic.

City	**Country**	**City popul.**	**Urban area of the city**	**Type of public transport system**	**Strategies used**
Sidney	Australia	5,3 millions of inhabitants (2018)	12367,7 km²	9 subway lines and one train line	There is no capacity to clean en-route buses during shifts. They requested to avoid travelling during rush hours if possible and to limit travels to those who are strictly necessary.
Lima	Peru	8,8 millions of inhabitants (2017)	2672,3 km²	2 subway lines and 5 BRT lines	Since Monday, March 16th, 2020, only BRT operates, the other systems are closed. BRT is working with the Saturday schedule with difficulties for the transport of operators. Cleaners and all employees of the system have gloves and masks.
Shenzhen	China	12.53 millions of inhabitants (2017)	1748 km²	8 subway lines and bus system	Buses are disinfected after each trip. At night, some routes are suspended. Floor markings (also adopted in Europe) are used as a guide to minimum distances between passengers for social distancing.
Madrid	Spain	3,2 millions of inhabitants (2019)	604,45 km²	13 subway lines, tramway and bus system	The transport offer must be reduced to at least 50%. The subway prioritized stations near hospitals. The use of the two lines of seats closest to the driver is prohibited.
Santiago	Chile	6,25 millions of inhabitants (2017)	837,89 km²	7 subway lines and bus system	Buses are sanitized more often. From March 22nd, 2020, they adjust and reduce the hours of operation.
Singapore	Singapore	5,6 millions of inhabitants (2017)	697 km²	6 subway lines and bus system	Two campaigns: (1) protect employees by disinfecting drivers' seats and the use of protective items such as gloves, and (2) avoid contact with employees at information points as much as possible, which includes "safe distancing".
Kuala	Malaysia	7,59 millions of inhabitants (2016)	243,65 km²	BRT system	They took temperature measurements of the drivers and the system team before starting the shift. In addition, the hygiene days of the buses and the system facilities tripled.
Jakarta	Indonesi	10,3 millions of inhabitants (2017)	750,28 km²	6 train lines and a bus system	They reduced the service of the TransJakarta system: 248 routes were reduced to only 13 with buses traveling every 20 minutes.
Buenos	Argentin	3 millions of inhabitants (2017)	203 km²	6 subway lines and a bus system	Long distance trains and buses suspended their services. Buses and trains in the Buenos Aires metropolitan area operated only with seated passengers

City	**Country**	**City popul.**	**Urban area of the city**	**Type of public transport system**	**Strategies used**
Stuttgart	Germany	634 830 inhabitants (2019)	207,36 km²	train and bus system	The trains reduced their frequency to every 30 minutes; there are no night or weekend buses. Service to and from the airport was suspended. Payment in cash was prohibited. The ascent-descent of passengers is only allowed through the farthest door from the driver.
Panama City	Panama	880 691 inhabitants (2013)	275 km²	2 subway lines and a bus system	They included maximum capacity for buses and distance marks inside the buses. The "adopt your hero" campaign was implemented to raise awareness about the drivers' work. They disabled the seats closest to the driver and the rest of the interleaved-use seats.
Curitiba	Brazil	1, 8 millions of inhabitants (2015)	412 km²	BRT system	Initially, they reduced the supply of buses but since the quarantine was not official, the system had to increase the supply again due to demand.
San	U.S.A	805.235 inhabitants (2010)	121 km²	Light train and bus system	The frequency of the service was reduced and if the buses are full they will not stop to pick up passengers. Additionally, there was a reduction in routes.
Paris	France	2,18 millions of inhabitants (2017)	105,4 km²	14 subway lines, 13 train lines, 11 tramway lines and bus system	The frequency of the routes was reduced and they generated a real-time report of the offer of each of the transport services.
London	England	9,7 millions of inhabitants (2018)	1572 km²	11 subway lines and bus system	Metro stations are closed and using the system is only recommended if essential. They suspended the subway service on Friday and Saturday nights, but the bus service continues to operate for essential workers. They suspended the service in the city center and communicate by email with registered users
Vancouver	Canada	2,2 millions of inhabitants (2016)	114,97 km²	3 skytrain lines, SeaBus (ferry) and bus system	The free service was implemented. There was a change in frequencies. In addition, the entry and exit of passengers was required only through the back door or the one furthest from the driver. They increased the disinfection of buses per day.

Table 1: Policies adopted at the beginning of the pandemic by COVID-19

3.2 Benchmarking of the occupancy

After adopting some of the decisions mentioned above, TRANSMILENIO S.A. faced a new situation, in which the economy was progressively being reactivated. At the international level, there were restrictions to the occupancy of public transport, in cities such as: Shenzhen, where the limit in place was of the 50% (Ma, 2020); Jakarta, where public transport was shut down and then, on June 8th, 2020 opened at 50% of its capacity (Widadio, 2020), or Mumbai, where the occupancy limit was also 50% (Mumbai Mirror, 2020). At the national level, the order was to have a 35% capacity limit. The main reason to do this was that the local health authorities considered that public transport could be a place where massive contagion clusters of the virus SARS-CoV-2 could appear.

However, more international evidence about the behavior of the contagion clusters started to appear and it suggested that public transport was not as risky as thought. First, discussing the recent epidemics caused by other Coronaviruses (SARS and MERS), Avineri, Musselwhite, and Susilo (2020) argued that there was no significant evidence of reduction of the contagion in the cities that closed their transport system.

Second, referring to the COVID-19 pandemic, the evidence collected from the tracking and contact tracing strategies did not suggest a statistically relevant effect of public transport on contagion. For example, Japan, at the beginning of its outbreak, followed a strategy that consisted in detecting contagion clusters. Despite its robust contact tracing strategy, no single cluster was detected in passenger trains (Normile, 2020). Likewise, in New York, from 1300 patients admitted with positive COVID-19 results, only the 4% of them affirmed to have used public transport in recent days (Shwartz, 2020). With those results, the next step was to ask why public transport seems safer than other crowded and enclosed places. Fig. 2 shows the overall map of the cities consulted.

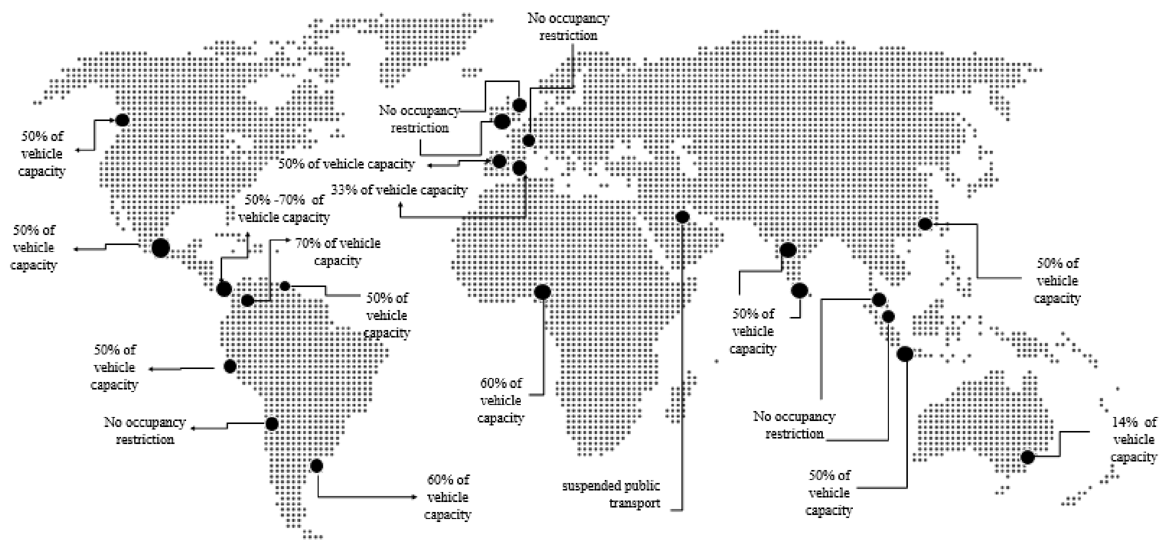

Figure 2: Map of the consulted cities

The evidence found suggested that the transmission of the virus is low, if users wear their masks in the appropriate way and if they do not talk at all during their trip, although the evidence was not yet conclusive (Tirachini & Cats, 2020). Even though inside the vehicles, that are enclosed places, there are concentrations of people who do not keep the prudent distance, but the implementation of other non-pharmaceutical measures, such as the use of mask or the prohibition of speaking (as in the case of Singapore), helps to reduce the probability of contagion (Tirachini & Cats, 2020). Attending to these data, in Colombia the occupancy limit went from 35% to 50%, while trying to ensure that people could make the appropriate decisions about the use of masks, and silence, for protecting themselves from the virus.

4. INSTITUTIONAL POLICIES ADOPTED

This section explores the different measures and strategies adopted by TRANSMILENIO S.A. in response to the pandemic, and the need of reducing the occupancy of the system. First, there were a set of sanitary measures that intended to reduce the contagion probability, as well as other that were meant to increase the supply of the system. The second section shows some demand management strategies that were implemented with other public offices.

4.1 Sanitary measures

Given the importance of mobility in a city, the district entities in this sector must face the critical impacts of the coronavirus, making a change in demand that contributes to the safety of passengers and operating personnel of the system. TRANSMILENIO S.A. focused its service on measures that promote social distancing and biosafety standards in accordance with the regulations issued by the Nation and the District. Therefore, the maximum offer of the system was modified, a monitoring tool with public access was generated and cooperation measures were agreed with other entities to characterize users, among other strategies that are detailed below. The measures were related to the resolutions issued at the national level.

On March 6th,2020, the first case of COVID-19 was diagnosed in Bogotá D.C. By March 12th, there were already 5 cases diagnosed and a yellow alert was emitted. In Bogotá, people started to diminish the use of public transport. On March 16th, an orange alert was emitted, and some temporary bike lanes were made by the city administration. Afterward, the national government announced a “national quarantine” since March 25th.

The government started to permit the opening of some economic activities since April 27th until July 13th, when the city administration made localized confinements, so that part of the city could maintain the economic activities, while the other was in a strict confinement. On August 28th, this policy ended and, on September 1st, another policy called “Nueva realidad” (New Reality) started, which limited de working days per economic sector, and assigned entrance and exit hours for each one of them. The regulations were modified slightly during the next months, until almost the whole scheme was derogated by November. Fig. 3 summarizes the policies implemented.

Decree	Expedition date	Measure applied by TRANSMILENIO S.A.
081, 2020- Sanitary measures	11th March 2020	Installation of 134 portable sinks Daily washing and disinfection of stations and buses
087, 2020- Public calamity	16th March 2020	Pedagogical prevention activities
090, 2020- Vital Drill exercise	19th March 2020	Fleet coordination Demand reduction (87% BRT component and 80% bus service with validation on board component)
457, 2020- Mandatory isolation	22nd March 2020	Creation of the public control board Control of user influx Mandatory use of face masks in the system System offer between 50% and 75% from March 20th to April 29th, 2020 Health routes
593, 2020 and 121, 2020 - Opening of economic sectors	24th April, 2020 and 26th April, 2020, respectively	User characterization New access scheme to critical stations Chair marking Offer increase to 100% Demand management app - "Full bus"

Table 2: Decrees issued by the District of Bogotá for COVID-19

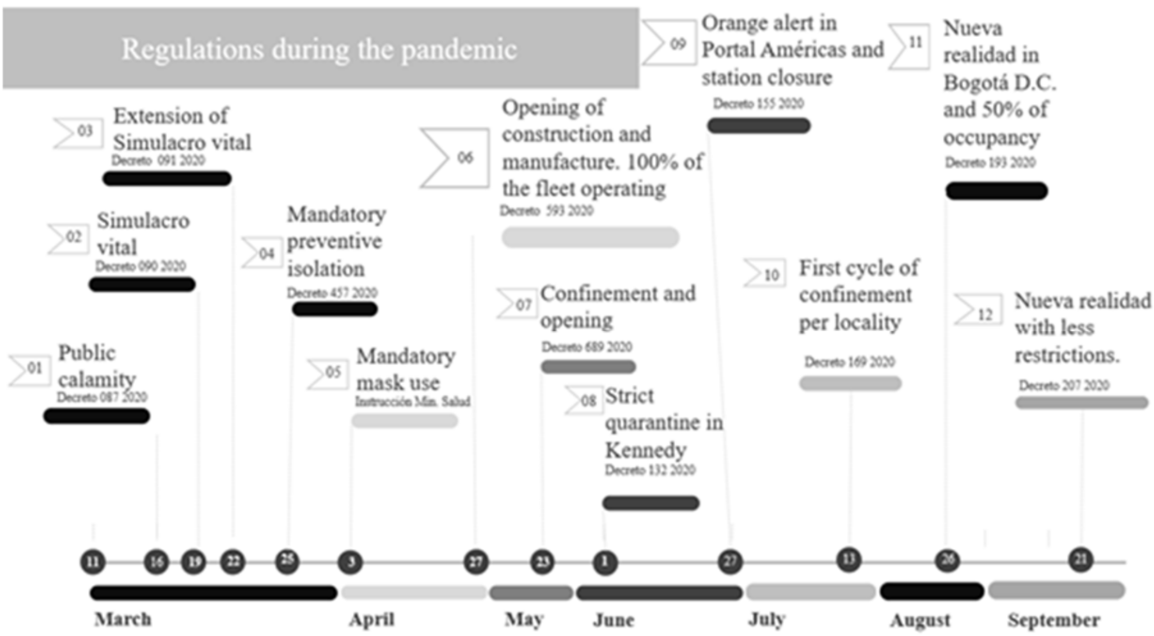

Figure 3: Timeline of the general policies implemented

4.2 Demand management: Public officers' demand management and Universities

An additional policy implemented by TRANSMILENIO S.A. and Bogotá D.C. was to organize public employee's schedules in different turns, as well as pilot schedules for some universities. Due to the occupancy limit of 35% (and then 50%), if activities were to be made in person once again, the transport system would not have been able to maintain a low occupancy, especially in some points of the city and during rush hours.

The most important schedule was developed with the Departamento Administrativo del Servicio Civil, the entity that regulates the exercise of public employees in Bogotá D.C. They designed a survey which asked, first, basic data, such as the institution they worked for, their municipality and department of residence, and, if the place of residence was Bogotá, their locality, and the planning unit they lived in. Second, there were some questions about the days of the week they worked and the mean of transport they used. On the following lines, there is a brief illustration of the descriptive statistics relevant for TRANSMILENIO S.A. As of June 23rd, there were 12.329 observations of the survey, but the size of the sample was different, according to the institutions where the instrument was applied. Fig. 4 represents the day of the week in which the public servers work, according to this survey.

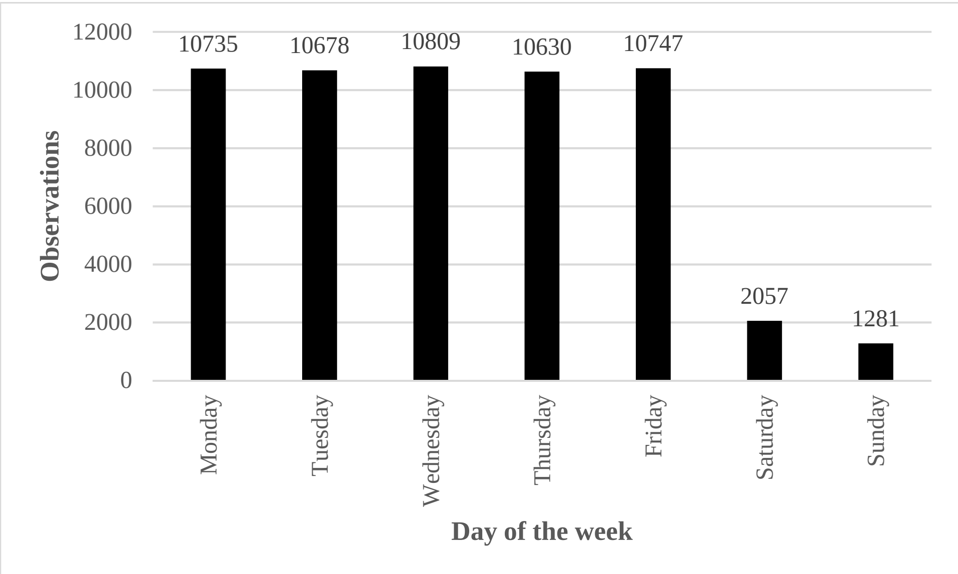

Figure 4: Day of the week in which the officer works

In general, it was observed that most public servers worked from Monday to Friday. Most of the records corresponding to Saturdays and Sundays belonged to health sector workers. This pattern indicated that some of the district servers could work during the weekends, without adding extra pressure to the system occupancy. This aspect depended on how they made their risk-benefit balance and took the most rational decision to maximize that benefit, while minimizing the risk of contagion, given the restrictions that could be held at that time.

However, to obtain internal validity, these analyses need to be representative of the level of the entities and must provide information about the number of people that could use the system. In this way, it could be possible to make projections and formulate alternatives for schedules and labor days, according to the impact of the demand generated by public servers on punctual zones of the city, close to their workplaces. Assuming that the collected sample was representative and using the data that belongs to the Departamento Administrativo del Servicio Civil of the number of public servers per entity in Bogota, an expansion factor was generated from the sample of the institution. With the obtained data, the analyses that required orders of magnitude were performed.

The first graph on Fig. 5 represents the percentage of district servers who answered if they used the on board validation bus service, at least, one business day of the week, to transport themselves. A percentage of 39% of them answered that they did use it.

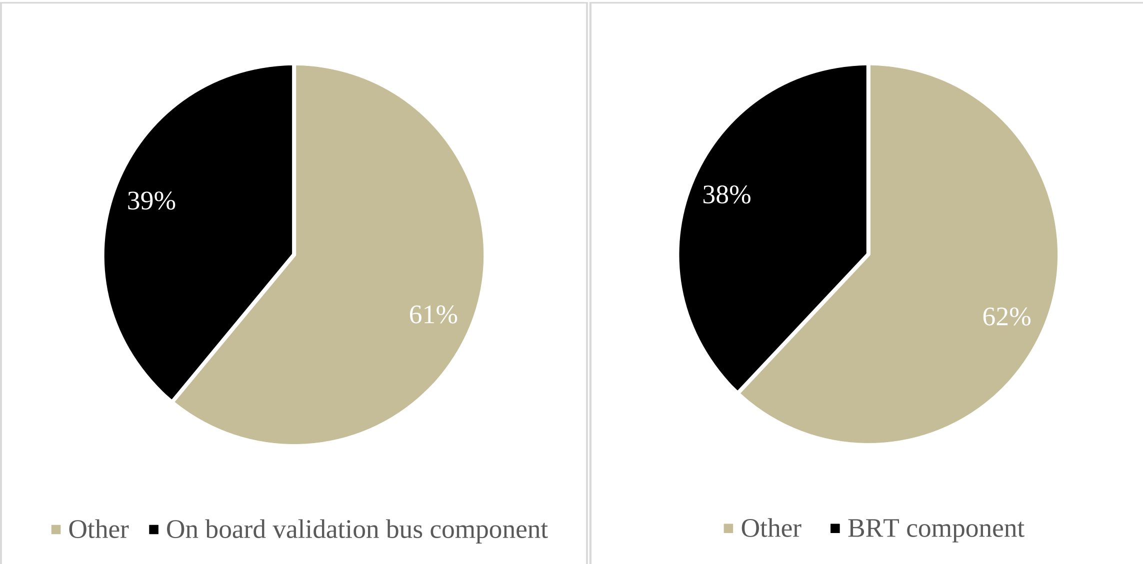

Figure 5: Use of the on board validation bus component and the BRT component

Since the public employees could answer with more than one means of transportation per week, it is not possible to distinguish either if someone used both system components or if they had a main mode of transportation. This means that the data of both components should be analyzed separately. The second graph on Fig. 5 represents the percentage of district servers that answered if they used the BRT, at least, one business day of the weekend, to transport themselves. A 38% of them answered they did use it.

These preliminary data indicated that the expanded sample of public employees of Bogotá D.C. could be subjects of interest for TRANSMILENIO S.A. Initially, these possible trips were used to identify the zones with more density of district employees who made trips in the transport system. This is the most relevant geographic information used to build the maps shown below.

Fig. 6 shows the spatial distribution, and the magnitude of the trip attraction zones. They are in the same spots where there is a big concentration of public employees, or public hospitals.

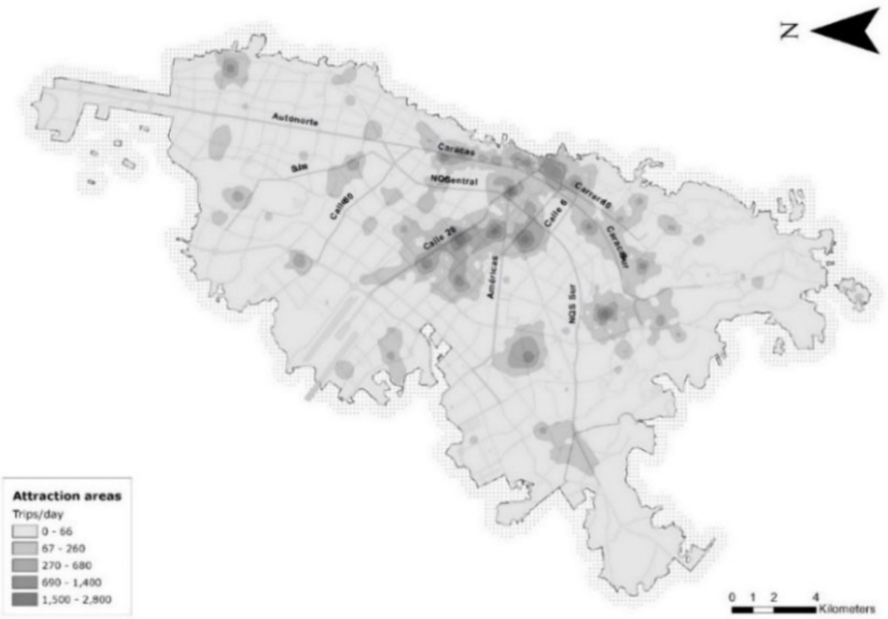

Figure 6: Geographic distribution of public officers

Afterward, the team assigned the expanded observations of the survey to the nearest bus stop, for the Bus Rapid Transit (BRT), or bus stops for on board validation bus service, of the surrounding area. If there were two or more nearby bus stops or stations, it was supposed that their demand was distributed in the same way as the demand of a normal day, punctually, March 11th/2020. For example, A and B are two stations, and on March 11th/2020 the demand of A+B was of 100 passengers. A total of 60 of them went to A, while 40 of them went to B. This means that, for entity E, which is in between A and B, the team assigned 60% of the demand entity E generated to A, and 40% to B. Fig. 7 illustrates this process with the BRT.

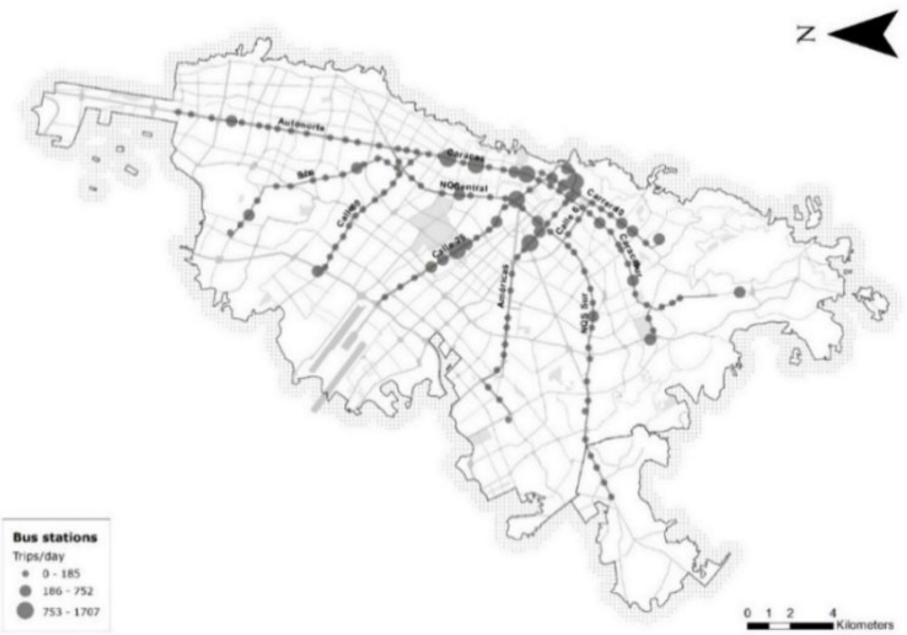

Figure 7: Geographic distribution of public officers. Trunk component.

The stations that would probably receive more demand from public servers were Museo del Oro, Calle 34, CAD, Concejo de Bogotá, Salitre-El Greco, and El Tiempo-Maloka. The process was repeated with the bus stops of the on board validation bus service, and the results are shown on Fig. 8.

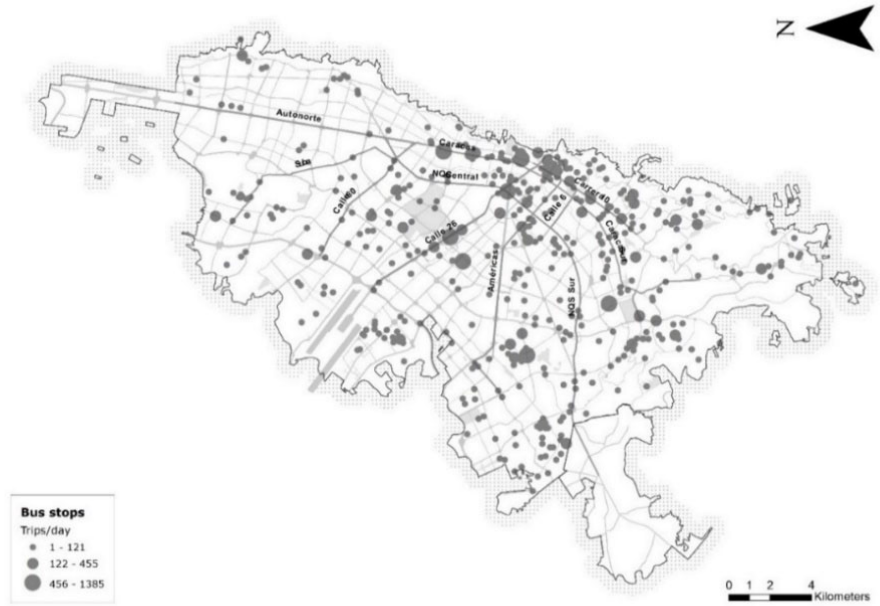

Figure 8: Geographic distribution of public officers. Zonal component

However, the analysis of the on board validation bus service was not considered, because it was close to surpass the current threshold set by the local government, that is, the 35% of the occupancy. For the BRT, the team made a projection of the maximum additional demand that the public employees could represent, given that 38% of the public servers, in average, would rather choose to use it. The value obtained was added to the demand profile observed recently, for visualizing at what times of the day the demand could get over the 35% limit. Fig. 9 represents the results obtained for the CAD station.

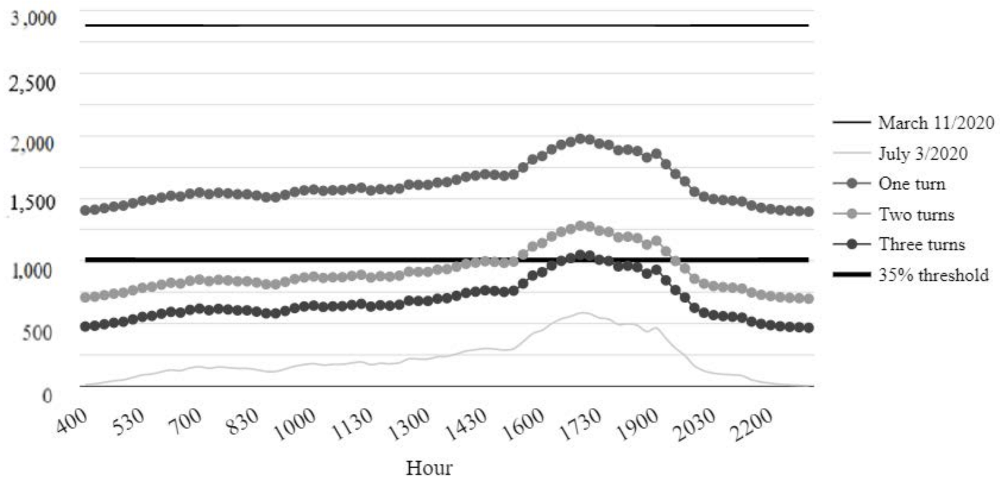

Figure 9: Scenarios for the CAD Station

The uppermost or first horizontal line represents the maximum number of ticket validations observed during an hour on March 11th /2020, day in which the system reached its highest demand on the year. The second line represents its 35%, which was the threshold in July. The light gray line shows the volume of ticket validations observed on July 3rd, which was the day when the maximum demand was observed after the first confinement. The first dotted line represents the biggest extra demand that the station could receive during an hour if all public employees in Bogotá D.C, registered in the Departamento Administrativo del Servicio Civil, went out at the same time. The second and third dotted lines expose how much variation on the hourly demand could be observed if these people went out of their jobs in two or three different, but equal in the number of employees, turns, etc.

The second profile can be interpreted as public employees who worked close to the CAD station and divided into three equal groups at the end of their working day. In this case, the station could surpass the 35% threshold at, about, 17:00. Consequently, TRANSMILENIO S.A. recommended that the institutions located near CAD returned to in person activities in two or three turns, but avoiding the station rush hours (15:30 to 19:30 for two turns, or 16:30 to 17:30 for three turns). This process was repeated with the other stations selected.

The analysis for the universities was made in a similar way. First, the team took data from the Encuesta de Movilidad 2019, which is a survey made by the mobility authority (Secretaría Distrital del Movilidad-SDM) and contains information about the purpose of the trips and the zones that attract them, among other aspects. Two simulation scenarios were formulated. In the first of them, the total trips with going to study as main purpose were considered to add them to the observed hourly demand profile on July 3rd/2021. The objective was to predict the best and the worst hours of the day for planning massive trips, according to the decisions of the universities, which would probably aim to maintain a low occupancy of their campus, with the rationale mentioned in the literature review. This occupation was supposed to be of about 50%, 30%, or even 10% of the normal occupancy. That extra demand was added to the observed profile, thus representing again a threshold of the 35% of the demand observed on the maximum demand hour of March 11th/2020. Fig. 10 represents the main scenarios.

The line marked with Univ_50 represents the scenario in which the universities restrict their occupancy to the 50% of their campus' capacity, supposing that all students who assist go out at the same time of the day. The reader can observe that, during rush hours, the demand ff the whole system could surpass the 35% occupancy limit, when adding linearly the extra demand to the observed demand profile of July 3rd. The other lines show that, if the campus capacities were lowered, the impact on the whole system would be small enough for it to respect the imposed threshold. But the question about what could happen to the stations located close to the campuses remained.

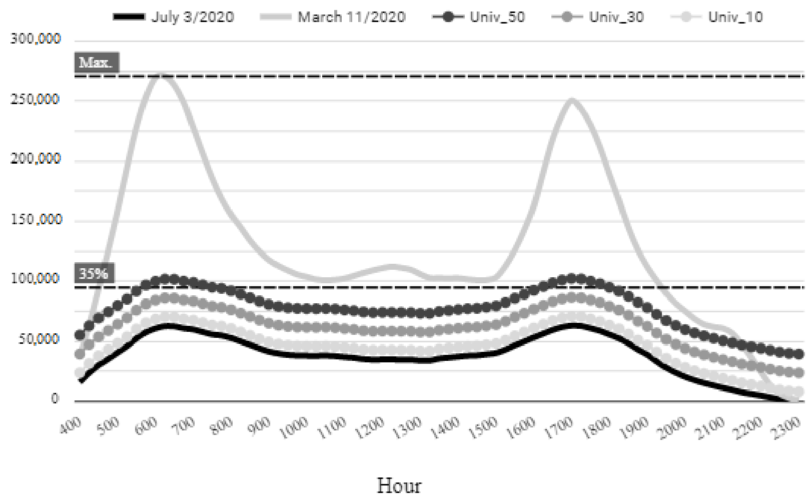

Figure 10: Potential extra demand due to the return to presential activities universities

The second scenario tried to answer it. The database provided by the SDM had also information disaggregated by Zona de Análisis de Transporte (ZAT), which are geographic demarcations of the territory that contain trips of people with similar conditions. The ZAT located downtown, in the historic center, were eligible for the analysis, because that zone concentrates most of the private universities. For each one of them, the team calculated the percentage of trips per purpose, and chose those ZAT where the trips that had "education" as their purpose were predominant. Then, we took the sum of the expansion factor of the observations that had education as their purpose and assigned them to three stations located in the area. (Museo del Oro, Las Aguas and Universidades), with the same three occupancy restrictions. Fig. 11 shows the result, with the same 35% threshold.

It can be observed that, although the scenario with the 30% of the normal occupancy of the campus do not exceed the threshold imposed to the system, the limit is surpassed in the stations that attend the ZATs analyzed. So, as in the case of the public employees, the recommendations had to seek to change people's behavior in a sectorized way

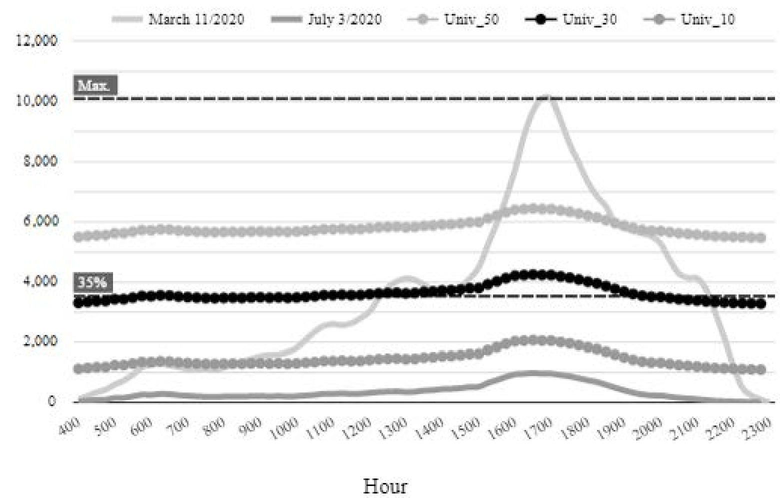

Figure 11: Change in the demand if universities return to presential activities

5. RESPONSE OF THE DEMAND

This chapter has three sections, the first is about the context in which this study identifies the variation of demand, the second is about vulnerability to COVID-19 for the transport system and finally, the third is the main section in this paper about demand graphical analysis.

5.1 Context

The transport demand was heavily affected by the collective and administrative response to the COVID-19 pandemic. Fig. 12 illustrates the daily behavior of the demand from March 1st/20 through March 26th/2021.

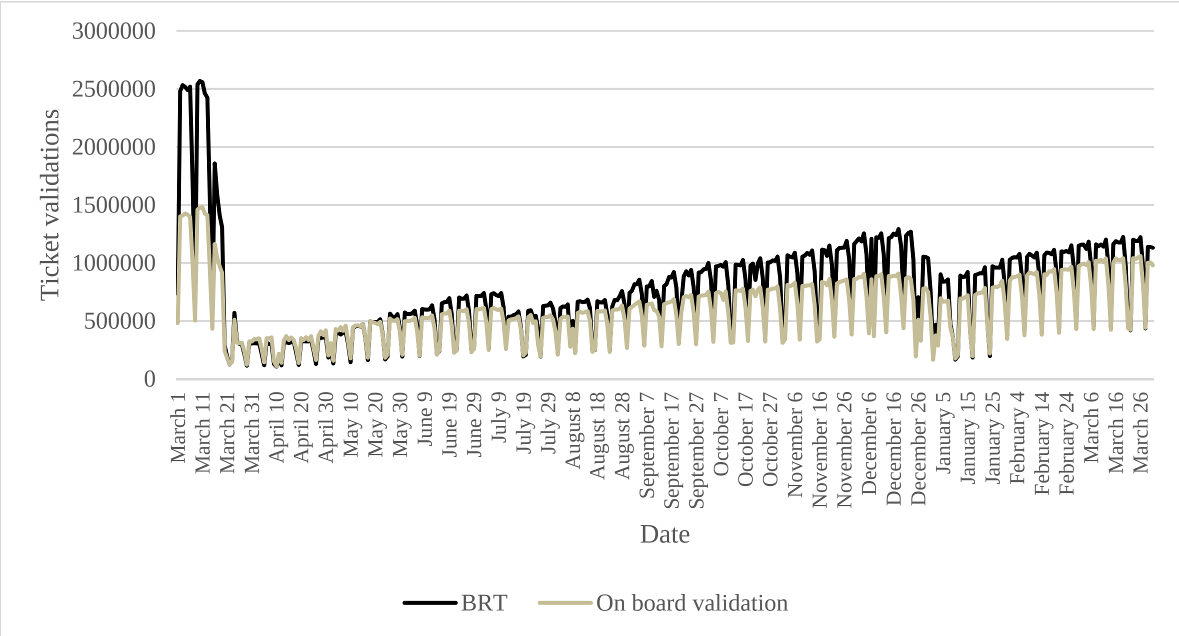

Figure 12: Comparison of the demand of the BRT and on board validation bus service.

It is possible to observe a reduction of the demand since March 12th/2020 y until March 19th/2020, which reflect a modification in the behavior due to the announces of the pandemic. On March 6th/2020, the first case of COVID-19 was diagnosed in Bogotá D.C. During those days, the demand maintained stable, and reached its annual peak on March 11th/2020. But, by March 12th there were already 5 cases diagnosed and a yellow alert was emitted. In Bogotá, people started to diminish the use of public transport. But the tendency went steeper when, on March 16th, an orange alert was emitted, and some temporary bike lanes were made by the city administration. We assume that, during those days, the reduction of the demand was caused more by the announces made by the authorities, rather than by impositions. It was rational for Bogota´s habitants to avoid the crowded places and the contact with other human beings, so they started to make choices to protect themselves. The steep decline of the demand was followed by the enforcement of a “simulation of isolation”, which was meant to prepare the citizenship for a prospective confinement There is a small peak of demand on March 24th, because it was the last normal workday of the year. The national government had announced a “national quarantine” since March 25th.

The demand dropped to previously unsuspected levels but started recovering even before the government started to permit the opening of some economic activities (April 27th), but then is when demand started increasing progressively. This tendency was maintained until July 13th, when the peak first wave of the pandemic was taking place. The policy adopted by the city administration was to do localized confinements in some localities, in a way in which part of the city could maintain the economic activities, while the other was in a strict confinement. The demand dropped initially but recovered in a small proportion during the next day. On August 28th, this policy ended, and, on September 1st, it started another one called “Nueva realidad” (New Reality), which limited de working days per economic sector, and assigned entrance and exit hours for each one. The regulations were modified slightly during the next months, until almost the whole scheme was derogated by November. The demand increased in a steeper manner than the one observed previously, and kept doing it until December 18th, when the Christmas celebrations had started. That is a normal seasonal change observed in year by TRANSMILENIO S.A. Then, from January 5th to January 28th, there was another cycle of localized confinements, but the demand grew during all the time, until March, when the increasing tendency started to stabilize.

5.2 Vulnerability to COVID-19 and the transport system

The entity responsible for the planning, collection, processing, analysis and dissemination of official statistics of Colombia, Departamento Administrativo Nacional de Estadística” ((DANE), 2020), carried out an analysis in which an index of vulnerability to COVID-19 considering demographic characteristics such as age and population density, as well as their previous health conditions. Fig. 13 illustrates this indicator.

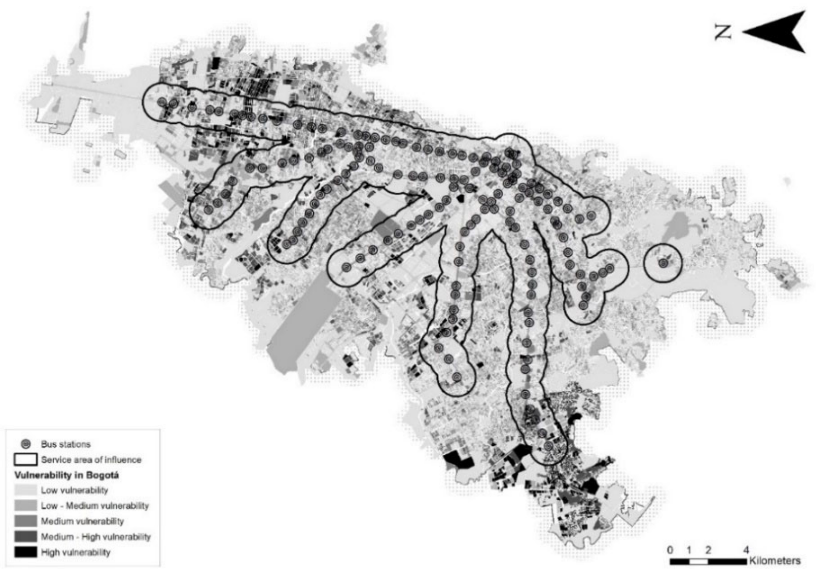

Figure 13: Vulnerability to COVID 19. Source: Own elaboration based on data from ((DANE), 2020)

Based on the previous study, it was possible to know the risk that the main users of the BRT have. The analysis using ArcGIS included the population that is 1km away or the so-called last mile and consisted of identifying the level of vulnerability our users are in the highest proportion. As shown in the following table, the highest proportion of vulnerability is found in the range of low and medium-low vulnerability with 41% and 36% respectively.

Vulnerability category	Percentage
Low vulnerability	41%
Medium - Low vulnerability	36%
Medium vulnerability	15%
Medium - High vulnerability	5%
High vulnerability	2%

Table 3: Vulnerability proportion

Vulnerability could be a factor that explains people's behavior related to the interaction with public transport. People would probably use more public transport if their risk perception due to the vulnerability of their home was low, and if they did not coexist with relatives with previous health conditions.

5.3 A brief graphical analysis

We are going to present some descriptive analysis of statistics, that can be explained by the influence of political decisions (which work as restrictions to people's behavior). The first one of them is Fig. 14, a graph that relates the percentage of decrease in the demand of both, BRT and on board validation bus service, with the COVID-19 cases identified, by the date in which the results of the tests were given. The focus of the analysis will be the two waves of cases that can be identified, particularly bnentetween July 11th/2020 to August 28th/2020 and from December 14th/2020 and January 31st/2021, and the time after they took place.

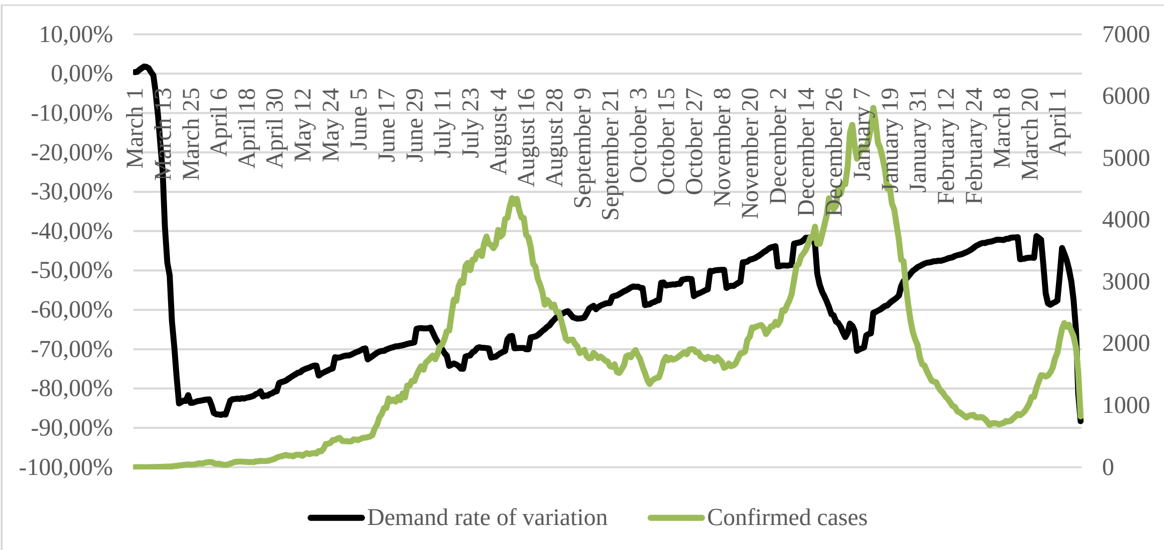

Figure 14: Change in the demand and cases by diagnose date

On the first interval, it is observed that, as the cases start to rise, the administration takes restrictive measures to prevent the effective contacts between people. This reflects in the transport system as a strong decline on the daily demand. Then, the demand of the system starts growing slowly, while cases continue increasing. After that, the ticket validations keep growing even when the diagnosed cases start dropping. Once the wave passed, the demand of the system continued to grow in a quicker way, but the number of confirmed cases kept stable during most of the "valley" observed.

On the second interval, the pattern is similar. The growth of cases can be observed since November 21st, day in which the anniversary of the national strike was commemorated. This was followed by a decrease on the demand of the system since December 18th, not due to the policies chose by the administration anymore, but because of the Christmas celebrations. As the demand of the system decreased, reaching its lowest point on January 5th (which was the first day of the second cycle of localized confinements), the confirmed cases grew onto the peak of the second wave of the pandemic. When the cases started to decline, the demand was already growing. This can be evidence of the uncorrelatedness of COVID-19 cases with the use of public transport.

A counterargument can be that the effect of the confinements or the dropping of the demand can be lagged. One way in which this can be observed is by taking the cases by the date on which the first symptoms appeared. However, this data is incomplete in the Health Department (Secretaría Distrital de Salud - SDS) dashboard's downloadable data because there are 203.211 (of 713.559, by April 9th/2021) observations without any date assigned. The tendencies described above do not change, as shown in Fig. 15 .

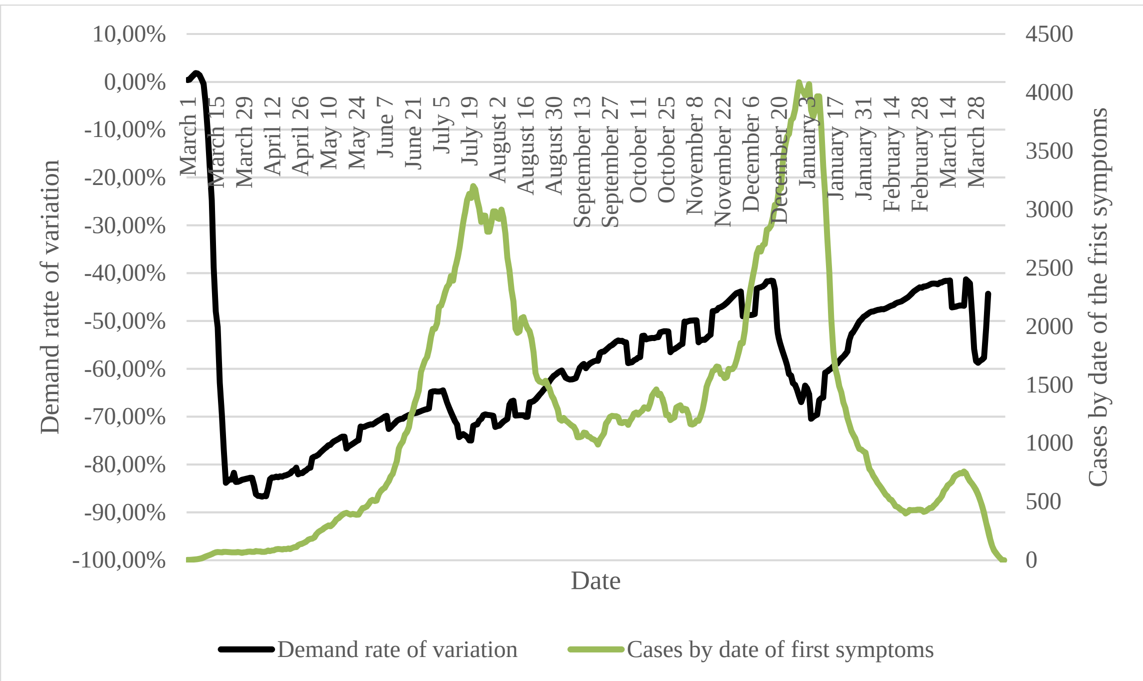

Figure 15: Change in the demand and daily confirmed case by date of symptoms

Furthermore, the decisions taken during the peak of the first contagion wave seem to coincide with the stabilization and start of decline of the cases, while, during the second wave, the new symptoms observed rose just as the demand of the public transport declined. An objection for the second analysis is that, on average, the symptoms start to appear some days after the contagion occurs. That can be answered with another indicator generated by the SDS: the effective reproduction number, which is calculated subtracting five days to the date in which the symptoms were initiated, with a time window that may vary through time. We use the latest boundary of the window. Fig. 16 illustrates this indicator:

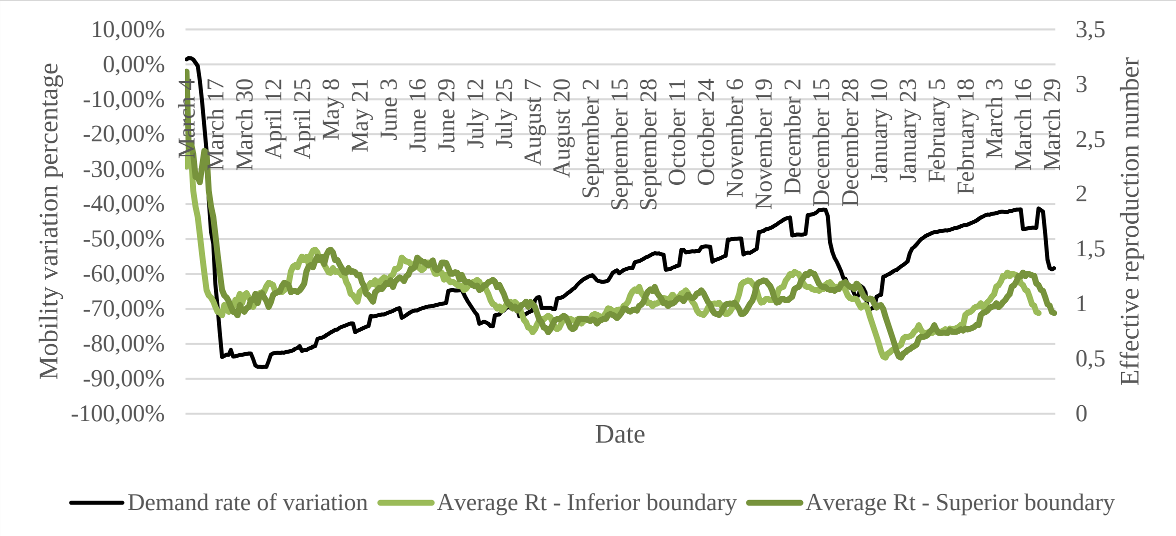

Figure 16: Daily effective reproduction number and demand rate of variation

The patterns do not reflect the behavior of each other. For example, after December 15th the demand drops two weeks earlier than the effective reproduction number or even three weeks superior boundary is used. The last figures indicate that the big changes in the relevant variables of the pandemic depend on factors that are different from the decisions taken with respect of the transport system. So, there is not a direct relationship between the evaluated variables and the contagion could be explained by other social interaction patterns, as well as by the natural behavior of the virus.

6. CONCLUSIONS AND POLICY LESSONS

The use of geographic information tools helps public transport systems to manage the demand variations, caused by the response to the state of the COVID - 19 pandemic, to make informed and focused decisions to prevent and mitigate the contagion on each of the areas of the city.

Analyzing the data of one year of the pandemic, during the time lapses when there was a progressive increase in demand for the TRANSMILENIO system, this slow growth does not appear to have a direct relationship with the number of infections or the reproduction rate of COVID - 19.

It was possible to show that the policies of the decrees implemented in Bogotá are reflected in the changes in the demand of public transport which shows that most of the population effectively complies with social isolation and biosafety measures.

For the next research, this study suggests analyzing the possible causal or non-causal link between the contagion and the public transport system.

ABSTRACT

This study presents the methodology used by TRANSMILENIO S.A. –the company in charge of managing the BRT lines in Bogotá, Colombia– to renew its operational design. TRANSMILENIO S.A. is increasing its bus fleet by acquiring higher capacity bi-articulated buses. This process demanded a redefinition of the frequencies, stops, and type of bus for all routes in the system. Therefore, a line scheme was selected based on the number of trips between corridors. A non-linear optimization model was then used to establish an initial route design that could satisfy passenger demand in the morning rush hour.

Five algorithms were implemented to adjust the initial route design to the actual restrictions, namely, fleet and bus capacity at stops. The algorithms modified the type of bus employed, the defined stops of routes, and eliminated low demand routes. Different alternatives were tested for the execution order of algorithms. The alternative to implement was selected based on compliance of the defined restrictions. Algorithms were iteratively run. Between iterations, a trip assignment model was used to adjust route frequencies based on demand.

The execution order of algorithms, its impact on the level of service indicators, and compliance of restrictions are part of this study's discussion. Particular relevance and effects of each algorithm are also analyzed. Both methodology and results might be tested, adapted, and improved in further studies by other BRT systems as a reference or input for their own route design process.

1. INTRODUCTION

Bus Rapid Transit systems have proven to be a sustainable solution for cities' mobility and economic development. This means of transport based on segregated lanes for bus circulation reduces the use of private cars, improves air quality, mitigates traffic accident rates, and generates employability (WRI, 2013). For its part, the city of Bogotá is responsible for 30% of the Colombian PIB and is one of the principal population center in the country (Hernández, 2020). TransMilenio is the name of Bogotá´s BRT system, one of the largest BRT systems in the world (WRI Brasil Ross, 2021). This system is managed by TRANSMILENIO S.A. a company owned by several public authorities of the city and is in charge of planning and managing the public transport system in Bogotá (which also includes regular bus routes and cable cars). Furthermore, this company does not own or operate buses but assigns routes to private transport operators.

Transport operators are privately-owned companies that own the buses and manage the hiring of drivers, and the maintenance, repair, washing, and operation of the buses. Transport operators are typically selected through a bidding process (including price per traveled kilometer and other factors) and awarded term-limited concessions to operate. City administration is currently making considerations to create a public-owned Transport operator.

Within the bidding process, a collection operator is also selected whose duty lies in the ticket purchase and the required hiring and maintenance for box-office operations. Tickets are sold in the form of electronic cards which are purchased by users in box-offices and “loaded” with a balance in currency.

The ticket value is then subtracted from the balance at the entrance of BRT stations or at non-BRT bus doors. The collection operator is also in charge of providing and maintaining the required electronic equipment in buses and stations, and the databases of user’s balance.

On the other hand, the city administration oversees the construction and maintenance of the infrastructure. Some infrastructure (e.g., parking lots, maintenance, washing, and facilities) is given to the operators to use and maintain during concessions. The city administration also provides capital to subsidize the system reducing the fare paid by users. Some financial institutions are also involved in saving resources and distributing them among the involved parties.

1.1 Operational Design

Bogotá city requires basic infrastructure and resilience services able to face the emerging challenge of growth. Hence, TRANSMILENIO S.A. performed two priority public bids (TMSA, 2018) which incremented the number of buses in the system.

The new fleet was divided into 67% bi-articulated and 33% articulated buses. The entity set off the design of a renovated operational design which apart from establishing the operable conditions for the new fleet, must guarantee general attention of Bogotá's BRT demanded trips. Likewise, BRT systems, unlike rail schemes, have a set of operational parameters that must be defined for service coverage. Particularly, BRT system has higher flexibility since its infrastructure can be adapted to the existing needs of a given space (CEPAL, 2012) and is not tied to rail infrastructure. Therefore, when planning the scheme of routes for this type of system, the followed variables must be considered:

- The number of routes offered per corridor or line.
- The defined path for each route.
- The stops within those routes.
- The frequencies with which of the routes to attend the trip demand.
- The type of bus to be used for each route.

These variables highlight the requirement to generate a process in which all are analyzed in a holistic and coordinated methodology. A methodology that leads to the execution of the process called Operational Design.

2. INITIAL SOLUTION

2.1 Existing methodologies

Planning public transport has been widely analyzed in the literature. In this section, two types of methodologies are presented: the first one related to a regular bus routes design, and general guidelines specifically for a BRT system.

In the first case, the principal process to evaluate a design is based on three main steps according to (Ceder, 2007): Initially, a feasible solution is proposed based on the different OD pairs with higher demand.This will result in a first approximation of the model.
Then, these groups of routes are evaluated based on the attended demand. Subsequently, an evaluation of frequencies and network performance is executed according to selected indicators such as fleet size, rules for insertion or elimination of nodes in existing routes, among others. Finally, it is obtained an improved solution after removing, dividing, or interchanging the routes.

The second one comprises a BRT Planning guide (ITDP, 2017) which shows the guidelines for executing the service planning. In the document, mainly in chapter 6, the different indicators and considerations for basic service planning are presented. Some of these are saturation, speed, travel time, service frequency and headways, direct and express services. However, these guidelines are presented from a general strategic perspective. In the present document, it is presented a combination of both methodologies.

2.2 Lines selection

One of the main objectives with the accomplishment of the new operational design was to migrate from one current system divided into trunk lines to one with lines, similar to urban rail transport systems like metros. Since Bogotá's BRT system currently has eleven trunk lines, analyzing all the possible lines becomes an unfeasible task because of communication to users, design complexity, and efficiency (not all the lines would have a significant number of travels).

To generate an initial approximation of this design, the first duty was to analyse the trip demand between all the origin-destination pairs in the possible lines to retain the most important ones, as mentioned by Ceder (2007). The trip demand used was the morning peak hour (6:30 to 7:30) estimated in a study for the integral structuring of the trunk component operation of TransMilenio System (Temporary Union SDG-PHR-KPMG, 2018).

Furthermore, in this contract, the lines with a demand of 6.000 trips per day and up to 9.000 trips were kept as "main lines", a step that was followed in this evaluation. Nevertheless, this process left some original trunk lines outside the proposed principal lines. To circumvent this issue, the lines with higher demand among the ones including the left-behind trunk lines were added to the "principal lines" set. At the end of the process, 22 lines were considered as main lines.

2.3 Optimization model and preliminary design

For each of the major lines selected a simple optimization model was developed in Excel to create a set of "seed routes" implemented within the following steps.

All the models constrained the maximum number of resulting routes to five (except for two lines for which the demand was too high and hence the number of routes was greater), all with a similar frequency (between nine and twenty bus/hour) while maximizing the number of biarticulated buses and avoiding leaving any station with no service. To define the objective function, all the origin-destination pairs in the line were ranked following the number of trips, and the pairs with more trips than the percentile 95, were marked. The objective function was defined as a maximization of the number of principal O-D pairs covered with no need for transfers.

3. ADITIONAL RESTRICTIONS

The preliminary design, which resulted from the initial optimization model required to be adjusted to the existing restrictions to be implemented successfully. These restrictions are described below.

3.1 Available buses

The resulting operational design should require no more buses than the available in the system. This parameter is given by the total amount of buses in the system minus a percentage of buses which is receiving maintenance or are kept in reserve to attend emergencies during operations. In TRANSMILENIO S.A. 2% of the total fleet is reserved for these purposes. This led to 736 articulated and 1263 bi-articulated buses available to operate.

3.2 Bus type restrictions at stations

After the acquisition of the new bi-articulated buses, this type of vehicle will constitute the majority in Bogotá's BRT system. However, a bi-articulated bus commands larger stations, stop points, and doors. However, not every station in the system is adequate to operate with this vehicle type. The resulting design must ensure that there are no bi-articulated bus routes designed to stop in stations without the adequations required.

3.3 Bus station capacity

TransMilenio stations have one or more gates (stop points) for buses to stop in each direction. The number of buses that can stop at the same gate in a period is limited. When the number of buses increases above this limit, queues might form with a higher frequency, which can cause delays. Using traffic simulations and field observations TRANSMILENIO S.A. had previously defined capacity values for each station (buses per hour per direction). This was the greater restriction, and after consulting with the company team responsible for this data, a station was considered to comply if the number of buses was within 110% of the defined capacity value, otherwise, the station is considered to be saturated.

3.4 Headway restrictions

Headway between buses on the same route has a direct impact on user waiting time, and therefore, on the perceived level of service. To avoid long waiting times, TRANSMILENIO S.A. has established a seven (7) minute limit for the maximum headway allowed. This limit must be observed even when route demand could be served with a higher headway, therefore, complying with this condition might require more buses. A limit of two (2) minutes for the minimum headway allowed has also been established to avoid bus bunching.

4. DEVELOPED ALGORITHMS

To adjust the preliminary operational design to the current restrictions, four algorithms were developed that iteratively modified the initial scenario. A transit assignment model was used for the evaluation of the different supply scenarios. The model used was previously developed for TRANSMILENIO S.A. as part of the consultancy by Temporary Union SDG-PHR-KPMG (2018) and uses EMME transport planning software. Algorithms were implemented using python scripts. For more information on transit assignment models refer to Ortúzar and Willumsen (2011), chapter 10.6.

4.1 Relevant OD pairs inclusion

Although the initial optimization model sought to maximize the number of DO pairs that were directly connected, the solution obtained did not directly connect (that is, by the same route and without the need for transfers) all the pairs. In particular, some of the OD pairs with high trip numbers were not directly connected. Consequently, the first algorithm seeks for the OD pairs with the highest number of trips in the origin-destination matrix and connects them. OD pairs with several trips within a percentile that is received as a parameter are searched for.

Finally, once the largest OD pairs have been found, those that are not directly connected, a route is searched that passes through the corresponding origin and destination stations, and the mentioned route is used to connect the OD pair. In case of finding several routes, the route with the lowest volume of passengers at the station of origin is used. If no routes are found, the OD pair remains without direct connection. This algorithm is executed once (not iterative).

4.2 Capacity adjustment in stations

This algorithm was developed to reduce the formation of queues in the stations of the system and adjust to the measured capacity of the stations. The algorithm takes the current design, and searches for stations that are saturated (as defined in section 3.3) in any of the two directions, then eliminates the stop of the route with the least number of total movements (ascents and descents in both directions). Therefore, the selected route will no longer stop at this station.

After eliminating a route stop for each of the saturated stations, an assignment and headway adjustment (as described in 4.5) is carried out. The stop elimination process is repeated, continuing iteratively. The algorithm ends when the percentage of saturated stations falls below a defined threshold or is 0 (when there are no saturated stations), or when the maximum iteration defined number is reached.

4.3 Change to biarticulated type

Followed by the execution of any of the algorithms, it might result that the obtained operational design does not comply with the available fleet restriction. A particular case is that the design required more articulated buses than those available, and less bi-articulated than those available.

It is also possible that highly demanded routes that are candidates for using bi-articulated buses (for their higher passenger capacity) could not be initially designed with this vehicle type. This is caused now that the restriction of infrastructure. Hence, after executing the algorithm for capacity adjustment in stations, those routes were debugged to suspend stop in stations with biarticulated restrictions.

With those cases in mind, an algorithm was designed to seek those routes that are being served by articulated buses and stops only in stations equipped for bi-articulated buses. The algorithm modifies the type of bus of all the routes found from articulated to bi-articulated and performs a frequency adjustment and assignment process. This is not an iterative process, and all the routes found are modified at once.

4.4 Fleet adjustment

For the other cases in which the available fleet restriction is breached (even after executing the algorithm for changing to bi-articulated bus type), two algorithms were developed. These algorithms are designed to be executed consecutively.

4.5 Change to articulated type

The first algorithm seeks to comply with the restriction of bi-articulated buses and is executed when the current operational design requires more bi-articulated buses than those available. In each iteration, it looks for the route of bi-articulated buses with the lowest demand (fewer total boardings) and modifies it to articulated bus type. After each iteration, an assignment and headway adjustment (as described in 4.5) is carried out. The algorithm continues to iterate until the design meets the available fleet of bi-articulated buses.

4.6 Routes Elimination

After completing the first algorithm, and if the available articulated bus fleet restriction unfulfilled, the second algorithm will search for the articulated bus route with the least demand (least number of total boardings) and eliminate it. The algorithm continues to iterate until the design meets the available fleet of articulated buses. After each iteration, an assignment and headway adjustment (as described in 4.5) is carried out.

4.7 Assignment and headway adjustment

As stated above, between the iterations of the algorithms a process or assignment and headway adjustment was executed. This process was implemented to improve transit assignment results and adjust route frequencies to actual demand conditions. It consisted of three steps, as described below:

- The first step was to equal the headway from all routes. This was done in preparation for a transit assignment process, to equalize the perceived waiting time for the user. The subsequent transit assignment was therefore reliant on in-vehicle time and transfers, and less dependent on headway results from previous iterations.
- The second step consisted of a transit assignment using EMME’s optimal strategies (Spiess and Florian 1989) extended transit assignment algorithm, followed by a headway adjustment which was the third step. Headway adjustment consisted of calculating the frequency required for each route to be able to transport the passenger demand at the segment with the higher load; this was done by dividing hourly passenger demand at the highest loaded segment between bus passenger capacity.

> The resulting value was the required route frequency (in buses per hour) from which headway in minutes could be obtained. Capacity values used for articulated and biarticulated types were 160 and 260 passengers, respectively.

A relatively simple methodology for transit assignment was used, as the effects of vehicle capacity, parallel lines, and overlapping routes were not addressed. An alternative for the future improvement of this methodology is the use of more sophisticated assignment models, such as those developed by Verbas and Mahmassani (2016), or Schmöcker and Fonzone (2011).

4.8 Special route protection

In addition to all system routes, it exists a set of routes that stop in all stations along their path. These are known in the city as “easy” routes. There’s typically one of these routes for each main line in the system.

Due to their low speed, these routes often have a lower demand, and therefore relatively high headways. The existence of these routes usually ensures that all stations are interconnected, and helps new or occasional users to easily use the system.

Likewise, to prevent any of the algorithms to erase or modify these routes, a functionality was implemented to “protect routes” by marking them using a dummy variable in the software. Marked routes could be subjected to changes in the type of bus used, and their frequencies were adjusted to demand in every iteration (section 4.5) but were ignored by algorithms that eliminated routes or route stops.

Initially, only “easy” routes were protected. However, as planning process progressed, this functionality proved to be useful and was extended to other routes. The reason is briefly explained in section 7.

5. PERFORMANCE INDICATORS

To evaluate the performance of the developed algorithms, the overall design, and the resulting routes, were based on six indicators previously selected. Indicators were calculated between every iteration. These variables cover different parameters as bus fleet, waiting times in stations, and time in vehicles, among others. A description of each indicator will be shown below.

5.1 Bus fleet

After the renovation of the bus fleet, the quantity of articulated and bi-articulated buses available to operate is limited: 736 and 1263 respectively. These are target values as described in section 3.1.

5.2 In-vehicle time

In the transit assignment process (INRO, 2020), a time in vehicle is generated for each iteration. This is obtained by multiplying the transit times by a perception factor. These values were compared with the actual values corresponding to the base scenario.

5.3 Waiting time

Like in-vehicle time indicator, this indicator is obtained through the transit assignment algorithm by INRO (2020). This corresponds to the weighted average of passengers waiting times. These values were also compared with the actual values corresponding to the base scenario.

5.4 Average boardings

Indicates the average number of boardings passengers have to make to reach their destinations, including transfers. Values close to one indicate a low number of transfers in the system. Similar to the time in vehicle indicator, this variable is obtained by the transit assignment algorithm. These values were also compared with the actual values corresponding to the base scenario.

5.5 Saturated stations

This indicator shows the number of saturated stations (as defined in section 3.3) in relation to the total stations in the system. The indicator is presented as a percentage.

5.6 Generalized cost

This corresponds to the impedance function in the EMME algorithm. The total impedance is the sum of perceived time and cost components (total waiting times, total boarding times/costs, in-vehicle times/costs, auxiliary transit times/costs) where the perceived component is the actual component multiplied by the corresponding perception factor (INRO, 2020).

6. DEVELOPMENT PROCESS AND EXECUTION ORDER

Initially, only Fleet Adjustment (FA) algorithm (section 4.4) and Capacity Adjustment in Stations (CAS) algorithm (section 4.2) were developed. FA was intended to precede CAS, but this intended execution order proved inadequate. As a result, the execution order was inverted and further issues were identified, which lead to the development of the other two algorithms.

Scenarios 351 and 361 were both built using the preliminary design as the starting point (section 2.2). For scenario 351 FA was executed before CAS. When issues with scenario 351 were identified, scenario 361 was created with the execution order inverted. Issues with the first scenario are evident when compared to the second one, as is shown below.

For scenario 351, Change to Articulated Type (CAT) algorithm (section 4.4.1) was performed from iterations 1 to 8, when the bi-articulated fleet restriction was fulfilled. Route elimination (RE) algorithm (section 4.4.2) was subsequently performed until iteration 22, and CAS was then executed until iteration 42. At iteration 42 CAS maximum iteration number was reached without achieving convergence.

For scenario 361, CAS was executed from iterations 1 to 21, when the desired convergence was reached (5% of stations saturated). CAT was performed until iteration 30 when the bi-articulated fleet restriction was fulfilled. RE was then executed until iteration 50 when the maximum iteration number was reached (20 iterations).

Figure 1 shows the required number of bi-articulated buses along algorithm execution. This figure shows that CAT had the desired effect by reducing the number of required bi-articulated buses. However, required buses also vary when CAS is executed.

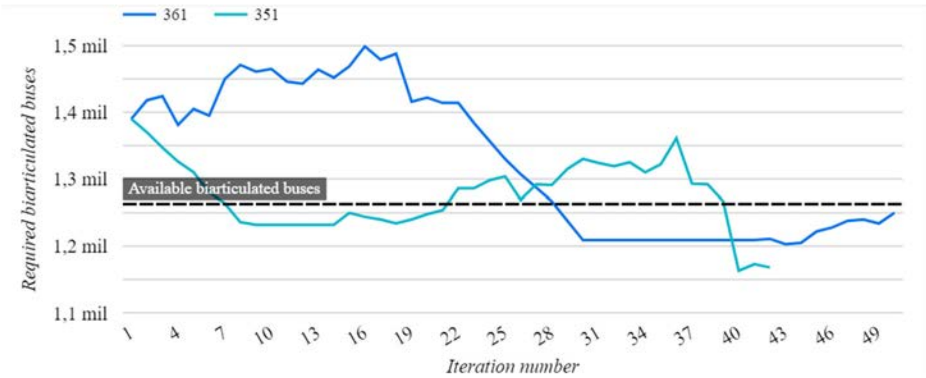

Figure 1: Required number of biarticulated buses throughout algorithm execution, scenarios 361 and 351

Figure 2 shows the required number of articulated buses along algorithm execution. This figure also shows the desired effect of RE algorithm in reducing the number of required articulated buses. It can be observed that required articulated buses also vary when CAS is executed.

Figure 2: Required number of articulated buses throughout algorithm execution, scenarios 361 and 351

By comparing both scenarios it was clear that progress obtained by FA algorithm could easily be undone by CAS. On the other hand, the inverse relation was not true. As shown in figure 3, the Percentage of saturated stations was effectively reduced by CAS and it was not significantly increased when executing FA. It was then decided to execute FA after CAS.

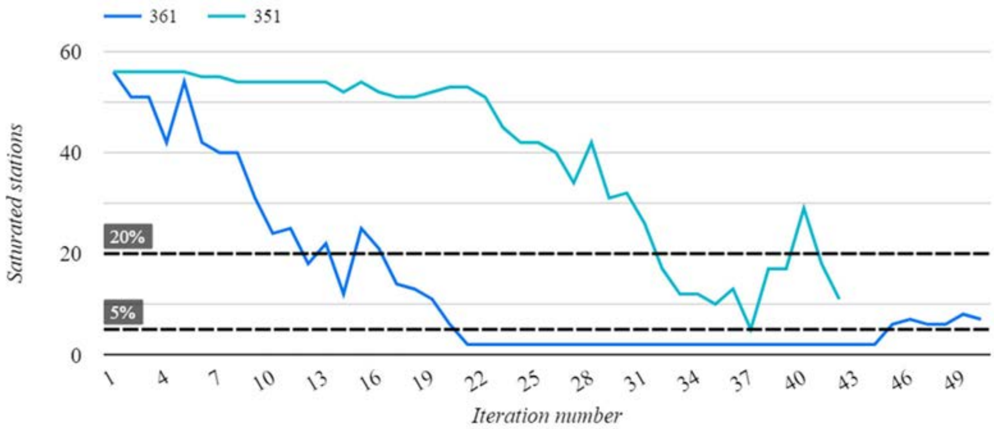

Figure 3: Percentage of saturated stations throughout algorithm execution, scenarios 361 and 351

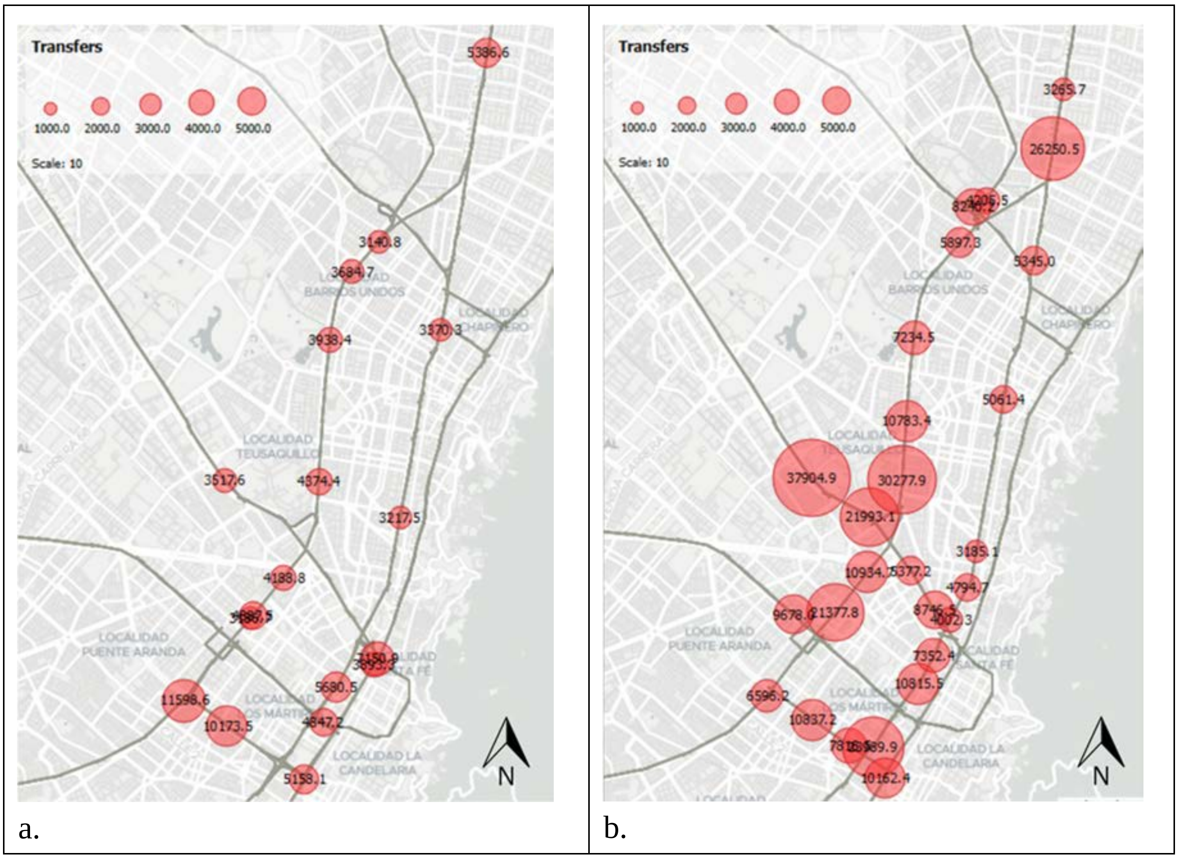

Figure 4: Stations with more than 1000 transfers base scen. (a) and scen. 361 (b)

FA and CAS algorithms were effective at complying with system restrictions. However, since both eliminated routes and routes stops, more transfers were required in the system. Even though for some stations the number of transfers diminished, for others, it augmented dramatically. “Calle 100” station, for example, went from nearly 2.350 transfers to 26.250; more than 11 times the initial value.

To address this problem, Relevant OD Pairs Inclusion (RPI), and Change to Biarticulated Type (CBT) algorithms (sections 4.1 and 4.3) were developed. CBT was executed between CAS and FA and two options were evaluated for the execution of RPI. RPI was run immediately after CAS in scenario 403, and before CAS (at the beginning of the whole process) in scenario 413.

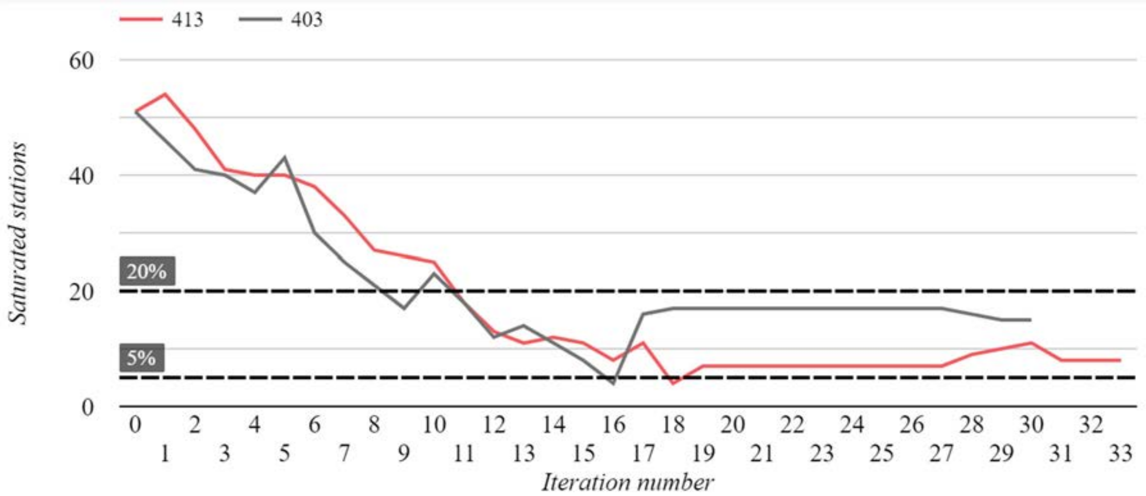

Figure 5: Percentage of saturated stations throughout algorithm execution, scenarios 413 and 403.

Except for the percentage of saturated stations, there were no significant differences in performance indicators between scenarios 403 and 413. Figure 5 shows that some of the progress achieved by CAS was undone by RPI in scenario 403 (Iteration 16 to 17). It was then decided to execute RPI before CAS.

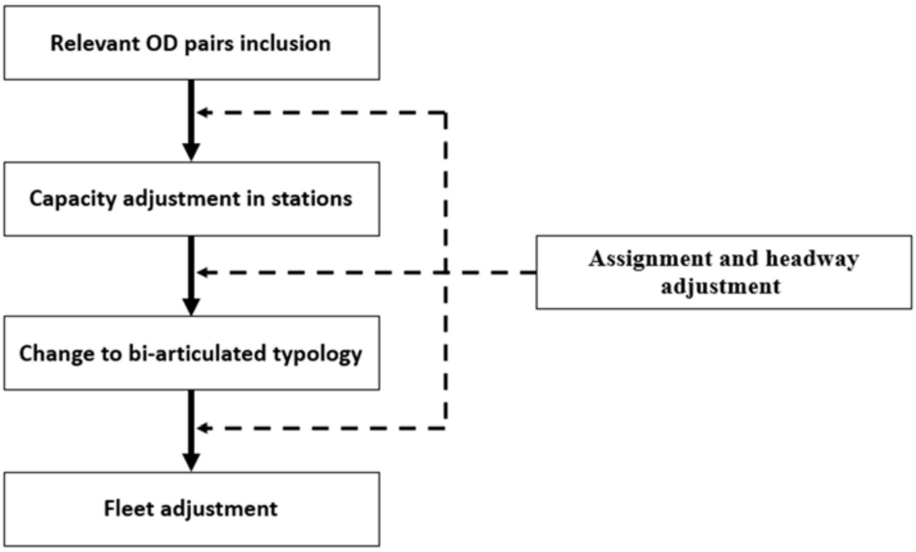

Figure 6: Selected algorithm execution order

Figure 6 shows the selected order of execution for the algorithms. Note that the assignment and headway adjustment (section 4.5) was not only performed between each of the algorithms, but also in every iteration.

6.1 Capacity adjustment in stations algorithm convergence

As stated above, the execution of CAS algorithm was completed when the percentage of saturated stations was 5% or less. This value was selected as a convergence threshold because complete compliance of station capacity restriction (0% saturated stations) could not be achieved though the continued execution of the algorithm.

Furthermore, in the scenarios when CAS was executed beyond reaching 5% of saturated stations, it continued to eliminate route stops increasing the number of transfers therefore deteriorating the overall route design.

7. RESULTS

CAS and FA algorithms were designed to achieve target values in saturated stations and bus fleets. The two are effective in this matter. A negative effect in the use of these algorithms is the increase of transfers at one or more stations, usually caused by the elimination of a route or a route stop that was the only direct alternative for a particular group of users.

To reduce transfers in a particular station, relevant origins and destinations were identified for the users performing such transfers. A stop or route that eliminated the need for transfers was then added to the preliminary design, and the algorithm was again executed. If necessary, some routes were protected from deletion as described in section 4.6.

This process was repeated iteratively for all stations with more than 4000 transfers/hour generating several scenarios until a stable point was reached. Consequently, this section presents the results for scenario 744, which satisfied system restrictions and had reasonable amounts of transfers at most stations.

CAS algorithm ran from iteration 1 to 15, and stopped when the proportion of saturated stations was under 5%. As shown in figure 7, this percentage was relatively stable for the remaining of the process, never exceeding 10%.

After CAS and CBT were completed, CAT algorithm was initiated at iteration 16. Figure 8 shows a drop in the required number of bi-articulated buses during CAT, and figure 9 shows an increase in the required number of articulated buses. CAT ended at iteration 28 when the target value was met.

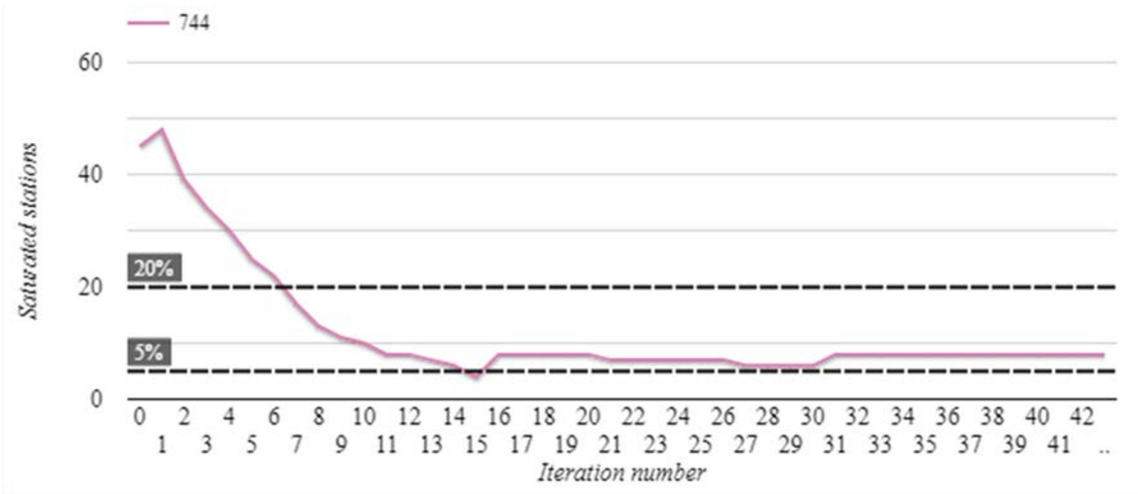

Figure 7: Percentage of saturated stations throughout algorithm execution, scenario 744

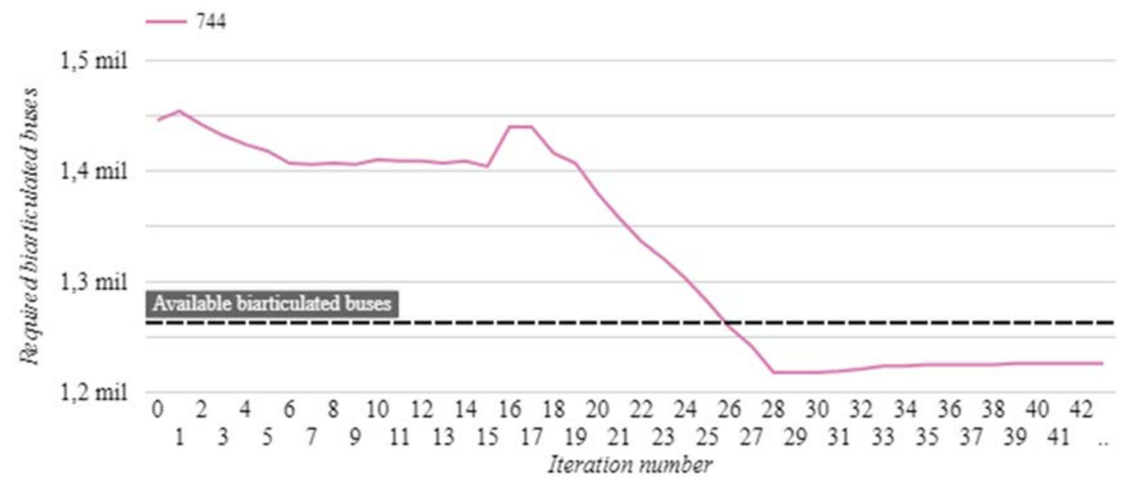

Figure 8: Required number of articulated buses throughout algorithm execution, scenario 744.

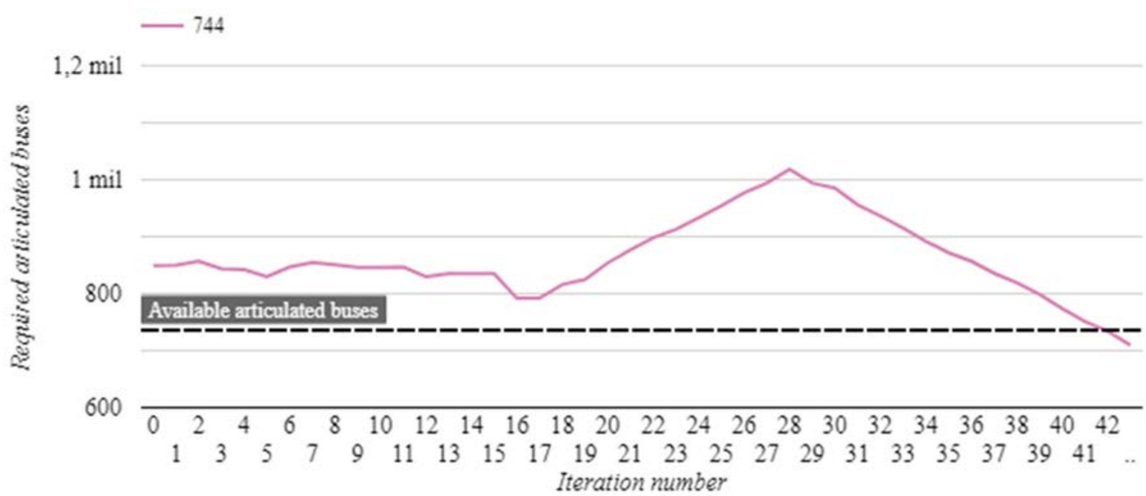

Figure 9: Required number of articulated buses throughout algorithm execution, scenario 744.

Figure 9 shows that the required number of articulated buses decreased as RE algorithm ran from iterations 28 to 43. The required number of bi-articulated buses and the percentage of saturated stations remained under acceptable ranges.

For the other indicators described in section 5, their value improved **between** base scenario and the preliminary design, but there were no significant variations when the algorithm was executed.

8. CONCLUSIONS

Process automation aids to create an operational route design proposal for a BRT system by considering a broader set of restrictions when compared with traditional methodologies.

It is possible to develop algorithms that adjust an initial route proposal for a BRT system to existing restrictions of station capacity and available bus fleet. However, the developed algorithms have an impact on system direct connectivity. In this case, planners had to manually resolve high transfer rates at some stations.

The execution of the described algorithms was not sufficient to achieve a fully applicable operational design. In the case studied, the attained percentage of saturated stations was 8%, meaning that 12 stations were to be analyzed manually to avoid sending more buses than their capacity.

Based on the iterations carried out with the CAS algorithm, it was reasonable to infer that a convergence scenario with 0% of saturated stations was not reliable, regarding the current conditions of the system. Since the saturation values in stations did not exceed the threshold of 5% in the iterations process, regardless of the elimination of service stops. Thus, in this research, it was necessary to manually restrict the algorithm to avoid undesired exclusion of several routes per station that can bring detrimental effects (stations or OD pairs not attended) so it must stop once the threshold is reached.

Despite the existence of international methodologies to generate an operational design for BRT systems, these methodologies are not definitive and do not include specific guidelines for addressing the station capacity and available fleet restrictions. The planning process for a BRT system is still open for improvement and debate.

Vehicle capacity, parallel lines, and overlapping routes can affect the results of transit assignment. Using an assignment model that takes these factors into account could improve the assignment results, and therefore the overall operational design.

METRO SYSTEMS IN LATIN AMERICA, COMPARISON OF PLANNING AND DEVELOPMENT MODELS VERSUS OTHER REGIONS IN THE WORLD

Efraín Bastidas-Zelaya
PhD candidate, Universidad Politécnica de Valencia, España

ABSTRACT

The population growth in cities pushes to seek solutions for the mobility of people, one of the most efficient but at the same time more expensive solution is a rapid transport system, commonly known as metro systems. In last 50 years, Latin America has seen how many of its cities have grown to have populations of several million inhabitants and therefore they have considered the development of a first metro line or if they already had existing lines, expand the metro network. This study seeks to understand the planning and development models of metros in Latin America and analyze the traits of these systems, compared to metros in other regions of the world. The conclusions of this study will not only be useful for local planners, but also for development banks and other international organizations in a way that they can understand and adapt their processes to local conditions. The research uses statistical information from benchmarking groups of metro systems throughout the world, as well as information presented in annual reports of companies operating metro systems. Academic documents are also used, as well as reviews and analytical studies by experts from international organizations and multilateral banks. In the first section of the paper, planning models to develop a metro project are analyzed, then a comparison is made between levels of demand or passenger flows and economic-financial variables and finally the operation models are studied. Conclusions are presented with the most relevant factors to consider when planning and developing a metro system in Latin America.

1. INTRODUCTION

1.1 The Latin American context: the demographic explosion and the construction of metro systems

During the last century and a half, the Latin American region has experienced explosive demographic growth, going from a population of 75 million in 1900 to 165 million inhabitants by 1950, continuing growing to 510 million inhabitants by 2000 and it is estimated that in 2025, the population will reach 783 million inhabitants (Ortiz Álvarez et al., 2003), this means an increase of more than 1000% in the period stated. But not only the population grew, but it has also become more urban, going from an urbanization level of 25% in 1925 to a percentage of urban population of 75,3% in 2000, and its projected urban population will reach 82,2% in2025, also being the region of the planet with the greatest changes in population growth and levels of urbanization (Lattes, 2001). As for the most populous cities in Latin America in 1900, none exceeded the figure of one million inhabitants, by 1950 six cities in the region had exceeded one million inhabitants, and by 1995 39 cities within the region had exceeded that population, including three cities that had more than ten million inhabitants (Ortiz Álvarez et al., 2003).

At a global level, the phenomena of population growth and urbanization have led to public transport having a substantial weight in the dynamics of large cities and urban metropolitan railways, commonly called “metros” which are among the most implemented solutions in large cities. Studies cite that the 10 largest metro systems in the world transported more than 22,000 million passengers in 2013, equivalent to three times the world population (Brage-Ardao et al., 2015). In Latin America the trend towards the construction of metro systems has not been different from the rest of the world. Throughout the 20th century, metros had been built in thirteen cities in Latin America, but in just two decades of the new millennium ten new cities in the region joined the club of cities that have metro systems (Clemente, 2013).

1.2 The particularities of Latin America in transportation investments

Latin America is in a construction boom of metro systems, but this region has its own conditions that are not necessarily similar to other regions of the world where many metro systems have been built, such as in Europe, North America, and Asia.

Latin America is a developing region, with a series of social challenges, including considerable levels of poverty, political instability in its governments, and difficulties in state finances that lead to limitations on public investment. The region has been involved in successive financial crises, which has influenced the capacity of state or local governments to make investments, which has been reflected in the fact that it is the region of the planet with the lowest level of investment in infrastructure, just 1.8 % of GDP, which has led it in recent years to focus on different types of concessions or public-private participation (PPP) (Vassallo Magro, 2015). It is essential to study the planning and management models of transport infrastructures in the region, addressed in section number two of this document. Although the population's transportation needs are high since the region is very populous and with high levels of urban concentration in large cities; on the other hand, the aforementioned financial limitations at the level of investment in infrastructure lead to unique phenomena in terms of demand levels and use of metro systems in the region. These phenomena will be explored later in a comparison by regions. Finally, the permanent tension due to financial issues in the region prompts a search for financing sources of various origins and that many metro systems in the region have a vocation for financial self-sustainability.

Given the nature of this research, the main method of gathering information will be by bibliographic sources, including scientific articles, reports from operators or concessionaires of metro lines, comparative reports from benchmark associations of comparative analysis and by studies, reports and reports of multilateral development and investment banking

2. LITERATURE REVIEW

Due to their nature of large-scale works, metro systems have been inserted in urban spaces and with constructions that require underground works or viaducts, present construction complexities and high investment costs. According to an analysis of 40 metro lines in the world, their construction costs range from US $ 50 million to US $ 150 million per kilometer of construction (Flyvbjerg et al., 2008), and a study by the same author shows that the presence of cost overruns are on average 45% above the original budget (Flyvbjerg, 2007). Other authors have studied the causes of cost overruns, finding in 75% of the cases incomplete or low-quality designs, work delays and administrative problems between the parties involved (Cantarelli et al., 2010). The problems in the metro systems do not end with their construction, since their operation also involves great challenges, both in terms of demand coverage and financial sustainability. Flyvbjerg reports that worldwide 9 out of 10 projects do not meet expectations for passenger demand ranges, with three-quarters of those projects falling below 40% of forecast demand (Flyvbjerg, 2007); moreover metro projects are the most inaccurate at the level of demand forecasts in the field of transport, which has been maintained for several decades (Siemiatycki & Friedman, 2012). Lastly, financial sustainability is a critical factor in metro systems worldwide, and it is thus that in benchmark reports comparing metro systems in various continents, very few operators achieve a degree of cost coverage equal to operating revenues, commonly called the “coverage index” (ALAMYS, 2013; Condry, 2013). This inability to achieve financial equilibrium at cost level and operating income indeed leads metro operators to demand high levels of subsidies from central or regional governments. Given the fact of presence of various levels of risks in terms of: design, construction, demand forecast, and political, some mechanisms have been found at international level in order to transfer this risks to private parties, under various administrative modalities of operation contracts, concessions and public-private participations (PPP) that allow transferring the risk from the infrastructure developer to the private sector (Siemiatycki & Friedman, 2012), existing a diverse variety of models ranging from the traditional model where the project developer is responsible for all phases, to complex and varied alternatives where one or more phases of the Design (D), Build (B), Operate (O), Finance (F) stages are transferred to the private party and - if applicable - the Transfer (T) or Property (O) of the project. Hence, progressive models of involvement of the private sector as a concessionaire are described. Each acronym described represents the commitment that the private sector acquires in the PPP such as: DB, DBO, BOT, BOO, until reaching the broader risk transference model the DBFOT, also called “turn key”, here, the project developer leaves everything in the hands of the private company that takes action in all activities from design, through construction, to long-term operation (Clemente, 2013; Delmon, 2010; Wojewnik- Filipkowska, 2012).

There are other factors that influence metro systems, beyond the development models of the projects. On the one hand, studies show that there are particularities or conditions both in favor and against for those "greenfield" type projects that correspond to absolutely new infrastructures for the environments where they are implanted, compared to "brownfield" type projects, which are those that are an extension or are very similar to an existing project (Amos, 2004; Gago De Santos, 2014) and the literature consulted agrees that among the advantages of greenfield projects are the high degrees of freedom to start a project without previous conditioning factors, meanwhile among the disadvantages is the lack of experience in these projects. And finally, another major issue that influences metro projects is the approach to receive technical support and financing from multilateral entities ,or development banks compared to new technical and financial parties such as Asian governments. In this sense, multilateral financial entities not only act as lending banks, but there is also a strong focus on developing internal capacity of project operators by improving institutional capacities and technical and knowledge transfer (Sagasti & Prada, 2002). Faced with this alternative, in the last two decades, there has been a strong influence of new actors such as the case of China, a new infrastructure lender in the region (Gallagher et al., 2013; Slipak, 2014), although these credits are linked to obligations to contract Chinese companies and under the conditions that their government requires, according to Gallagher and Slipak.

3. COMPARISON OF LATIN AMERICA METROS VS. OTHER REGIONS OF THE PLANET

Obtaining data from all metro systems in the world is an extremely complex task, not only due to the high number of existing metro systems, which by 2018 were 182 cities (UITP, 2018), but also because many of those systems do not carry complete statistics on their operations; moreover, even if they have statistics, they do not have standardized indicators that allow comparisons between equivalent parameters. Therefore, in order to be able to compare Latin America’s metro systems with metros in other regions of the world, the data and information have been taken from some metro systems that are representative of each region and for which there are sufficient data and harmonics with one another. The information come from public use of benchmarking metro associations such as reports from the Asociación Latinoamericana de Metros y Subterráneos (Latin American Association of Metros and Subways) (ALAMYS, 2014), Community of Metros Benchmarking Group (Anderson, 2006; Anderson, Findlay and Allport, 2010; Condry, 2013) and the Union Internationale des Transports Publics (UITP, 2012, 2016, 2018) as well as annual reports or official reports from metro operators (Azienda Trasporti Milanesi, 2015; Taipei Rapid Transit Corporation, 2015; Transport for London, 2015; CRTM, 2015; Delhi Metro Rail Corporation Ltd., 2015; Metro Sao Paulo, 2015; Metropolitan Transportation Authority - MTA, 2015; MTR, 2015; SMRT, 2015; BVG, 2016; Washington Metropolitan Area Transit Authority, 2016; San Francisco Bay Area Rapid Transit, 2016; Metro Rio, 2017) and of multilateral entities or investment and development banks from consultants or analysts of these institutions (Rebelo, 2006; Mitric, 2013; Ardila-Gomez and Ortegon-Sanchez, 2015; World Bank et al., 2015; European PPP Expertise Center, 2016; Pulido, 2016; Pulido et al., 2018)

3.1 Demand level versus the size of the metro network

The first feature which has been found particularity in metro systems in Latin America compared to other regions, is the high demand they have in relation to the size of those metro networks. To carry out the analysis, it is necessary to compare the variables "number of annual travelers" expressed in millions of passengers (MMpax) with "network size" expressed in kilometers. Some metro systems have been selected from each region among the most representative operations. These data are observed in table 1, and in graph 1.

City - Operator	**Region**	**Network Length (km)**	**Annual passengers (MMPax)**	**Passengers by Network Length (MMPax/km)**
New York City Subway	North America	485	1751	3,61
Washington Metro	North America	171	209	1,22
Montreal Metro	North America	71	280	3,94
San Francisco BART	North America	197	128	0,65
Average metros selected North America		**231**	**592**	**2,56**
London Underground	Europe	402	1265	3,15
Metro de Madrid	Europe	294	561	1,91
Berlin U-Bahn	Europe	175	500	2,86
Metro de Milan	Europe	97	350	3,61
Metro de Valencia	Europe	147	60	0,41
Average metros selected Europe		**223**	**547**	**2,45**
Hong Kong MTR	Asia	185	1578	8,53
Shanghai Metro	Asia	613	2500	4,08
Singapore MRT	Asia	142	1200	8,45
Delhi Metro	Asia	212	780	3,68
Taipei Metro	Asia	129	680	5,27
Average metros selected Asia		**256**	**1348**	**5,26**
Mexico City Metro	Latin America	200	1580	7,90
Metro Sao Paulo	Latin America	75	800	10,67
Metro de Santiago	Latin America	105	650	6,19
Subte de Buenos Aires	Latin America	45	380	8,44
Metro Rio	Latin America	45	200	4,44
Metro de Medellín	Latin America	35	201	5,74
Average metros selected Latin America		**84**	**635**	**7,55**

Table 1: Passengers by Network Length (MMPax/km)

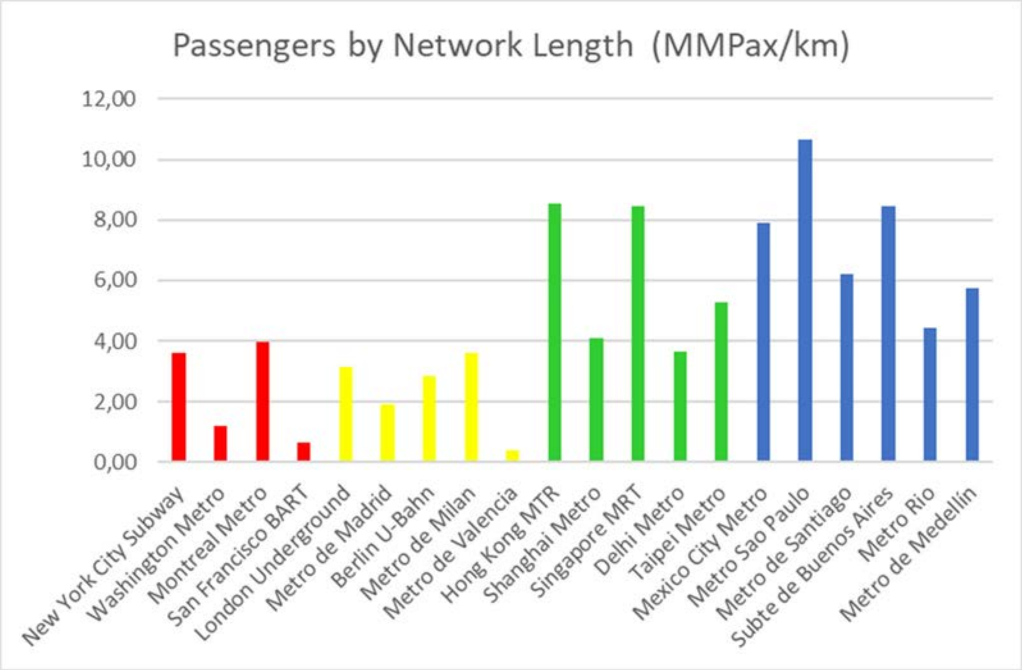

Figure 1: Passengers by Network Length (MMPax/km)

The calculation of the average of the selected metro systems shows that the metro systems in both Latin America (7.55 MMpax / km) and Asia (5.26 MMPax / km) have higher levels of demand for the lengths of the metro networks than their counterparts in North America (2.56 MM / km) and Europe (2.45 MM / km). Actually, passenger load per km in Latin America is the highest in the world.

3.2 Financial Sustainability

In order to evaluate this parameter, two variables will be analyzed; on the one hand, the quotient called "recovery ratio" which represents a relationship between operating income versus operating costs, in such a way that a recovery ratio greater than 1 represents that all the operating costs are paid with operating income received and therefore the operation of the metro system is financially sustainable, and a ratio lower than 1 represents that the operation does not cover its costs and will permanently need government subsidies. The second variable used is “additional or non-tariff income”, which corresponds to all commercial activities that are not related to transport activities but generate income in a metro system. Among these are commercial advertising in stations or on trains, businesses related to telecommunications within the metro network including mobile telephony, the rental of store places within metro stations and even activities outside the metro system like real estate activities related to administration of residential buildings and shopping centers in areas near metro stations. The comparative data of the two mentioned variables can be seen in Table 2.

City - Operator	**Region**	**Recovery Ratio**	**Percentage of revenues not related to transport**
New York City Subway	North America	50,3%	7,3%
Washington Metro	North America	36,5%	5,0%
Montreal Metro	North America	64,0%	6,0%
San Francisco BART	North America	67,0%	9,9%
Average metros selected North America		**54,5%**	**7,1%**
London Underground	Europe	100,6%	16,0%
Metro de Madrid	Europe	73,9%	6,2%
Berlin U-Bahn	Europe	57,6%	12,9%
Metro de Milan	Europe	91,9%	8,6%
Metro de Valencia	Europe	52,5%	4,2%
Average metros selected Europe		**75,3%**	**9,6%**
Hong Kong MTR	Asia	183,8%	29,3%
Singapore MRT	Asia	128,1%	26,8%
Delhi Metro	Asia	149,7%	7,7%
Taipei Metro	Asia	118,5%	16,1%
Average metros selected Asia		**145,0%**	**17,9%**
Mexico City Metro	Latin America	41,7%	4,6%
Metro Sao Paulo	Latin America	102,7%	11,5%
Metro de Santiago	Latin America	103,3%	19,8%
Metro Rio	Latin America	170,9%	8,1%
Metro de Medellín	Latin America	153,1%	5,4%
Average metros selected Latin America		**114,3%**	**9,9%**

Table 2: Recovery ratio and Percentage of revenues not related to transport

It is notable that in terms of the recovery ratio, very few operations in Europe and North America manage to cover all their costs with operating income, while in the case of the metro systems in Asia and Latin America, several of them exceed the recovery ratio of 100%. In fact, when evaluating all the systems in Latin America and Europe, there are 5 metro systems that are financially self-sustainable and a similar number that approach recovery ratios equal to or greater than 100% in Latin America, whereas in Europe there is only one metro with a ratio of recovery greater than 100%. By comparing averages of the recovery ratio for the metro systems selected, it is observed that Asia has a recovery ratio of 145% and Latin America 114.3%, while Europe has 75.3% and North America 54.5%.

A similar situation occurs with incomes that does not come from transport activities, and looking to the average of the metros selected, it is noticeable that the Asian metro systems lead in obtaining this type of non-tariff income with a 17,9% average of in revenues not related to transport, followed by the metro systems of Latin America (9.9%) and Europe (9.6%), and at a greater distance those of North America (7.1%).

Considering the two variables, it can be concluded that in Asia and Latin America there is a strong effort to obtain financial sustainability, while in North America and Europe there is no high interest in achieving it. This goes hand in hand with the social perspective existing in most European countries, where transport systems are a service and a fundamental citizens' right.

3.3 Greenfield projects, degrees of freedom and technical experience

As mentioned above, there are brownfield-type metro projects that are extensions of previous projects (such as a new metro line in an existing system or the extension of a line) and greenfield-type projects where there are no pre-existing metro lines in the same city or even in many cases, within the same country. Greenfield projects have advantages and disadvantages. One of the advantages is the possibility of working with a greater degree of freedom, since there are no conditions for following the standards of previous or existing metro lines that force the use of technical specifications such as platform size, voltage levels, train width, among others; which for the project developer and the builders is favorable since it allows greater freedom for the designs and construction. In contrast, the biggest disadvantage of a greenfield project is that there is no prior technical experience; therefore, there are no local engineers knowledgeable about these systems and acquiring that experience has considerable costs.

In Latin America, with the exception of Brazil, which has several metro systems and extensive metro construction experience, for the rest of the countries the metro systems development processes have fallen into the typology of greenfield projects, and for their developers this has demanded strong learning and costs associated with this need to learn and to acquire urban rail technology. Statistics show that in eight Latin American countries there is only one city that has a metro system: Argentina, Colombia, Chile, Ecuador, Panama, Peru, Puerto Rico and the Dominican Republic (Clemente, 2013). In other words, for those eight countries, the metro systems have been greenfield projects. And even more, given the low regional integration of Latin America, the developments of new metro systems in other countries of this region will also fall into the greenfield typology, unlike Europe or North America where there is high regional integration and railway experts can relocate labor very easily from one country to another.

3.4 Public Operation and Public-Private Participations

Several studies confirm that unlike in Europe, Asia and North America, where Public-Private Partnerships (PPP) are frequently used in the operations of metro systems, in Latin America PPPs have not been used frequently, or instead, these concessional models are fairly recent or appear as a result of a continuity crisis due to poor performance (Leipziger and Lefevre, no date; Schwartz, Corbacho and Funke, 2008; Chang, 2013; Carpintero and Helby Petersen, 2014; Gago De Santos, 2014; World Bank, 2014).

In Latin America, there are currently PPPs in Brazil in the cities of São Paulo and Rio de Janeiro; Argentina in the city of Buenos Aires (Rebelo, 2006), and Lima in Peru (Ositran, 2017), all these PPPs have appropriate financial and operational results for cities and their users, according to the sources cited above. But besides these mentioned cases, in the rest of the 22 metro systems in the region, the operation by themselves is imposed at the level of public sector equity companies. Furthermore, in the case of Rio de Janeiro and Buenos Aires, these concessions are from recent times and in the case of São Paulo, they only correspond to one line of the entire system. This shows that despite PPP models attempts have been introduced in the region, they still do not have strong acceptance by local or national governments that are the owners of the metro systems.

4. CONCLUSIONS

The comparisons that have been presented allow us to find some particular characteristics of the metro systems in Latin America in terms of high levels of passenger demand, a permanent concern for the financial sustainability of metro operations, the preeminence of greenfield type projects in the region and, finally the little acceptance that PPPs have had in the region's metro systems.

Understanding the particularities of the metro systems in the region and making good use of this information will be very useful for transport planners, development bank executives, railway constructors, metro operators and finally for politicians and policy makers in general, who will be able to better adapt their vision on how metro lines are developed and built in Latin America.

GENERAL GUIDELINES FOR THE DESIGN OF BRT ROUTES IN THE PUBLIC TRANSPORT INTEGRATED SYSTEM OF BOGOTÁ

John Moreno Triviño
Universidad Nacional de Colombia
William Castro García
Universidad Nacional de Colombia

ABSTRACT

The objective was to establish general guidelines for the design of the BRT route network in Bogotá's Public Transport Integrated System – SITP – in terms of geographical layouts, stop points, and frequencies. The demand for the morning rush hour in a typical business day before COVID-19 was contemplated.

The research methodology had three phases. 1) Establish several sets of preliminary guidelines for route network design in the Bogotá BRT System – TransMilenio –. 2) Development of a methodology – based on a transport model implemented in PTV-Visum – to assess different routes scenarios designed following those sets of preliminary guidelines. 3) Application of this assessment methodology to quantify the impact of each set of preliminary guidelines for route network design, thus choosing the best alternatives.

The outputs can be divided into two categories. 1) Heuristic processes for the systematic design of routes in the BRT system. 2) Selected guidelines for the design of route network in TransMilenio. This report will be focused on the second category of outputs. Among the conclusions, the BRT services in Bogotá should be designed with a multi-criteria approach, which implies a relatively complex route network. A very simplified route network has proven to be inconvenient. On the other hand, in the short term, it is recommended to maintain diametrical routes to avoid the collapse of central stations due to increased transfers. However, in the medium term, the paradigm must evolve to radial routes design. This approach would make it possible to significantly reduce the minimum required fleet, improving headways, increasing comfort within buses, and/or reducing investment in rolling stock. Furthermore, it has been shown that the radial routes approach would require four new central interchange stations in Bogotá.

1. INTRODUCTION

Bogotá's BRT - TransMilenio - constitutes the backbone of mobility in the city (TransMilenio, 2019). Beyond its qualities or problems, the sustainability of this transport system is essential to guarantee the correct development of urban activities on a day-to-day basis. This sustainability is the result of a combination of many factors related to various areas of knowledge, and among them, transportation planning is one of the branches that can contribute the most to the success of a transit system.

1.1 Background

The design of the route network in transit systems, as part of the transportation planning process, is a problem whose solution can significantly affect some aspects of the service (Ceder, 2001). In this way, the research problem to be solved was the determination of guidelines for route network design in BRT systems, specifically for TransMilenio in Bogotá.

The main objective of the research was "To establish general guidelines for the design of the BRT route network in the Integrated Public Transport System -SITP- of Bogotá, at least in terms of geographical layouts, stop points, and frequencies." Its importance lies in the fact that it is necessary to seek innovative solutions that optimize, even more, the use of available resources to improve the service level offered to the user. This becomes even more relevant considering that, before the COVID-19 pandemic, TransMilenio supported over 45,000 passengers per hour in a single direction (TransMilenio, 2020), and therefore, historically high levels of overcrowding have been notorious.

1.2 State of the art

As defined in the main objective, this research has covered three aspects of the route network design in a BRT system: the design of geographical layouts, the choice of stop points, and the assignment of frequencies. Thus, in this review, literature has been grouped according to its relevance in each of these three items.

According to Kepaptsoglou and Karlaftis (2009), the literature on geographical layouts for route network design can be classified into three levels:

- Design objectives: maximization of the benefit to the user (Lee and Vuchic, 2005; Zhao and Zeng, 2006); minimization of operating cost (Ceder and Israeli, 1997); maximization of total well-being (Fan and Machemehl, 2006); maximization of transport capacity (Morlok and Viton, 1984); energy conservation / environmental protection (Delle and Filippi, 2001).
- Operational parameters: priority decision variables (Van Nes, 2003); network structure (Chang and Schonfeld, 1993); demand patterns and characteristics (Zhao and Zeng, 2007; Tom and Mohan, 2003; Chakroborty and Dwivedi, 2002).
- Methodology used: conventional methods vs. heuristic methods.

As regards methodologies, it is worth digging a little deeper. Conventional methods (Morlok and Viton, 1984; Van Nes et al., 1988; Delle and Filippi, 2001; Chang and Schonfeld, 1993; Van Nes, 2003) include analytical methods and those that involve some type of mathematical programming. However, due to their high complexity and combinatorial and multi-objective nature, these methods are only suitable for problems where it is necessary to generate general policies but not complete detailed designs. In general, they are only theoretical interests, according to Kepaptsoglou and Karlaftis (2009).

Thus, the heuristic approach becomes the dominant methodology for dealing with real-life problems using reasonable computational power. There are at least two heuristic paths to be followed. The main of these, and that has been adopted in this research, consists of the following steps:

- Previous processes for consolidating demand data, road network information, and setting restrictions.
- Generation of a set of candidate routes through heuristic processes based on algorithms. (Lee and Vuchic, 2005; Ceder and Israeli, 1997; Tom and Mohan, 2003; Chakroborty and Dwivedi, 2002).
- Configuration of routes through processes in which frequencies are iteratively determined and demand is assigned, the best routes are selected according to previously defined indicators, these selected routes are improved, and the iterative cycle is resumed. (Zhao and Zeng, 2007; Fan and Machemehl, 2006; Cipriani et al., 2005).
- Final selection of the optimal set of routes and their associated frequencies.

The other possible path starts with the direct construction of the set of routes through a heuristic process that considers operational restrictions and that can be based on geographical considerations, and travel demand flows (Carrese and Gori, 2002). It can also be based on "ant colony algorithms" (Hu et al., 2005; Yu and Yang, 2006; Yang et al., 2007).

Turning to the literature on the choice of stop points, a problem that has received a little more attention than geographic layouts design, it is possible to cite studies based on mathematical optimization models on the design of express services in corridors with capacity restrictions (Leiva et al., 2010; Larraín et al., 2010; Larraín and Muñoz, 2019). Likewise, also notable publications are Scorcia (2010), with a work of design and evaluation of BRT express services in Chicago. Hart (2016) with a methodology to evaluate the potential of express services in corridors where regular services also operate. Ghaderi et al. (2017), which method focused on reducing users’ travel times through the spatial analysis of the stop points and their locations. Luo et al. (2017) with a heuristic for the design of express services at rush hour with a fixed-size fleet; and (García and Jaramillo, 2019) where it has been sought to maximize the users' comfort within buses through an improvement of express services.

Regarding the literature on the assignment of frequencies to services, Campos (2016) proposes a "Lego" type heuristic that would allow obtaining a reasonable frequency assignment for the BRT system in Bogotá. Meanwhile, Peña et al. (2016) present a mathematical model adapted to TransMilenio's case to optimize its operation by adjusting frequencies and variations in the scheduled departure times for the different routes. Additionally, a heuristic methodology based on an evolutionary algorithm to simultaneously undertake the design of routes and the assignment of their frequencies is developed by Martínez et al. (2017), with a case of theoretical application to various BRT systems in Colombia.

Finally, two books have been vital to the development of this research. One of these books (Ceder, 2007) constitutes a whole compendium that anyone designing and operating public transport systems should review. The other reference text (Norambuena, 2002) has as its main objective the formulation of a heuristic that allows obtaining an efficient route structure for a public transport system, with application case for transit corridors in Santiago, Chile.

From the above, it has been possible to conclude that although there is a certain amount of literature that addresses the route network design problem from a theoretical perspective, it is not so common to find studies applied to real-life transport systems, particularly regarding the sup-topic of geographical layouts. It is even less frequent to find works that covers simultaneously all the relevant sub-topics – geographical layouts, stop points and frequencies – related to route design in BRT systems. Thus, the present research aims to fill this gap, offering comprehensive guidelines for route network design in BRT systems, with an application case focused on TransMilenio.

2. METHODOLOGY

The methodology implemented was of the hypothetical-deductive type, as shown in the diagram in Figure 1:

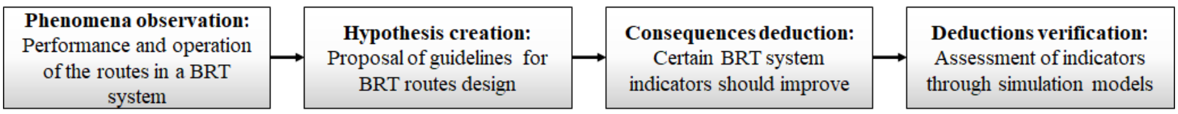

Figure 1: Hypothetical-deductive scheme of the research.

2.1 Experimental design

The phases of the research methodology are shown in Figure 2. In its first phase, the research had a qualitative design. Through a review of the existing literature, international study cases, and interviews with experts in the area, several candidate sets of guidelines for route network design were established. This process will not be covered in this document, but it can be consulted here (Moreno, Unpublished results).

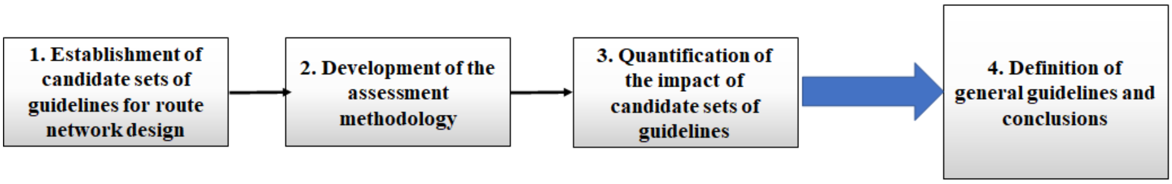

Figure 2: Phases of the research methodology.

Once the candidate sets were established, a quantitative approach was adopted: the impact of the various sets of proposed guidelines was quantified numerically to select the best solution alternatives to the research problem. All this through experimentation with a PTV-Visum simulation model.

2.1.1 Population and sample

The object of the study is to create design guidelines for Bogotá's BRT route network and their impact. However, as these guidelines have an intrinsically abstract nature, it is necessary to generate a transport model that simulates the behaviour of different variables that adequately describe the system's performance. Regarding the population and sample data for this transport model, the demand of internal trips in the BRT system has been considered:

- Population: trips, or trip segments, of the morning rush hour on Bogotá's BRT, establishing their origin and destination as stations in the system.
- Sample: a statistically representative collection of trips belonging to the previously defined population and presented in the form of a travel matrix.

The 2019 Bogotá Mobility Survey (SDM, 2020), the input and output records from the stations' turnstiles (TransMilenio, 2020), the seed matrix – calibrated to 2019 – of internal trips of the BRT system, and the study with the evasion baseline in TransMilenio (UNAL, 2019) have been used for the elaboration of the travel matrix.

The aforementioned data sources have been combined to generate a travel matrix updated to February 2020 – before the pandemic – by implementing a generation and attraction sub-model, and a distribution sub-model by Fratar. The final matrix estimated for the morning peak hour - 06:15 to 07:15 - contains 265,000 internal trips - for Bogotá's BRT. Additional details on the construction of the travel matrix can be found in (Moreno, Unpublished results).

2.1.2 Operational variables and objective function

These are the operational variables defined to characterize the transport model:

- t_{wait}: first boarding wait time (min)
- t_{travel}: onboard travel time (min)
- t_{trans}: transfer time (min)

- $\boldsymbol{N_{seats}}$: total number of seats (size of the minimum required fleet – bus seats)

The access time has not been considered since it has been assumed that users are already inside the stations in the internal transport model. The user fare cost has not been taken into account either because there is a flat fee to access any of the stations in Bogotá's BRT. Thus, the total fare does not depend on the number of transfers within the BRT system, or the distance travelled: it is the same for every individual in the BRT system.

Based on the first 3 operational variables, the objective function that allowed the assessment of the candidate sets of guidelines has been defined as the sum of perceived travel times for **n** trips:

$$F_U = a_{wait} \sum_{i=0}^{n} t_{wait} + a_{travel} \sum_{i=0}^{n} t_{travel} + \sum_{i=0}^{n} t_{trans} \quad (1)$$

For the first two time-weighting coefficients, these values were used (Ortuza and Willumsen, 2001):

$$a_{wait} = 2 \quad (2)$$

$$a_{travel} = 1 \quad (3)$$

Meanwhile, the transfer time was broken down into three components, as allowed by PTV-Visum:

$$t_{trans} = a_{walk\ trans} * t_{walk\ trans} + a_{wait\ trans} * t_{wait\ trans} + P_{trans} * N_{trans} \quad (4)$$

where:

- $\boldsymbol{t_{walk\ trans}}$: walking time during transfers (min)
- $\boldsymbol{t_{wait\ trans}}$: waiting time during transfers (min)
- $\boldsymbol{P_{trans}}$: penalty for each transfer (min)
- $\boldsymbol{N_{trans}}$: total number of transfers (dimensionless)

For the coefficient of walking time during transfers, again a classic value suggested by the literature is taken (Ortuza and Willumsen, 2001):

$$\boldsymbol{a_{walk\ trans} = 2} \quad (5)$$

On the other hand, for the two remaining coefficients, three simulation cases were defined:

- Low penalty transfers:

$$a_{wait\ trans} = 2 \cap P_{trans} = 2{,}5_{min/trans} \tag{6}$$

- Medium penalty transfers:

$$a_{wait\ trans} = 3 \cap P_{trans} = 5_{min/trans} \tag{7}$$

- High penalty transfers:

$$a_{wait\ trans} = 4 \cap P_{trans} = 7{,}5_{min/trans} \tag{8}$$

Additionally, for the assessment of the various scenarios, the minimum fleet required was also taken into account, estimated as the total number of seats:

$$N_{seats} = N_{f\ dual} * 80 + N_{f\ art} * 160 + N_{f\ biart} * 240 \tag{9}$$

where:

- $\boldsymbol{N_{f\ dual}}$ corresponds to the required number of 80-seats dual buses.
- $\boldsymbol{N_{f\ art}}$ corresponds to the required number of 160-seats articulated buses.
- $\boldsymbol{N_{f\ biart}}$ corresponds to the required number of 240-seats bi-articulated buses.

2.2 Assessment methodology

From the elaboration of state of the art, four groups of guidelines were defined. Namely:

- Simple design: this group of guidelines refers to the design of the route network must be as simple as possible.
- Multi-criteria design: this group of guidelines seeks that the route network design adopts multiple strategies and criteria that are necessary to optimize transport operation, even if this implies generating a complex route network.
- Radial design: this group of guidelines refers to the geometry of the routes layouts. Specifically, it is suggested that the routes should start from trip-generating areas, travel to a trip-attracting zone in the downtown, and then return to the initial point of origin.
- Diametrical design: in this case, it is suggested that the routes should start from a trip generating area and make their tour to another trip generating area, at the opposite side of the city, passing through the downtown.

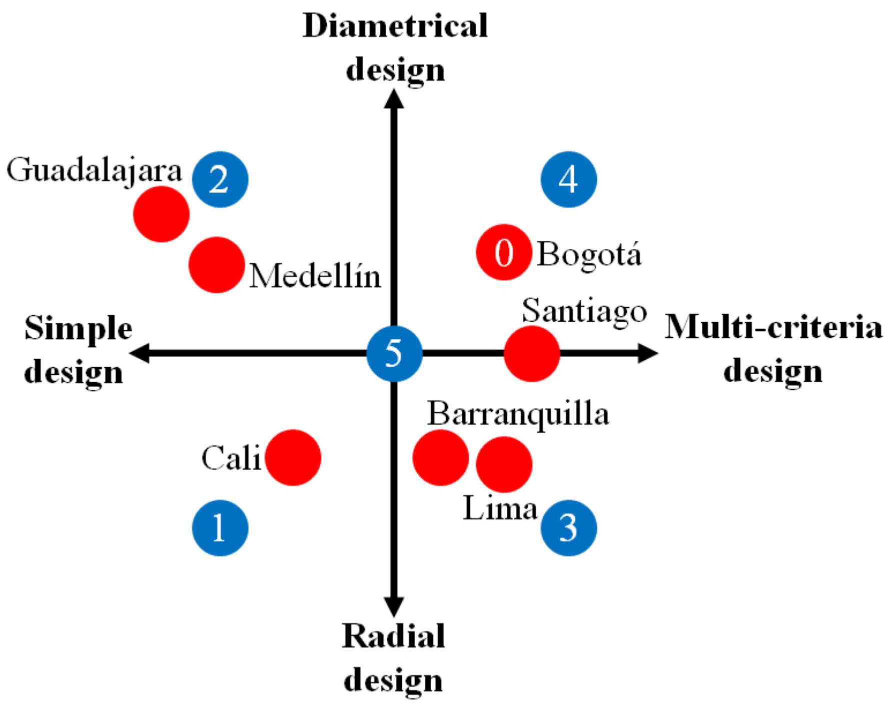

Figure 3: Cartesian plane of candidate sets of guidelines for route network design.

Combining these guidelines groups, as shown in Figure 3, five candidate sets of guidelines were obtained for the route network design. From each of these candidate sets, a route network scenario was generated by implementing a heuristic process. A route network scenario 0 (zero) was added, containing the actual services – February 2020 – of Bogotá's BRT. Therefore, it was possible to compare the solution given by the current route network vs. the solutions given by the new candidate sets of guidelines. The following are the route network scenarios generated:

- Scenario 0: 2020 route network.
- Scenario 1: radial routes with a simple design approach.
- Scenario 2: diametrical routes with a simple design approach.
- Scenario 3: radial routes with a multi-criteria design approach.
- Scenario 4: diametrical routes with a multi-criteria design approach.
- Scenario 5: routes based on different guidelines sets (radial + diametrical + multi-criteria design approach).

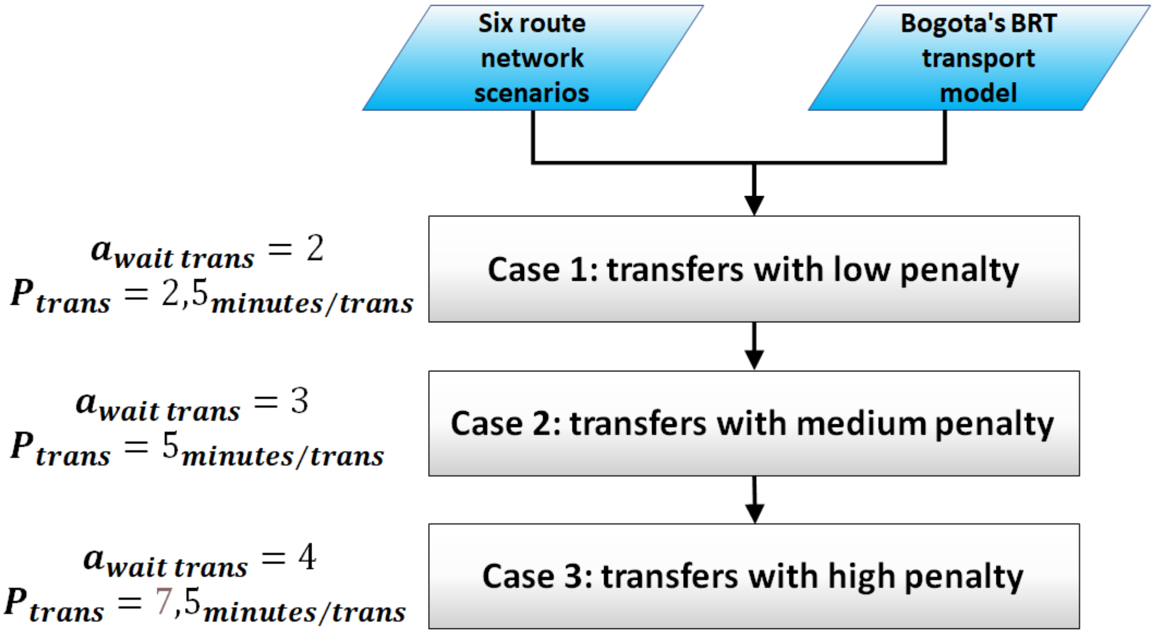

Figure 4: Structure of simulation cases.

Details of the heuristic processes developed for the generation of the route network for each candidate set of guidelines will not be covered in this document. They are widely explained in the thesis book generated for this research (Moreno, Unpublished results). Meanwhile, Figure 4 illustrates the simulation cases that were run to assess the different route network scenarios.

3. RESULTS

Table 1 summarizes the route network scenarios that were generated. In this table, the corresponding roundtrip services are counted as a single route. The total number of routes per scenario corresponds to the sum of its number of radial and diametrical routes.

Esc.	Geographical Guidelines	Design Approach	# Radial Routes	# Diametrical Routes	# Regular Routes	# Express Routes	# Super Express Routes	# Partial Routes
0	Actual	Actual	27	38	9	50	6	8
1	Radial	Simple	46	0	9	37	0	0
2	Diametrical	Simple	5	20	6	19	0	0
3	Radial	Multi-criteria	85	0	9	54	22	14
4	Diametrical	Multi-criteria	9	45	6	32	16	10
5	Rad/Diam.	Multi-criteria	34	32	6	40	20	11

Table 1: Synthesis of the six simulated route network scenarios.

Furthermore, Table 2 shows the results obtained for the six route network scenarios in each of the three simulation cases.

Scenario		Typology (Seats/Bus)			Fleet Size		F_U = Travel Time (min)		% Trips by required transfers

3	**5**	304	614	1128	2046	393280	50,9	42,7	28,0%	59,3%	12,4%	0,3%

Table 2: Quantified results of the simulation cases per scenario.

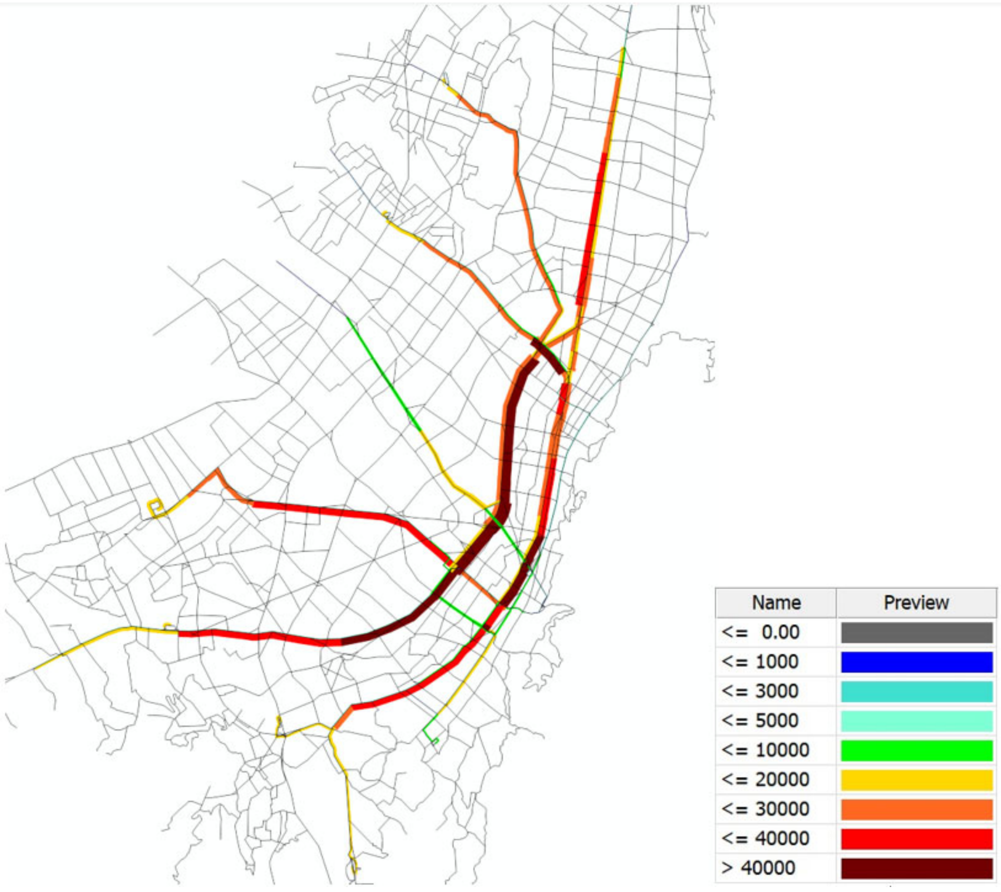

Figure 5: Passenger volume per arc in Case 2, Scenario 0 - Route network 2020 -.

Meanwhile, Figure 5 shows an example of the result of a trip assignment process. This example corresponds to Case 2: medium transfer penalty – Scenario 0: 2020 route network. In the whole exercise, a total of 18 trip-assignment processes were executed: 3 simulation cases x 6 route network scenarios.

4. DISCUSSION

Figures 6 and 7 show the results related to the average perceived travel time ($\boldsymbol{F_U}$) and the total number of seats ($\boldsymbol{N_{seats}}$). The figures compare the data obtained for the real route network (in gray tones), route networks with simple design (green tones), and route networks with multi-criteria design (in golden tones). These tones get darker as the transfers are penalized more in the transport model.

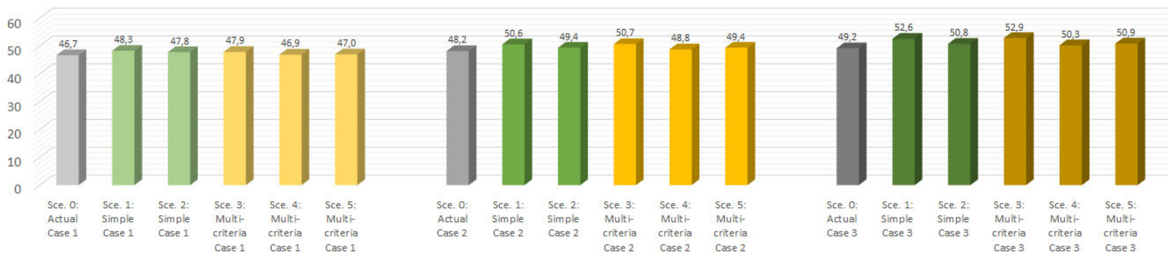

Figure 6: Average perceived travel times – F_U – per case and scenario (min).

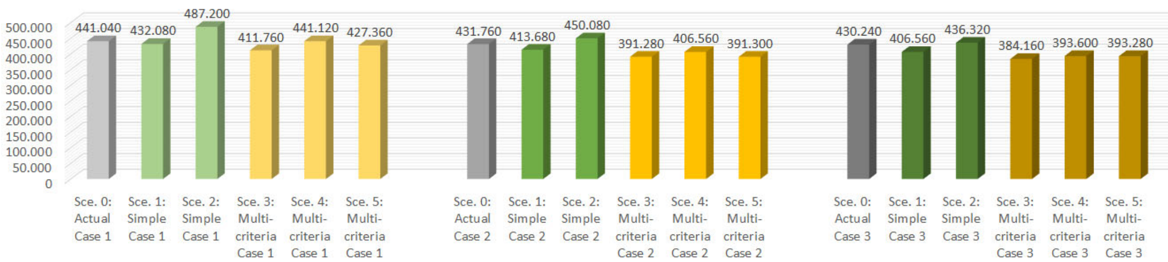

Figure 7: Minimum Required Fleet – N_{seats} – per case and scenario (seats).

At this point, it is convenient to explain that the reason why three simulation cases with different transfer penalties - low, medium, and high - have been defined is that the weighting of the transfer time from the users point of view depends, to a great extent measure, of the installed infrastructure: it is not the same to make a transfer within a comfortable station, with shops and restaurants, than to do it in a station in the most dangerous zone of the city, without a roof that covers the head and under unfavourable weather conditions. Thus, the proposed scheme of the three simulation cases allows to analyse the results for different infrastructure situations.

4.1 Simple design vs. multi-criteria design

There is no appreciable difference between route networks designed with a simple approach and those designed with a multi-criteria approach in terms of perceived travel times.

The difference is only 1.0% on average in favour of the multi-criteria approach, which is negligible.

On the side of the minimum required fleet, the differences are noticeable. It is noteworthy that route networks designed with a multi-criteria approach require fewer seats than the real route network (-7.4% on average) and fewer seats than route networks with a simple design approach (-8.2% on average). In terms of investment or user comfort level, this savings in required fleet is highly important.

The percentages provided in this comparison exercise correspond to the average of all simulation cases - low, medium, and high penalty for transfers - assessing the modelled indicators of real routes, simple approach, or multi-criteria approach scenarios, grouped according to their type.

4.2 Radial design vs. diametrical design

From the previous discussion, it is possible to conclude that the multi-criteria design approach is desirable over the simple design approach. Therefore, the performance of radial routes vs. diametrical routes will be compared, considering only the multi-criteria route network scenarios 3 and 4. The visualization of the modelled indicators from real route network is maintained, to have an additional point of comparison.

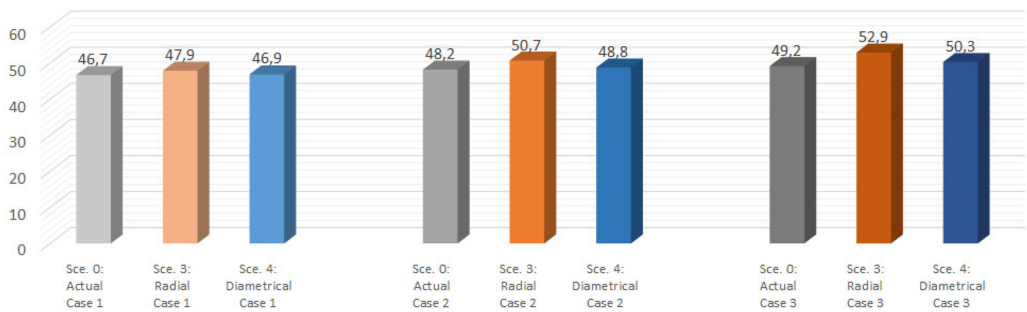

Figure 8: Average perceived travel times – F_U – per case and scenario (min).

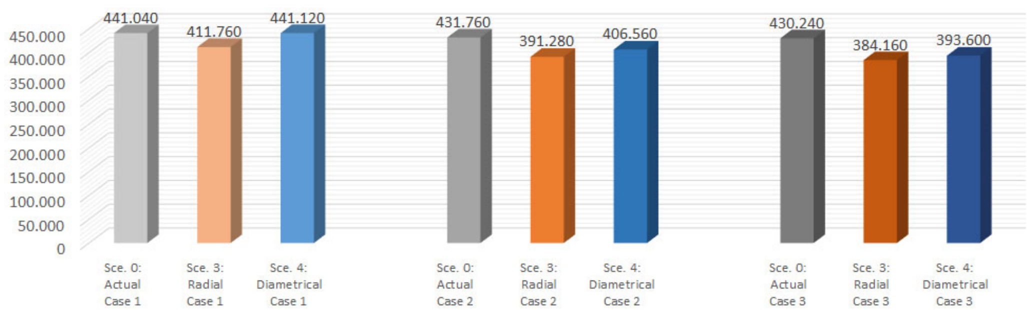

Figure 9: Minimum Required Fleet – N_{seats} – per case and scenario (Seats).

Figures 8 and 9 show the results for scenarios 0, 3, and 4, related to the average perceived travel time ($\boldsymbol{F}_{\boldsymbol{U}}$) and the total number of seats ($\boldsymbol{N_{seats}}$). Note that real routes scenarios are kept in gray tones, while the radial routes scenarios are shown in orange tones, and the diametrical routes scenarios are depicted in blue tones. Again, these tones get darker as transfers are more penalized.

Regarding perceived travel times, the route network with radial multi-criteria design has perceived travel times 5.2% greater than those of the real route network, on average. While the increase is 3.8%, on average, when compared to the route network with diametrical multi-criteria design. This is undoubtedly a product of the increase in the number of required transfers in a radial route scheme, in which a significant number of people are expected to make additional transfers at central interchange stations. Nevertheless, if the general results in Table 2 are considered, and if the net travel times are compared (net travel times without time weighting coefficients), the differences between the three assessed scenarios are reduced to the order of 1,0%. In other words, radial routes implementation does not significantly impact the net travel times, but it does on the times perceived by the user.

On the side of the minimum required fleet, the radial route network offers a savings of 8.9% in the number of seats concerning the real route network and 4.4% of savings compared to the network of diametrical routes. Again, this is highly significant in terms of investments in rolling stock, as fewer buses are required to meet demand; or in terms of user comfort, as it would be possible to schedule services with higher frequencies.

5. GUIDELINES FOR ROUTES DESIGN IN TRANSMILENIO

The foregoing discussion leads to the conclusion that the most recommended approach is to implement routes with radial and multi-criteria design guidelines: scenario 3. To give an explicit answer to the research question, the specific guidelines - radial and multi-criteria - that were applied to the design of the selected scenario are listed below:

- Geographical layouts:
    - Taking into account the current infrastructure of TransMilenio, today's day it is recommended to maintain a route network in which the diametrical design predominates. This is because the current infrastructure would not support the higher number of transfers at the central stations in the case of implementing radial routes, there is not enough space.
    - In the short term, a broader implementation of partial routes – routes starting and ending at intermediate stations, other than main portals – is recommended.

  - In the medium term, Bogotá's BRT system should migrate towards a radial route network that allows reducing the minimum required fleet to serve demand. This will require the construction of central interchange stations.

- Stop points:

  - In the medium term, central interchange stations must be implemented in certain geographical locations identified in this research. These stations must have capacity enough to serve passengers who make a transfer and allow buses operational return, in the case of implementing radial routes. Figure 10, on the next page, shows the identified places for this central stations and their passengers demand.
  - In the short term, it is recommended to expand the implementation of super-express services, both from main portals and from the intermediate stations with the highest demand.
  - In the short term, it is suggested to implement routes with asymmetric stop points for each direction, according to actual passenger flows.
  - In the short term, it would be convenient to test routes whose stops points are assigned to serve specific destination areas in the central corridors.

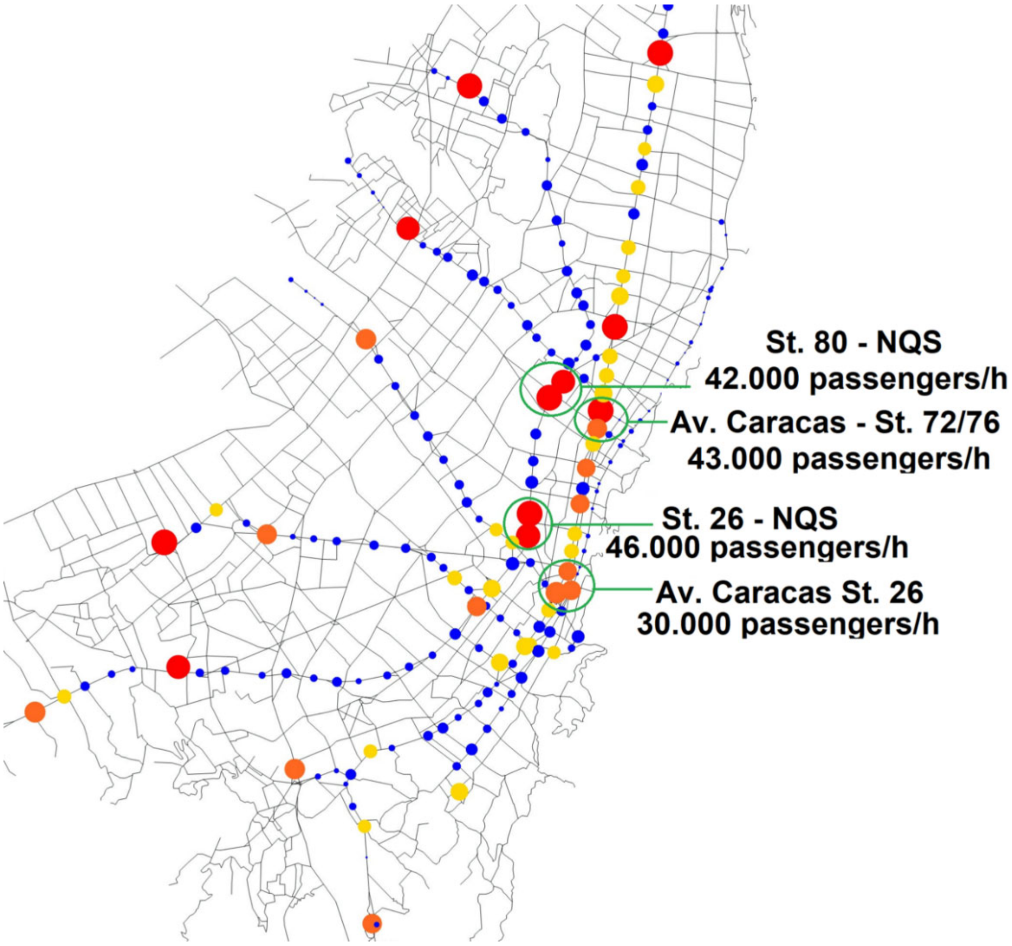

Figure 10: Location and stopping passengers of proposed central interchange stations.

- Frequencies:
    - It is not recommended to implement a route network that is too simple in Bogotá's BRT, since this would imply too short step intervals for the services, with its consequent effects on convoys formation and long lines of buses waiting at the stations. Scheduled intervals shorter than two minutes may be not suitable for actual operation.
    - The implementation of route networks designed with multi-criteria guidelines is recommended, so that the scheduled intervals are within reasonable limits – 2 to 7,5 minutes – for the rush hour operation of a BRT system such as TransMilenio. See Figure 11 at the end of the next page.

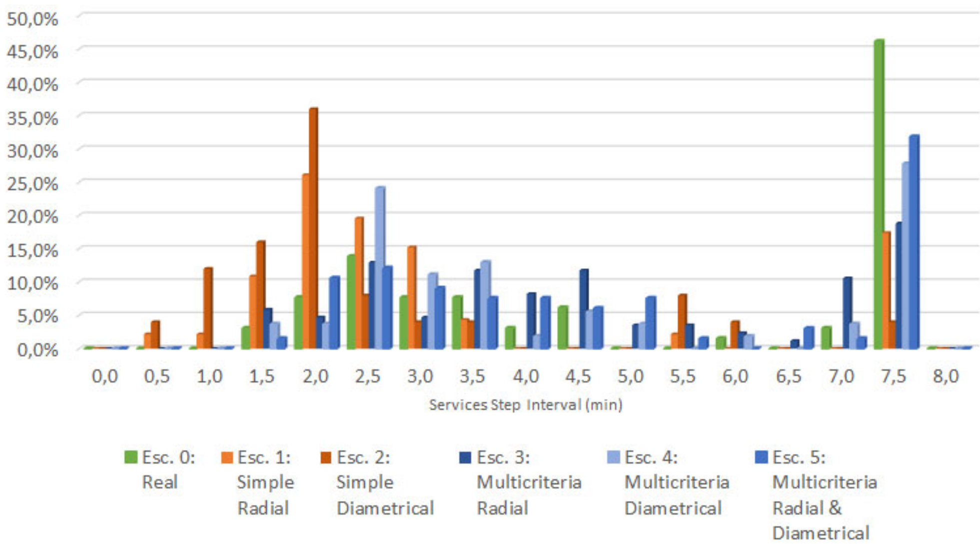

Figure 11: Percentual distribution of services scheduled intervals per scenario.

Finally, and as a reference, Figure 12 shows the route network scenario 3, which would be the most recommended: radial routes plus a multi-criteria design approach.

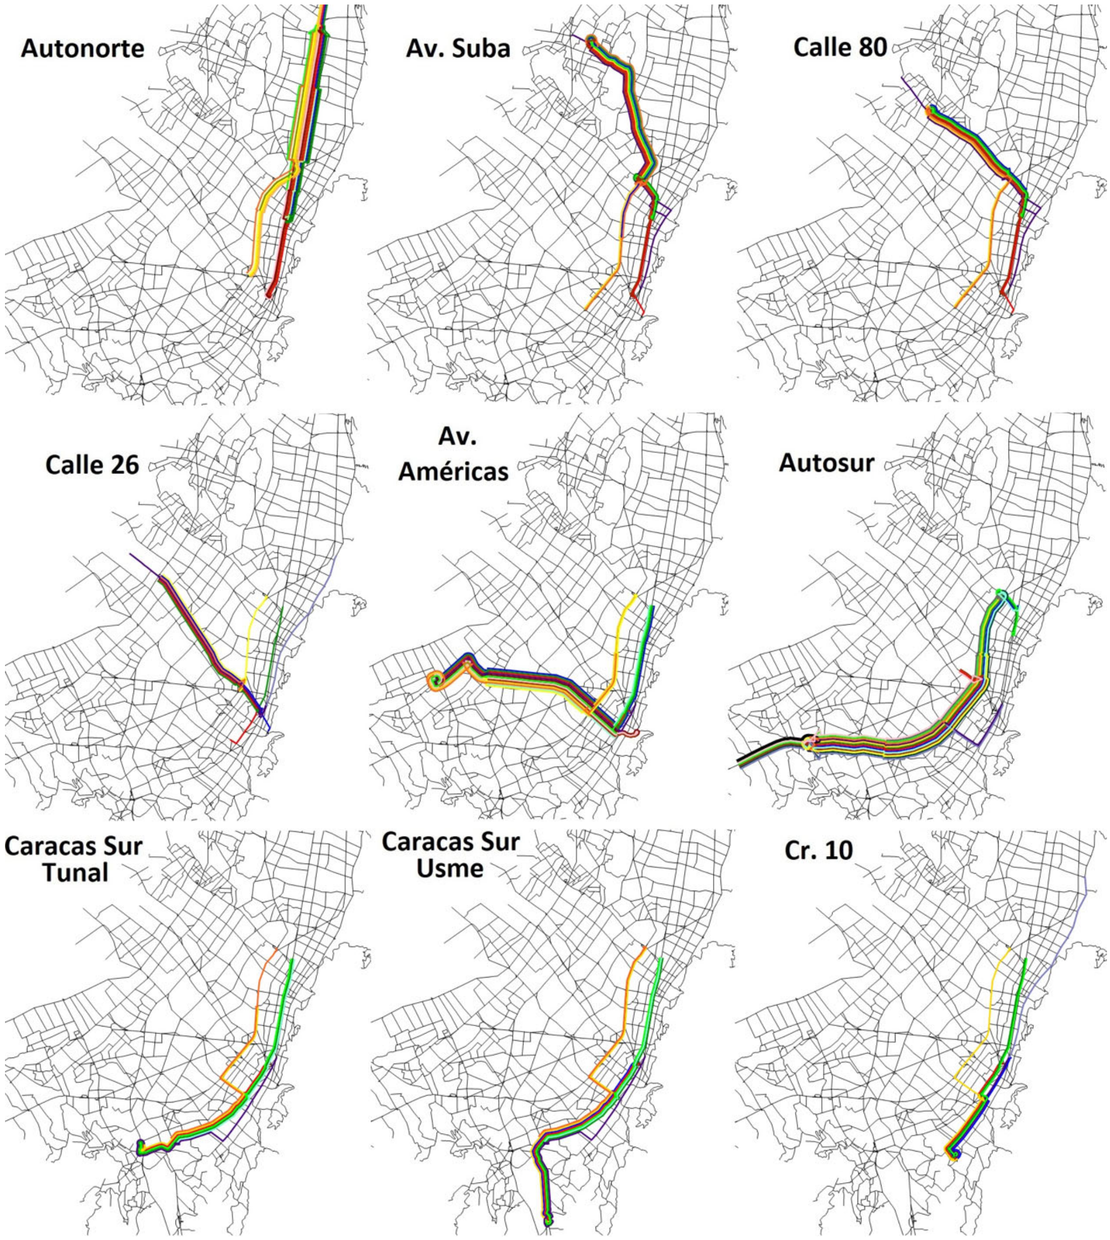

Figure 12: Scenario 3: radial route network with multi-criteria design approach.

6. CONCLUSIONS

Regarding the average perceived travel times, it has been shown that the multi-criteria design approach does not present significant advantages over the simple design approach. However, if the minimum required fleet is considered, the difference is more noticeable, with the multi-criteria approach achieving valuable seats savings. Compared to the scenario of the real route network of Bogotá's BRT, the multi-criteria approach results in slightly higher average perceived travel times. However, in terms of the average net travel times (without time weighting coefficients) the difference is negligible. As for the required fleet, the multi-criteria approach would allow, according to the simulations, significant savings in the number of seats compared to the real routes.

On the side of the comparison between multi-criteria radial routes vs. multi-criteria diametrical routes, the latter provide a slight improvement in average perceived travel times compared to their radial equivalents. However, the real route network would have slightly shorter perceived travel times than those on the multi-criteria diametrical route network. In any case, if the average net travel times are compared, again the difference between the real, radial multi-criteria, and diametrical multi-criteria route network scenarios is negligible. In addition, if the minimum required fleet is considered, the radial routes with a multi-criteria approach offer seats savings of 8.9% with respect to TransMilenio real routes, and 4.4% compared to the scenario of diametrical multi-criteria routes.

Considering the above, the main conclusion is that the scenario of radial multi-criteria routes would offer the best response to TransMilenio's needs. However, today's day it would not be possible to implement these radial routes without first building four central interchange stations that allow handling the higher flows of transferring passengers and returning buses in the expanded centre of the city.

6.1 Scope, limitations, and next steps

With respect to the research scope, these results are valid for Bogotá's BRT and its passengers demand before the pandemic. However, the developed methodology can be reproduced in any other BRT system around the world and can be scaled to cover the entire transportation system of Bogotá metropolitan area.

Among research limitations and next steps is the fact that possibly, once the pandemic ends, it will be necessary to re-evaluate the route network scenarios according to the new passenger demand after COVID-19. In addition, given that research results have been obtained through transport model simulations, these results are subject to the possible deviations of a model that merely emulates the real world. Thus, a real-life pilot in some BRT corridor would be convenient. It is also necessary to say that the transport model developed does not consider micro-simulation details of a traffic model, which development would be too helpful to assess the impact on BRT traffic due to the proposed guidelines.

AKNOWLEDGEMENTS

Special thanks to the Department of Civil Engineering of the National University of Colombia, for their support in this work. Likewise, to the consulting company GSD Plus for providing the modeling software licenses, and to Lisa Losada – PhD Candidate at Purdue University – for her review and comments on this paper.

ADAPTACIÓN DE SERVICIOS DE MOVILIDAD AL NUEVO ESCENARIO DE LA COVID-19: LA EXPERIENCIA DEL GRUPO ALSA CON EL PROGRAMA "ALSA MOVILIDAD SEGURA"

Alberto Cillero Hernández
Director Estudios y Licitaciones, ALSA, España
Paula Bouzada Outeda
Subdirectora de Estudios y Licitaciones, ALSA, España

RESUMEN

Uno de los retos más importantes para administraciones y operadores de transporte público de viajeros está siendo abordar los efectos de la Covid-19 y adaptar la oferta de servicios y su financiación a una realidad de movilidad muy distinta a la conocida hasta 2019.

Las expectativas de los viajeros han cambiado y los transportes colectivos están muy penalizados frente al coche privado por la percepción del viaje seguro.

En 2020 el Grupo ALSA desarrolló el programa “Alsa Movilidad Segura”, diseñado e implementado en plena pandemia. Este programa ha ido más allá de cumplir normas y recomendaciones sanitarias, y se orienta a ofrecer una experiencia de viaje segura, para los clientes y los empleados. El programa es objeto de mejora continua, con iniciativas que se van incorporando semana a semana a partir de los insights de clientes y el benchmarking de otros modos y sectores.

“Alsa Movilidad Segura” tiene como objetivo convertir el autobús en un espacio seguro para viajar, mitigar los riesgos derivados de la Covid-19 y ofrecer las máximas garantías y confianza a los clientes en todos los servicios.

La recuperación de la movilidad del transporte público va a ser un proceso lento y progresivo en el tiempo. Con umbrales de mercado inciertos y que dependerán de factores exógenos a los propios operadores y a las administraciones, como pueden ser la recuperación económica y del turismo, la consolidación del teletrabajo a medio y largo plazo, el comercio on-line, la enseñanza a distancia, etc.

La experiencia del programa “Alsa Movilidad Segura” nos está permitiendo identificar cambios en las percepciones y hábitos de viaje de nuestros clientes, y en base a estos insights adaptar en lo posible nuestra oferta de servicios de movilidad.

1. SITUACIÓN DE PARTIDA Y CONTEXTO DEL PROYECTO

ALSA es la mayor empresa operadora de servicios de transporte público de viajeros en España. En 2019, año inmediatamente anterior a la pandemia, transportó 393 M de viajeros/año, con 15.487 empleados, 4.446 vehículos y una facturación de 941 M€.

La compañía está presente en todo el territorio nacional, gestionando más de 150 contratos de servicios públicos de movilidad. Además, ALSA aborda un importante proceso de internacionalización, con presencia consolidada (entre otros países) en mercados de Marruecos, Suiza, Portugal, Francia y Puerto Rico.

Al igual que otros operadores de movilidad, esta compañía se vio impactada súbitamente desde marzo de 2020 por el impacto de la Covid-19. La afección ha sido gravísima (cierre 2020) con una caída del -62% en la demanda de las líneas interurbanas de la compañía y más de 100 M€ de pérdidas en el ejercicio. Los siguientes datos publicados por el Instituto Nacional de Estadística (INE) evidencian la gravedad de las caídas de movilidad interior en el transporte público, afectando a todos los modos y segmentos de viajes. Es especialmente significativa la caída de los viajes interurbanos (y la movilidad no obligada en general).

	Viajeros transportados (miles)	% de variación Año 2020
TOTAL	2.691.617	-46,7
Transporte urbano	1.680.181	-45,8
Metro	672.741	-47,3
Autobús	1.007.440	-44,8
Transporte interurbano	754.786	-46,9
Autobús	397.327	-45,5
Cercanías	288.675	-44,9
Media distancia	102.616	-46,0
Larga distancia	6.036	-61,4
Ferrocarril	334.896	-47,4
Cercanías	308.328	-45,8
Media distancia	14.748	-55,6
Larga distancia	11.888	-65,6
AVE	7.603	-66,0
Resto Larga Distancia	4.285	-64,8
Aéreo (interior)	16.910	-60,5
Peninsular	5.507	-67,7
Peninsular-Resto territorio	8.360	-58,5
Interinsular	3.043	-46,1
Marítimo (cabotaje)	5.611	-52,1
Transporte especial y discrecional	256.649	-51,6
Especial	204.053	-35,8
Discrecional	52.596	-75,2

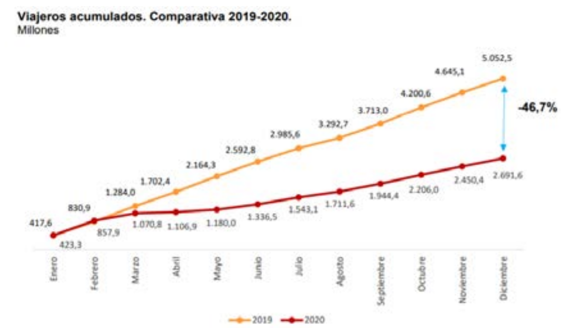

Figura 1: Datos de evolución de la demanda de los transportes públicos en España, cierre 2020 (INE).

El impacto negativo continúa 2021. Es previsible que la incidencia perdure todavía muchos meses y los umbrales de recuperación efectiva a conseguir son todavía muy inciertos.

Es significativo que la Covid-19 está afectando muy distinto a los transportes públicos y al vehículo privado. Los estudios e indicadores de movilidad publicados durante la pandemia, en muchos casos basados en técnicas de big-data con telefonía móvil (MITMA, INE Experimental, Ayuntamientos), coinciden en señalar que la movilidad general se recupera a tasas comparativamente más altas que la recuperación de los transportes colectivos (autobús, tren, metro). Esto evidencia un desajuste a la baja en la cuota de mercado del transporte público, que de continuar en el corto y medio plazo puede poner en riesgo los objetivos globales de sostenibilidad y minoración de emisiones.

Subyace un problema de falta de confianza de los usuarios hacia los transportes colectivos, lo cual ha podido constatar el Grupo ALSA en las investigaciones de mercado realizadas en el marco del programa “Alsa Movilidad Segura”.

2. OBJETIVOS Y METODOLOGÍA DE TRABAJO

El objetivo principal de este programa es convertir el autobús en un espacio seguro para viajar, mitigando los riesgos derivados de la Covid-19 y ofreciendo las máximas garantías y confianza a los clientes y empleados en todos los servicios.

Para el diseño e implementación de “Alsa Movilidad Segura”, especialmente en los primeros meses de la pandemia, el Grupo ALSA siguió las normas y recomendaciones de las autoridades sanitarias, laborales y de transporte, así como buenas prácticas observadas en otros sectores a través de la realización de un benchmarking nacional e internacional.

Una característica diferencial de “Alsa Movilidad Segura” ha sido ir más allá de estas normas y recomendaciones. Una vez cumplidas éstas, a modo de mínimos, la prioridad es ir más allá y definir una experiencia de viaje nueva, basada en el viaje seguro y confiable.

Sobre esta premisa, el programa “Alsa Movilidad Segura” se diseñó a partir del Pasillo del Cliente de ALSA (customer journey), herramienta desarrollada e implantada desde hace años en la compañía y que tiene en cuenta todos los momentos de interacción con los clientes (antes, durante y una vez finalizado el viaje). Con la intención de transformar y mejorar el Pasillo del Cliente al nuevo contexto de la Covid-19. Ofreciendo para ello garantías y compromisos de viaje seguro en todas las fases del servicio, y sobre la base del conocimiento del cliente de que dispone la compañía (insights de encuestas y otras técnicas de investigación de mercados) en las fases del Pasillo.

El Pasillo del Cliente es una representación de las fases por las que atraviesa un cliente en su proceso de concienciación, información, elección, compra, uso y valoración de cualquier bien o servicio. Es una herramienta que racionaliza el proceso mental subjetivo de las personas a la hora de consumir, identificando sus preferencias y necesidades, y detectando los puntos más importantes en el proceso, sobre los que actuar para conseguir una mejora efectiva en las ratios de compra y satisfacción con el consumo realizado.

La siguiente imagen representa el Pasillo del Cliente de ALSA para servicios interurbanos. La compañía aplica además esta metodología para servicios urbanos y metropolitanos. Su desarrollo es fruto de un importante esfuerzo de estudio y conocimiento de clientes, a través de encuestas (presenciales y on-line), dinámicas de grupo, literales de clientes (sugerencias, reclamaciones) y auditorías visión cliente. El Grupo ALSA trabaja con métricas e indicadores de calidad percibida, siendo los principales el "Customer Satisfaction Index" (ISC), "Net Promoter Score" (NPS), "Value for Money" (VFM") y "Net Emotional Value" (NEV).

Figura 2: Pasillo del Cliente del Grupo Alsa (servicios interurbanos).

El programa "Alsa Movilidad Segura" partió del Pasillo del Cliente, y sobre esta base se trabajan (mejora continua) iniciativas para mejorar la percepción del viaje seguro en todas las fases, siempre desde la perspectiva del viajero: información y venta, tránsito en estaciones y dársenas, embarque en el vehículo, cartelería y señalética, ventilación interior, limpieza y desinfección, medidas de protección de empleados, por citar las más significativas.

El programa se diseñó y comenzó a implantarse a través de 15 áreas de trabajo, que resumimos a continuación y que actualmente siguen vigentes:

Alsa Movilidad Segura		
Nuevos estándares de servicio	Protocolos y procedimientos	Equipos de Protección
Adecuación de flota	Adecuación de instalaciones	Servicios a bordo y estaciones
Canales de compra	Información a los clientes	Comunicación y marketing
Limpieza y desinfección	Formación y concienciación	Comunicación con Reguladores
Garantías de ejecución efectiva	Certificación y homologación	Insights de los clientes

Figura 3: Áreas de trabajo del programa "Alsa Movilidad Segura".

Para su desarrollo se ha creado un equipo de trabajo transversal, que afecta a todos los departamentos de la compañía, empleando metodologías colaborativas de design thinking y co-creación. En el proyecto están implicadas más de cien personas de forma directa, en el diseño e implantación de las medidas, a los que se añade la totalidad del personal operativo (incluyendo más de 5.000 conductores y personas con trato directo al cliente) en su aplicación final al servicio. El proyecto se ha llevado a cabo gracias al alineamiento de toda la compañía, siendo una iniciativa liderada por la alta dirección de ALSA (CEO, DG España y Direcciones de Negocio) desde sus inicios. La coordinación del programa se asume desde la dirección de Estudios y Licitaciones de ALSA, en la que se integran las áreas funcionales de insights de clientes, experiencia de viaje y mejora de servicios. Este planteamiento asegura la orientación del programa a la satisfacción de necesidades de los viajeros y a la mejora continua de la oferta de servicios.

Las metodologías aplicadas de design thinking y trabajo colaborativo permiten que, una vez identificada una posible mejora o actuación en cada área, el equipo responsable la evalúa y prioriza, poniendo en marcha su implantación en el menor tiempo posible.

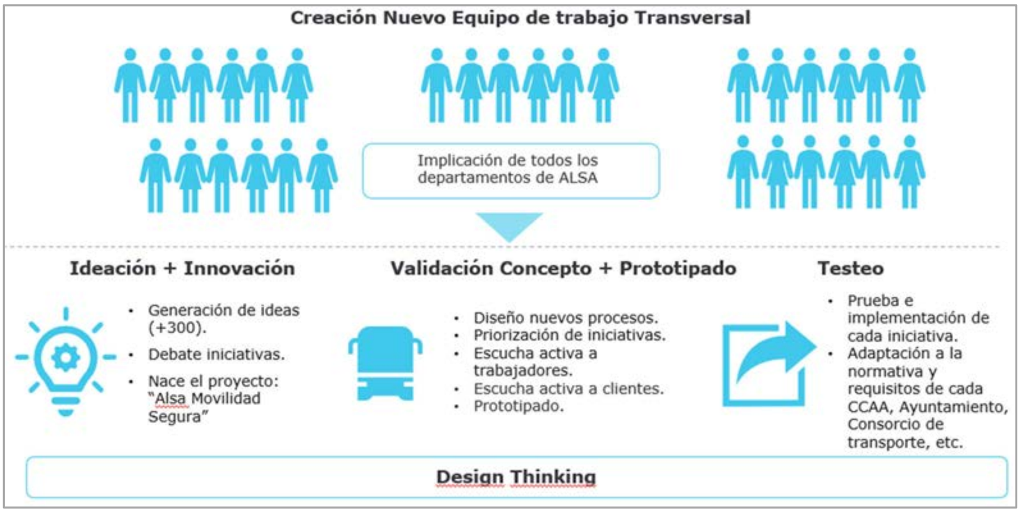

Figura 4: Proceso de diseño y validación de las mejoras.

3. DESARROLLO DEL PROYECTO

El programa "Alsa Movilidad Segura" se traduce en la definición de cinco estándares específicos, para cada una de las tipologías de servicios de la compañía: "urbano-metropolitano", "regional", "larga distancia", "discrecional" y "turísticos". Estos estándares son normas de aplicación obligada y están implantados ya al 100%.

Hasta la fecha se han introducido más de cien iniciativas de mejora a lo largo del Pasillo del Cliente, relacionadas todas ellas con el viaje seguro (mejora de la seguridad de clientes y empleados) y afectando no sólo a la operativa si no, también, a la información y comunicación de los servicios.

A continuación, se muestra el desglose de las 114 iniciativas implantadas en el marco del programa a fecha de elaboración de esta ponencia. Para su comprensión, se presentan diferenciadas para cada una de las fases del Pasillo del Cliente ("decisión y compra", "gestión previa", "estación/parada", el "viaje" y el "post-viaje"); y en función de la dimensión afectada por la iniciativa ("comunicación", "clientes", "empleados", "procesos").

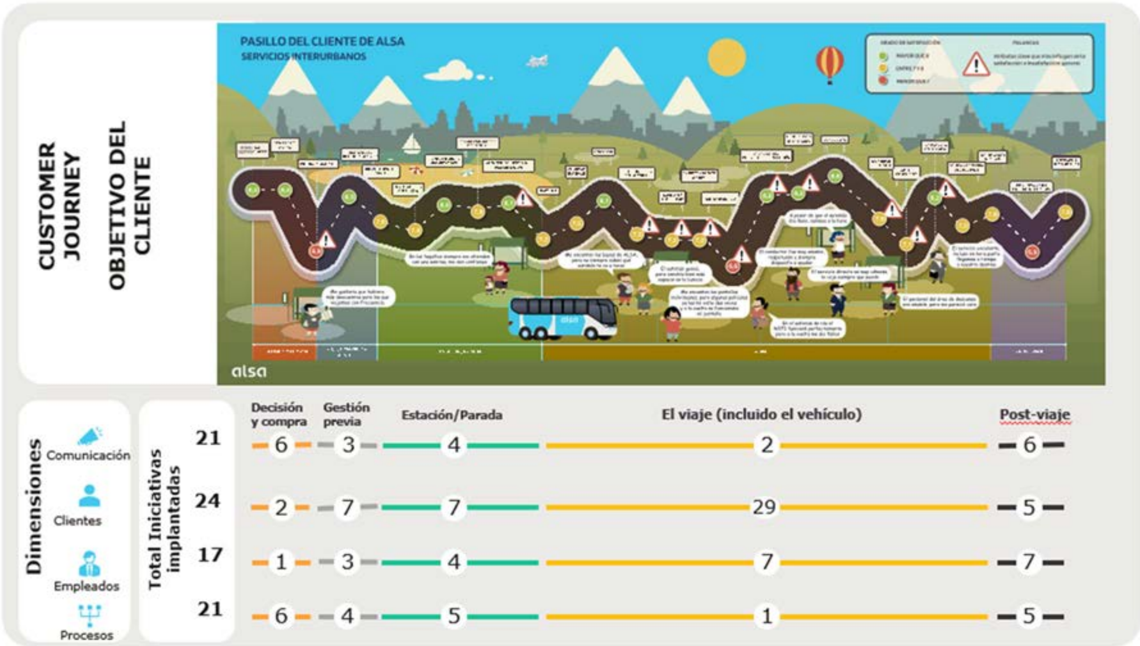

Figura 5: Desglose de las iniciativas implantadas en el programa "Alsa Movilidad Segura", alineadas con el Pasillo del Cliente.

Además, cada iniciativa se extiende a toda la compañía, incluyendo (hasta la fecha) la realización de acciones de formación para 7.380 empleados, la dotación de equipos de protección y mejora para 5.427 conductores, dotación de elementos de mejora en 2.981 vehículos, actuaciones en web y apps, y mejoras en todas las estaciones y puntos de parada.

Una característica determinante del programa es su mejora continua e iterativa, basada en la interacción con clientes y en los insights que se van identificando a nivel diario y semanal con técnicas de investigación de mercados.

Una vez implantada la primera fase del programa (ideación, definición de estándares y protocolos, acopios de elementos, primeras implantaciones, formaciones a empleados), se diseñó un modelo de mejora continua del mismo, basado en:

- el feedback de clientes (encuestas, literales)
- la realización de auditorías visión cliente (para evaluar la implantación de las mejoras a todos los niveles y en todos los ámbitos geográficos);
- benchmarking permanente de nuevas medidas implantadas en otros sectores y países; y
- análisis de nueva normativa y estándares internacionales.

Resumimos a continuación las magnitudes de los insights que hemos recogido en el programa "Alsa Movilidad Segura" en su primer año de implantación, que dan idea de la magnitud y complejidad del proyecto y de su fundamentación en la opinión de los clientes.

Figura 6: Principales insights de clientes utilizados como fuente de información para la mejora continua del programa “Alsa Movilidad segura” (marzo 2020 - abril 2021).

Sobre esta importante base de conocimiento, actualizada a nivel diario y semanal (encuestación post-viaje diaria), se trabaja de manera continua, adaptativa e iterativa para cumplir y superar unos estándares siempre cambiantes, y satisfacer así las expectativas de movilidad segura en el contexto de pandemia.

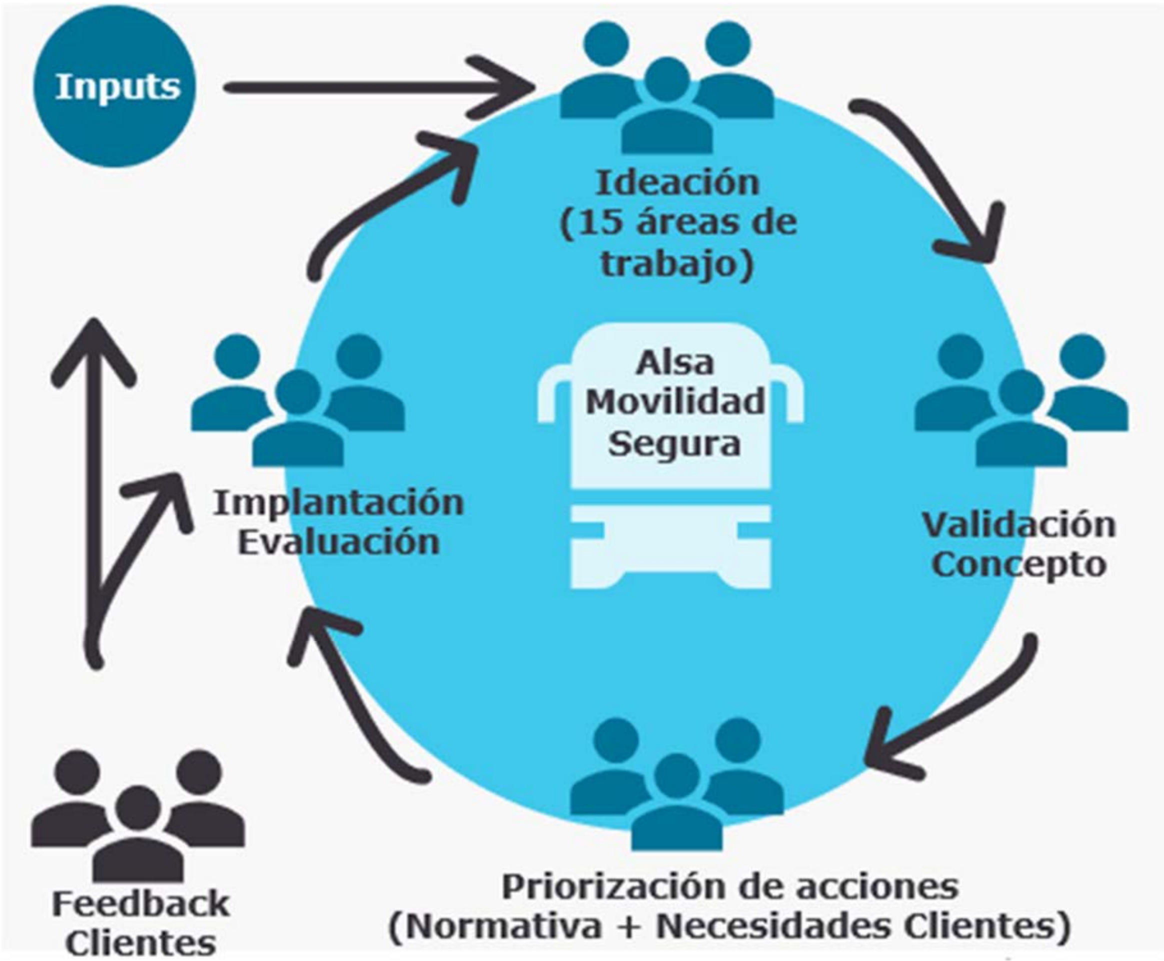

Figura 7: Proceso de mejora continua y adaptación de los estándares de servicio.

4. INICIATIVAS IMPLANTADAS

Detallamos a continuación algunos ejemplos de mejoras implantadas en el marco del programa “Alsa Movilidad Segura”, para ofrecer una experiencia de viaje con las mayores garantías de seguridad.

Fase previa al viaje:

- Información al cliente. Se ha implementado una nueva landing en la web www.alsa.es con recomendaciones para los viajeros, incluyendo además información sobre todas las medidas implantadas por la compañía para garantizar el viaje seguro.
- Mapa interactivo en la web sobre restricciones COVID a nivel nacional, en todas las CCAA y provincias.
- Nuevo formato de los títulos de transporte incluyendo con información sobre normas y recomendaciones a la hora de viajar.
- Se ha potenciado la compra por canales digitales.
- Se han flexibilizado las condiciones de cambios y anulaciones de billetes.
- Numerosas mejoras en la información en estaciones y paradas.
- Se han implementado nuevos protocolos de embarque, minimizando además el pago en efectivo a bordo.

Figura 8: Ejemplo de nueva landing “Alsa Movilidad Segura” con toda la información sobre las medidas implantadas y las recomendaciones de viaje.

Durante el viaje:

- Nuevo protocolo de ventilación interior que, junto con los sistemas de climatización y aire acondicionado de última generación de los vehículos, permite garantizar la máxima renovación de aire interior, forzando su renovación con aire exterior.
- Realización de estudios técnicos y mediciones de calidad del aire interior en los (interurbanos, metropolitanos y urbanos), empleando técnicas de sensorización monitorización on-line. Cada 2-3 minutos se renueva completamente el aire del habitáculo de pasajeros con aire procedente del exterior.
- Purificadores de aire y filtros de carbón bioactivo. Se han instalado purificadores de aire y filtros de carbón bioactivo que eliminan el 99% de partículas y destruyen contaminantes biológicos como bacterias y virus.
- Nuevo sistema de desinfección. Se ha desarrollado junto con BIOW un nuevo sistema de desinfección complementaria del aire interior, que cuenta con un filtro azul antibacteriano, un filtro "Hepa", un filtro de carbón activado, doble luz UV antibacteriano y un ionizador de plasma.
- Lámparas de luz ultravioleta en WC. En los servicios de largo recorrido se han instalado lámparas de luz ultravioleta "tipo C" para la desinfección automática de los WC después de cada uso. Así se consigue llegar a todos los rincones del habitáculo, destruyendo los virus y bacterias en cuestión de minutos
- Dispensadores de gel hidroalcohólico. Numerosos servicios cuentan con dispensadores de gel hidroalcohólico en accesos para su uso por los viajeros.
- Retirada de alfombras. Se han retirado las alfombras de los vehículos para facilitar las labores de limpieza y desinfección
- Entrega de toallitas o kits higiénicos. En servicios de largo recorrido se entregan toallitas o kits higiénicos a los pasajeros.
- Cartelería y elementos multimedia. Todos los vehículos cuentan con cartelería y elementos multimedia con las normas y recomendaciones de viaje
- Limpieza y desinfección. Se han reforzado las medidas de desinfección en los autobuses. Mediante un estricto protocolo, complementado con técnicas novedosas como la micropulverización, se garantiza una limpieza y desinfección profunda de los vehículos con periodicidad mínima diaria. Se presta especial atención a los elementos de mayor contacto como: pulsadores de acceso, asideros, pasamanos, reposabrazos, respaldo y cabecero de las butacas, bandejas individuales, WC, etc.

Figura 9: Ejemplos de cartelería y elementos informativos implantados en el programa “Alsa Movilidad Segura”.

5. RESULTADOS QUE ESTAMOS OBSERVANDO

El programa tuvo una implantación muy rápida, en su primera fase, que permitió llegar a tiempo a la compañía para el levantamiento del primer estado de alarma (junio 2020), con un producto mínimo viable que progresivamente está siendo objeto de mejoras. Gracias al arranque rápido, ALSA fue la primera compañía del sector de la movilidad en España en obtener el Certificado de Buenas Prácticas contra la Covid-19 de AENOR (Asociación Española de Normalización y Certificación). Esta acreditación conlleva además una auditoría periódica, lo que garantiza la implantación efectiva de las medidas. Además, también ha obtenido el sello “Safe Tourism” del ICT (Instituto de Calidad Turística).

Figura 10: Sellos y estándares obtenidos por “Alsa Movilidad Segura”.

El reto principal del programa, como se comentó, persigue recuperar la confianza del cliente en el transporte público, y en concreto en el modo autobús, a la hora de viajar. Para tener indicadores continuos de la percepción del viajero, ALSA ha adaptado las metodologías de insights de clientes a este nuevo contexto, implementando varias mejoras en sus procesos de investigación de mercado:

- Introducción de una nueva pregunta específica en la encuesta post-viaje, relativa a valoración de medidas de “Alsa Movilidad Segura” (escala de 0 a 10) y percepción general de la seguridad del viaje. Ofreciendo además a los viajeros la posibilidad de que responder mejoras o sugerencias de tipo cualitativo si lo desean.
- Lanzamiento de encuestas específicas de caracterización del perfil de cliente, necesidades de viaje y hábitos de movilidad a corto-medio plazo. Desarrolladas en diferentes momentos temporales durante la pandemia, y permitiendo observar una evolución en el comportamiento del cliente.
- Nuevo reporte de indicadores diarios de satisfacción, incluyendo conclusiones de indicadores relativos del programa “Alsa Movilidad Segura”, facilitando el acceso rápido a la información (decalaje de 3-5 días entre las fechas de encuesta y de remisión del dato) y agilizando la toma de decisiones derivada.
- Auditorías visión – cliente para verificar el cumplimiento efectivo de todas las mejoras implantadas.
- Numerosas acciones de concienciación y formación de la plantilla, basadas en la opinión del cliente y las mejoras de servicio implementadas.

Los resultados de este proceso de aprendizaje y mejora continua, que toma como base la opinión de los clientes y los propios empleados que tienen contacto directo con el servicio, están siendo muy positivos y permiten extraer conclusiones claras sobre los efectos de la pandemia sobre la movilidad y las necesidades de mejora en el corto y medio plazo.

A modo de ejemplo, el siguiente gráfico resume las mejoras solicitadas por clientes que hacen uso de los servicios (encuesta post-viaje diaria a viajeros de líneas regulares interurbanas). Se observa claramente la importancia que tienen, en el momento actual, las medidas que aseguren una mayor distancia entre viajeros a bordo y las limitaciones en la capacidad de plazas ofertadas en vehículos.

Ambas medidas tienen una traslación directa e implicaciones sobre el coste de funcionamiento de los transportes públicos, y su puesta en marcha trasciende del ámbito de decisión de los operadores al afectar el equilibrio económico de los contratos. Podemos concluir no sólo que la demanda del transporte público se ha contraído en su vertiente cuantitativa, sino que además los clientes que necesitan estos servicios tienen prioridades y consideraciones nuevas a la hora de elegir el modo con el que viajar.

Las variables cualitativas del viaje, perceptuales y emocionales, son determinantes en el contexto actual, y deben ser tenidas en consideración por las administraciones reguladoras y las empresas prestadoras de los servicios de movilidad.

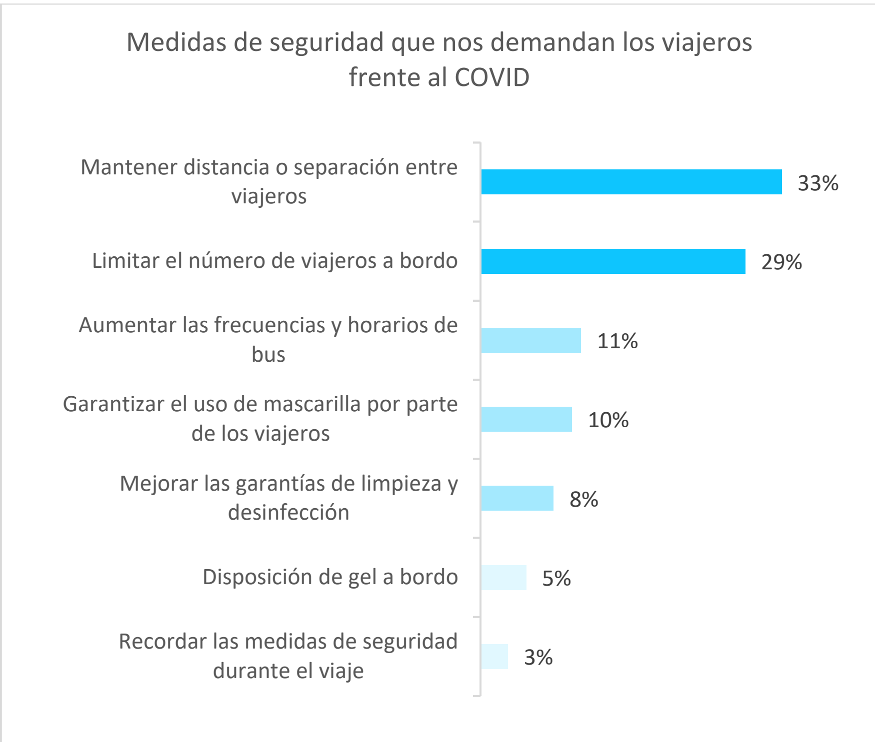

Figura 11: Medidas de seguridad que demandan los viajeros frente a la Covid-19 (resumen de respuestas de clientes de ALSA en la encuesta post-viaje diaria realizada en trayectos interurbanos 2020-2021).

6. CONCLUSIONES

La evolución de la pandemia ha constatado el valor estratégico del programa "Alsa Movilidad Segura", gracias al cual la compañía está consiguiendo recuperar progresivamente la confianza de los clientes en el transporte público, en los contratos de servicios de movilidad que gestiona a nivel nacional.

La iniciativa se desarrolla en un entorno de gran complejidad por las restricciones en los servicios públicos de movilidad y la reducción de oferta de servicios (cierres perimetrales, prohibición de la movilidad interurbana) que penalizan en gran medida la calidad percibida.

Gracias a este programa, ALSA ha implementado una propuesta nueva de valor de los servicios, basada en el viaje seguro y con garantías en todas las etapas del Pasillo del Cliente. El impacto de la pandemia continúa y va a perdurar muchos meses. "Alsa Movilidad Segura" es un programa vivo, que evoluciona implantando acciones nuevas basadas siempre en la opinión de clientes y empleados.

El programa se ha considerado un referente en el sector, y ha tenido múltiples reconocimientos de nuestros reguladores (incluyendo el Ministerio de Transportes, Movilidad y Agenda Urbana). En 2020 ALSA obtuvo el Sello BCX 2020 a "Mejor empresa de transporte de España".

Se han introducido nuevas métricas de valoración de medidas frente a la Covid-19, con seguimiento diario.

"Alsa Movilidad Segura" está permitiendo recuperar progresivamente los indicadores de satisfacción (ISC, NPS, VFM, NEV). Los ratios actuales son todavía inferiores a los registrados antes de la pandemia, si bien la calidad percibida está mejorando desde el peor momento vivido en el otoño de 2020 tras la proclamación del segundo estado de alarma.

RESUMEN

En nivel de seguridad de los vehículos se ha incrementado significativamente en los últimos años gracias al desarrollo e implementación de sistemas electrónicos que suplen o complementan al conductor. Sistemas cómo el ABS (antibloqueo de ruedas durante la frenada), el ESP (control de estabilidad) o AYC (control de la guiñada) monitorizan la respuesta dinámica para predecir y actuar en situaciones de riesgo.

Una de las herramientas utilizadas por estos sistemas para monitorizar la respuesta dinámica es lo que se conoce como regiones de estabilidad, también denominadas regiones r–β (velocidad de guiñada-deriva del vehículo). Estas regiones permiten definir los límites de estabilidad de los vehículos.

El trabajo propuesto plantea utilizar esas regiones en la fase de diseño, buscando como objetivo su maximización. Son varios los elementos constructivos de un vehículo que tienen influencia en estas regiones, como puede ser el sistema de suspensión (muelles, amortiguadores...), los neumáticos o el sistema de dirección. En este trabajo, se analiza la influencia de los elementos elásticos del sistema de suspensión, definiendo la configuración óptima para un vehículo y condición operativa concreta. Para ello, se utiliza un modelo completo del vehículo implementado en un software de simulación multicuerpo (MSC Adams/View®) y se aplican diferentes técnicas de optimización.

1. INTRODUCCIÓN

Cuando un vehículo se pone en movimiento y circula está sometido a la interacción con el entorno, la vía, otros vehículos, etc, se genera una “demanda” de seguridad activa. Esa demanda, condicionada por las acciones del conductor, deberá ser inferior a los límites para que la circulación vial sea segura para todos los usuarios.

Estos límites son función de las condiciones de la carretera (el pavimento, agentes externos como una mancha de aceite o la meteorología), del neumático (desgaste, temperatura, etc), del tipo de conducción que se lleve a cabo, del estado del vehículo, entre otros (Luque y Mántaras, 2007), Figura 1.

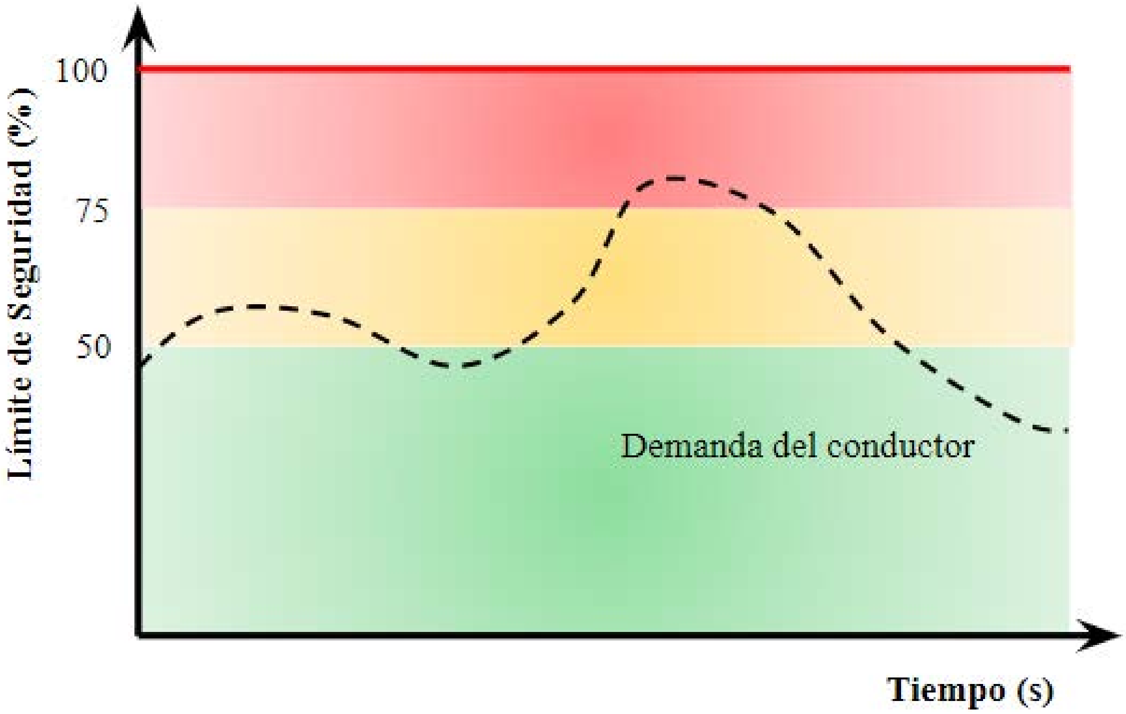

Figura 1: Evolución de la demande de seguridad en conducción y representación de los márgenes de seguridad disponibles en cada instante de tiempo.

De todos los factores que tienen influencia en la seguridad en carretera, uno de los más importantes es el vehículo y su comportamiento dinámico.

Entre los diferentes sistemas que componen un vehículo, los sistemas de suspensión y de dirección (Allonca, 2019) son la base de la respuesta dinámica del vehículo, por lo que su diseño, desde el punto de vista de la seguridad, es clave para mejorarla.

En un sistema de suspensión, son muchos los componentes que se pueden modificar para conseguir variar el comportamiento del vehículo, desde amortiguadores, muelles o silentbloks, hasta la geometría de la suspensión o los neumáticos.

En este artículo se analizará, desde el punto de vista de la seguridad, la influencia de las rigideces de los muelles de suspensión del vehículo (delanteros/traseros) y el coeficiente de amortiguamiento de los amortiguadores (delanteros/traseros), en función de variables operativas como la velocidad y la carga.

Para ello, se analizarán variables de estado como las aceleraciones longitudinal y lateral, la velocidad lateral, los ángulos de deriva, o las velocidades de cambio de los mismos y, en base a las líneas de trabajo abiertas junto al funcionamiento de los sistemas de control de vehículos, se utilizará un métrico objetivo que permite conocer el nivel de seguridad disponible (Alonso, 2019) a partir de las denominas Regiones de Estabilidad (Bobier, 2012; Beal, 2013; Bobier y Gerdes, 2013; Erlien, 2015) obtenidas a partir de los parámetros r-β (yaw rate-slip angle), Figura 2.

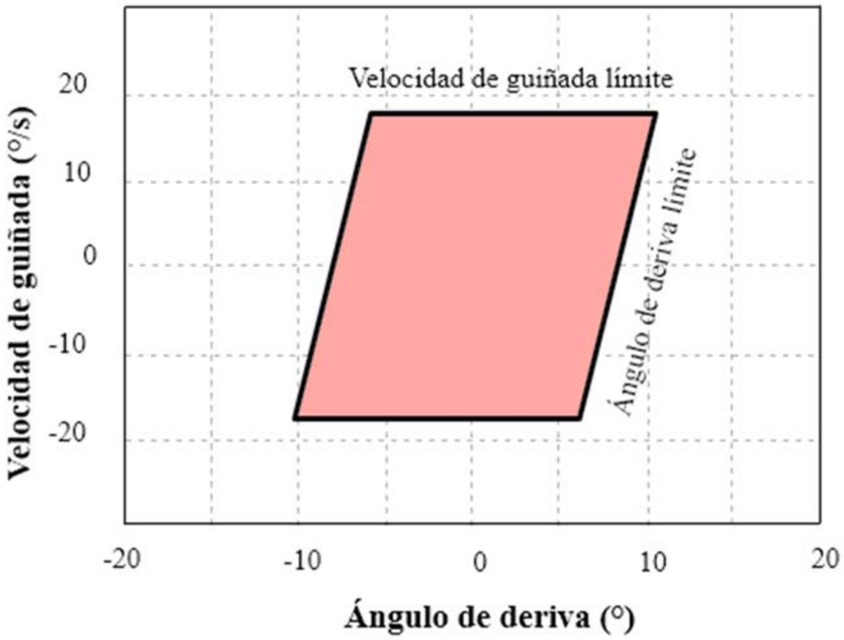

Figura 2: Región de estabilidad definida a partir de los valores límites de la velocidad de guiñada y del ángulo de deriva del vehículo.

Estas regiones de estabilidad dependen de la configuración de carga, de la velocidad de circulación y de la adherencia entre el neumático y la carretera (parámetro que no se tendrá en consideración en este análisis). Por tanto, con su utilización son varios los parámetros que se tienen en cuenta, y que afectan de manera significativa al comportamiento dinámico del vehículo.

2. METODOLOGÍA

2.1 Modelo virtual de vehículo

Para la realización de los ensayos se ha utilizado un modelo 3D, implementado en el programa de simulación dinámica multicuerpo MSC Adams View® y validado para reproducir fidedignamente el comportamiento dinámico del vehículo real, Figura 3.

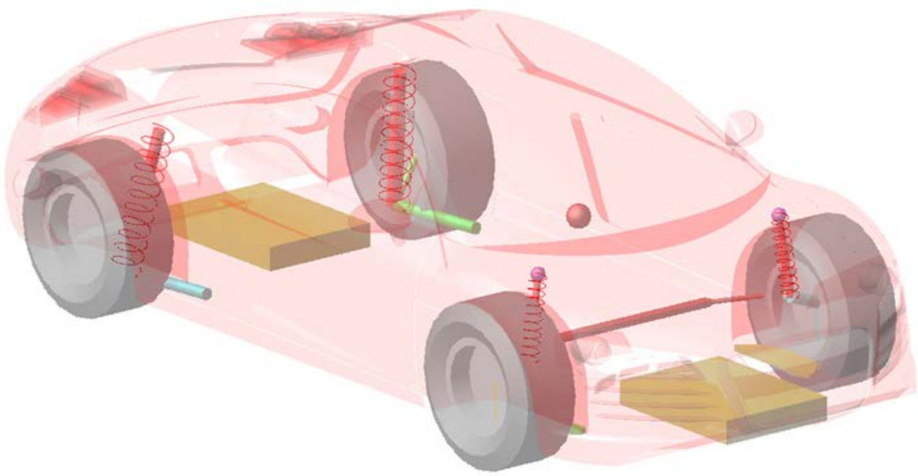

Figura 3: Modelo virtual utilizado para los ensayos de Ramp Steer

Se trata de un modelo con 16 grados de libertad y 21 partes móviles, con una suspensión delantera tipo Mcpherson y trasera independiente de brazos arrastrados.

Las características iniciales del vehículo, y que a posteriori se modificarán para el estudio de optimización, se indican a continuación, Tabla 1:

Masa OM (kg)	% Peso Delante	% Peso Detrás	L1 (m)	L2 (m)	Batalla (m)	Ancho Vías (m)	Kd (Nm)	Kt (Nm)	ξd (Ns/m)	ξt (Ns/m)
1642,8	59,7	40,3	1,07	1,57	2,64	1,6	33000	44000	2200	2000

Tabla 1: Carcaterísticas geométricas del vehículo utilizado

Para analizar la influencia de los parámetros en el comportamiento dinámico del vehículo, y así conocer el nivel de seguridad disponible en el vehículo, se realizan ensayos de tipo step-steer. Éstos consisten en introducir en la dirección un ángulo de volante determinado en un tiempo concreto, Figura 4, de forma que se puede analizar tanto la respuesta transitoria del vehículo como la permanente y, con ello, los efectos de la transferencia de carga debida a los elementos del sistema de suspensión.

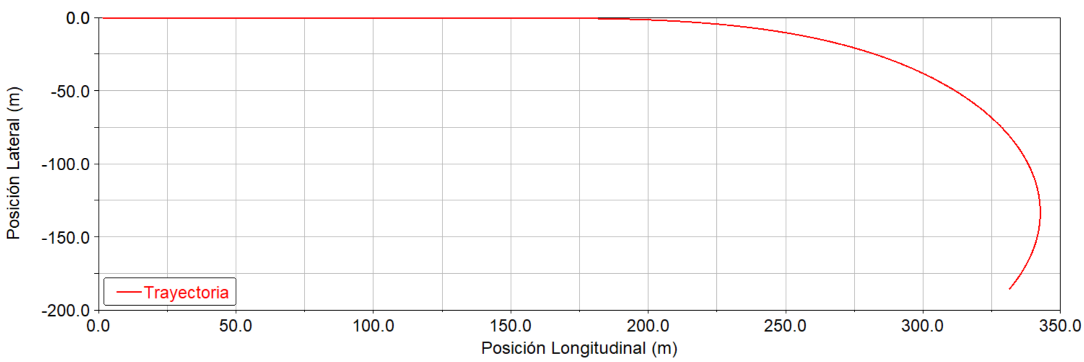

Figura 4: Ensayo de Ramp Steer aplicado sobre el modelo 3D

En este estudio no se han alcanzado situaciones próximas a las condiciones de deriva límite del neumático (derrape del vehículo). Se han considerado las tres configuraciones de tracción posibles sobre un vehículo de dos ejes, tracción delantera, tracción trasera y tracción 4x4.

2.2 Regiones de estabilidad

Cuando un vehículo toma una curva se desarrollan fuerzas laterales en el neumático, perpendiculares a su plano medio, que son función del ángulo de deriva, Figura 5.

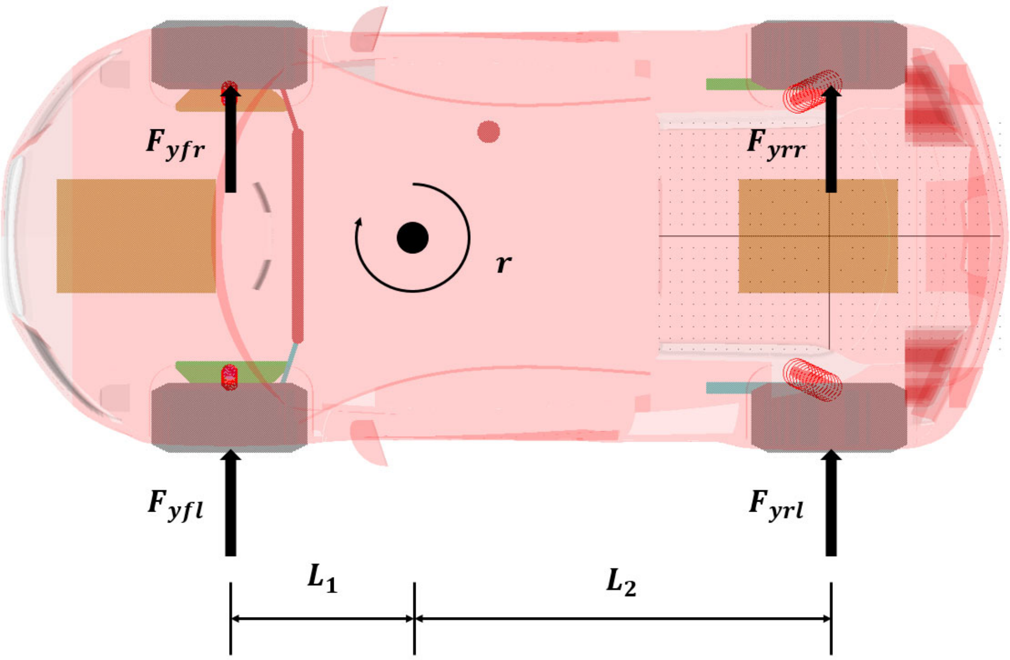

Figura 5: Representación de las fuerzas debidas al giro. Fy es la fuerza lateral por neumático y r la velocidad de guiñada en el centro de gravedad.

En un análisis cuasiestático del giro del vehículo los efectos debidos a las inercias se desprecian (Wong, 1978), con lo que la aceleración de la velocidad de guiñada debe satisfacer la siguiente ecuación:

$$\dot{r} = (L_1 \cdot (F_{yfr} + F_{yfl}) - L_2 \cdot (F_{yrr} + F_{yrl}))/I_{zz} \quad (1)$$

donde:

- $\dot{r}$: Aceleración de la velocidad de guiñada.
- Fyf: Fuerza lateral en el eje delantero (suma de la fuerza de ambas ruedas).
- Fyr: Fuerza lateral en el eje trasero (suma de la fuerza de ambas ruedas).
- $L1$: Distancia entre el eje delantero y el centro de gravedad del vehículo.
- $L2$: Distancia entre el eje trasero y el centro de gravedad.
- Izz: Momento de inercia respecto al eje vertical.

Además, en condición de giro cuasiestático se debe cumplir la siguiente condición:

$$F_{yf} = L_2/L_1 \cdot F_{yr} \quad (2)$$

La región de estabilidad se define en función de los límites de fuerza lateral que son capaces desarrollar los neumáticos, es decir, cuando se alcanza la fuerza lateral máxima en uno de los ejes (condición de saturación del eje), ya sea el delantero o el trasero.

La fuerza lateral máxima en el eje depende de la fuerza lateral máxima en cada rueda, siendo ésta, fundamentalmente, función de la carga vertical sobre el neumático y de la adherencia neumático/carretera.

Para determinar su valor es necesario un ensayo de caracterización sometiendo al neumático a una deriva variable. A continuación, se muestran las fuerzas laterales en los neumáticos, obtenidas a partir de un ensayo virtual de neumático realizado con el software MSC Adams® para cada configuración de carga y una adherencia de 0,9, Figura 6.

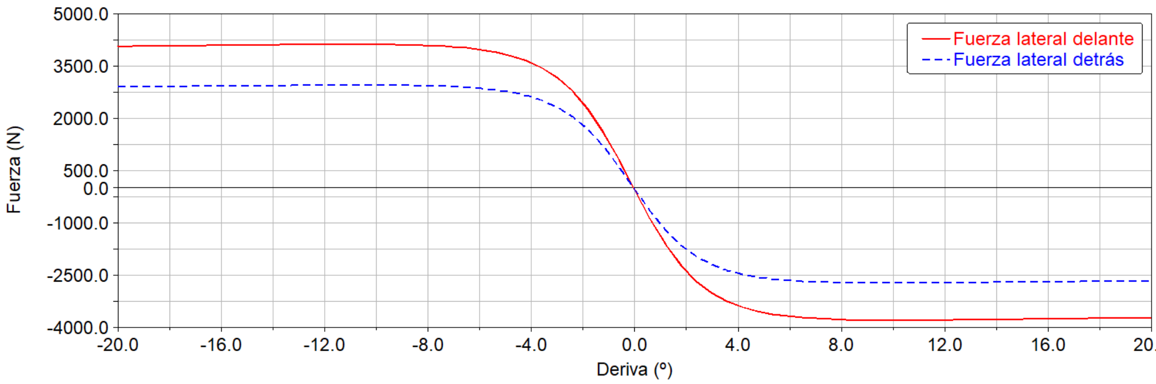

Figura 6: Ensayo virtual realizado con MSC Adams® para las dos configuraciones de carga y una adherencia de 0.9

Cuando se cumple la condición de la expresión (3), se ha alcanzado la saturación del eje delantero, siendo éste, el que define los límites de la región de estabilidad.

$$F_{yfmax} < L_2/L_1 \cdot F_{yrmax} \quad (3)$$

En caso contrario, es el eje trasero el que alcanza la saturación en primer lugar y, por tanto, es el que define los límites de la región de estabilidad, cumpliéndose la siguiente ecuación:

$$F_{yfmax} \geq L_2/L_1 \cdot F_{yrmax} \quad (4)$$

Considerando lo anterior, la velocidad de guiñada límite se calcula de acuerdo a las siguientes ecuaciones:

$$r_b = \{[F_{yrmax} \cdot (1 + L_2/L_1)/(m \cdot v_x) \text{ para } F_{yrmax} \geq (L_2/L_1) \cdot F_{yrmax}], [F_{yrmax} \cdot (1 + L_1/L_2)/(m \cdot v_x) \text{ para } F_{yrmax} < (L_2/L_1) \cdot F_{yrmax}]\} \quad (5)$$

Para el cálculo de los límites debidos al ángulo de deriva se utiliza un modelo de vehículo simplificado, conocido como modelo bicicleta y con dos grados de libertad, Figura 7.

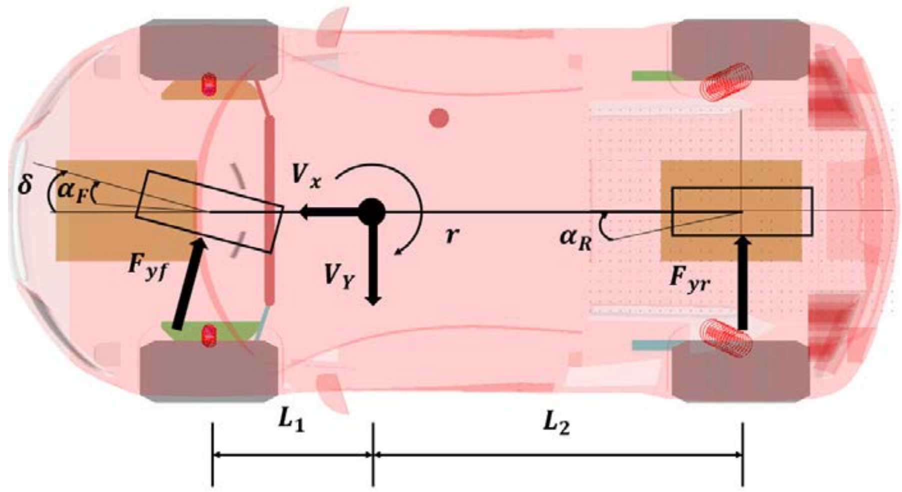

Figura 7: Representación de los parámetros del modelo bicicleta

La situación más peligrosa se produce cuando se satura el eje trasero del vehículo, ya que el vehículo se vuelve direccionalmente inestable. Esto ocurre cuando las ruedas traseras alcanzan la fuerza lateral máxima y el ángulo de deriva que corresponde con dicha situación es el siguiente:

$$\beta_b = \alpha_{r\text{lim}} + (L_2/v_x) \cdot r_b \quad (6)$$

2.3 Métricos de seguridad

En la Figura 8, se muestran los parámetros para definir la seguridad disponible en cada caso, aplicando las ecuaciones 7 y 8.

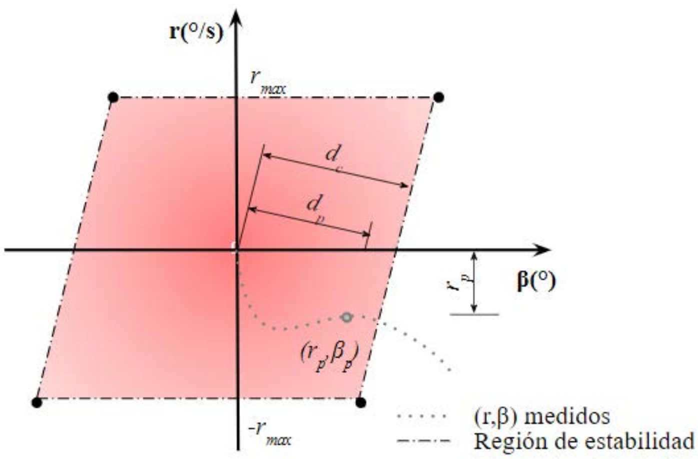

Figura 8: Parámetros para definir la seguridad disponible en cada caso

$$S_\beta(\%) = ((d_c - d_p)/d_c \cdot 100) \quad (7)$$

$$S_r(\%) = ((r_c - r_p)/r_c \cdot 100)) \quad (8)$$

3. RESULTADOS

Para analizar la influencia de cada uno de los parámetros de diseño del vehículo considerados en este trabajo, se ha utilizado el software estadístico IBM SPSS®.

Figura 9: Datos en el software de análisis estadístico IBM SPSS

Mediante el software de simulación dinámica multicuerpo MSC Adams® se realizan simulaciones modificando las rigideces de los muelles de la suspensión, el coeficiente de amortiguamiento de la suspensión, la posición del centro de gravedad (longitudinal y vertical), la masa o la velocidad (variables independientes). Como resultado se obtienen los valores de velocidad de guiñada y ángulo de deriva para la determinación del métrico de seguridad.

Para un vehículo de tracción trasera:

$$S_r = -0.001 \cdot A_d - 23.087 \cdot L_2 - 0.00012 \cdot K_d - 2.915 \cdot V_x + 160.262 \quad (9)$$

$$S_\beta = (1.87E-5) \cdot K_d + (2.14E-5) \cdot K_t - 3.53 \cdot L_2 - 0.007 \cdot M + 1.135 \cdot V_x - 4.417) \quad (10)$$

Según los resultados obtenidos para un vehículo tracción trasera, la seguridad disponible en guiñada, es inversamente proporcional a la rigidez de la suspensión delantera, a la velocidad y al amortiguamiento delantero. Valores elevados de estos parámetros, penalizan la seguridad disponible en el vehículo.

Por otro lado, en el caso de la seguridad disponible en deriva, ésta, es directamente proporcional a las rigideces, tanto delantera como trasera, y a la velocidad, mientras que una posición adelantada del centro de gravedad y una gran masa penalizan su valor. En este caso, tener valores de rigidez delantera y trasera elevados y una posición retrasada del centro de gravedad mejoran la seguridad disponible.

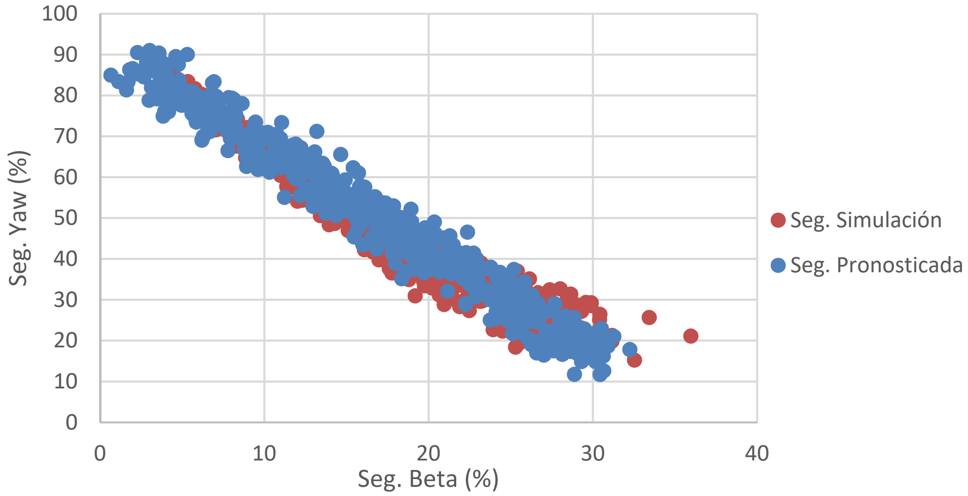

Figura 10: Comparación entre la seguridad obtenida de simulación y la pronosticada para un vehículo de tracción trasera

Se comete un error en el pronóstico de S_β del 4%, mientras que en S_r es del 3.5%.

Para un vehículo de tracción delantera:

$$S_r = -0.000106 \cdot K_d - 0.000106 \cdot K_t - 27.422 \cdot L_2 - 2.622 \cdot V_x + 164.615 \quad (11)$$

$$S_\beta = (5.72E-5) \cdot K_t + 3.429 \cdot H - 4.433 \cdot L_2 - 0.01 \cdot M + 1.135 \cdot V_x - 4.343) \quad (12)$$

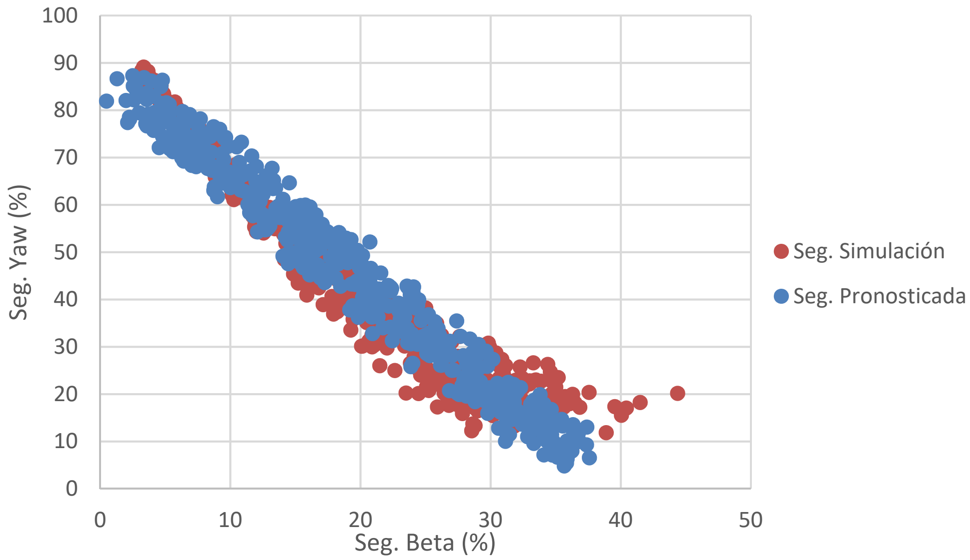

Figura 11: Comparación entre la seguridad obtenida de simulación y la pronosticada para un vehículo tracción delantera

Como se puede apreciar, en comparación con el modelo de ajuste para el vehículo de tracción trasera, en el vehículo de tracción delantera, las variables utilizas para el pronóstico han cambiado.

Por un lado, para la seguridad disponible en guiñada, son ahora las dos rigideces, delantera y trasera, las que afectan de forma negativa, además de la velocidad y la posición del centro de gravedad. Una posición del centro de gravedad adelantada, valores de rigidez de la suspensión altos y una velocidad elevada, perjudican el valor de la seguridad disponible.

Analizando la seguridad disponible en deriva, se obtiene, que una rigidez trasera alta, un centro de gravedad elevado (en altura) y una velocidad elevada, aumentan el valor de la seguridad, mientras que una posición adelantada (longitudinalmente) del centro de gravedad y una masa grande, perjudican los niveles de seguridad disponible.

Se comete un error en el pronóstico de S_β del 4,3%, mientras que en S_r es del 7,0%.

Para un vehículo de tracción 4x4:

$$S_r = -0.000106 \cdot K_d - 0.000106 \cdot K_t - 27.361 \cdot L_2 - 2.591 \cdot V_x + 163.997 \qquad (13)$$

$$S_\beta = (5.339E - 5) \cdot K_t + 3.071 \cdot H - 4.228 \cdot L_2 - 0.01 \cdot M + 1.102 \cdot V_x - 3.960) \qquad (14)$$

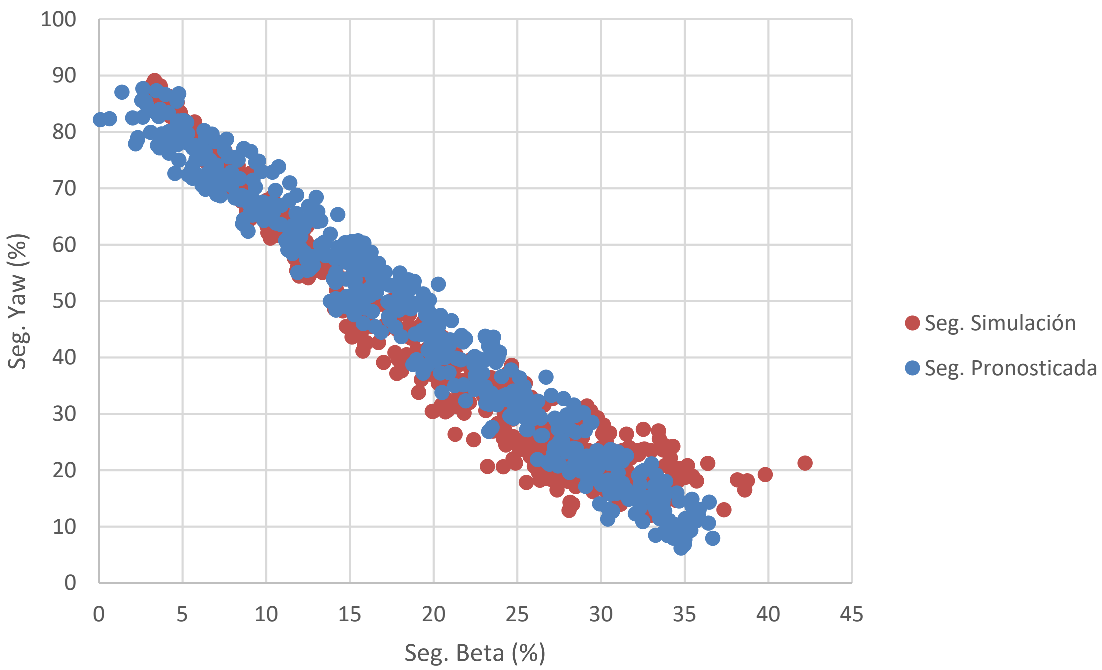

Figura 12: Comparación entre la seguridad obtenida de simulación y la pronosticada para un vehículo con tracción 4x4

Como se puede apreciar en los modelos de aproximación obtenidos para un vehículo 4x4 se parecen bastante a los obtenidos para un vehículo con tracción delantera. Existe una misma relación entre las variables, y el error cometido, es parejo. En las conclusiones, se analizará la posibilidad de unificar estos dos modelos (tracción 4x4 y tracción delantera), en uno solo que permita estudiar ambas configuraciones.

Se comete un error en el pronóstico de S_β del 4,1%, mientras que en S_r es del 7,0%.

4. CONCLUSIONES

En el presente trabajo se ha evaluado la aplicación de las regiones de estabilidad ($\dot{\varphi}$-β) al diseño de vehículos. Estas regiones definen los límites de conducción segura de un vehículo, por tanto, se plantea como objetivo maximizarlas en función de diferentes variables de diseño.

Como metodología para evaluar la aplicación de las regiones de estabilidad se ha desarrollado un diseño de experimentos, empleando un modelo virtual de vehículo sometido a una maniobra de giro. Se ha analizado la respuesta del vehículo en función de variables de diseño del sistema de suspensión y condición de funcionamiento, cuantificando el margen de seguridad disponible.

Tras analizar estadísticamente los resultados, se deduce, que para el diseño de vehículos de tracción delantera y de tracción 4x4, es significativa la influencia de los mismos parámetros, la altura del cdg (H), la posición del cdg (L), la rigidez del muelle trasero (K_t) y la masa total (M). Debido al rango de valores considerado y a la combinación de variables el incremento de la altura del centro de gravedad aumenta la región de estabilidad.

En vista de la gran similitud entre los modelos de pronóstico obtenidos, se plantea la posibilidad de usar un único modelo para pronosticar la seguridad disponible en ambas configuraciones.

$$S_r = -0.000131 \cdot K_d - 0.000131 \cdot K_t - 27.392 \cdot L_2 - 2.607 \cdot V_x + 164.306 \quad (15)$$

$$S_\beta = (5.561E - 5) \cdot K_t + 3.250 \cdot H - 4.430 \cdot L_2 - 0.01 \cdot M + 1.118 \cdot V_x - 4.151) \quad (16)$$

Con este ajuste, se comete un error en el pronóstico de S_β del 4,3%, mientras que en S_r es del 7,0%. Análogo a lo que se tenía anteriormente.

En el caso de vehículos de tracción trasera, es significativa la influencia de la rigidez de los muelles delantero y trasero (K_d) (K_t), la posición longitudinal del cdg (L) y la masa total (M).

Los errores que se comenten a la hora de realizar el pronóstico, pueden deberse a diversas causas, una de ellas, la existencia de otros parámetros de diseño de la suspensión que afecten a la seguridad durante la circulación del vehículo. Además, la linealidad del modelo utilizado, ya que, aunque los valores de R2, son del orden de 0.96-0.98, valores próximos a la unidad, éste dato, se puede mejorar.

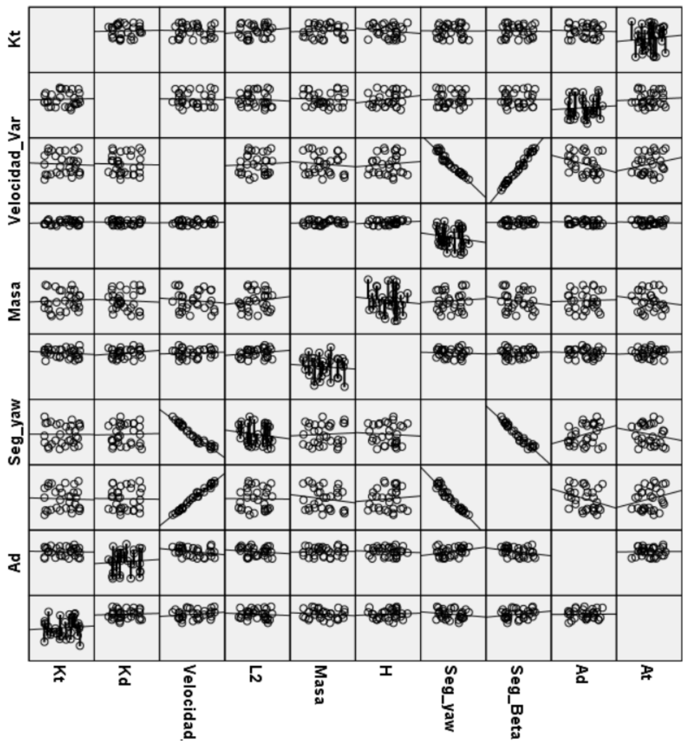

Figura 13: Matriz de correlaciones

Como se puede intuir en la matriz de correlaciones anterior, la variable velocidad, guarda una relación polinómica con la seguridad de guiñada disponible.

CONSIDERACIONES FUNCIONALES DE LAS CVTs INERCIALES

Francisco José Morales Sánchez
Ingeniería de los Transportes, AICIA, España.
Francisco García Benítez
Ingeniería e infraestructura de los Transportes, Universidad de Sevilla, España.

RESUMEN

Existen multitud de patentes y estudios centrados en transmisiones continuamente variables (CVTs) de tipo inercial. En estos documentos se presentan nuevos sistemas de este tipo apelando a la ventaja de autorregulación de la relación de transmisión que presentan. Sin embargo, este tipo de CVTs no han calado en el mercado actual de cajas de cambio. En este trabajo se analizan algunas de las cusas técnicas de este hecho. Específicamente, se analizan diferentes fuentes de vibraciones que son intrínsecas al funcionamiento de este tipo de transmisiones, que se unen al problema principal del uso de ruedas libres. Para llevar a cabo este trabajo se ha seleccionado un sistema CVT a modo de caso de estudio; sin embargo, las conclusiones son fácilmente extrapolables al resto de CVTs inerciales.

A pesar de que las vibraciones analizadas están asociadas al principio de funcionamiento de las CVTs inerciales y no pueden ser eliminadas, se proponen una serie de medidas para mitigarlas. Igualmente se demuestra que el funcionamiento de este tipo de transmisiones depende del tipo de motor de accionamiento mostrando diferencias de comportamiento cuando son accionadas por un motor eléctrico o por un motor de combustión interna.

Este trabajo se ha basado tanto en estudios analíticos como computacionales y los resultados han sido corroborados mediante ensayos reales.

1. INFORMACIÓN GENERAL

Una de las características fundamentales del funcionamiento de una CVT de tipo inercial es la regulación de un movimiento oscilante en alguna de las etapas de la transmisión (Morales y Benitez, 2014a; Morales y Benitez, 2014b).

Este movimiento oscilante (al tener no ser constante ya que tiene que ser regulado para el correcto funcionamiento de la CVT) será una fuente de fuerzas no equilibradas y por tanto igualmente de vibraciones. En este documento, se analizarán las distintas fuentes de vibración de este tipo de transmisiones asociadas a su principio de funcionamiento. Otras fuentes de vibración (tales como ejes desequilibrados, por ejemplo) quedarán fuera de este estudio.

Para una mejor comprensión del análisis realizado, se utilizará un ejemplo de específico de transmisión, sin embargo, todos los resultados obtenidos son fácilmente extrapolables a cualquier sistema de transmisión de la misma naturaleza dinámica. Para ello, se realizará una breve exposición de la transmisión utilizada como ejemplo, no siendo ésta la parte principal de este documento. Esta presentación se realizará en la sección 3.

En este análisis se demostrará igualmente, que el funcionamiento de una transmisión CVT de tipo dinámico está condicionado por la fuente de potencia. Es decir, el comportamiento de la transmisión será diferente en función de si se encuentra accionada por un motor eléctrico o bien por un motor de combustión interna. Este hecho no es fundamental en el caso de ensayos de transmisiones cinemáticas. Debido a esto, y a que su fabricación y control es más sencillo, la inmensa mayoría de los bancos de ensayo para transmisiones disponen de un motor eléctrico como accionamiento.

Por último, y basadas en las conclusiones del estudio, se realizan una serie de recomendaciones que, si bien no eliminan las vibraciones inherentes a este tipo de transmisiones, al menos pueden ayudar a mitigarlas.

2. ESTADO DEL ARTE

Las CVT de tipo inercial han sido ampliamente estudiadas desde los estudios pioneros de Hunt (1912). Uno de los trabajos más importantes en los orígenes de este tipo de transmisión fue realizado por Constantinesco (1922), el cual llegó a construir un prototipo funcional presentado en el Motor Show de Paris en 1926.

Después de esto, multitud de distintas CVTs de tipo dinámico han sido analizadas y patentadas. En Morales y Benitz (2014) se presenta una revisión detallada de este tipo de transmisiones las cuales llegas a clasificarse claramente de dos categorías: a) CVTs con masas oscilantes y b) CVTs con masas excéntricas. De la primera categoría, los desarrollos más importantes son los llevados a cabo por Howards (2005), Benitez et al. (2009) o Franch (1981). En cuanto al segundo grupo destacan los desarrollos de Chalmers (1932), Tam (1992), Williams y Williams (1999), Lester (2006) y Shea (1982). En este documento solo se citan unos pocos ejemplos de cada familia de CVTs inerciales, sin embargo, existen infinidad de dispositivos de este tipo patentados.

En estos trabajos anteriormente mencionados se presentan innovaciones de sistemas de transmisión, sin embargo, también existen estudios donde se analizan en detalle alguno de estos sistemas. Cabe destacar el trabajo presentado por Stecki (1981) en el que la transmisión patentada por Constantinesco es profundamente analizada, obteniendo para ello las ecuaciones de movimiento mediante el uso de la metodología “bond graph”. Este estudio es continuación de otras publicaciones previas (Berselli y. Stecki 2008; Berselli, 2004).

Mas recientemente, ejemplos que merecen un interés especial se encuentra en los trabajos presentados por S. Aliukov (2017) y Aliukov et al. (2018), en los que se analizan y proponen mejoras para el uso de CVTs inerciales. Aliukov continua en este trabajo con la misma línea en la que había presentado varios papers previamente (Alyukov y Keller, 2018; Alyukov, 2014; Alyukov y Gorshenin, 2014; Alyukov y Gladyshev, 2013 y Alyukov, 2010).

A pesar de la cantidad de patentes referentes a este tipo de CVTs, actualmente no existen soluciones comerciales. La principal razón de este hecho es que este tipo de mecanismos necesitan un sistema rectificador basado en ruedas libres (Morales y Benitez, 2014b). Las ruedas libres, en este tipo de transmisiones, están sometidas a altos pares y velocidades angulares. En la actualidad, no se comercializan ruedas libres que sean capaces de soportar conjuntamente altos pares y altas velocidades de oscilación. Además de este problema principal, en este documento otra serie de problemas intrínsecos a este tipo de CVTs son analizados siendo éstos la causa principal de que este tipo de transmisiones no hayan proliferado.

Como se ha mencionado anteriormente, uno de los principales problemas de este tipo de transmisión radica en las vibraciones del sistema. Enfocándose en vibraciones mecánicas, existen estudios específicos dedicados a cajas de cambio. Por ejemplo, destacan los trabajos realizados por Mehmet Bozca (Mehmet, 2010) en el que analiza la optimización de una caja de cambio desde el punto de vista de reducción de la vibración de traqueteo de los elementos que componen la transmisión. Otro ejemplo sobre la misma temática, es el trabajo realizado por Parra y Molina (Parra y Molina, 2017) en el que proponen dos métodos para modelar las vibraciones de trenes planetarios. Otros estudios interesantes son los presentados por Wojnar y Juzek (2018) y Grega at al. (2016).

Sin embargo, todos estos estudios se encuentran enfocados en fuentes de vibración típicas de sistemas mecánicos. En este documento, este tipo de vibraciones serán ignoradas, ya que se centra en identificar y analizar las vibraciones generadas por el principio de funcionamiento de las transmisiones inerciales.

3. CVT AUTOADAPTABLE

Como se ha mencionado anteriormente, este estudio se centra en CVTs de tipo inercial. En este tipo de transmisión, aparte de un sistema externo de regulación, el sistema se autorregula para adaptar la relación de transmisión a las condiciones a las que la transmisión está sometida tales como el par resistente y la velocidad de giro del eje de entrada.

A pesar de que las conclusiones de este estudio pueden extrapolarse a cualquier caja de cambios de tipo inercial, se ha seleccionado un caso de estudio para para facilitar la comprensión del análisis.

Se ha seleccionado como caso de estudio la CVT Autoadaptable patentada por Benitez et al (2009) y es por eso por lo que a continuación se dará una breve explicación de su funcionamiento (una descripción más detallada puede encontrarse en Morales y Benitez (2019) y en Centeno et al. (2010).

La CVT autoadaptable contiene un elemento inercial que consiste en un tren epicicloidal con una masa adicionad a la corona (Figura 1). Este elemento inercial es conducido por un mecanismo de accionamiento cuya función es transformar el movimiento constante del motor en un movimiento oscilante. Esto es necesario para tener continuos periodos de aceleración y desaceleración en el elemento inercial (corona del tren epicicloidal).

Disponer de aceleraciones continuas es necesario ya que durante los procesos de aceleración se transmite un par al eje de salida del epicicloidal (eje del planeta). El movimiento del planeta será igualmente oscilante, por lo que es necesario que el sistema disponga de una última etapa que rectifique este movimiento. Resumiendo, el motor se conecta al mecanismo de accionamiento que transmite un movimiento oscilante al tren epicicloidal que regula el par transmitido a la salida de éste en función de las variables tales como el par resistente y la velocidad de entrada y por último, un mecanismo rectificador convierte el movimiento oscilante en un giro en un único sentido.

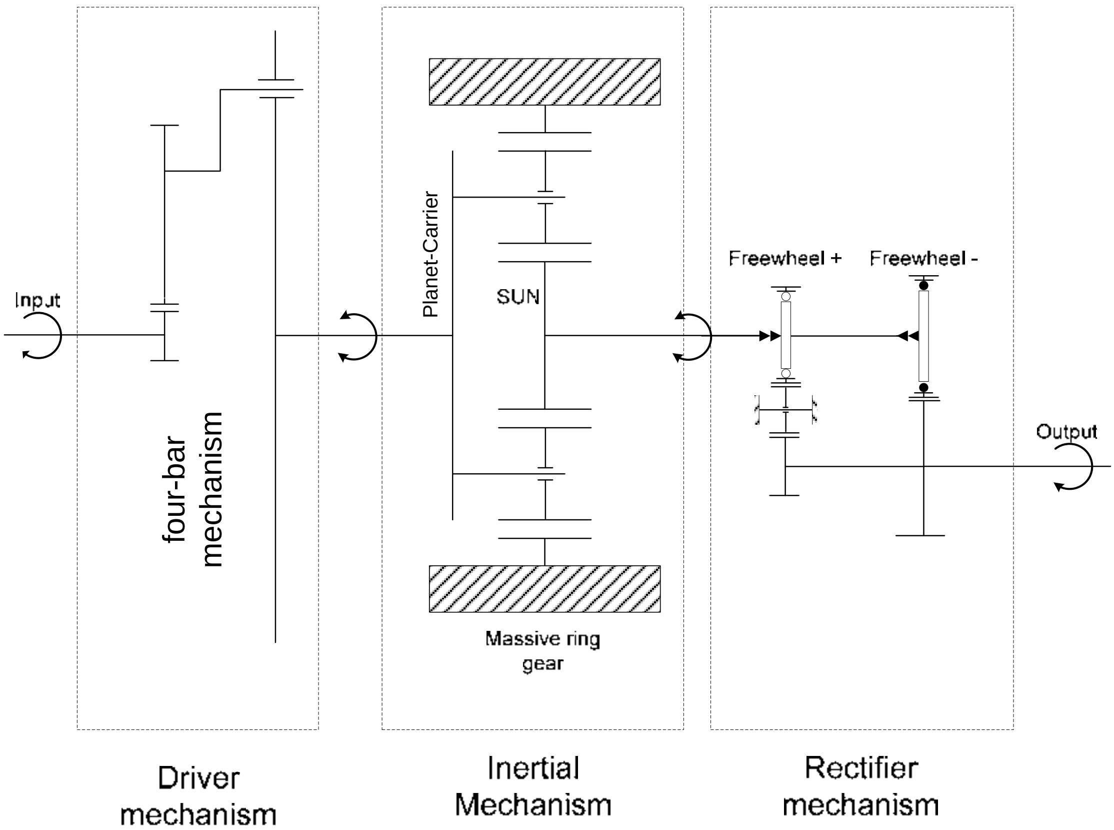

Figura 1: Esquema de la transmisión autoadaptable

4. VIBRACIONES DEBIDAS AL MECANISMO DE ACCIONAMIENTO

La más obvia y una de las más fuertes fuentes de vibración en este sistema de transmisión es la generada por el mecanismo de accionamiento. En la CVT seleccionada como caso de estudio el sistema de accionamiento es un mecanismo de cuatro barras (manivela-biela - balancín). En el análisis llevado a cabo en este estudio, la longitud de la manivela se ha mantenido constante haciendo que el sistema completo funcione como un convertidor de par (Centeno et al., 2010), ya que este estudio se centra en las vibraciones del sistema y, excepto por las vibraciones debidas al mecanismo de accionamiento que son tratadas en esta sección, este parámetro (longitud de la manivela) no es fundamental para entender cada una de las fuentes de vibración. En este caso particular (longitud de la manivela constante) es posible equilibrar el mecanismo de accionamiento (Berkof, 1973). Sin embargo, en la CVT real es necesario cambiar esta longitud de la manivela para poder modificar la relación de transmisión y de esta forma poder mantener la velocidad del motor a la velocidad deseada. De esta forma, al modificar la longitud de la manivela es necesario realizar igualmente un equilibrado que varíe con esa longitud. Este hecho es bastante complicado por lo que finalmente se producirá un desequilibrio al modificar la longitud de la manivela. Este desequilibrio se añade al resto de fuentes de vibración que serán enumeradas en este documento.

5. VIBRACIONES DEBIDAS AL PRINCIPIO DE FUNCIONAMIENTO DE LA CVT

El principio de funcionamiento de la CVT autoadaptable se basa en acumulaciones y cesiones de potencia por el sistema masivo (corona masiva de la Figura 2).

En el sistema, la corona masiva se usa como elemento intermedio entre la entrada (portasatélites) y la salida (planeta). De esta forma, la entrada de potencia que se introduce a través del portasatelite puede, o directamente ser transmitida hacia el planeta, o bien ser almacenada en el elemento masivo para ser utilizada posteriormente.

La potencia en cada elemento se representa por:

$$P_{PC} = T_{PC} \cdot \omega_{PC} \tag{1}$$

$$P_S = T_S \cdot \omega_S \tag{2}$$

$$P_{RG} = -I_{RG} \cdot \omega_{RG} \cdot d\omega_{RG}/dt \tag{3}$$

donde:

- P_{PC} es la potencia en el portasatélites
- T_{PC} el par en el portasatélites (par de entrada)

- P_S potencia en el planeta (salida)
- T_S par en el planeta (par resistente "visto" por el tren epicicloidal)
- P_{RG} potencia en la corona masiva
- I_{RG} inercia de la corona masiva
- ω_{PC}, ω_S, ω_{RG} son las velocidades angulares del portasatélites, planeta (eje de salida) y la corona respectivamente.

Como se ha mencionado anteriormente, el principio de funcionamiento de la CVT inercial se basa en generar aceleraciones en la corona masiva del tren epicicloidal. Debido a esto es por lo que se introduce un movimiento oscilatorio en el tren epicicloidal, resultando que ω_{RG} y $\frac{d\omega_{RG}}{dt}$ serán igualmente oscilantes y por consiguiente la potencia de la corona.

El par en la corona del tren epicicloidal viene dado por:

$$T_{RG} = I_{RG} \cdot d\omega_{RG}/dt \quad (4)$$

En estas ecuaciones, la potencia es positiva cuando entra en el Sistema. De esta forma, la potencia de la corona será negativa cuando este elemento almacena energía (cuando se acelera).

Realizando un equilibrio de potencias:

$$P_{PC} + P_{RG} + P_S = 0 \rightarrow P_{PC} = -(P_{RG} + P_S) \quad (5)$$

Según esta ecuacion (5), la entrada de potencia al sistema a través del portasatélites es igual a la absorbida por la corona del tren epicicloidal más la potencia transmitida a través del planeta. Igualmente, la potencia que transmite la corona masiva cuando cede su potencia acumulada viene dada por:

$$P_{RG} = -(P_{PC} + P_S) \quad (6)$$

De esta forma, la energía acumulada en la corona masiva será trasmitida o bien hacia la salida (a través del planeta) o será devuelta a la entrada (a través del portasatélites). La cantidad de potencia transmitida a cada elemento será función del par en cada uno de ellos.

Como ejemplo, la Figura 2 muestra la evolución de la potencia en cada elemento del tren epicicloidal cuando se introduce una señal senoidal (y por tanto oscilante) en el portasatélites y un par resistente constante en el planeta. En esta figura pueden apreciarse claramente tres diferentes modos de funcionamiento.

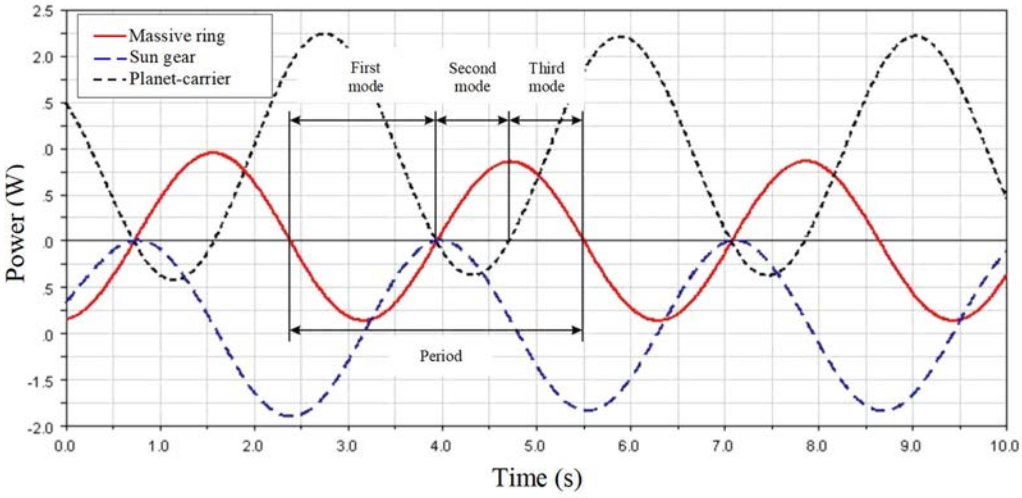

Figura 2: Evolución de la potencia en los elementos del tren epicicloidal

- Primer modo: La corona masiva almacena energía incrementando su velocidad angular. La potencia de la entrada es utilizada para acelerar la corona masiva y para mover el eje de salida.
- Segundo modo: Este modo es indeseado, ya que la corona masiva está transmitiendo potencia tanto a la salida (planeta) como a la entrada (portasatélites). Esta ultimo flujo de potencia es indeseado ya que parte de la energía se transmite a la entrada en lugar de la salida que sería el flujo correcto de potencia. Este modo de funcionamiento será una Fuente de vibraciones del Sistema.
- Tercer modo: En este modo, las dos potencias (la introducida por la entrada y la cedida por el elemento masivo al decelerarse) son transmitidas a la salida.

Según estos tres modos de funcionamiento, la potencia de la entrada (portasatélites) se transfiere a:

- dos elementos (modo 1)
- solo un elemento (modo 3), o
- recibe potencia del elemento masivo (modo 2).

Esto implica que el par en el eje de entrada siempre se ve alterado por los tres modos de funcionamiento. Al no ser un par constante, será una fuente de vibraciones indeseadas.

Debido a esto, para mantener constante la velocidad angular en el eje de entrada es necesario “frenar” el eje de entrada cuando recibe potencia de la corona masiva y proporcionar un par positivo en el resto de modos de funcionamiento. Si bien puede “frenarse” el eje de entrada si el mecanismo es accionado con un motor eléctrico, esto no será posible con un motor de combustión interna al no poder proporcionar un par negativo de forma que el eje acelerará y desacelerará en función del modo de funcionamiento en el que se encuentre el sistema.

Por esto, y como se ha mencionado anteriormente, el comportamiento del sistema será distinto en función del motor de accionamiento.

5.1 Sistema accionado por motor eléctrico

La peculiaridad del motor eléctrico es que, mediante un variador de frecuencia, es posible mantener una velocidad cuasi constante en el eje de entrada de la transmisión. El motor eléctrico proporcionará el par necesario, ya sea positivo o negativo, para que esto suceda.

Como se ha mencionado anteriormente, el par debe ser oscilante para mantener la velocidad constante debido a los tres modos de funcionamiento distintos del sistema de transmisión. Es decir, cuando la corona masiva ceda potencia hacia la entrada, el motor eléctrico debe proporcionar un par negativo para "frenar" el eje de entrada y un par positivo en el resto de casos. Este efecto será más severo en cuanto mayor sea el par resistente en el planeta del tren epicicliodal, ya que la corona masiva cederá más potencia hacia el elemento que menor resistencia ponga de las dos posibilidades que tiene (o hacia la entrada o hacia el planeta).

En otras palabras, si existe un par resistente pequeño (vehículo circulando en una carretera plana a una velocidad moderada), la corona masiva cederá una mayor potencia hacia la salida. Sin embargo, si el par resistente es alto (vehículo ascendiendo una pendiente y/o acelerando), la mayoría de la potencia será transmitida al eje de entrada cuando la transmisión se encuentre en el segundo modo de funcionamiento.

Por tanto, según las explicaciones dadas anteriormente, el par proporcionado por el motor eléctrico será oscilante y por tanto una fuente de vibraciones.

Este análisis fue corroborado experimentalmente mediante ensayos (los equipos utilizados y como se llevaron a cabo los tests se encuentra profundamente detallado en Centeno et al. (2010)). La figura 3 muestra el par medido en un ensayo real con un par resistente bajo. Como puede comprobarse, la señal no es simétrica respecto al eje y=0. Esto es debido a que, como el par resistente es bajo, existe una mayor cesión de potencia de la almacenada en la corona masiva hacia la salida y poca hacia la entrada, por lo que el motor eléctrico no tiene que ejercer un gran par negativo para evitar que se acelere la entrada.

Sin embargo, manteniendo la velocidad de entrada constante, pero aumentando considerablemente el par resistente a la salida de la transmisión, la corona cede una mayor potencia hacia la entrada necesitando el motor eléctrico proporcionar un mayor par negativo (Figura 4) llegando a ser prácticamente del mismo valor que el par positivo.

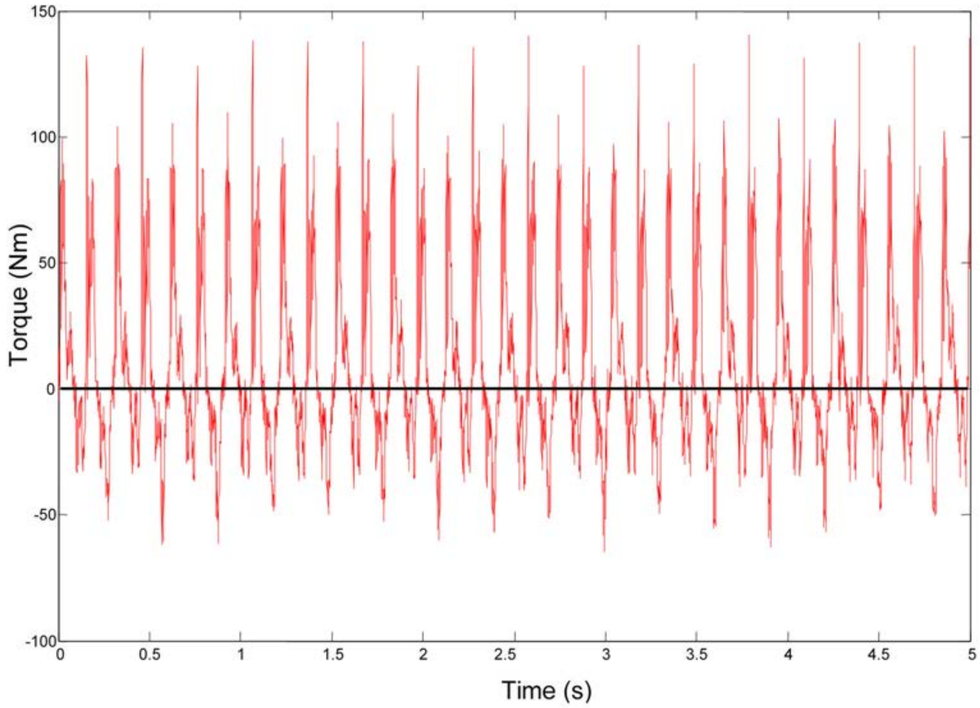

Figura 3: Par de entrada (bajo par resistente)

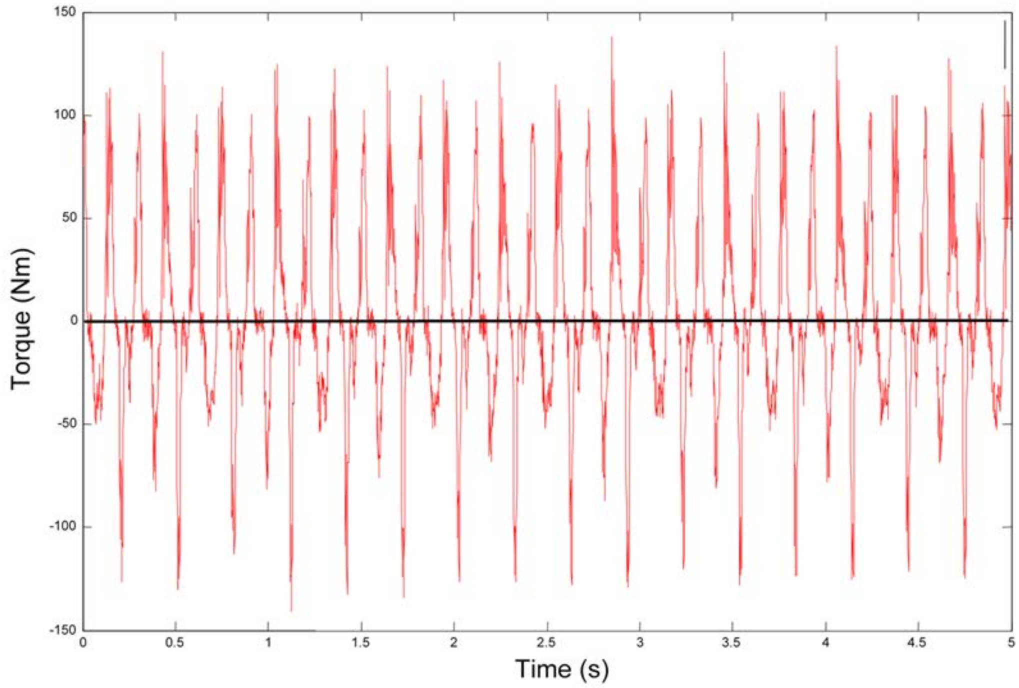

Figura 4: Par de entrada (alto par resistente)

Como se ha comprobado, el par de entrada que debe proporcionar el motor eléctrico es de naturaleza oscilante debido al principio de funcionamiento de la transmisión. Por la tercera ley de Newton, la carcasa del motor eléctrico transmite un par oscilante de la misma magnitud, pero de signo contrario, al chasis del banco de ensayos causando unas vibraciones indeseadas (Figura 5).

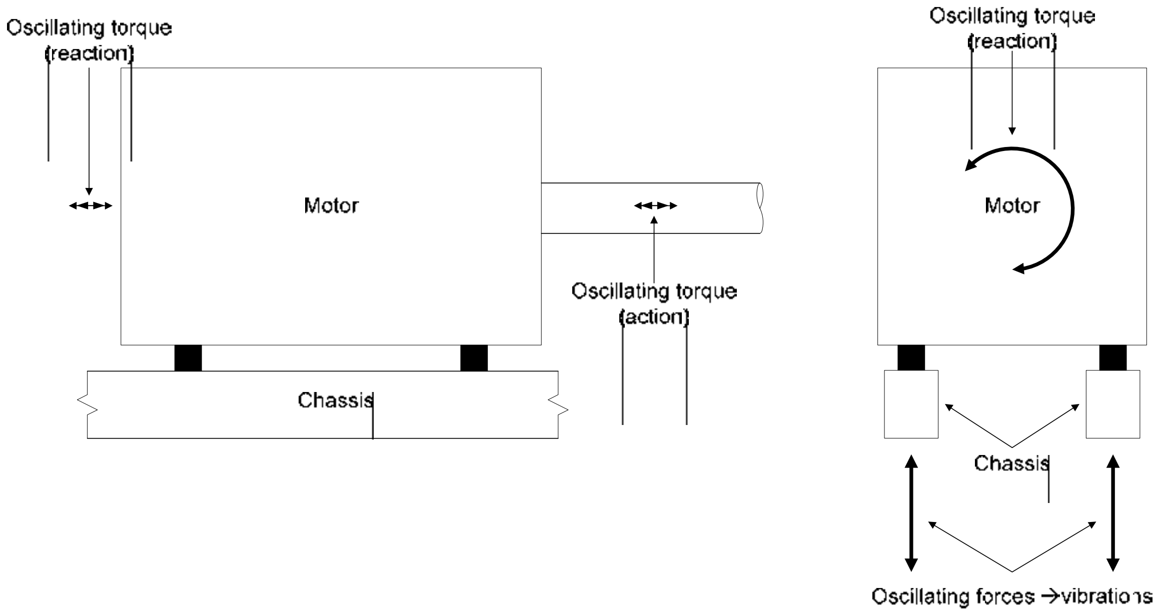

Figura 5: Transmisión del par oscilante al chasis del banco de ensayos

5.2 Sistema accionado por motor de combustión interna (ICE)

Este caso es diferente al anterior debido a que el motor de combustión interna no es capaz de proporcionar un par negativo. Esto implica que la velocidad del eje de entrada no podrá ser constante. Tomando el eje de entrada como elemento de control, el flujo de potencia presenta tres escenarios:

- durante el primer modo de funcionamiento, la entrada transfiere potencia hacia la salida (planeta del tren epicicloidal) y hacia la corona masiva
- Durante el segundo modo, el eje de entrada recibe potencia desde la corona masiva y finalmente,
- durante el tercer modo, la entrada solo transmite potencia hacia la salida (planeta).

Este flujo de potencia implica que el par resistente que “siente” el motor de combustión interna no sea constante y provoca que la velocidad del eje de entrada no sea constante tal y como se aprecia en la Figura 6. Estos resultados han sido obtenidos mediante un modelo realizado en un software de dinámica multicuerpo y previamente calibrado con ensayos reales (ver Morales y Benitez, 2019).

Cuando la corona masiva transfiere parte de su potencia hacia la entrada, el motor de combustión se acelera, incrementando la velocidad del eje de entrada. Sin embargo, cuando el motor de combustión transmite potencia hacia la salida y a la corona masiva, la velocidad del eje de entrada decrece.

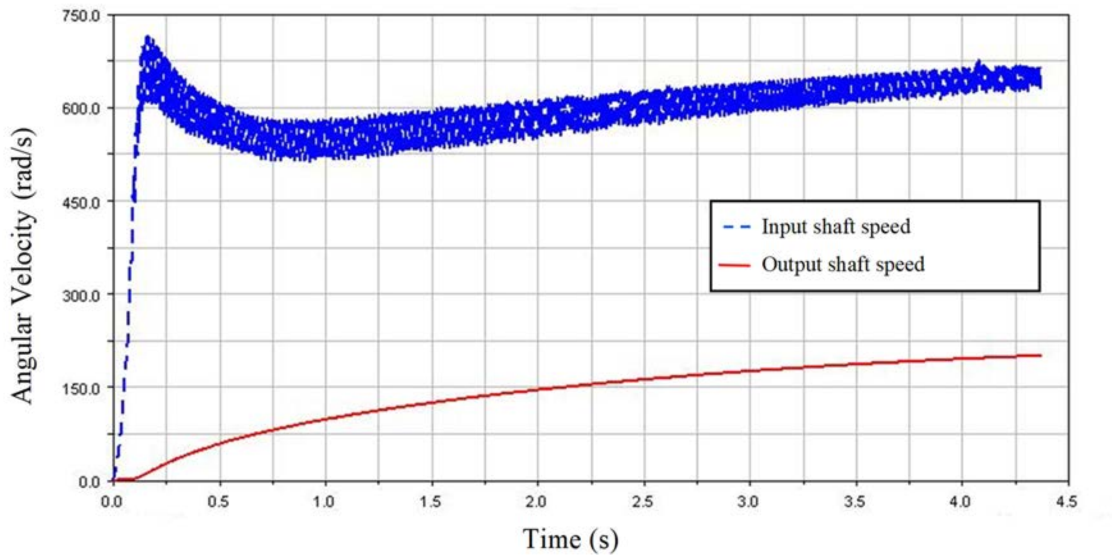

Figura 6: Oscilación de la velocidad angular del eje de entrada (ICE)

Este comportamiento puede ser explicado analizando el punto de equilibrio entre la curva de par del motor de combustión interna y la curva del par resistente. En el caso de las CVTs inerciales, el par resistente cambia dependiendo de los tres modos de funcionamiento descritos previamente (Figura 7). Esto hace que el punto de equilibrio cambie constantemente provocando una velocidad de entrada no constante.

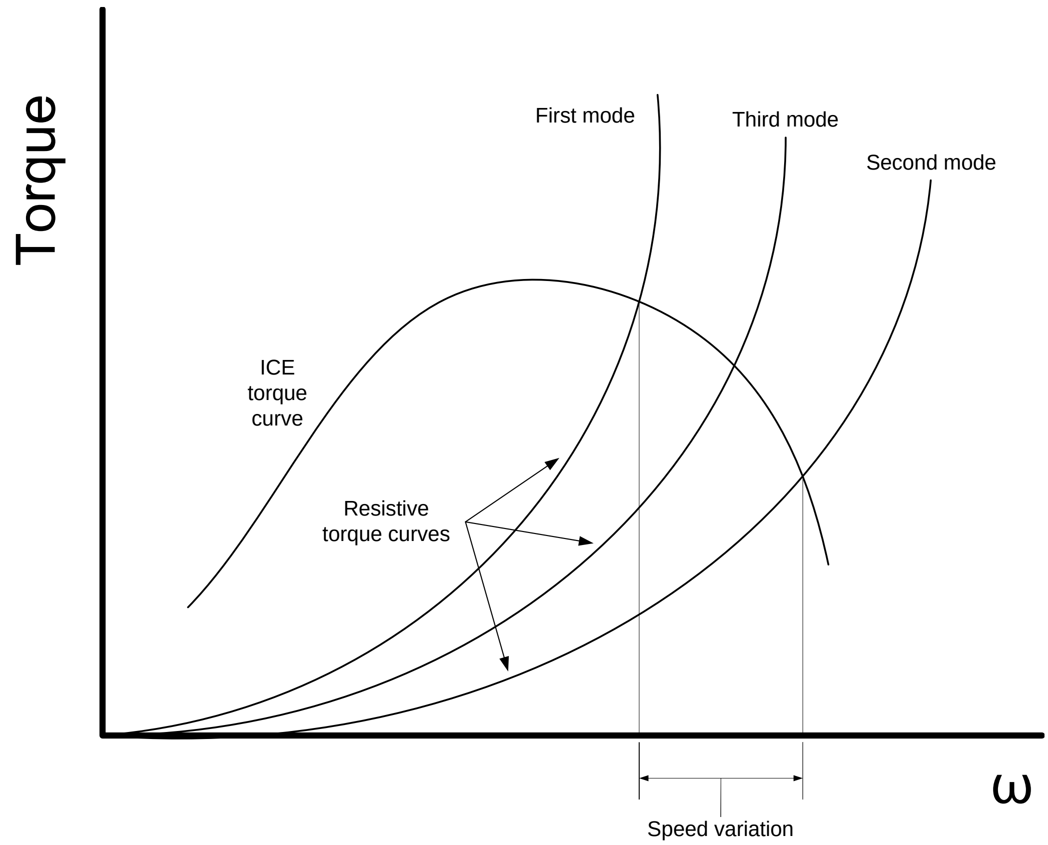

Figura 7: Punto de equilibrio entre la curva de par del motor de combustión y la curva del par resistente.

5.3 Soluciones propuestas para reducir vibraciones debidas al principio de funcionamiento.

Una vez conocida la naturaleza de las vibraciones debidas al principio de funcionamiento de este tipo de CVTs es possible proponer soluciones para reducirlas.

Ya es conocido que el par proporcionado por un motor de combustion interna no es constante y la solución para suavizar este par consiste en introducir un volante de inercia. Debido a esto, un primer método para reducir las vibraciones es aumentar la inercia de este volante de inercia. De esta forma, a la potencia cedida por la corona masiva hacia la entrada le costará más acelerar al eje de entrada. En la Figura 8 puede verse una comparativa entre el sistema con y sin disco de inercia aumentado en el eje de entrada. La figura muestra como la oscilación en la velocidad de entrada se ha visto drásticamente reducida. Sin embargo, se ha visto afectada la velocidad y la aceleración del vehículo a la salida. Debido a esto, debe llegarse a un compromiso para obtener un resultado final adecuado.

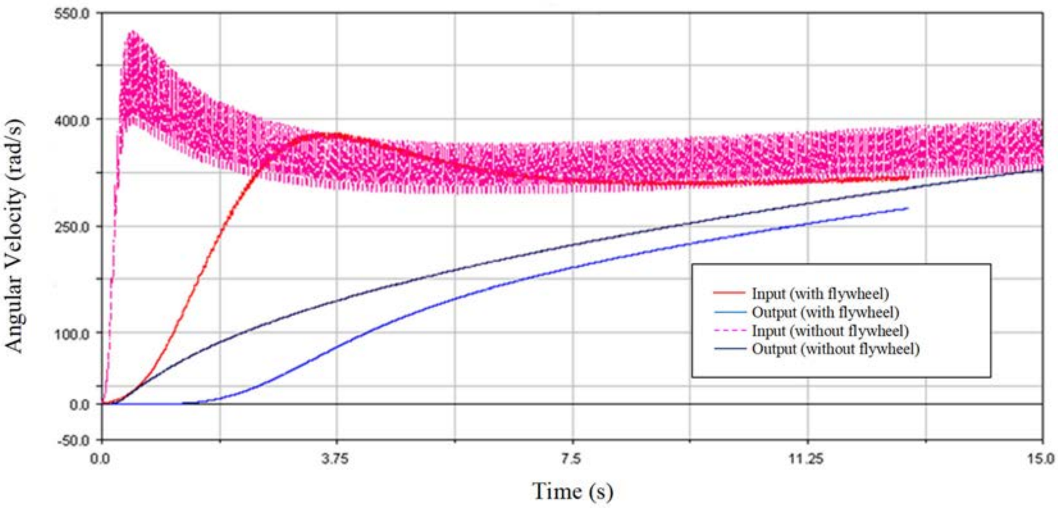

Figura 8: Comportamiento de la CVT inercial con y sin aumento de disco de inercia en el eje de entrada.

Puede proponerse una segunda solución teniendo en cuenta que las vibraciones debidas al principio de funcionamiento se deben a que la corona masiva tiene dos alternativas para transferir su potencia: i) hacia la salida (planeta del tres epicicloidal) o ii) hacia la entrada (portasatélites). En este último caso es cuando se generan las mayores vibraciones. Por tanto, si se reduce el par resistente en la salida del tren epicicloidal (planeta) una mayor proporción de potencia será transferida hacia esta salida. Sin embargo, el par resistente viene fijado por la dinámica longitudinal del vehículo, por lo que no puede ser modificado. Sin embargo, el par que afecta al tren epicicloidal y por tanto al que afecta a la cantidad de potencia transmitida hacia la salida es el par resistente que "ve" el planeta y éste si puede ser modificado utilizando un reductor como sistema rectificador (subsistema rectificador de la Figura 1). Esta solución se esquematiza en la Figura 9:

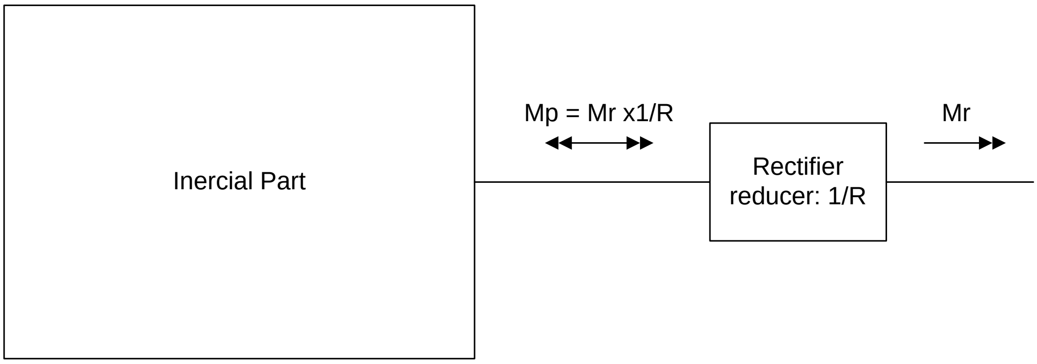

Figura 9: Esquema de la solución basada en el uso de un rectificador reductor

Con esta solución podría parecer que la velocidad del vehículo se vería reducida en la misma proporción. Sin embargo, aunque en principio parezca contradictorio, un reductor a la salida puede tener efectos positivos en la velocidad de salida. Esto se debe a que en el caso de una CVT inercial, cuando el par en el planeta (salida del tren epicicloidal) es reducido, se transfiere una mayor potencia desde el elemento masivo hacia esta salida (disminuyendo la potencia transferirá hacia la entrada y con ello las vibraciones indeseadas) haciendo que se aumente la velocidad final del sistema completo. Este comportamiento sucede hasta que el efecto de tener una reducción compensa al efecto de tener una mayor cesión de potencia hacia la salida (punto máximo en la Figura 10).

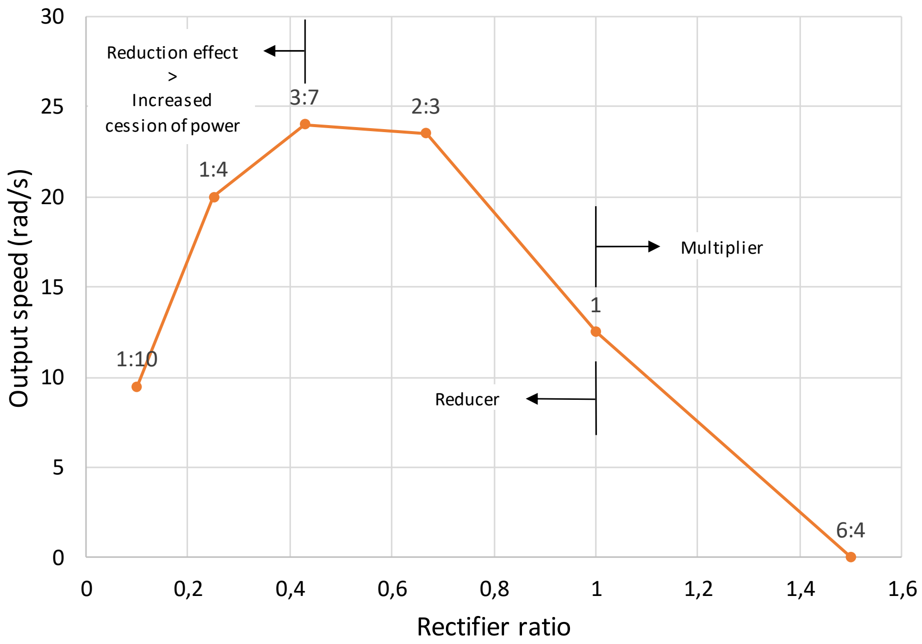

Fig. 10 – Efecto de usar un reductor/multiplicador como sistema rectificador

Los resultados mostrados en esta Figura 10 no son generales, ya que dependen de multitud de parámetros tales como la inercia del elemento masivo, la relación de transmisión del tren epicicloidal, el mecanismo de entrada, etc. Debido a esto, es necesario obtener la relación de transmisión del sistema óptima para cada caja de cambios de forma individual (una explicación más detallada de este comportamiento puede verse en Alyukov (2014)).

6. VIBRACIONES DEBIDAS AL MECANISMO RECTIFICADOR

Como se ha mencionado anteriormente, a la salida del tren epicicloidal se tiene un movimiento oscilatorio que es necesario rectificar para obtener un movimiento en un único sentido y poder ser utilizado por el vehículo. Tomando como ejemplo el sistema rectificador de la Figura 11, cuando el planeta del tren epicicloidal (sun) gira en sentido horario, la rueda libre positiva se encuentra bloqueada y la potencia se transmite a través de los engranajes G1, G2 y G3. Al mismo tiempo, la rueda libre negativa se encuentra desengranada. En la segunda mitad del periodo (cuando el planeta gira en sentido antihorario) la transmisión de potencia se realiza a través de los engranajes G4 y G5 (una explicación mas detallada del funcionamiento de este mecanismo puede encontrarse en Morales y Benitez (2014b).

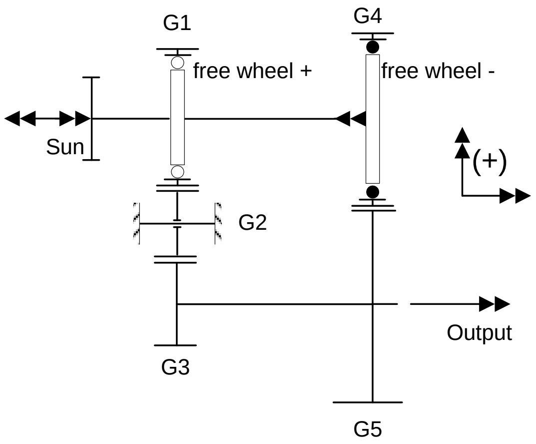

Figura 11: Mecanismo rectificador

Si se analiza por ejemplo las fuerzas transmitidas al chasis del banco de ensayos a través de G4 y G5 se obtiene que cuando se transmite potencia a través de ellas existen unas fuerzas de reacción en el chasis, en cambio, cuando la rueda libre alojada en el engranaje G4 se encuentra desacoplada estas fuerzas se anulan. Debido a esto existen unas fuerzas intermitentes (Figura 12) y consecuentemente unas vibraciones indeseadas.

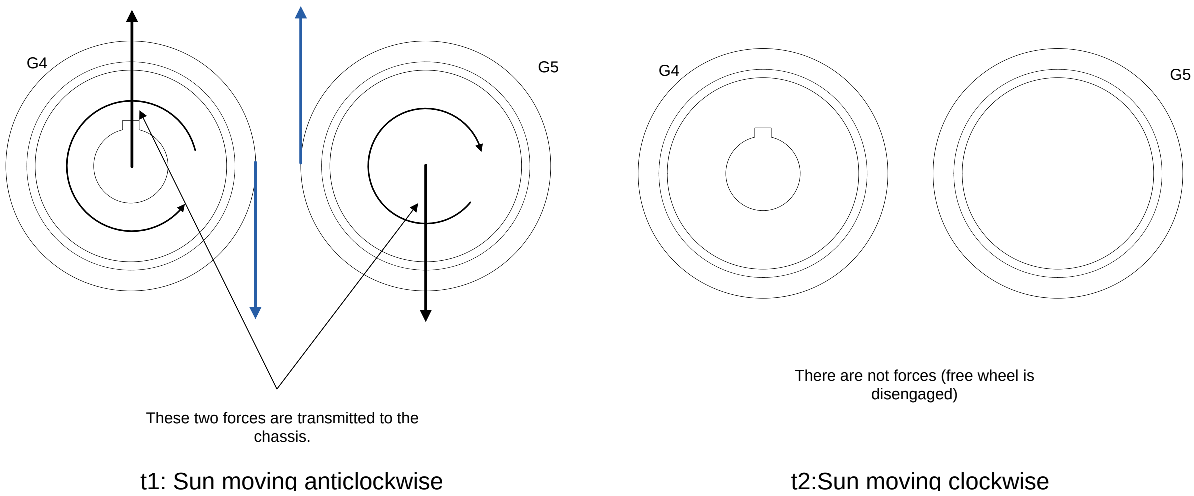

Figura 12: Fuerzas transmitidas por G4 y G5

6.1 Soluciones propuestas para reducir vibraciones debidas al rectificador

Una posible solución para reducir estas vibraciones es la de utilizar dos trenes epicicloidales trabajando en paralelo de forma que se compensen parcialmente las vibraciones entre uno y otro (Figura 13). Para que esta solución funcione correctamente, los sistemas de accionamiento de ambos trenes epicicloidales deben estar desfasados 90º.

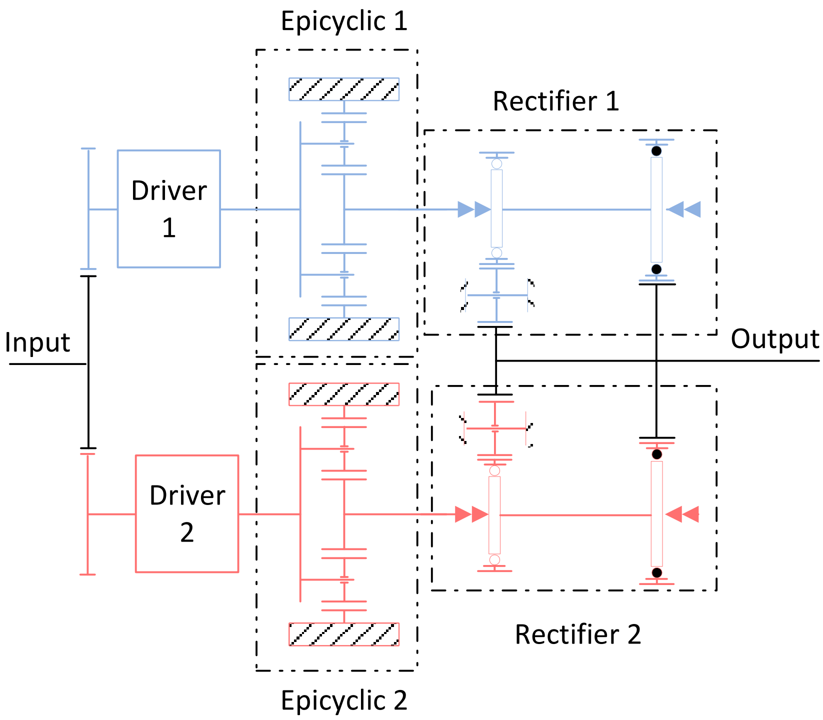

Figura 13: Esquema del sistema con dos trenes epicicloidales

Debido al desfase que existe entre los dos sistemas, cuando uno de ellos se encuentra en el segundo modo de funcionamiento, el otro se encuentra o bien en el 1 o bien en el 3, por lo que de esta forma también se compensan parcialmente las vibraciones debidas al principio de funcionamiento analizado anteriormente.

Analizando los pares transmitidos por las ruedas libres y las velocidades de los planetas (sun) de los trenes epicicloidales (Figura 14) puede comprobarse como el desfase introducido por los mecanismos de accionamiento se mantienen de forma que al menos una rueda libre siempre se encuentra transmitiendo movimiento y existe un solapamiento la mayoría del tiempo. Como en este sistema existen ahora 4 ruedas libres, el par transmitido por cada una de ellas es menor que en el caso de un único tren.

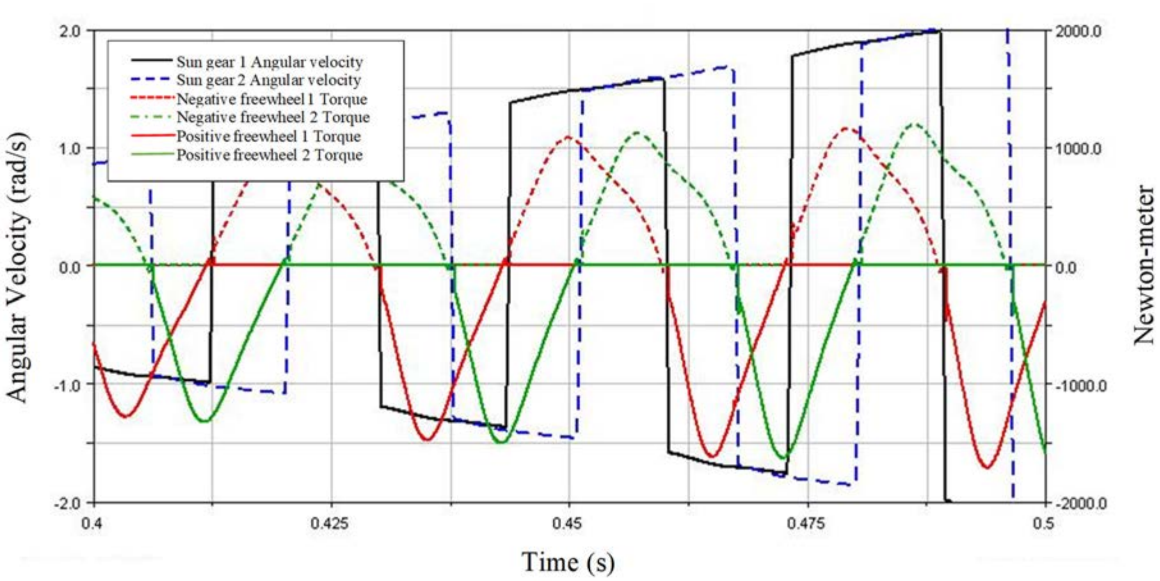

Figura 14: Pares transmitidos por las ruedas libres

Como conclusión, puede decirse que el hecho de usar dos trenes epicicloidales reduce las vibraciones del Sistema en base a:

- El par transmitido por las ruedas libres es menor.
- La velocidad de salida es mas suave debido al solapamiento entre la potencia transmitida por las ruedas libres.
- Hay una compensación parcial entre los modos de funcionamiento de los dos trenes epicicloidales reduciendo las oscilaciones del eje de entrada.

7. CONCLUSIONES

En este documento se analizan las distintas fuentes de vibraciones generadas por las CVTs de tipo inercial.

Las fuentes de vibraciones analizadas son intrínsecas al principio de funcionamiento de este tipo de CVTs y por lo tanto no pueden ser eliminadas. Sin embargo, se han propuesto una serie de posibilidades para reducir en lo posible estas vibraciones.

Para realizar estos análisis se han utilizado tanto modelos analíticos como computacionales y test en banco de ensayos.

Una conclusión importante de este estudio es que el comportamiento de una CVT inercial depende en gran medida de la fuente de potencia. Es decir, es dependiente de si se acciona mediante un motor eléctrico o mediante un motor de combustión interna y este hecho es fundamental a la hora de realizar ensayos, ya que la inmensa mayoría de los bancos de ensayo de transmisiones se encuentran accionados por motores eléctricos.

Este trabajo es parte de una línea completa de investigación. Este documento se ha centrado en las vibraciones de los sistemas de transmisión inerciales, pero no explica su principio de funcionamiento en detalle. Un estudio detallado de estos sistemas puede encontrarse en artículos y documentos previos (Morales y Benitez, 2019; Centeno et al., 2010; Perez, 2010; Morales, 2011).

AGRADECIMIENTOS

Uno de los autores expresa su gratitud al Ministerio de Economía y Competitividad por la ayuda parcial del programa Torres Quevedo (PTQ-17-09128).

Los ensayos en laboratorio no podrían haberse llevado a cabo sin la inestimable ayuda de Antonio Valverde Martín.

ABSTRACT

This article analyzes the influence of the proper modeling of the anti-lock brake system control loop components. Both the use of a stationary tire model and not considering the delays due to measurement, estimation, and actuation tend to be overlooked. Therefore, this affects the efficiency of the control algorithms developed through simulation. Thus, this work proposes to analyze the influence of the modeling of the components by performing experimental tests on a flat-track test bench. These tests demonstrate the need for taking these effects into account.

1. INFLUENCE OF TIRE DYNAMICS ON A BRAKING PROCESS WITH ABS

Correct modeling of the anti-lock brake system (ABS) components is crucial in the process of setting and optimizing a control algorithm through simulation. Therefore, this paper models all the components and analyzes their influence on the controllability of the braking system. The ABS control loop (Fig. 1) is composed of 4 main components: The system to be controlled, also called plant (tire-road interaction), the actuator (braking system), the measurement and estimation system (speed sensing), and finally the control algorithm.

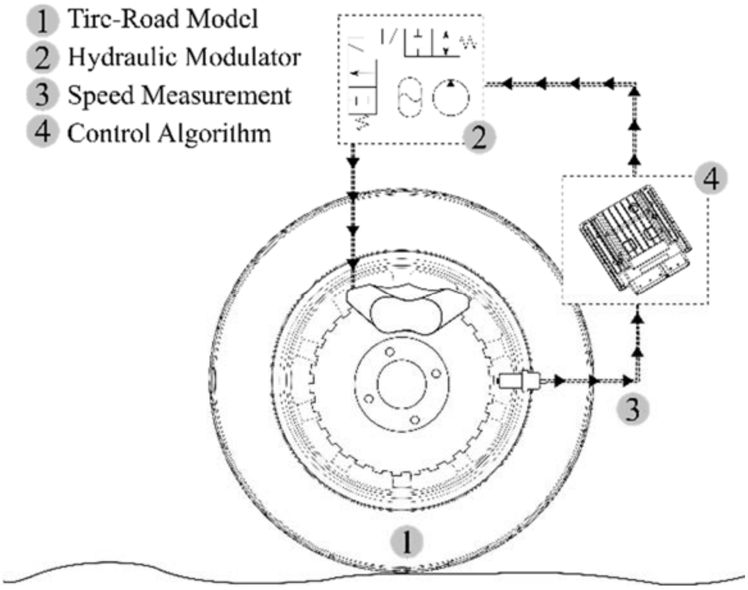

Figure 1: ABS Control Loop

First of all, the most commonly used tire model is the well known Pacejka's Magic Formula in its steady-state formulation (Pacejka, 2012). This model (1) relates the friction coefficient (μ)defined as the coefficient between the longitudinal and vertical forces to the slip ratio (κ) according to expression (2).

$$\mu = D_x sin[C_x\ arctan\{B_x\kappa - E_x(B_x\kappa - arctan(B_x\kappa))\}] \quad (1)$$

$$\kappa = -V_{sx}/|V_x| = (R_e\omega - V_x)/|V_x| \quad (2)$$

Where R_e is the wheel effective radius, ω the wheel angular speed, V_x the vehicle speed and (B_x, C_x, D_x, E_x) are the stationary parameters of the tire obtained on a test bench.

Since wheel locking occurs in a short time and with large variations in the contact forces (Arrigoni et al., 2017), a transient model (3) has to be used (Pauwelussen et al., 2003). This model uses the relaxation length (σ_κ) to add a delay between the transient longitudinal slip (κ') and the corresponding longitudinal force.

$$\kappa\sigma_\kappa \cdot d\kappa'/dt + |V_x|\kappa' = \sigma_\kappa\dot{\kappa}' + |V_x|\kappa' = -V_{sx} \quad (3)$$

Because the tire model parameters are obtained at a constant speed in test benches, it does consider the speed variation during braking processes. In Cabrera et al. (2018), this dependence is analyzed and is included in the tire model (4):

$$\kappa\lambda_{\mu x} = P_{x1} + P_{x2}exp(-P_{x3}\kappa'\, V_x) \quad (4)$$

Where (P_{x1}, P_{x2}, P_{x3}) are the parameters that describe the increase in adherence. All this modifies the adherence and optimal slip ratio (Ružinskas & Sivilevičius, 2017) throughout the braking process.

The actuator commonly used is a hydraulic control valve system (Tavernini et al, 2019) which, by increasing or decreasing the pressure, changes the contact force between the brake pads and the disc. This control system has an opening and closing time modeled using a first-order system including the fluid and friction dynamics (5) with a time constant (τ).

$$\tau\, dT_b/dt = \tau\, \dot{T}_b = K_b P_b - T_b \tag{5}$$

The torque applied (T_b) by the braking system is proportional (K_b) to the brake pressure (P_b). The measurement of the variables to be controlled is either carried out by sensors in a direct mode or by estimating their value in an indirect mode. The main variables in a braking control system are the speed of the vehicle and the speed of the wheel to be controlled. The latter is measured using a sensor that produces a wave whose frequency is proportional to the rotation speed. Both the variable resolution and the delay of the wheel speed sensor have to be considered to fit the one used in the vehicle. On the other hand, the speed of the vehicle is obtained indirectly as the technology that allows its direct measurement for commercial vehicles is costly. Therefore, the estimator used has to be implemented in the simulation in order to include the delays associated with estimation. Finally, the last of the four main components are the control algorithm that regulates the pressure to maximize the adherence preventing the wheel from locking. The simulation of an ABS optimizes this component to maximize braking. The main contribution of this research is to ensure that the simulation is accurate, so it behaves in the same way as the real. Therefore, it is proposed to keep the control algorithm fixed, with a simple control logic (6), (7) and analyze how the model of the other components influences the simulation and the real experimentation.

$$P_b = \{[P_{max} \quad \kappa' < \kappa_{opt}], [P_{min} \quad \kappa' > \kappa_{opt}]\} \tag{6}$$

$$\kappa_{opt}(\lambda_{\mu x}) = \lambda_{\mu x} \cdot P_{C_x} P_{D_x} \tan\left(\frac{\pi}{2 P_{C_x}}\right) / P_{B_x} \cdot \kappa = -V_{sx}/|V_x| = (R_e \omega - V_x)/|V_x| \tag{7}$$

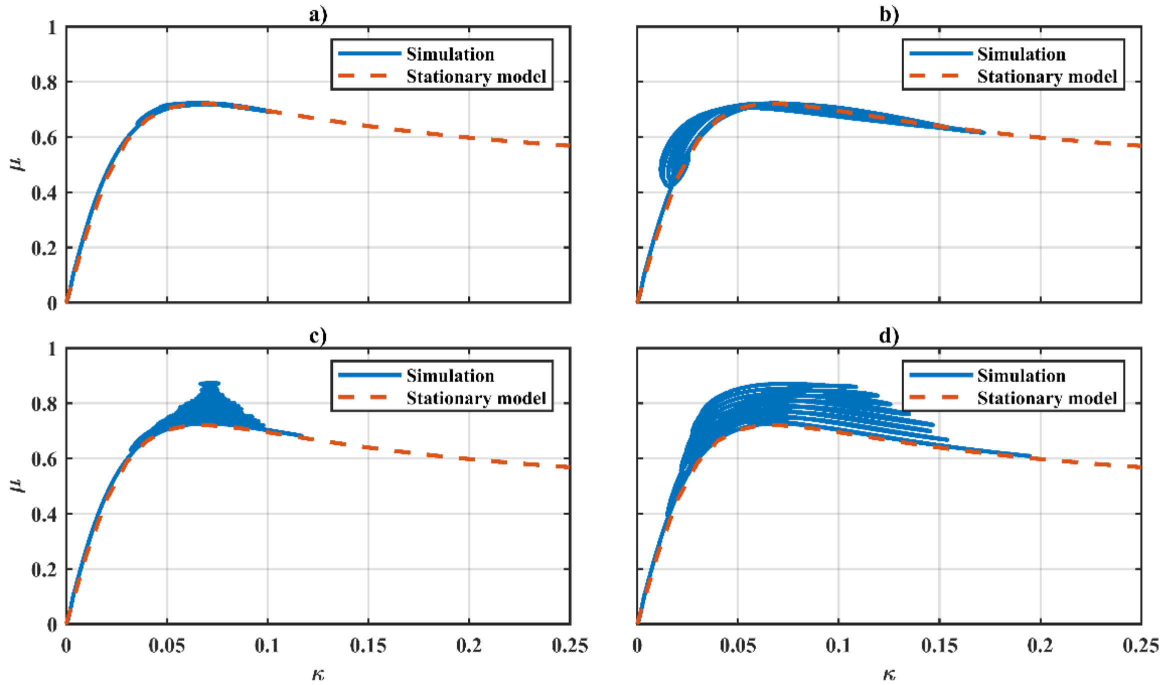

Figure 2: Influence of increasing adherence and measuring time in simulation: none (a), only measuring time (b), only increasing adherence (c), both (d).

2. CONCLUSIONS

The following conclusions can be drawn after analyzing the modeling of the different components of the ABS control loop. Both the adherence dependence with speed and the delays due to the measurement or estimation of variables are the ones that cause more fluctuations in the system response (Fig. 2). These introduce large oscillations, as well as affect the friction coefficient obtained throughout the simulation. In addition, both components tend to go overlooked in most of the literature that develops control algorithms for ABS systems. Usually, they are not supported by experimental tests or they do not show a proper fit with the simulation. This paper tries to emphasize the importance of the proper modeling of the ABS control loop components as well as to highlight the importance of experimental validation when developing control algorithms.

ABSTRACT

The present study is focused on the dynamic simulation of a car frontal crash against a lateral protection system for semitrailers. This system is a barrier fixed laterally to each side in semitrailers, designed to reduce damages on car passengers in case of lateral collision. From the basis of an already existing design, different designs and finite element models where created, adapting the system to the European regulation UNECE nº 73, concerning lateral protection devices' homologation. Finite element models were developed and different materials were considered on the metallic barrier beams. Then, crash simulations using the software LS-DYNA were performed, where a passenger car Toyota Yaris Sedan (2010 model) was impacted against the barrier at 50 km/h, 90 km/h and 120 km/h. Results such as maximum car displacements and deceleration on passengers could be analysed in these simulations. It was assessed the possibility of achieving a weight reduction of the barrier by means of design and material modifications.

1. INTRODUCTION

Current European lateral protection devices installed in semitrailers are designed according to UNECE regulation no 73 (UNECE, 2011), which is focused on the protection of vulnerable road users such as pedestrians, cyclist and motorcyclist, preventing them from being dragged and ran over by the semitrailer's wheels in the event of a collision. In this sense, this regulation defines dimensional, strength and stiffness requirements for the lateral protection systems. Nevertheless, this regulation does not offer protection for more aggressive impacts such as those in which a car collides head-on against the lateral of the semitrailer. In many of these accidents, the car passes through the semitrailer and its roof is torn apart, often resulting in fatal consequences for the car occupants. Considering all kind of vehicles, it can be pointed out that fatalities in lateral and frontal-lateral collisions represented 12% of the total casualties (at 24 h) reached between 2015-2019 at Spanish intercity roads (Observatorio Nacional de Seguridad Vial, 2021). It is also reported that considering all kind of accidents involving heavy goods vehicles in the European Union during 2016-2018, the share of car occupants killed in collisions accounted for 50% of all deaths (Adminaité-Fodor & Jost, 2020). Therefore, it seems plausible that future safety developments and regulations contemplate this type of collision and include more stringent stiffness and strength requirements for lateral protection devices, in the same way as current rear protection systems assembled to semitrailers are demanded to protect car occupants in frontal collisions. In this sense, in the U.S. a new regulation on mandatory requirements to prevent side and front underride accidents was discussed in the “Stop Underrides Act” (H.R.1511, 2019). Crash simulation with finite element software offers the possibility of modeling and simulating the crash behavior of new protection devices at lower costs than actual tests where vehicles are needed to be crashed; in order to guarantee an accurate numerical-experimental correlation several prototypes should always be tested, though. For instance, simulations performed with LS-DYNA could greatly contribute to estimate the vehicles’ crash performance, when new designs of lateral protection systems are included in the model. In order to explore simulation possibilities on this scenario, this paper is focused on the finite element simulation of a semitrailer’s lateral protection system in a car frontal crash situation, with the car colliding perpendicularly to the semitrailer. It was analyzed not only the device’s mechanical performance for different materials and geometric configurations, but also the deceleration reached inside the car and the car displacement when is running at different speed values before hitting.

2. MATERIALS AND METHODS

2.1 “AngelWing” side guard

On the one hand, the starting point was an already existing lateral protection system called “AngelWing” developed by the manufacturer “Airflow deflection” (airflowdeflector, 2021). It was assembled to both sides of a semitrailer and then crash-tested by the IIHS (Insurance Institute for Highway Safety) in 2017 against a Chevrolet Malibu (2009 model) impacting frontally. The test proved that the passive safety offered by this truck side guard prevents the car from underrunning the semitrailer: according to the manufacturer, the guard prevents Passenger Compartment Intrusion at speeds of up to 64.37 km/h (40 mph). Therefore, this device added to other car safety devices such as seat belts, airbags, proximity sensors and emergency brake systems, can highly improve the survival chances for the car occupants. This guard was made of galvanized ASTM A500 steel beams, its global dimensions were

6090×584×2565 mm and its weight was 364 kg; according to the manufacturer, this guard is currently sold by length and truck application.

2.2 Regulation no 73

On the other hand, European regulation no 73 contains the requirements that lateral protection devices (LPD) for vehicles of categories N2, N3, O3 and O4 must comply for their approval in the European Community. Concerning the analysis included in this paper, it has been considered a semitrailer with a maximum mass exceeding 10 tonnes, which corresponds to vehicle category O4 (European Parliament, 2007). The following points, extracted from regulation no 73, detail the dimensional requirements established for LPD in O4 vehicle category:

- LPD shall not increase the overall width of the vehicle and the main part of their outer surface shall not be more than 150 mm inboard from outermost plane of the vehicle. Their rearward end shall not be more than 30 mm inboard from the outermost edge of the rear tyres over at least the rearmost 250 mm.
- LPD may consist of a continuous flat surface, or of one or more horizontal rails, or a combination of surface and rails: when rails are used they shall be not more than 300 mm apart and not less than 100 mm high and essentially flat (O4 case).
- The forward edge of LPD shall be not more than 250 mm to the rear of the transverse median plane of the support legs, if support legs are fitted, but in any case the distance from the front edge to the transverse plane passing through the centre of the kingpin in its rearmost position may exceed 2.7 m.
- Where the forward edge lies in an open space of more than 25 mm, the edge shall consist of a continuous vertical member extending over the whole height of the device; the outer and forward faces of this member shall measure at least 100 mm rearwards and be turned 100 mm inwards or have a minimum radius of 100 mm.
- The rearward edge of LPD shall not be more than 300 mm forward of the vertical plane perpendicular to the longitudinal plane of the vehicle and tangential to the outer surface of the tyre on the wheel immediately to the rear; a continuous vertical member is not required on the rear edge.
- The lower edge of LPD shall at no point be more than 550 mm above the ground.
- The upper edge of LPD shall not be more than 350 mm below that part of the structure, cut of contacted by a vertical plane tangential to the outer surface of the tyres.

With respect to strength and stiffness performance, regulation nº 73 defines the following requirements:

- LPD shall be essentially rigid, securely mounted (not liable to loosening due to vibration) and made of metal or any other suitable material. LPD shall be considered suitable if they are capable of withstanding a horizontal force of 1 KN applied perpendicularly to any part of their external surface by the centre of a ram the face of which is circular and flat, with a diameter of 220 mm ± 10 mm, and if the deflection of the device under load measured at the centre of the ram is then not more than 30 mm over the rearmost 250 mm of the device; and 150 mm over the remainder of the device.

As stated before, while these mechanical requirements are focused on protecting vulnerable road users, it is clear that they are not stringent enough to avoid severe damages in high energy collisions such that with a car hitting the device laterally. For instance, rear protection systems are required to reach much higher forces when tested according to regulation no 58 (UNECE, 2017), with a maximum of 100 KN or 180 KN depending on the location of the points tested.

2.3 Finite element models created for the lateral protection systems

Taking into account all the previous considerations, three different finite element (FE) models were created. Figure 1 shows the six-post model and its main structural dimensions. It used shell elements and consisted of four longitudinal beams (100×100×3 mm) joined by six vertical posts (100×50×3 mm) at each side and six sets of crossed beams (100×50×3 mm) transversally connected to the posts. Bolted and weld joints were simplified by means of equivalent nodes between adjacent parts. Two more variants were created as a simplification from this model: three-post model and two-post model, which are showed in figure 2 and were also analysed.

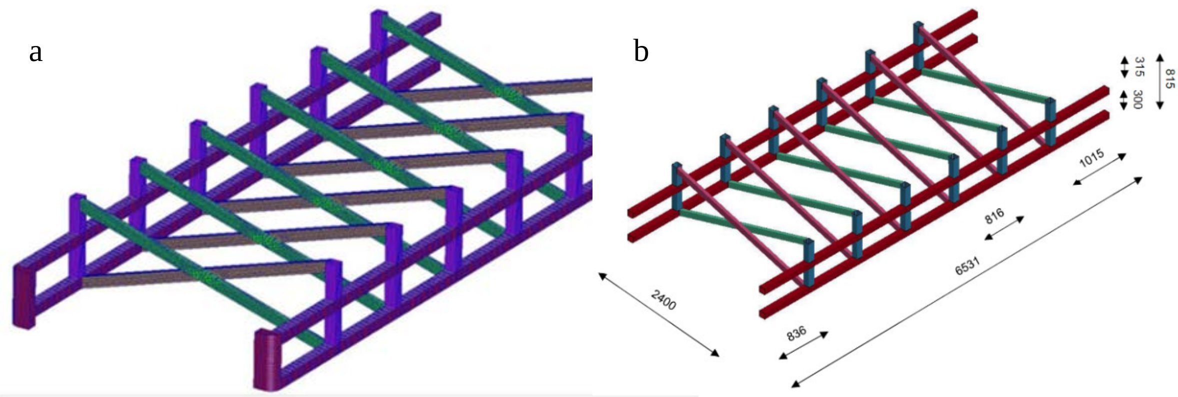

Figure 1: (a) Six-post lateral protection system's FE model; (b) Main structural dimensions

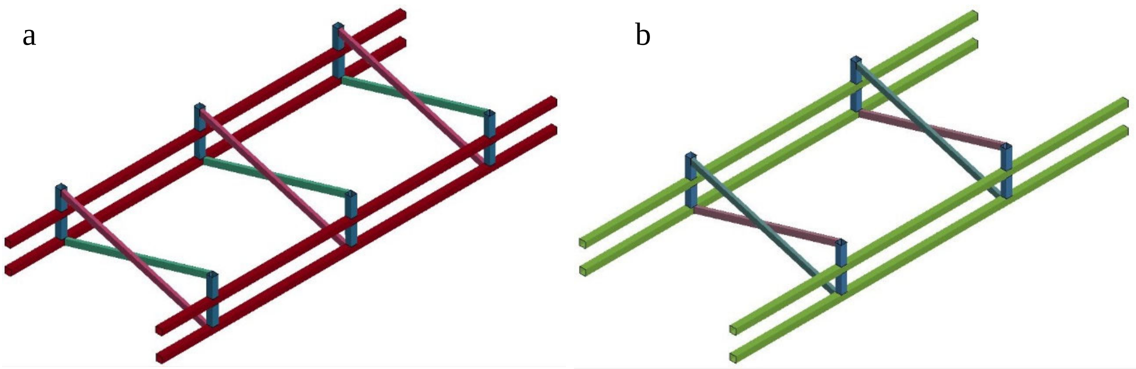

Figure 2: (a) Three-post lateral protection system's FE model; (b) Two-post lateral protection system's FE model

All were modeled using 4-node shell elements with Hughes-Liu formulation and a mesh size of 20 mm. They were created with the software MSC Patran and later on imported in LS-DYNA prepost. The crash behavior of each model was simulated and compared using three different materials for the whole system: S275 (structural steel), Strenx Tube 700MH (high strength steel) and AL 6005A T6 (aluminium alloy with cooling in press). Table 1 shows the main mechanical properties of materials considered in the models and table 2 shows the total weight that resulted from each lateral protection system design.

Material		Density (kg/m^3)	Young modulus (MPa)	Poisson ratio	Yield strength (MPa)	Ultimate strength (MPa)	Elongation at break ($^{o}/_{1}$)
Steel	S275 [8]	7850	210000	0.33	275	500	0.2
	Strenx Tube 700MH [9]	7850	210000	0.33	700	850	0.1
Aluminium	6005A – T6 [10]	2710	69500	0.33	215	255	0.08

Table 1: Mechanical properties of materials considered in the FE models

Material		Six-post model Weight (kg)	Three-post model Weight (kg)	Two-post model Weight (kg)
Steel	S275	526.61	388.58	342.60
	Strenx Tube 700MH			
Aluminium	6005A – T6	184.77	137.12	121.25

Table 2: Total weights of the lateral protection systems simulated

2.4 Finite element car model for the crash simulation

All the crash simulations were performed using LS-DYNA, and the FE car model was a Toyota Yaris Sedan (2010), which is available at the National Highway Traffic Safety Administration (NHTSA) web page and has been used in support of several NHTSA programs (NHTSA, 2021). This FE car model was developed by a reverse engineering process at the George Washington University National Crash Analysis Center (NCAC). Its collision performance has been validated with the NCAP 5677 and 6221 tests against a rigid wall (impacting at 40.23 and 56.32 km/h) and it presents also a robust response for the study of a variety of crash scenarios (Marzougui et al., 2012; NCAC, 2011). This model consists of 1480422 nodes and 1514068 elements and it is showed in Figure 3.

3. CALCULATION. BOUNDARY CONDITIONS AND LOAD CASES

In the first place, the EuroNCAP (European new car assessment programme) full width frontal impact test against a concrete barrier (Euro NCAP, 2019) was used as reference, in order to assess the car's deceleration values obtained during the collision against the lateral protection system. The concrete barrier was simulated with rigid shell elements, as showed in figure 3. In this case the car was simulated impacting at 50 km/h, 90 km/h and 120 km/h speed. Since the total mass of the car was 1306.29 kg, the kinetic energies involved in the collision were respectively 125994.49 J, 408215.62 J and 711274.9 J. It can be noted that, starting at a collision speed of 50 km/h, an increase of 40 km/h leads to 3.2 times higher kinetic energy and an increase of 70 km/h leads to 5.6 times higher kinetic energy. Being the wall completely rigid, these simulations represent a highly unfavorable crash situation where all the plastic strain energy was absorbed by the car structure (mainly by the front structural components).

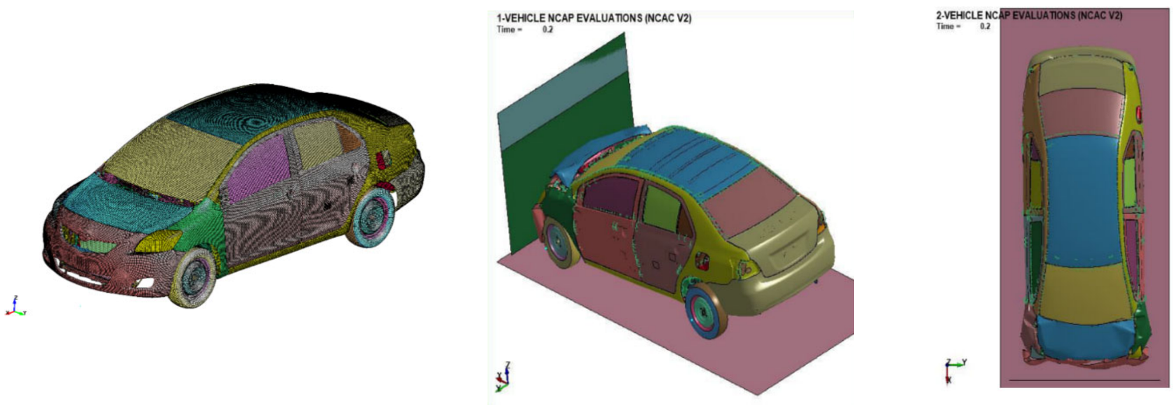

Figure 3: NCAC's FE model for the 2010 Toyota Yaris Passenger Sedan and EuroNCAP full width frontal impact test simulation

In this way, the deceleration results obtained for the lateral protection systems simulated later on, could be compared with these previous results obtained colliding the car frontally against a rigid wall. A rigid shell element simulated the ground and all the nodes of both the wall and the ground were fully constrained (all linear and rotational degrees of freedom). An initial velocity condition was applied to all nodes of the vehicle, with an additional rotational velocity at those nodes comprising the wheels' parts; it also included the gravity acceleration and a general contact condition applied to all the elements of the model.

Regarding the crash simulations for the lateral protection systems analysed, an equivalent approach was considered. In this case, all the nodes located at the top of the vertical posts were fully constrained, corresponding to those regions welded or bolted to the semitrailer's structure. This boundary condition represented a much stiffer situation than what occurs in reality, since the semitrailer's structure could also absorb some strain energy during the collision. Moreover, depending on the energy level involved, among other factors, the semitrailer could even gain kinetic energy and be pushed laterally by the car through the ground. Therefore, the simulations performed were conservative and peak deceleration values reached inside the car were expected to be higher under simulation conditions than under real conditions.

Figure 4 shows the constrained nodes at the top of the posts beams (blue posts in the figure) and the numerical model for simulating the collision against the six-post lateral protection system. In all simulations performed for this study, the car was positioned colliding at the centre of the barrier.

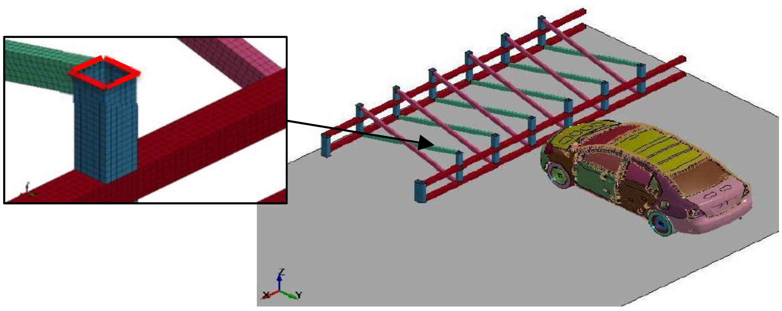

Figure 4: Numerical model simulating a collision against the six-post lateral protection system. Detail with constrained nodes at the top of the posts

4. RESULTS AND DISCUSSION

4.1 Variation in the lateral protection system's geometry

Once the models were created, the first analysis was focused on comparing the performance of the three different designs considered. Figure 5 shows the final frame at the end of each simulation, all calculated with the car impacting at 50 km/h and applying S275 steel to the barriers. While the six-post and the three-post systems were able to stop the car and performed correctly, the two-post system was not stiff enough and collapsed completely. The car model has an accelerometer positioned at its center of gravity for registering the acceleration inside the vehicle. Since the impact time is around 0.14 s, the impact's frequency is near 7 Hz. Then, a 7-Hz low-pass SAE filter was applied to the acceleration signal in order to filter higher frequencies. The car deceleration values, measured in g's, and the car total displacements registered during these simulations can be seen in figures 6 and 7 respectively.

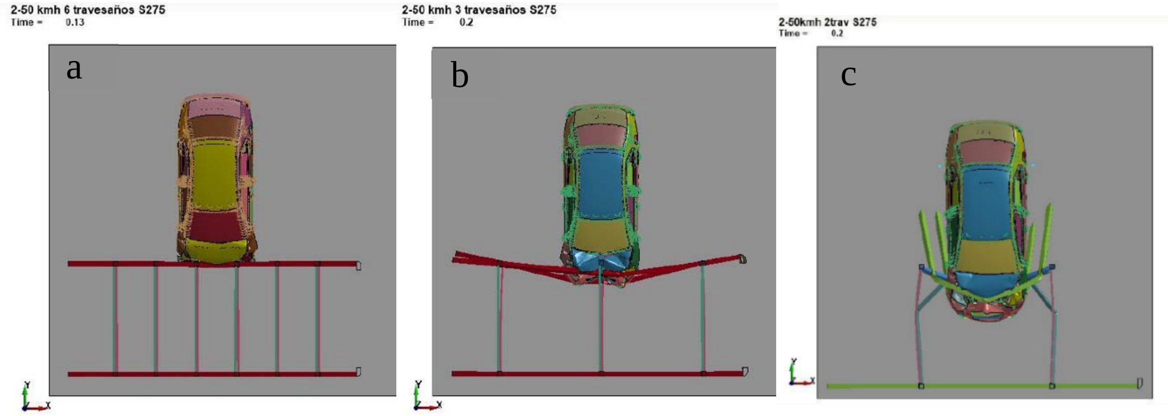

Figure 5: Final frame for simulations at 50 km/h with S275 lateral protection systems: (a) Six-post system; (b) Tree-post system; (c) Two-post system

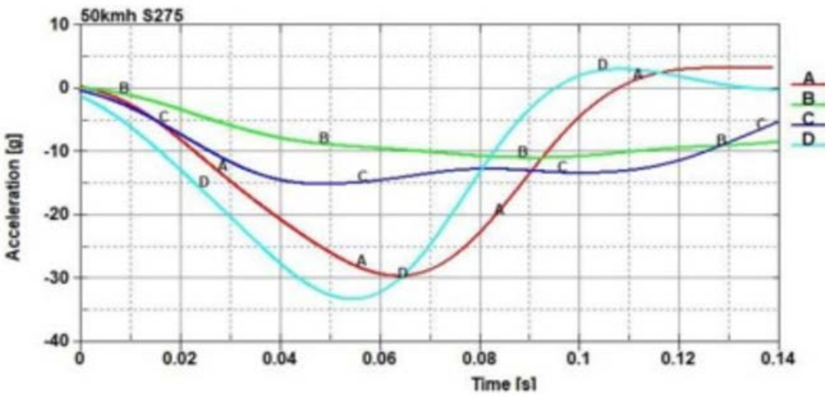

Figure 6: Car deceleration (g's) for simulations at 50 km/h with S275 lateral protection systems: (A) Six-post system; (B) Two-post system; (C) Three-post system; (D) NCAP rigid wall

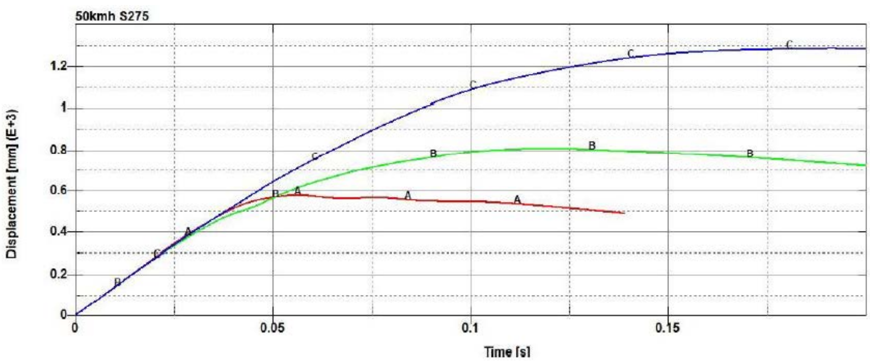

Figure 7: Car displacements (mm) for simulations at 50 km/h with S275 lateral protection systems: (A) Six-post system; (B) Three-post system; (C) Two-post system

While the two-post system collapsed and was not able to stop the car properly, with a displacement value of 1.2 m, the other two systems stopped the car with quite lower displacement values: 0.8 m in the two-post system and near 0.57 m in the six-post system. From these graphs, it can be observed that the three-post system produced a maximum deceleration of 15 g's and the six-post system produced a maximum deceleration of 30 g's. Therefore, the three-post design was preferred to the six-post design. The latter performed with a much stiffer response, with its peak deceleration very close to the rigid wall's one (approximately 33 g's).

4.2 Variation in the lateral protection system's material

In order to compare the performance for the three materials considered (steel S275, high strength steel Strenx 700 MH and aluminium alloy 6005 A-T6), the three designs were simulated applying the same material to all barrier components, at each case. Figure 8 shows the final frame at the end of each simulation for the six-post system. Likewise, they were all calculated with the car impacting at 50 km/h.

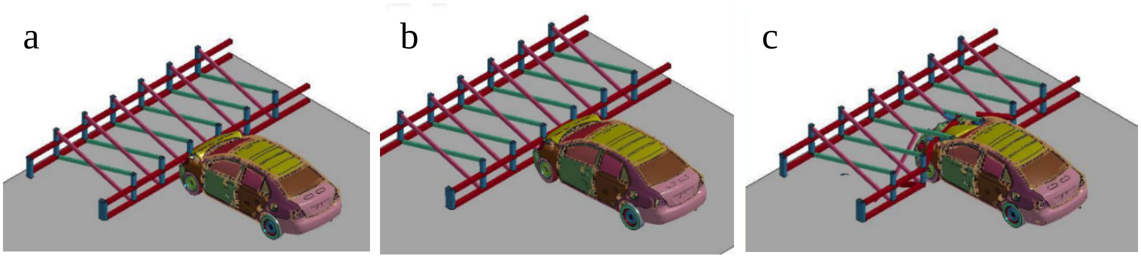

Figure 8: Final frame for simulations at 50 km/h with different materials in the lateral protection systems: (a) S275; (b) Strenx 700 MC; (c) AL 6005A-T6

Figure 9 shows the deceleration values for the simulations with the six-post design, as well as the NCAP rigid wall test' deceleration values (in g's). Figure 10 shows the car displacement values in mm.

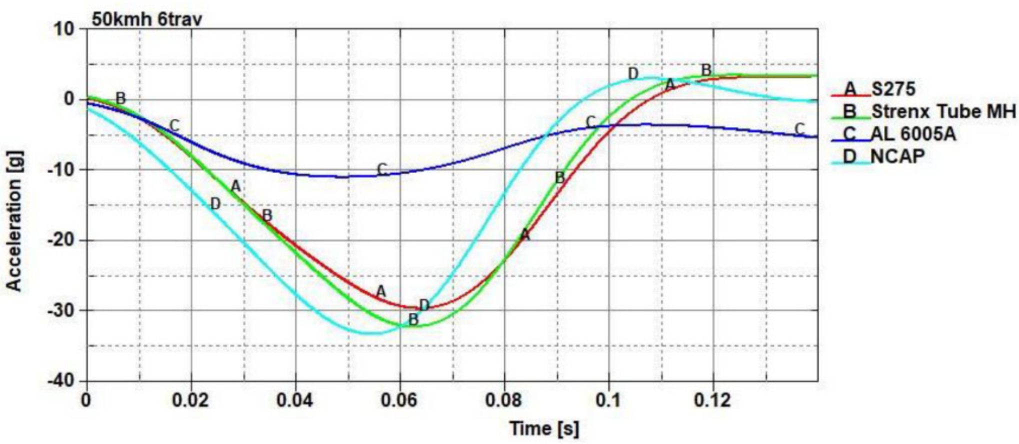

Figure 9: Car deceleration (g's) for simulations at 50 km/h applying different materials to the six-post system: (A) S275; (B) Strenx 700 MH; (C) AL 6005A-T6; (D) NCAP rigid wall

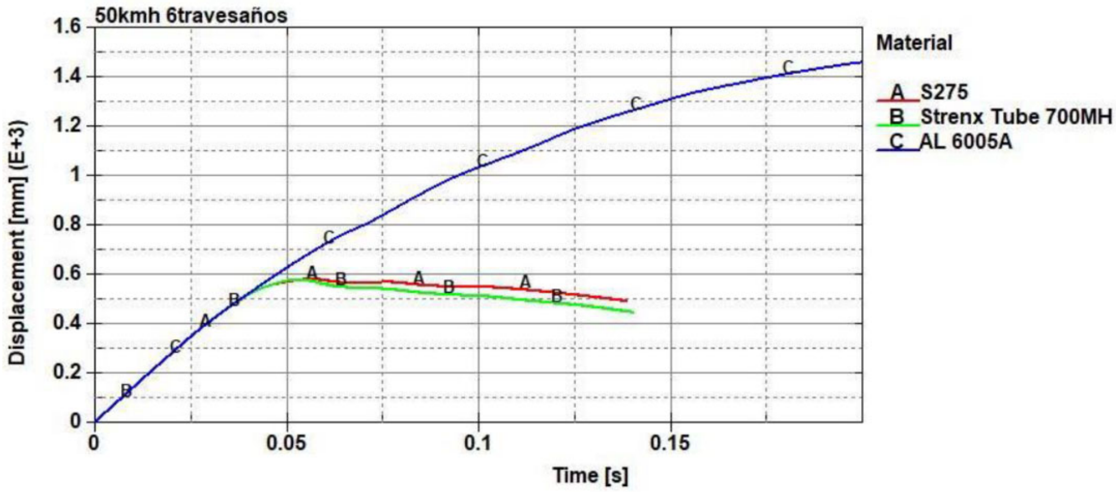

Figure 10: Car displacement (mm) for simulations at 50 km/h with different materials in the lateral protection systems: (A) S275; (B) Strenx 700 MH; (C) AL 6005A-T6

As can be observed from figure 9, the application of high strength steel gave a closer response to the rigid wall collision simulation. However, the aluminium design could not stop the vehicle, with the barrier failing and the car passing through it, as can be observed from figure 10. Both steel systems showed a maximum car displacement of approximately 0.57 m.

4.3. Variation in car's impact velocity

The performance of the lateral protection system with the car colliding at different speed values was also assessed. A collision case at 50 km/h could correspond to an urban road, but, depending on the road category and the speed limits allowed, the lateral collision may take place with the car running at higher speeds.

In order to analyze the system's response at higher kinetic energies, all designs were also simulated applying initial velocities of 90 km/h and 120 km/h. Figure 11 shows the final frame of the simulations with the car impacting at 50 km/h, 90 km/h and 120 km/h, all against the same three-post S275 design.

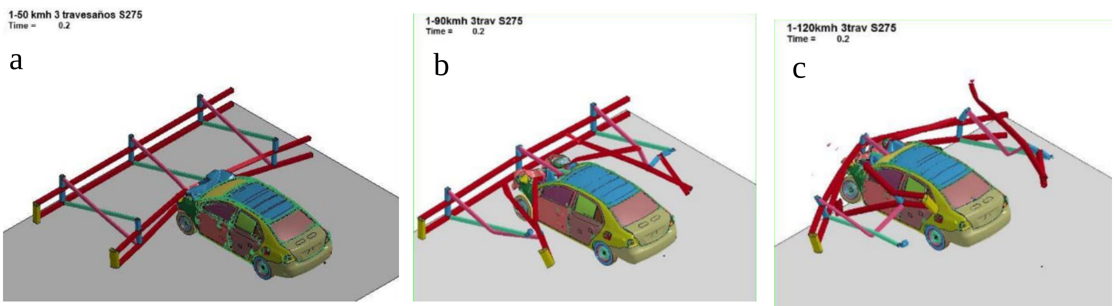

Figure 11: Crash against S275 three-post system: (a) 50 km/h; (b) 90 km/h; (c) 120 km/h

As can be observed in figure 11 (a), the S275 three-post protection system was able to stop the car impacting at 50 km/h, with the energy absorption shared between the protection system and the car's frontal.

Nevertheless, at higher collision speeds of 90 km/h and 120 km/h, the device could not stop the car due to the higher energies involved (respectively, 3.2 and 5.6 times as much as the 50 km/h case), which led the barrier to a full collapse. In both cases the car would continue its movement through the semitrailer, which would be fatal for the car occupants. Figure 12 shows the car deceleration values measured in g's for these simulations. Figure 13 shows the car displacement values in mm.

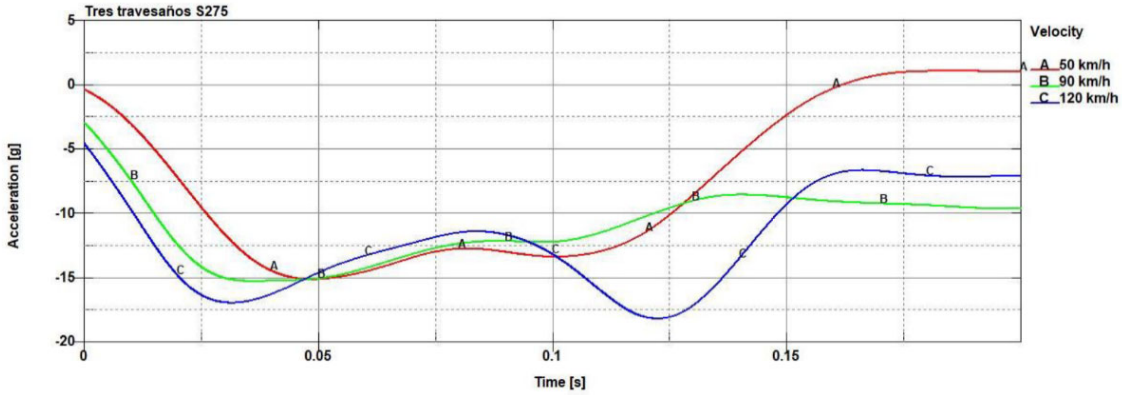

Figure 12: Car deceleration (g's) for S275 three-post system: (A) 50 km/h; (B) 90 km/h; (C) 120 km/h

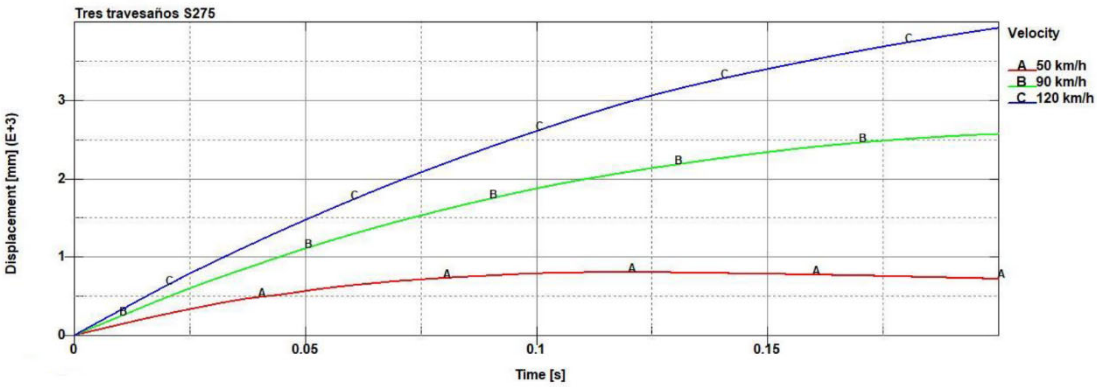

Figure 13: Car displacement (mm) for S275 three-post system: (A) 50 km/h; (B) 90 km/h; (C) 120 km/h

5. CONCLUSIONS

Crash simulation numerical tools can contribute to develop efficient and effective lateral protection systems for semitrailers. On the one hand, in order to improve safety in frontal-lateral car-semitrailer collisions, these systems should be able to resist a certain kinetic energy level as well as to avoid the underrun phenomenon. On the other hand, taking into account that semitrailers must normally cover long range travels, it is desirable to produce light designs that do not lead to an increase in fuel consumption and CO_2 emissions. It has been analysed a car frontal crash against a lateral protection system for semitrailers adapted to the European regulation by means of finite element dynamic simulations performed with the software LS-DYNA. Three different models were created using beam with rectangular hollow sections, referred to as the two-post, three-post and six-post lateral protection systems, varying their number of posts and cross-members. Three different materials were compared: S275 structural steel, Strenx Tube 700MH high strength steel and aluminium alloy 6005A T6. Lastly, three different car impact speeds where simulated: 50 km/h, 90 km/h and 120 km/h.

For simulations with the car running at 50 km/h, the aluminium stiffest design (the six-post one) was not able to resist the energy level involved. Therefore, all aluminium alloy designs were discarded despite their lower weights. At 50 km/h, the two-post system performed poorly in general, all producing underrun situations. On the contrary, the six-post system was found to be excessively stiff in both structural steel and high strength steel models, producing high deceleration peak values inside the car, that could damage the occupants. Then, at that speed, the intermediate three-post system with S275 was the preferred option in terms of cost, weight and safety. The car stopped with a 15 g's peak deceleration and the strain energy was absorbed with better balance by both the barrier and the car.

Therefore, this design could be supposed to perform adequately in urban roads. However, when the car was launched at 90 km/h and 120 km/h, the three-post system was not able to stop the car, and the underrun would be fatal to its occupants. As the kinetic energy level in these collisions depends on the mass and the speed of the car, the results suggest that these lateral protection systems could be designed to offer a proper response at a certain kinetic energy range. A trade-off between peak deceleration values and the allowable car displacement due to the barrier deformation will always be necessary. For instance, although highly stiff designs could lead to peak decelerations near to the rigid wall test's values and would probably add a higher structural weight, they could possibly avoid the car underrun in non-urban road accidents.

THERMAL COMFORT IN CONVENTIONAL VEHICLES (ICE) AND ELECTRIC (EV) - EVALUATION METHODS

Bernardo José Mirones Gómez
Valladolid University – Spain

ABSTRACT

Development and fine-tuning of a procedure for measuring the temperature in the car windshield area, with respect to the European demisting standard (CEE 78/317): by using a high-speed infrared thermography camera.

Carry out a differential analysis of the experimentally obtained results both in terms of thermal comfort, between vehicles equipped with ICE technology (conventional) and vehicles equipped with EV technology.

1. INTRODUCTION

Electric mobility is expanding at a rapid rate. Electric car deployment has been growing rapidly over the past ten years, with a global stock of electric passenger cars surpassing 5 million in 2018, a 63% increase over the previous year.

About 45% of electric cars on the road in 2018 were in China, a total of 2.3 million, compared with 39% in 2017. By comparison, Europe accounted for 24% of the world's fleet, and the United States 22%.

Sales of electric vehicles in the world grew 64% in 2018. Sales of electric vehicles in the world during 2018 reached 2.1 million. 69% of sales were all electric (EV) and 31% were plug-in hybrids (PHEV).

These figures include electric and plug-in hybrid passenger cars, light trucks in the US and Canada, and light commercials in Europe and China.

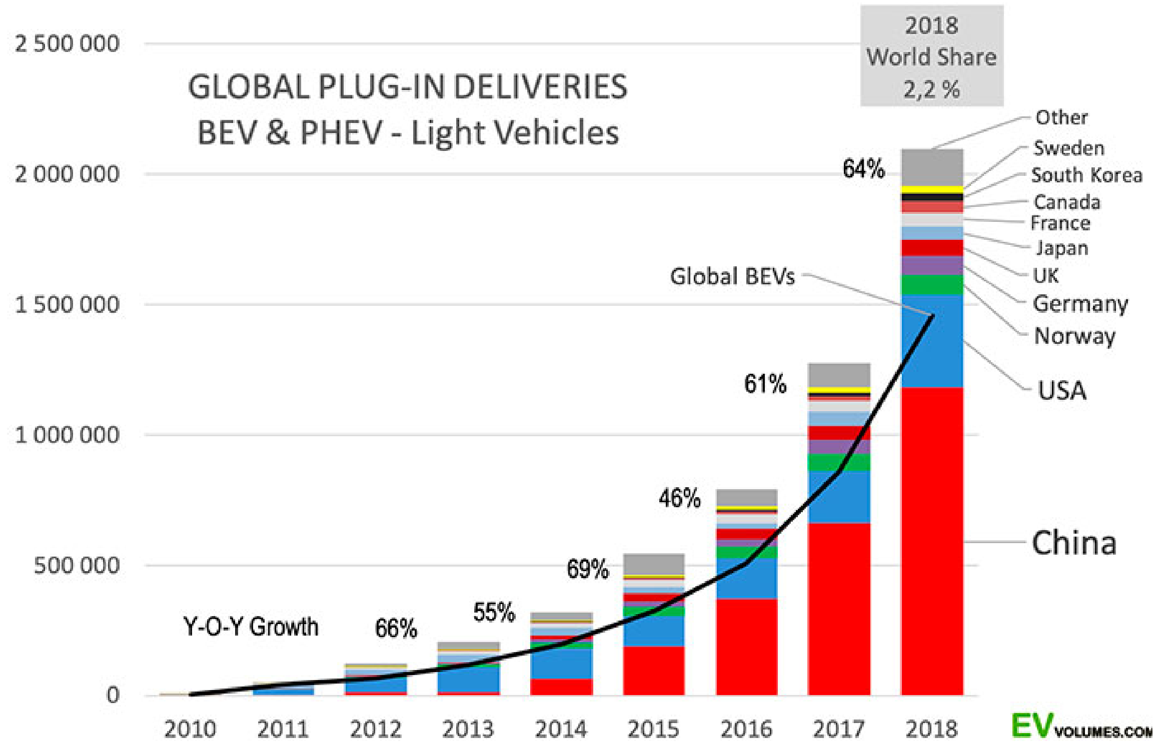

Figure 1: Global BEV & PHEV Light Vehicles Deliveries

69% of sales were all electric (EV) and 31% were plug-in hybrids (PHEV). Fully electric vehicles have reached a 3% share since 2017. The causes, according to the Swedish consultancy EV-volumes, lie mainly in three factors. The first, growth in China. The second, the arrival of the Tesla Model-3. The third, the losses for PHEVs in Europe due to the entry into force of the WLTP protocol.

The largest contributor to growth, by far, was China. Its electricity sales increased by more than 500,000 units, to 1.2 million in 2018. It represented 56% of all electrified sales. (Figure 1).

Growth in Europe was moderate, at 34% (Figure 2). It was held back by limited ranges and long waiting lists for popular EVs. Also, due to the exhaustion of sales of PHEVs in stock. In the US, sales were up 79% and the expected Tesla Model-3 contributed 138,000 units. It became the best-selling EV of all categories in 2018. It even dominated luxury car sales in North America. Sales outside of China, Europe and the US were 150,000 units (+ 39%), with Japan again the opposite. However, other markets such as Canada and South Korea grew much faster than average.

2. PURPOSE

Development and fine-tuning of a procedure for measuring the temperature in the car windshield area, with respect to the European Standard for demisting (CEE 78/317): by using a high-speed infrared thermography camera.

In this study, we aim to evaluate the effectiveness of windshield demisting systems in electric vehicles by using thermography (IR) techniques and infrared image analysis. Thermography allows obtaining objective information (temperature values) in relation to the condition of the windshield, unlike other studies in which the evaluation of thermal comfort inside vehicle cabs is based on subjective evaluations. Due to the use of other methods, such as digital thermometers and liquid crystals, there are few previous works where infrared thermography is used for the evaluation of temperature or thermal comfort inside vehicle cabs.

3. MATERIALS AND METHODS

3.1 Thermal camera:

- InfraTec ImageIR.
- Software: IRBIS 3 Professional.
- Lenses: 100mm + 500mm.
- Minimum spatial resolution of 30 µm.
- Image size: 320 x 256 pixels.
- Speed: 1000 fps.
- Resolution: 30 mK @ 30 ºC
- Integration times from 1 µs to 10 ms.

We check that the entire windshield of the car is at -2ºC of temperature, we start the engine, we close all the aerators except those for demisting the windscreen, we close all the doors and gate, we begin the test t = 0 at the right moment to start the engine. (Figure 3)

Test carried out on 3 vehicles: one equipped with a conventional heat engine (ICE), an EV equipped with resistance, and an EV equipped with a heat pump.

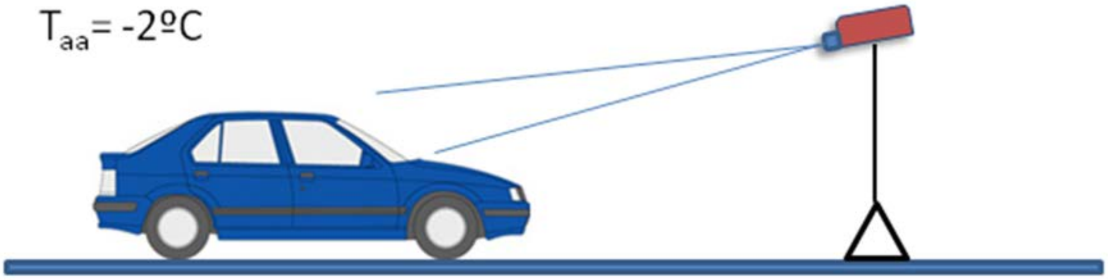

Figure 3: Scheme of the Measurement Method

Average temperature on the windshield at the beginning of the Test, the average temperature is -2º C (We perfectly comply with the European Regulation CEE78 / 317, which requires between -1ºC and -3ºC), see Figure 4, average temperature throughout the windshield (for the 3 models tested, stabilized 24 hours):

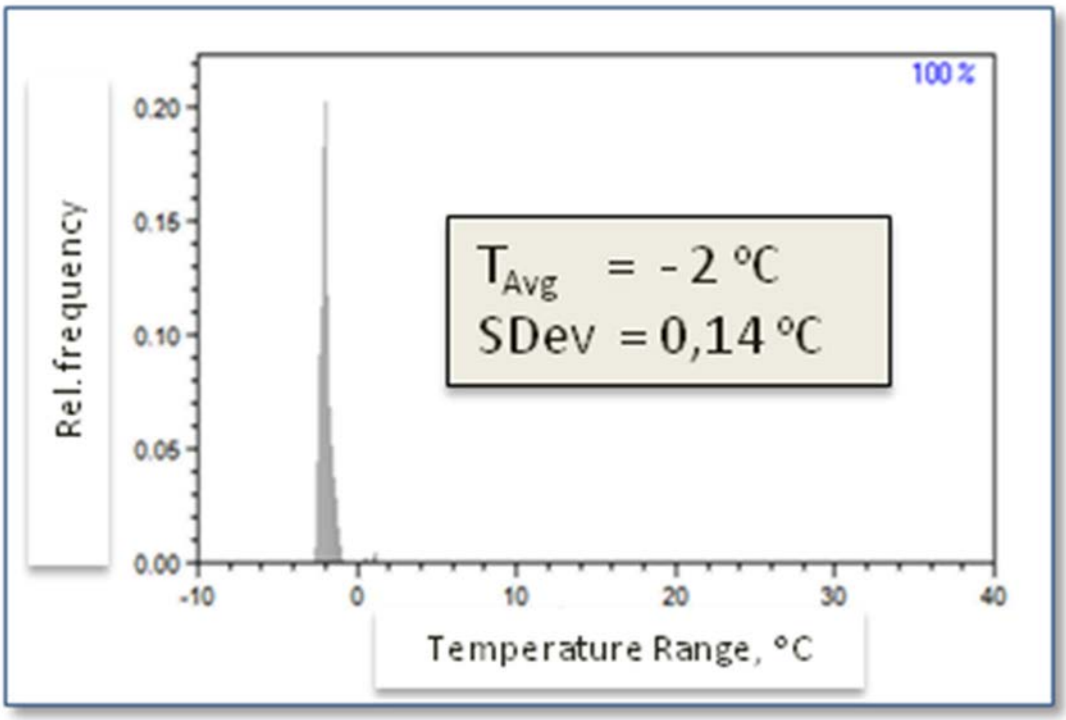

Figure 4: Average temperature on the windshield at the beginning of the Test

4. RESULTS

Illustrative example: Minute 5, Thermal ICE (Figures 5 & 6)

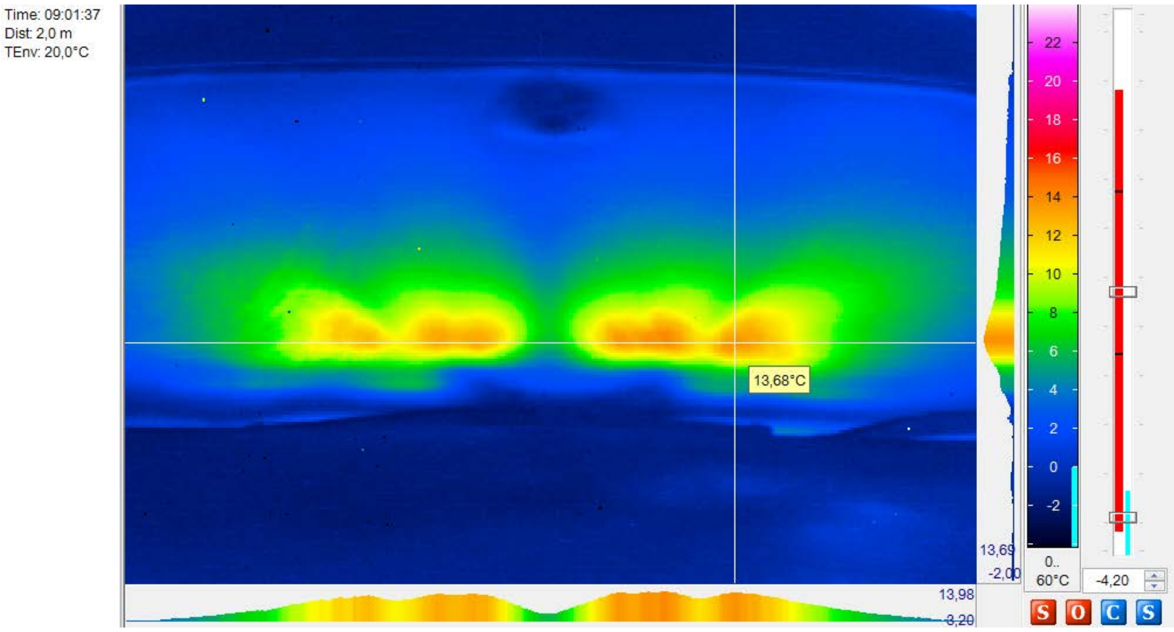

Figure 5: Example: Thermography map on the windshield (minute 5 – ICE Vehicle)

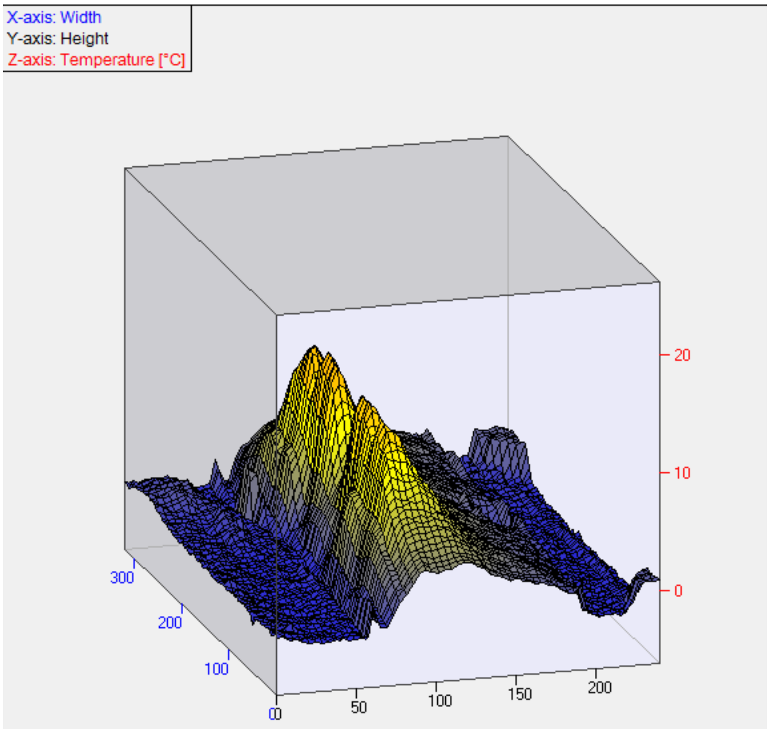

Figure 6: 3D graph of temperature on the windshield

Making a summary graph by average, maximum and minimum temperature in area R1, during the 20 minutes that the Test lasts, we obtain the following (ICE – Figure 7):

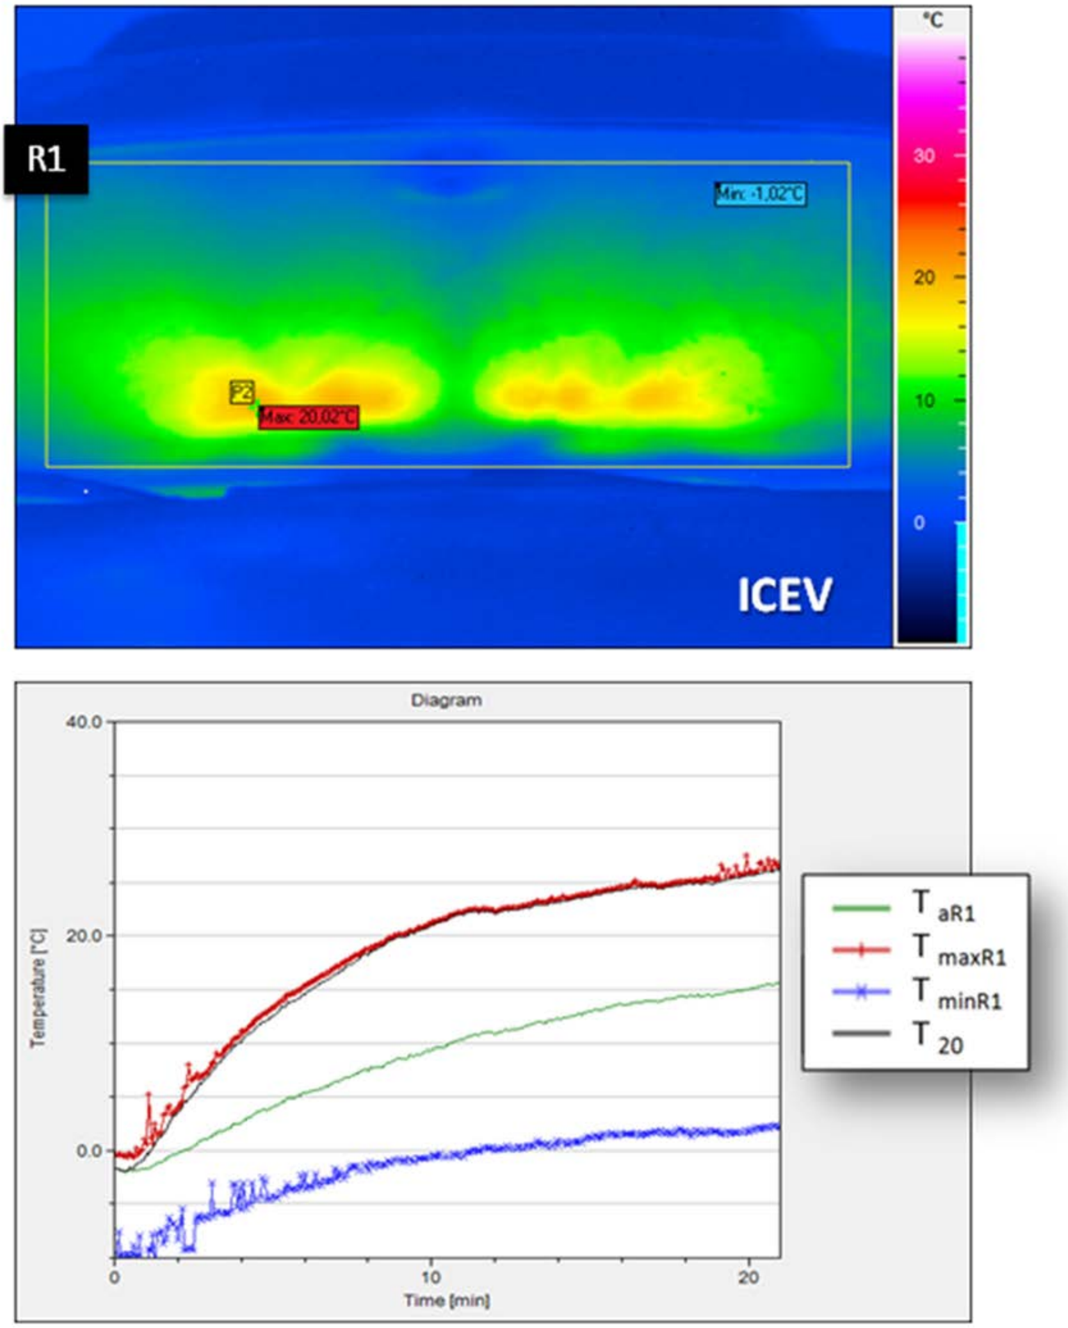

Figure 7: Average, maximum and minimum temperature in area R1 - ICEV

Making the same summary graph by average, maximum and minimum temperature in area R1, during the 20 minutes that the Test for the Electric Car with Resistance Heating lasts (Figure 8):

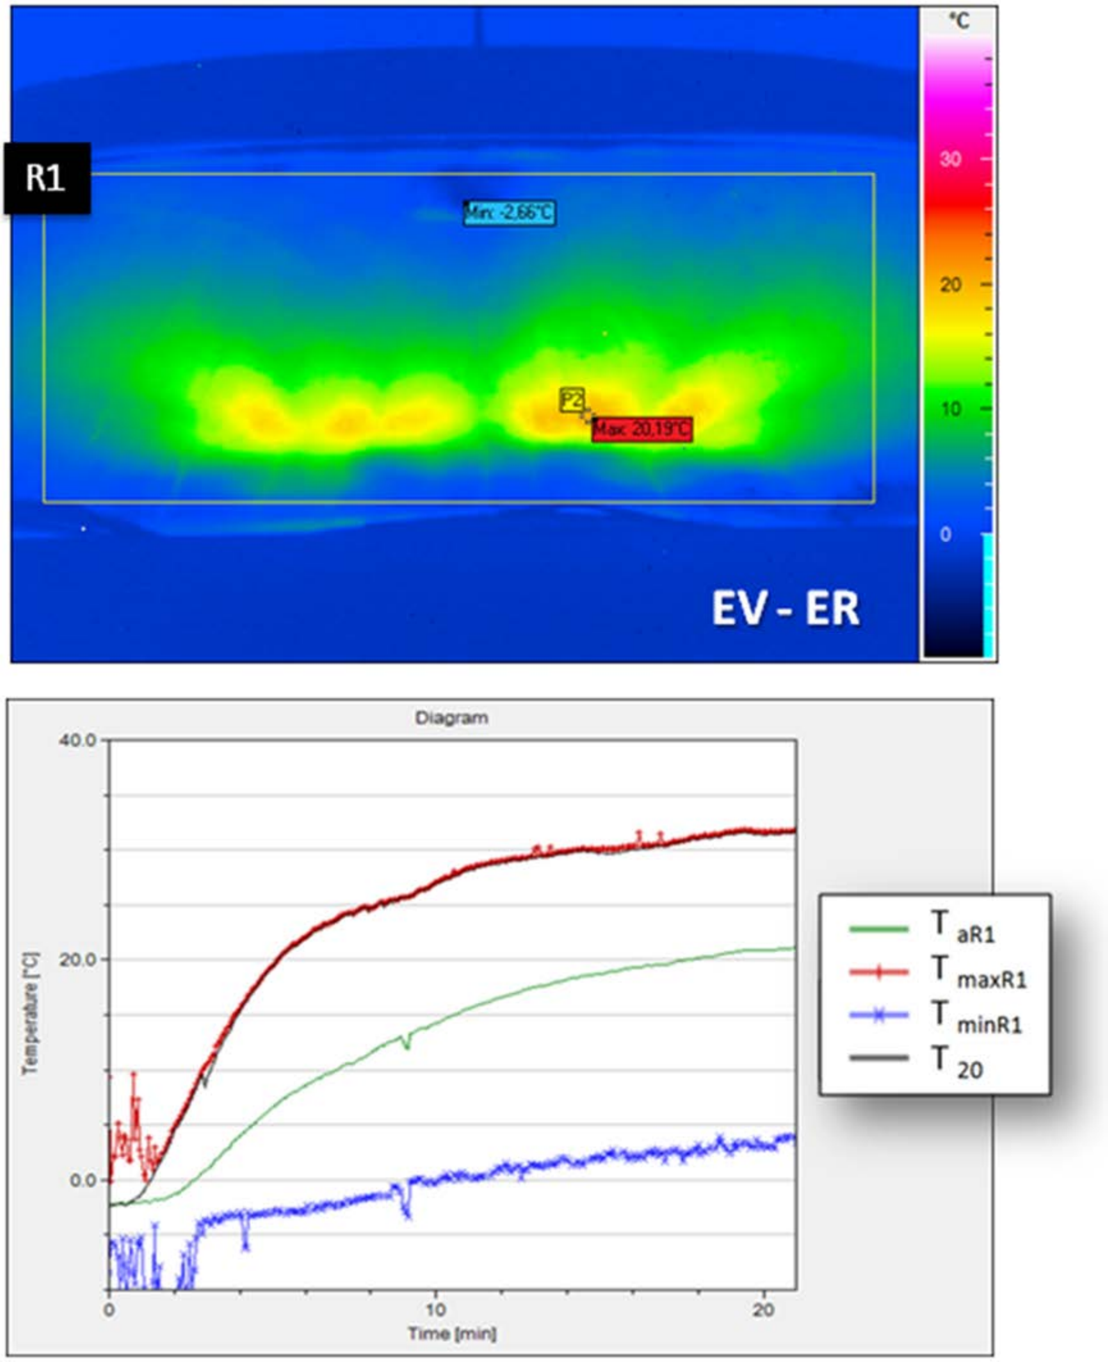

Figure 8: Average, maximum and minimum temperature in area R1 – EV-ER

Making the same summary graph for average, maximum and minimum temperature in area R1, during the 20 minutes that the Test lasts, we obtain the following for the Electric Car with Heat Pump Heating (Figure 9):

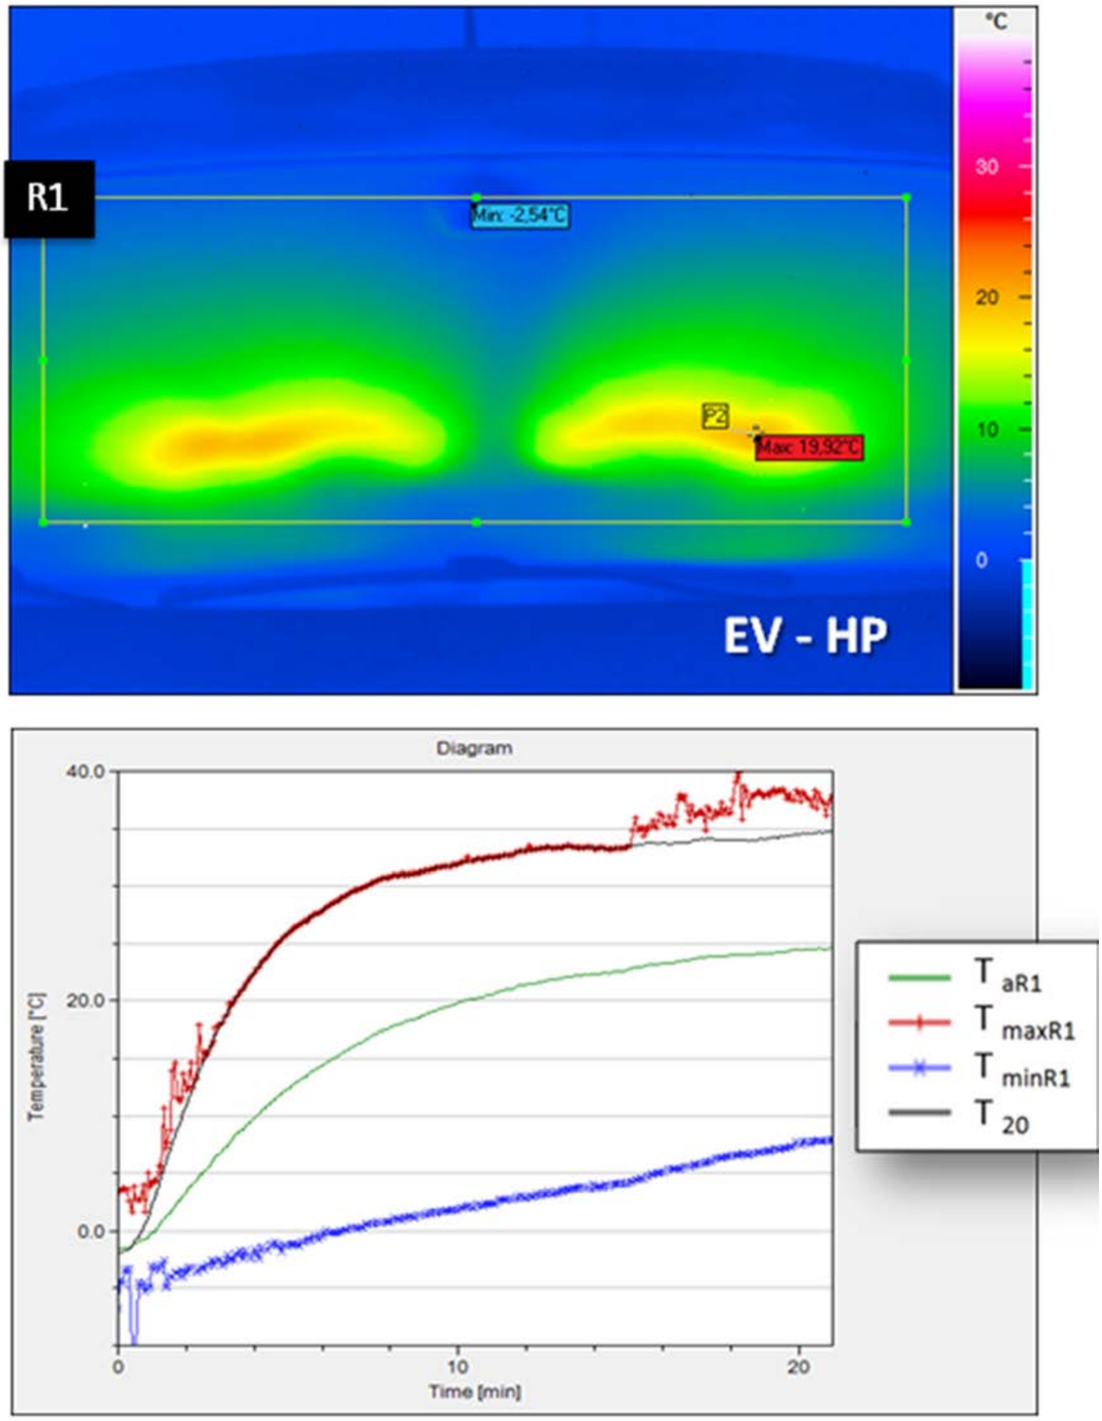

Figure 9: Average, maximum and minimum temperature in area R1 – EV- HP

5. CONCLUSIONS

We can see in these Thermographic measurements that the most efficient vehicle in the demisting function is the EV (with heat pump), we rely on the following graphs and Tables to make it clear (Figure 10): We make a graphical comparison Tª-time of the 3 models by average T, highlighting the time to reach 10º C in area R1 (Windshield):

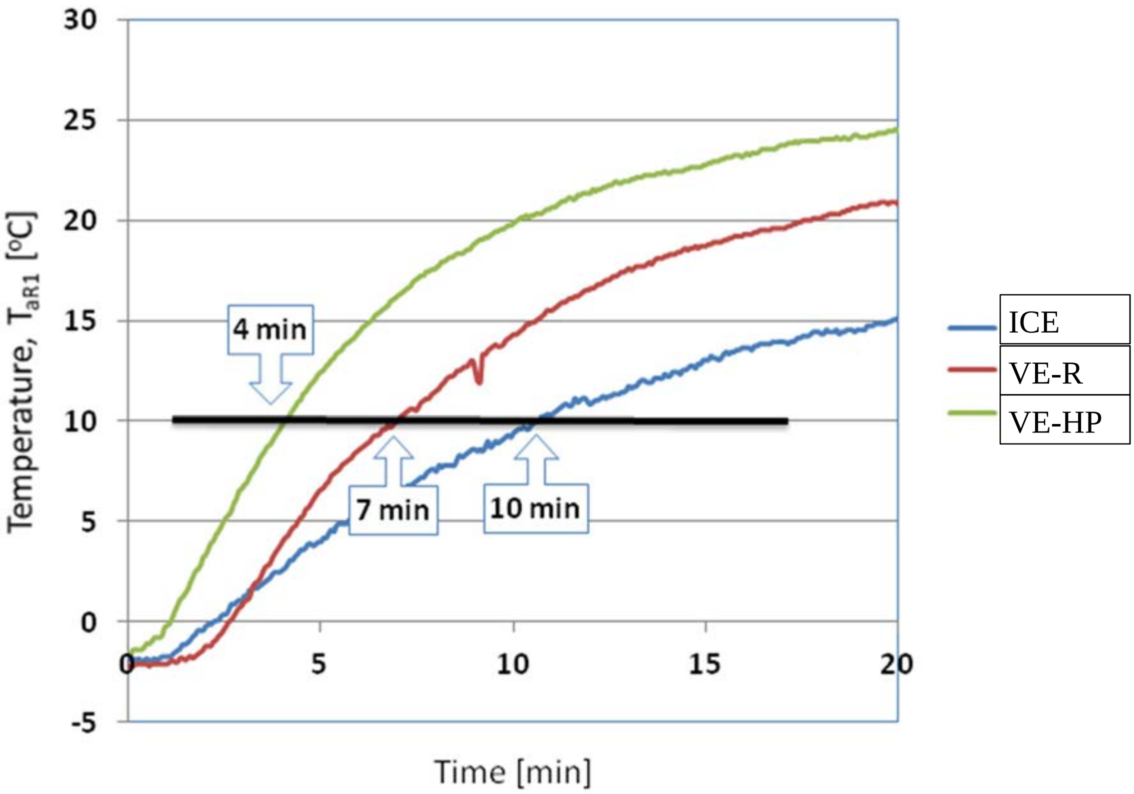

Figure 10: Graphical comparison Tª-time of the 3 models by average T

Lastly, these 2 graphs that show more clearly if possible that the demisting efficiency is VE-HP> VE - R> ICE, it shows the percentage of the area R1 whose Tª is above a certain value at t = 10 minutes; this % is cumulative, that is, it is the sum of the areas whose temperature is above a certain temperature (in percentage).

	> 20	> 18	> 16	> 14	> 12	> 10	> 8	> 6	> 4
ICEV	0.4%	4.1%	8.3%	14.4%	23.7%	38.1%	56.0%	76.0%	97.2%
EV - ER	15.1%	24.3%	34.8%	48.7%	64.2%	80.5%	94.8%	100.0%	100.0%
EV - HP	39.0%	53.5%	67.5%	81.1%	92.8%	100.0%	100.0%	100.0%	100.0%

Fig. 11 - Percentage of the area R1 whose Tª is above a certain value at t = 10 minutes

5. CONCLUSIONS

IR Thermography demonstrates the relevance of using this medium as an analysis and validation tool in the homologation of the defrosting / demisting performance of vehicles for the EU (according to current EEC 87/318 Regulation)

The electric vehicles tested are more efficient in the demisting task than the thermal vehicle.

Of the 2 electric vehicles tested, the EV equipped with a heat pump is more efficient than the EV equipped with a PTC resistor.

The range (or Battery autonomy) lost in this test is of the order of 25% for the VE with PTC resistance and 20% for the VE with heat pump, this, taking GENERAL MEASUREMENT of the STARTING TEMPERATURE of the TEST: the average temperature is -2ºC: according to the European Regulation CEE78 / 317, which requires between -1ºC and -3ºC, taking into account the little autonomy that these cars already enjoy, making this point a great burden on the customer satisfaction.

In conclusion, the electric vehicle enjoys greater thermal comfort compared to its equivalent of combustion, but at the same time it demands a more demanding job in the "non-loss" of range or autonomy that we "sacrifice" in this comfort, with ample possibilities of tuning one with respect to the other.
