PRESENTACIÓN

Tras varias ediciones por diferentes ciudades y universidades españolas, el XIV Congreso de Ingeniería del Transporte (CIT 2021) recae en Burgos (España) en 2021. El CIT 2021 forma parte de una serie de congresos que se inició en Sevilla (1993), y tiene periodicidad bianual desde Madrid (1996), promovido por el Foro de Ingeniería de los Transportes (FIT). En el caso del año 2020, debido a la crisis del COVID-19, se pospuso la XIV edición al año 2021, que finalmente se realiza en modalidad online.

La organización de XIV Congreso de Ingeniería del Transporte ha estado a cargo del Grupo de Investigación en Logística e Ingeniería del Transporte de la Universidad de Burgos. Más de 210 ponencias han sido aceptadas para ser presentadas en el mismo, y se recogen en estas Actas.

Queremos agradecer a los ponentes el esfuerzo realizado para preparar sus trabajos y vídeos, y presentarlos durante las sesiones técnicas de este Congreso. En segundo lugar, agradecemos al FIT la confianza depositada para organizar este Congreso. Gracias a la Universidad de Burgos y en particular a la Escuela Politécnica Superior por su inestimable colaboración. Queremos también extender nuestro agradecimiento a las personas que nos han ayudado en la organización, con especial mención a los miembros de la Junta Directa del FIT: Andrés Monzón de Cáceres, Alfredo García García, Margarita Novales Ordax, Juan de Oña López, Ana Rivas Álvarez, Felipe Jiménez Alonso, Julián Sastre González, José María Díaz y Pérez de la Lastra y Daniel Álvarez Mántaras.

Nuestro agradecimiento a las personas que han ejercido el papel de Presidentes moderando las sesiones técnicas, y también a todos los miembros del Comité Científico que nos ayudaron en la tarea de revisión de ponencias. Y un último agradecimiento a nuestros compañeros de Área, con mención especial a Maria Nadia Aponte Sanjínez y a Alaitz Linares Unamunzaga.

Finalmente, gracias a todas las empresas e instituciones patrocinadoras y colaboradoras del Congreso, en especial a PTV Group.

El Comité Organizador del CIT 2021

PRESENTATION

After various editions in some Spanish towns and Universities, the XIV Conference on Transport Engineering (CIT 2021) comes to Burgos (Spain) in 2021. The CIT Conference started in Sevilla (1993) and has a biannual frequency from Madrid (1996), promoted by the The Forum of transport engineering (FIT). In 2020, due to the Covid-19 pandemic, it was postponed into 2021, and it is finally developed in a virtual mode.

The organization of the XIV Conference on Transport Engineering has been in charge of the Researching Group in Logistics and Transport Engineering of the University of Burgos. More than 210 papers have been accepted to be presented in it, and are included in these Proceedings.

We want to thank the speakers for the effort made to prepare their papers and videos, and present them during the technical sessions of this Conference. Secondly, we thank the FIT for the trust they placed in us for organizing this Conference. Thanks to the University of Burgos and in particular to the Higher Polytechnic School for their invaluable collaboration. We also want to extend our gratitude to the people who have helped us in the organization, with special mention to the members of the FIT Board: Andrés Monzón de Cáceres, Alfredo García García, Margarita Novales Ordax, Juan de Oña López, Ana Rivas Álvarez, Felipe Jiménez Alonso, Julián Sastre González, José María Díaz y Pérez de la Lastra and Daniel Álvarez Mántaras.

Our gratitude to the people who have served as Presidents moderating the technical sessions, and also to all the members of the Scientific Committee who helped us in the task of reviewing the papers. And our last thanks to our Area mates, with special mention to Maria Nadia Aponte Sanjinez and Alaitz Linares Unamunzaga.

Finally, thanks to all the partners, companies and institutions that sponsor and collaborate with the Conference, especially to PTV Group.

Our acknowledgement to:

ABSTRACT

Traffic Prediction (TP) is a key element in Air Traffic Management (ATM), as it plays a fundamental role in adjusting capacity and available resources to current demand, as well as in helping detect and solve potential conflicts. Moreover, the future implementation of the Trajectory Based Operations (TBO) concept will impose on aircraft the compliance of very accurately arrival times over designated points. In this sense, an improvement in TP aims at enabling an efficient management of the expected increase in air traffic strategically, with tactical interventions only as a last resort. To achieve this objective, the ATM system needs tools to support traffic and trajectory management functions, such as strategic planning, trajectory negotiation and collaborative de-confliction. In all of these tasks, trajectory and traffic prediction represents a cornerstone. The problem of achieving an accurate and reliable trajectory and traffic prediction has been tackled through different methodologies, with different levels of complexity. There are two main aspects to be considered when assessing the most appropriate forecasting methodology: (a) time-horizon: depending on the timescale (anticipation before the day of operations), the level of uncertainty associated to the prediction will be different; and (b) input data: both the source and the quality of the input data (completeness, validity, accuracy, consistency, availability and timeliness) are key characteristics when assessing the viability of the prediction. This study develops a methodology for TP and traffic forecasting in a pre-tactical phase (one day to six days before the day of operations), when few or no flight plans are available.

This should be adjusted to different time scales (planning horizons), taking into account the level of predictability of each of them. We propose a data-driven, dynamic and adaptive TP framework, which can be accommodated to different Airspace Users' characteristics and strategies.

1. INTRODUCTION

To face the increasing air traffic demand, the future Air Traffic Management (ATM) system will rely on the Trajectory Based Operations (TBO) approach, which will require aircraft to follow an assigned 4D-trajectory (time-constrained trajectory) with high precision. TBO involves separating aircraft via strategic (long-term) trajectory definition, rather than the currently practicing tactical (short-term) conflict resolution. The main goal is to increase air traffic capacity by reducing the controllers' workload. Nevertheless, real time measures (over the trajectory) will be required to improve reliability, react to unplanned conditions and thus maintain the expected capacity.

The 4D-trajectory concept is based on the integration of time into the 3D aircraft trajectory, defining each point by position (latitude, longitude and flight level) and time. In the same way that there are restrictions associated with flight levels, the future operational framework foresees restrictions regarding time. It aims to ensure the flight is on a practically unrestricted, optimum trajectory for as long as possible in exchange for the aircraft being obliged to meet very accurately an arrival time over a designated point. In the context of TBO, Airspace Users (AUs) will agree a preferred trajectory with Air Navigation Service Providers (ANSPs) and airport operators (AOs). Aircraft and ground systems will exchange information regarding the trajectory and the expected airspace capacity, in order to foresee the ability to meet the assigned Controlled Time of Arrival (CTA).

The benefits of the 4D-trajectory approach on the ATM framework are: (a) improvement of air traffic operations reliability by increasing the overall traffic predictability; (b) optimal operations for airlines (aircraft using preferred routes and levels); (c) better service provided (due to ground-ground and air-ground interoperability) and fewer trajectory distortions; (d) potential absorption of delays; (e) enhanced safety with less controller workload (fewer conflicts, strategic management, information rich environment with data in advance); (f) reduction of costs (e.g. fuel and/or time); (g) increased airspace capacity; and (h) reduction of the environmental impact through reduction of emissions and noise.

To exploit these benefits accurate and reliable trajectory prediction (TP) is required. Enhanced traffic forecasts (which integrate uncertainty assessment and include different sources of relevant flight information) may enable improved demand-capacity balancing and conflict detection and resolution (CD&R) models. Moreover, new methodological approaches, as the exploitation of historical data by means of machine learning techniques is expected to boost TP performance.

In this context, this study has been able to develop a methodology framework for TP and traffic forecasting in a pre-tactical phase (from a few days to a few hours before the operations, when only a limited number of flight plans are available).

This has been adjusted to different time scales (planning horizons) supporting different operational scenarios, taking into account the level of predictability of each of them according to the available data. This step has resulted in an individual flight plan predictive model, which considers patterns in historical data to provide a pre-tactical prediction and incorporate “uncertainty” to Trajectory Prediction (as a probabilistic approach), incorporating also the possibility to self-calibrate with updated tactical data.

This way, we have not just obtained a specific implementation but a data-driven, dynamic and adaptive TP framework, suitable for further implementations. It is data-driven as the main study outcomes will be based on data analysis and interpretation, dynamic as can be adjusted to different planning horizons and adaptive as it can be enhanced iteratively with new tactical data. A fourth research objective of the study is for the TP framework to adapt to different Airspace Users’ characteristics and strategies. AUs will exhibit different strategies, as far as flight intentions and execution are concerned. The study has analysed and unravelled policies and features to apply the best TP for each AU according to observations.

We have validated the TP framework on a case study, including interviews to operational staff to understand the best way to apply such features. The proposed method aims to anticipate the needs of the ATM system; main applications of the model are related to reduction of complexity, demand-capacity balancing, conflict resolution, separation management, ANSP resource allocation.

The main results of the study are the specific implementation of the data driven analysis with Spanish data (the study also explores ECAC - European Civil Aviation Conference - area capabilities with existing datasets), the TP methodological framework and the mock-up comprising operational staff feedback.

2. BACKGROUND

2.1 Operational / technical context

Accurate and reliable trajectory prediction (TP) is a fundamental requirement to support trajectory-based operations (TBOs). Particularly, the mismatch between planned and flown trajectories (caused by operational uncertainties from airports, Air Traffic Control interventions, Airspace Users behaviour and changes in flight plan data) act as a driver for shortcomings in flow and capacity management (e.g. congestion and suboptimal decision making) and as a precursor for potential safety conflicts. Therefore, enhanced traffic forecasts (which integrate uncertainty assessment and include different sources of relevant flight information) may enable improved demand-capacity balancing and conflict detection and resolution (CD&R) models. Moreover, new methodological approaches, as the exploitation of historical data by means of machine-learning techniques is expected to boost TP performance.

2.2 Scope and objectives

Traffic prediction is a key element in Air Traffic Management (ATM), as it plays a fundamental role in adjusting capacity and available resources to current demand, as well as in helping detect and solve potential conflicts (Lymperopoulos & Lygeros, 2010). Moreover, the future implementation of the Trajectory Based Operations (TBO) concept will impose on aircraft the compliance of very accurately arrival times over designated points (SESAR, 2015; FAA, 2016). In this sense, an improvement in TP aims at enabling an efficient management of the expected increase in air traffic strategically, with tactical interventions only as a last resort. To achieve this objective, the ATM system needs tools to support traffic and trajectory management functions, such as strategic planning, trajectory negotiation and collaborative de-confliction. In all of these tasks, trajectory and traffic prediction represents a cornerstone (Rodríguez-Sanz et al., 2019).

The problem of achieving an accurate and reliable trajectory and traffic prediction has been tackled through different methodologies, with different levels of complexity (Alligier & Gianazza, 2015; Tastambekov et al., 2014; Wang et al., 2018; Wi et al., 2008; De Leege et al., 2013).

There are two main aspects to consider when assessing the most appropriate forecasting methodology:

- Time-horizon. Depending on the timescale (anticipation before the day of operations), the level of uncertainty associated to the prediction will be different.
- Input data. Both the source and the quality of the input data (completeness, validity, accuracy, consistency, availability and timeliness) are key characteristics when assessing the viability of the prediction.

The main target of the study is the development of a methodology for TP and traffic forecasting in a pre-tactical phase (from a few days to a few hours before the operations, when only a limited number of flight plans are available). This can be adjusted to different time scales (planning horizons), considering the level of predictability of each of them and the specific use case to where it should be applied. This initial step delivers a model that considers advanced tactical data to validate/enhance the previous pre-tactical prediction and incorporate "uncertainty" to Trajectory Prediction (as a probabilistic approach).

In this way, the study has obtained a data-driven, dynamic and adaptive TP framework: data-driven, as the main study outcomes is based on data analysis and interpretation, dynamic, as can be adjusted to different planning horizons, and adaptive, as it allows iterative enhancement with new tactical data.

Another objective of the study was, for the TP framework, to adapt to different Airspace Users' characteristics and strategies. Previous works showed that different AUs exhibit different strategies, as far as flight intentions and execution are concerned, affecting predictability, even at route level in some cases (SESAR P04.07.07, in EXE-04.07.07-VP-006 run in Barcelona ACC; statistical analyses carried out as part of the SESAR WpE project ELSA) (Gurtner et al., 2014; Gurtner et al., 2015). The implication is that different methodologies need to be used to develop the best TP for each AU.

3. LITERATURE REVIEW

The works developed around organization of airspace are globally focused in achieving an "ideal" airspace configuration, for this matter, dynamic sectorisation is considered with the corresponding problem of Demand-Capacity balancing. In a more in-depth analysis of the demand, the research is fixed in clustering techniques, improving the scope as well as the analysis of the data already available. Then, the trajectory prediction is enlarged by considering other type of data apart from the temporal and spatial, designated as contextual data.

From the point of view of clustering, several approaches can be stated. Clusters are formed from similar trajectories; this similarity trait requires an extensive analysis of origin/destination pairs, take-off patterns, weather deviations and any other type of data (De Leege et al., 2013). Considering a different approach, clusters are formed taking into account the relevant part of the trajectories, relevance is understood as a changing variable where markers to each of the route waypoints are assigned and added or discarded for each analysis (A Andrienko et al., 2017).

Contextual data can be chosen to cluster by relevance. Following this line, temporal characterization is thought to be of high importance (Enriquez, 2013), enabling the identification of salient traffic and temporal persistent flows. Temporal clustering has been implemented (Sidiropoulos et al., 2016) using a k-means algorithm, for the classification of arrivals and departures for Multi-Airport Systems. The final objective is to obtain a route that can be representative for each cluster, lowering the computational requirements.

In terms of the data available for clustering, Flight Plans (FP) are the most important resource and they are extremely dependent on the airline, consequently analysis of the behaviour of the airline have been developed (Calvo-Fernández & Cordero, 2013) obtaining patterns that can be posteriorly used for a more accurate prediction. This trait is measured with three indices: predictability, reliability and accuracy.

For further determination of the spatial-temporal state of the aircraft a variety of trajectory prediction methodologies have been developed that do not require any specific data of the performance of the aircraft, they do require aircraft state data, flight information, historical data or flight information from aircraft messaging. Environmental conditions are included in analysis (Stewart et al., 2015). In recent studies, the analysis and prediction is developed using Machine Learning techniques. Furthermore, in some references (Wanke et al., 2012) the trajectory (route terminology employed in the paper) is obtained from weighting a series of factors; concretely two groups of factors are considered: reaction (constraints to the route) and planned (changes in the route utilization). These factors are obtained using a regression model. In recent studies the analysis and prediction is developed using Machine Learning techniques (De Leege et al., 2013), the Hidden Markov Model is considered among several options.

An accuracy analysis is consistently associated to the trajectory prediction methods. The confidence level of the output is dependent on the quality of information extracted and varies depending on the phase of flight due to the difficulty of prediction for each of the phases (Gong & Mcnally, 2004), while in other studies (Wanke et al., 2004) a statistical model is used based on empirical observations and a Monte Carlo simulation is conducted. Other studies involve the use of a Distributional Robust Optimization formulation (Sidiropoulos et al., 2016), the uncertainty of the prediction is based on the drawing of information from different uncertain parameters by using probabilistic operations. To set the method in place, data is used from the Time Based Flow Management system obtaining this way the calibration.

For the demand-capacity balance instead of considering individual flights the approach is to consider a flow allowing independent flow routes, this is the Eulerian-Lagrangian (Rebollo et al., 2009) model where the optimization is solved using a Model Predictive Controller Technique minimizing the air and ground delay. Contrarily if individual flights are taken into account (which is typical for conflict resolution), interacting trajectories can be localized and modified in order to solve this problem, for this purpose collaborative reinforcement learning methods have been explored (Chen et al., 2016; Vouros et al., 2018). For the sector configuration, it is feasible to be obtained through a Branch and Bound algorithm choosing between the combinations available (Gianazza et al., 2009).

4. PREDICTIVE MODEL

4.1 Predictive model: High-resolution scenario analysis

The high-resolution analysis corresponds to operational data from Spanish Airspace extracted from the operational ATC platform (SACTA), including highly reliable data such as surveillance or every flight plan update.

In this initial phase of the analysis, a sample of relatively frequent flights (of relatively frequent airlines) in January, March and August 2018 is selected. Callsigns flying less than 10 times in a month and airlines with less than 200 flights in a month are discarded. These numbers are set accordingly to cumulative graphs.

Using this dataset, a clustering process is applied. The main “dissimilarity measure” used in the analysis is:

d = 1- (common wp / max wp), where:

- common wp: number of waypoints appearing in both the first and the last Flight Plan of each FPkey (last intended as last before estimated off-block time);
- max wp: maximum between the number of waypoints appearing in the first Flight Plan and the number of waypoints appearing in the last Flight Plan.

The histogram in Figure 1 represents the distribution of d in the different months. It is clear that 0 is the most common value and that the frequency of greater values rapidly decreases as the value increases: in particular, more than 70% of the Flight Plans do not show any difference in the first and the last path declared and that, in general, only 10% of the Flight Plans shares less than the 50% of waypoints between the first and last record before off-block time.

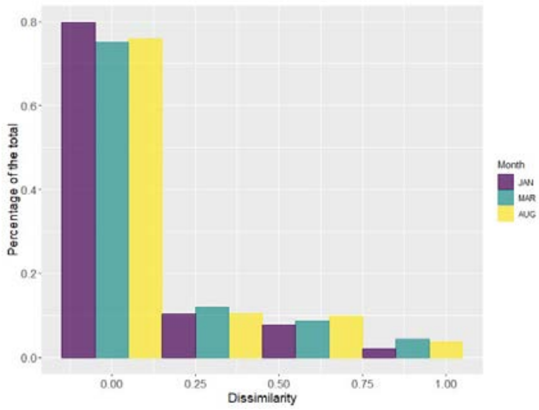

Figure 1: Histogram of the distribution of d in the different months analysed.

Furthermore, differences between months do not seem to be really relevant from this perspective. March and August behave almost identically, while in January there seem to be slightly smaller values of d.

The variable immediately associated to this d is a DeltaT variable defined as the difference between the expected off-block time of a flight and the record time of its first flight plan, in order to understand at what level of anticipation (before the beginning of departure operations) the flight plan was emitted.

As can be seen in Figure 2 (Dt is expressed in hours, and the categories are chosen as almost homogenous in size), d seems slightly or not dependent on the level of anticipation with which the flight plan is registered.
In fact, while the first histogram (less than 2 hours before EOBT – Estimated Off-Block Time) is different from the others, there is apparently no pattern in the following ones. The fact that the “< 2” section is composed essentially of observation with d=0 can be also because in many cases the first and last flight plan coincide. However, the graph remains meaningful as it shows that flight plans recorded in that time slot are almost surely reliable.

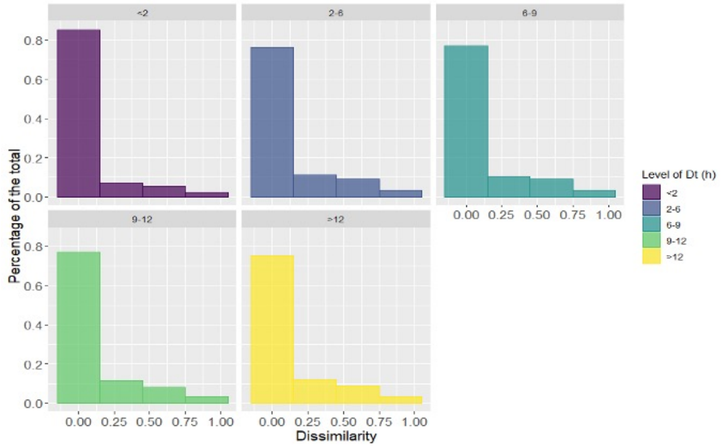

Figure 2: Representation of DeltaT (Dt) for different anticipations in the reception of the flight plan.

Another variable which seems not linked to the dissimilarity is the involvement in weather phenomena. The same comparison was performed distinguishing different weather conditions, in all the three months, leading to the same conclusions. Furthermore, no stable pattern is found also for aircraft type.

The distribution of d is also analysed for airlines, airports and routes. To associate a representative value of d to a group of flights, one possible choice is to use the average value of the variable in the group. The distribution of d is very asymmetrical and consequently the average is mainly determined by the highest values, possibly leading to a non-representative estimation. Because the median is 0 for every airline and airport (in fact, the 70% percentile of d is 0 for almost every subgroup), a possible choice is to consider another quantile; the most effective in discriminating the airlines and airports is found to be the 80% percentile.

The following graphs represent airlines in three groups (European Legacy, European Low Cost and Non-European). These graphs report the 80% percentile essentially for two reasons:

- This value is assumed by d, while this is not true for the mean.
- It has an "operational" meaning being x the quantile, it can be said that the 80% of data relative to the group assumes values smaller than x.

Furthermore, in Figure 3, Figure 4 and Figure 5, the size of every group is indicated.

Please be aware that these numbers indicate the occurrences in the selected samples (so, for example, infrequent flights are discarded) so they are just approximations of the real number of flights.

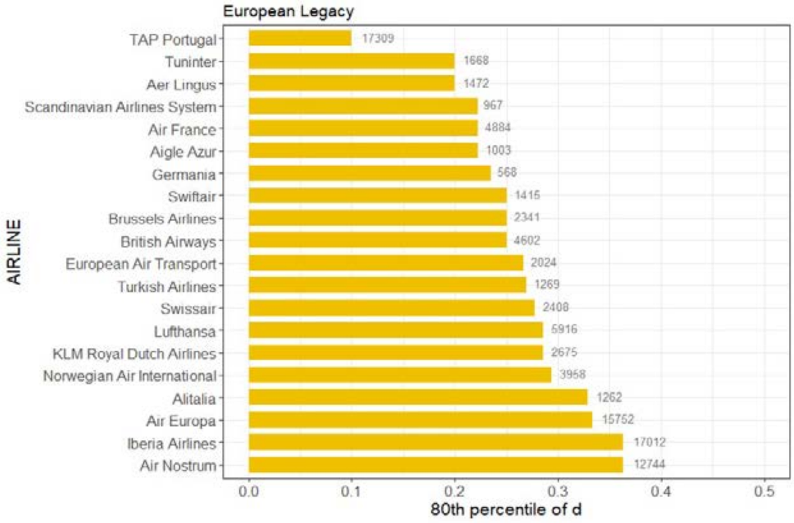

Figure 3: Representation of the 80th percentile for the Group of “European Legacy” airlines.

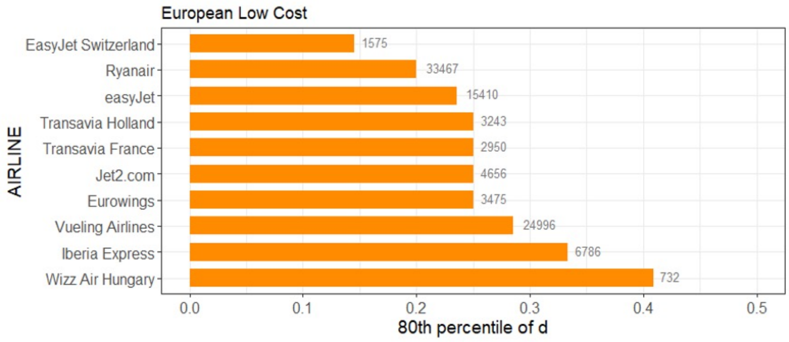

Figure 4: Representation of the 80th percentile for the Group of “European Low Cost” airlines.

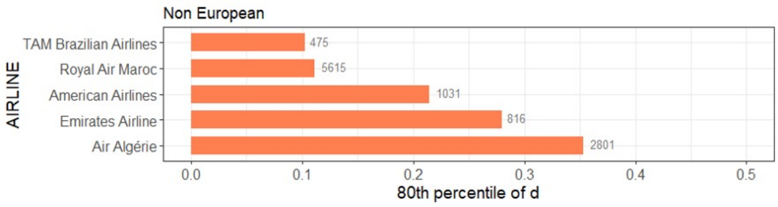

Figure 5: Representation of the 80th percentile for the Group of “Non-European” airlines.

Looking at the graphs above, there seems not to be great differences between the three groups (legacy, low cost, non-EU airlines); the major differences are, in fact, within each group.

The role of airports, instead, seems more decisive: departures from non-EU airports show lower values of d and departures from Madrid show much “less reliable” behaviours than the other frequent airports.

Arrivals, on the other hand, behave differently: non-EU airports show more variable values of d and often also higher values. This distribution is also reflected in the ranking of routes (e.g., flights departing from Madrid have higher d-values than flights arriving in Madrid).
Moreover, the Reliability time has been analysed. It is possible to estimate, for each flight number but also for each airline, the average time in which the flight plan became identical to the last one, plus a Confidence Interval based on the variance and size of data relative to that airline.

Figure 6 and Figure 7 are representative of the idea: the point is the average "reliable time" (sample mean), and the black line is the 95% probability interval of the mean.

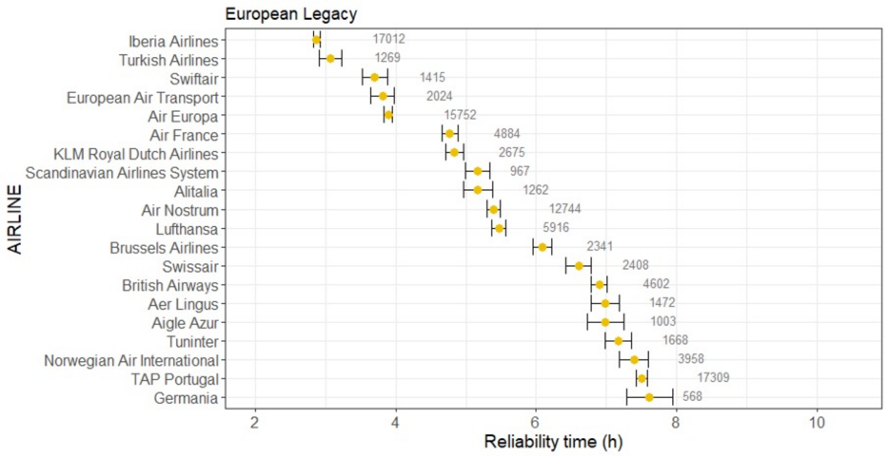

Figure 6: Reliability time for European Legacy Airlines.

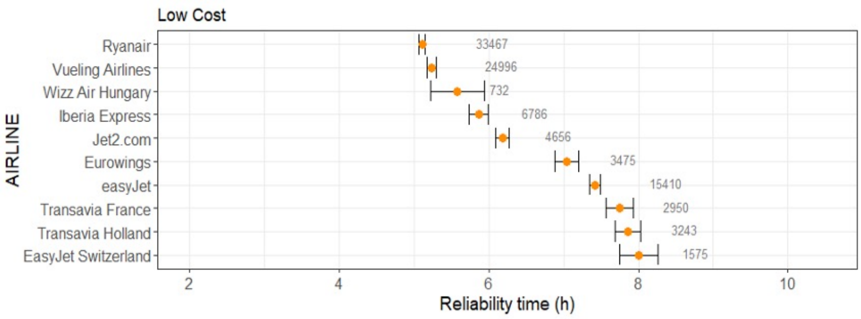

Figure 7: Reliability time for Low Cost Airlines.

Since the previous analysis indicates that the reliability of a flight plan depends essentially on the "intrinsic" properties of the flight and in some cases on the season, while the "contingencies" (e.g., weather, hour of the day, day of the week) play no or little role, the prediction presented here is only based on historical data; furthermore, this approach emphasizes the role of the companies' strategic reasoning.

The prediction is performed for different Δt's (where Δt is the difference between current time and off-block time): 8h, 4h, 2h, 1h.
For each Δt, the predictive methodology is the following:

- the current flight plan is compared with all the historical flight plans of the same flight (in this context, flight = callsign) at the same Δt, selecting all the past single flight's whose trajectories coincide with the current one.
- if the current flight plan is not the first one recorded that day, also the previous flight plans are compared with the corresponding past ones, discarding from the previously selected single flights all the ones that do not match.
- for all the selected single flights, the last-before-off-block-time planned trajectory is retrieved.
- the predicted trajectory is the most frequent one in this set.

In this case, this methodology is applied on two sets of data, different form the one used in first place for the dissimilarity measure:

- data from February 1st to May 31st, 2018 (in the following, denoted as spring)
- data from June 1st to September 30th, 2018 (in the following, denoted as summer)

and only to flights: classified as "Regular", flying at least 3 times a week, pertaining to the most frequent airlines, and with average levels of Δt sufficiently high.

To estimate the real usefulness of the prediction, its accuracy is compared with the one of the "default" prediction (i.e., the last trajectory is predicted to be the current one).

Accuracy is the percentage of trajectories that are correctly predicted for each flight (see Table 1 and Table 2).

SPRING	8h	4h	2h	1h
average *default* accuracy	76%	75%	82%	86%
average *prediction* accuracy	82%	82%	85%	87%

Table 1: Average Default and Predicted Accuracy in the different time horizons for the spring dataset analysed.

In spring the prediction is able, on average, to anticipate at Δt = 8 the accuracy that the default prediction has at time Δt = 2, so it reaches the same level of certainty 6 hours before.

SUMMER	8h	4h	2h	1h
average *default* accuracy	88%	76%	83%	88%
average *prediction* accuracy	92%	85%	87%	90%

Table 2: Average Default and Predicted Accuracy in the different time horizons for the summer dataset analysed.

It is important to remark the fact that the smallest accuracies appear in Δt = 4 and not in Δt = 8 can probably be explained with the fact that not all the flights considered record flight plans with the anticipation of Δt = 8 every day, so the values are computed on slightly different samples (and it can be reasonable to suppose that the sample relative to Δt = 8 is somehow more "reliable"). For this reason, Δt = 8 in these tables can be considered as a world apart.

Relative improvement in accuracy is computed for each callsign as follows:

(callsign prediction accuracy - callsign default accuracy) / callsign default accuracy

As could be expected, the relative improvement in accuracy is greater for and Δt = 4 than for the smallest Δt's, in both the seasons.

SPRING	8h	4h	2h	1h
average *relative improvement*	23%	29%	10%	6%

Table 3: Average Relative Improvement in the different time horizons for the spring dataset analysed.

SUMMER	8h	4h	2h	1h
average *relative improvement*	13%	59%	23%	13%

Table 4: Average Relative Improvement in the different time horizons for the summer dataset analysed.

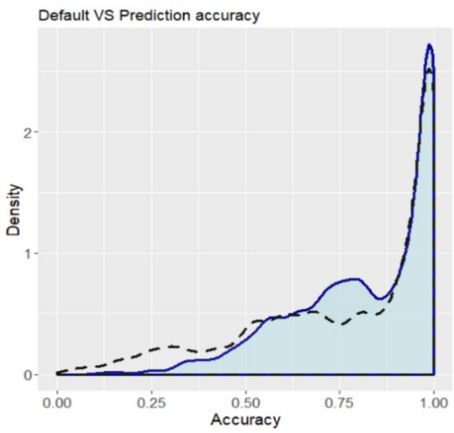

Figure 8: Comparison between default and predicted accuracy.

In Figure 8, *prediction accuracy* (in blue) and d*efault accuracy* (dashed line) at Δt = 8h in spring are represented (this representation is consistent with other Δt's and seasons). In view of this, three main considerations arise:

- the distribution of prediction accuracy is concentrated on highest values in general.
- the prediction accuracy has a negligible percentage of values lower of 0.5, so the biggest difference with the default accuracy is with regards to the lowest values.
- if values greater than 90% are concerned, the two densities appear almost overlapped.

So, the main conclusion seems to be that this *prediction* is particularly useful in enhancing accuracy for “very unpredictable” flights, while for very regular flights the *default choice* and the *prediction* are almost always the same.

This conclusion is confirmed by the correlation between the default accuracy and the relative increase due to the prediction, clearly represented in Figure 9 (Δt = 4h):

In the following, results about relative improvement are often reported only for Δt = 4h. The reason is that this Δt is computed on a larger sample than Δt = 8h, and at the same time the differences in relative improvement are more visible than for Δt = 2h and 1h.

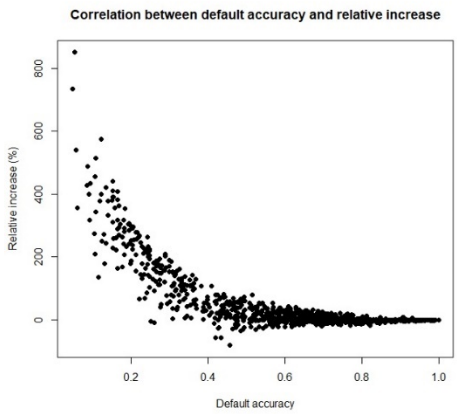

Figure 9: Correlation between default accuracy and relative improvement for the Δt = 4h time horizon.

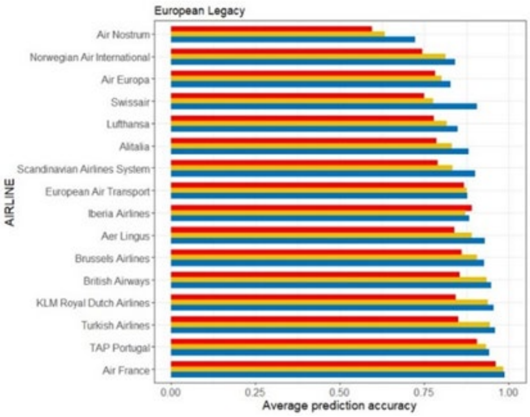
From Figure 9, it is also possible to understand the global distribution of the relative increase: the most frequent value is 0 and, though there are some (very few) negative values (which means, cases in which the default prediction would suggest the right trajectory while our prediction fails), the general mean is “pushed up” by the many high values. The maximum is around 800%, which means there are flights for which the accuracy of our prediction is 8 times greater than the default (e.g., 0.1 of default accuracy and 0.8 of prediction accuracy).

Now, we have a look at how the *prediction accuracy* is distributed with regards to airlines. These graphs are referred to spring; summer graphs are not reported since there are no meaningful differences. For the comparison to be meaningful, Δt = 8h was not represented, for the previously explained reasons.



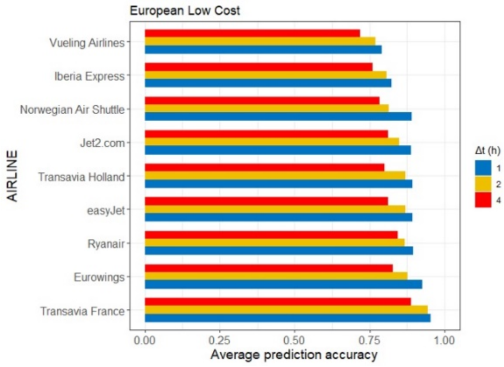


Figure 10 and 11: Average prediction accuracy for European Legacy and Low-Cost airlines.

Three main considerations arise:

- In most of the airlines the prediction accuracy increases as Δt decreases.
- There are some slight differences between airlines, but basically the prediction reaches a similar level of accuracy in for all the airlines, apparently without any bias.
- The level of accuracy is, on average, over 80% for the great majority of airlines.

What is probably of major interest is to evaluate the *average relative improvement* in accuracy for each airline. In fact, this value is informative: if it is high, it means that the unpredictability of that airline is “systematic enough” to become predictable, and so it is likely to be part of a strategy.

Graphs are relative to Δt = 4h, both seasons. The number of flights involved in the analysis is reported next to each bar. The horizontal axes have different scales in the two seasons since the relative improvement in summer has highest values. European airlines show a clear behaviour: Air Europa, Alitalia and Air Nostrum (legacy) and Vueling, Ryanair and Iberia Express (low cost) have significantly higher values than the others, in both seasons.

Also, the companies with the smallest values are consistent in the two seasons. The aforementioned airlines show the same behaviour also when we compare them with other airlines traveling on the same routes, as represented in Figure 11.

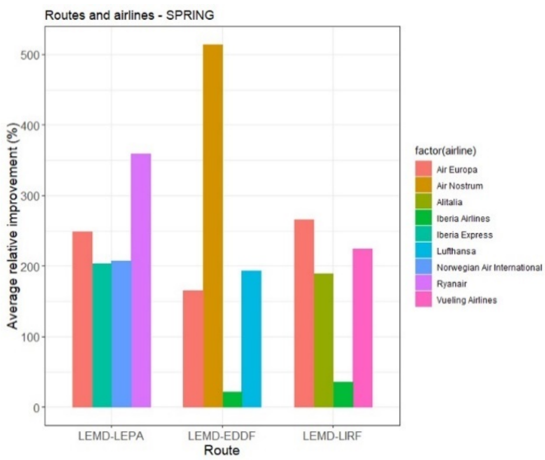

Figure 11: Comparison between airlines flying the same route in the spring period analysed.

By means of the previously described predictive model, it is possible to estimate the probability of change of every flight (given that the flight is a regular and frequent one). The following graph (Figure 12: Average probability of change of Lufthansa for Δt = 4h for different routes during the diurnal shift. is relative to the *diurnal shift* and it is referred to Δt = 4h. Callsigns with average probability of change less than 0.01 are not shown.

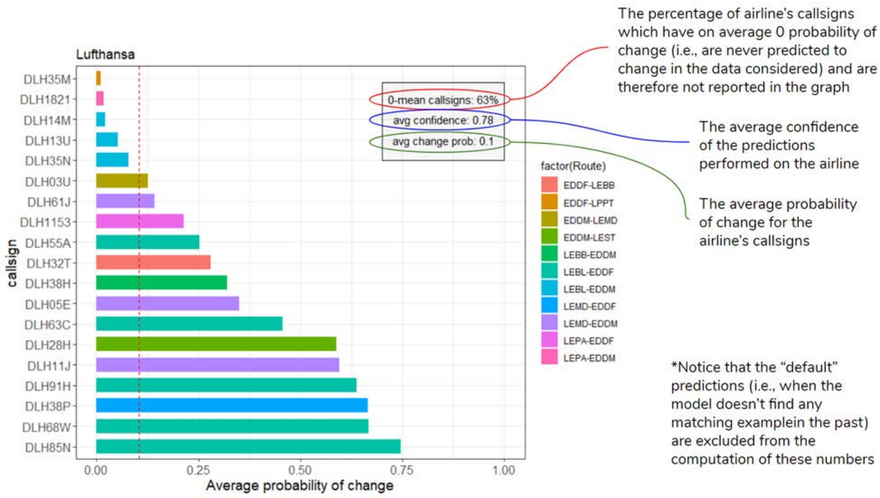

Figure 12: Average probability of change of Lufthansa for Δt = 4h for different routes during the diurnal shift.

Furthermore, the probability of change is not independent of the route; in Figure 13 and Figure 14, it is clear that the same airlines can behave in quite different ways on different routes, while on the same route, different airlines tend to behave in similar ways.

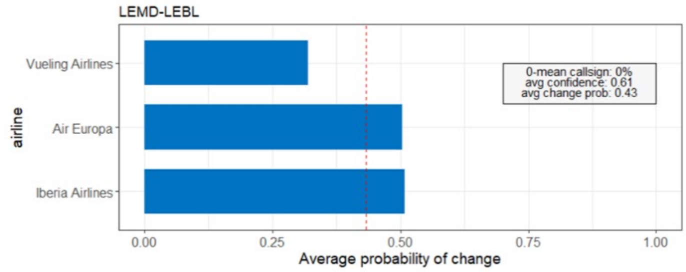

Figure 13: Average probability of change in the route LEMD-LEBL for the airlines: Vueling, Air Europa and Iberia.

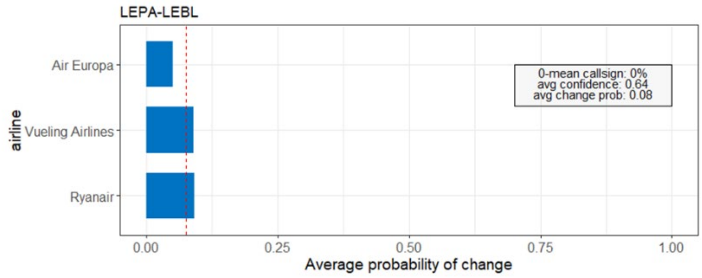

Figure 14: Average probability of change in the route LEPA-LEBL for the airlines: Vueling, Air Europa and Ryanair.

Another observation that deeper analyses suggest is that flights departing from some airports (especially the biggest ones) seem to have higher probability of change, e.g. LEMD.

4.2 Predictive model: Low-resolution scenario analysis

This scenario is referred to the ECAC (European Civil Aviation Conference) area, trying to apply similar analysis. Is to be noted that the European-wide data source (DDR – Demand Data Repository) is a determinant factor in what can be applied. The study has tried to illustrate the result by applying a similar approach to this scenario, for reference.

In order to render the low-resolution analysis comparable with the high-resolution one, we needed to find the correspondent definition of waypoints; to do so, we compared the trajectory description of DDR with the one in the data from the first scenario, whenever the same flights are involved (i.e., flights whose entire trajectory pertains to Spanish airspace).

Here is an example from the 1st of June 2018, a flight from Madrid to Valencia:

- high-resolution (spatial) trajectory description:
  MD14L; MD050; MD035; NANDO; MINGU; ABOSI; CLS; OPERA; VLCT
- low-resolution trajectory description:
  20180601142400:LEMD:NANDO1U:20:0:A:402820N0033339W::Y
  20180601142415::DCT:25:1:V:402759N0033304W:14:Y
  20180601142443::DCT:35:4:V:402657N0033121W:57:Y
  20180601142513:*MD50:NANDO1U:48:7:D:402554N0032937W::Y
  20180601142517::DCT:50:8:V:402538N0032900W:6:Y

20180601142600::DCT:70:13:V:402415N0032558W:38:Y
20180601142645::DCT:90:19:V:402237N0032219W:75:Y
20180601142709:*MD35:NANDO1U:100:23:D:402131N0031953W::Y
20180601142820::DCT:130:35:V:401902N0031206W:11:Y
….

This kind of behaviour is rather systematic, so to apply the model to the new scenario we used as waypoints the information in the second field of the variable. The low-resolution model was built by mimicking the high-resolution one, with the necessary adaptations. In fact, since in this scenario we only have one flight plan per day, the predicted trajectory is the most probable one given the flight plan of the day before.

The model, as in the high-resolution case, has two main functionalities: predict if the trajectory will change and predict the final trajectory (and its probability). The following results are relative to about 8000 flights (i.e., the ones flying every day) in June 2018.

The model was tested on the last week of the month; for each test day, all the preceding ones are used as training set. This assessment methodology is slightly different from the one adopted in the high-resolution scenario since in this case the order of days is absolutely not negligible.

For each flight, the predictive accuracy of the model was computed. The performance on low-resolution scenario is - quite predictably - lower than the high-resolution one. The main reason for this is the probability of change:

- In the high-resolution scenario, we compared the last-before-EOBT trajectory with the flight plan recorded 2h/4h/8h before, and in the vast majority of cases the input trajectory was already reliable, with a probability of change on average around 20%;
- in this low-resolution scenario, we compare today's trajectory with yesterday's one, and the probability of change is on average 55%.

Furthermore, this change rate (and therefore also the accuracy of the model) is distributed in quite an uneven fashion. Figure 15 shows the distribution of airlines' change rate, from which there are a huge amount of extreme values.

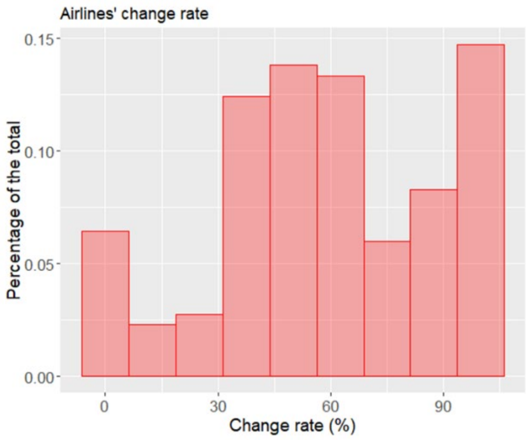

Figure 15: Airline's change rate.

For this reason, the median accuracy is considered, instead of the average one, since is more robust to extreme values:

- Median accuracy per flight of the model: 67%
- Median accuracy per flight without the model: 33%

As in the high-resolution case, we can retrieve some interesting information on airlines by looking at the distribution of the *average relative improvement per airline*. The median value is around 500% (e.g., if the probability of correctly predicting tomorrow's trajectories for an airline just trusting today's trajectories is 15%, on median thanks to the model it will be 75%). Also, in this case, values are actually very spread, and a central value cannot be representative.

Figure 16 shows the average relative improvement of some airlines. In general, all the values range between 0 and 3. Notice the x-axis is not expressed in percentage (e.g., 3 is 300%).

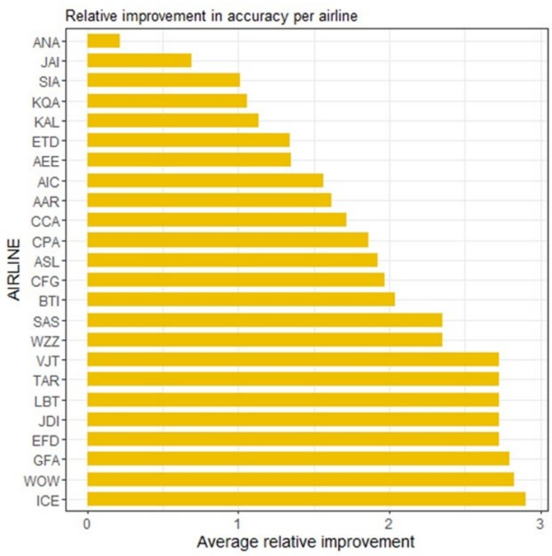

Figure 16: Average relative improvement of some airlines.

4.3. Use case application/Mock-up tool

The proposed model generates, for each individual scheduled flight of a given day, the prediction of the most likely flight plan (FP) submitted by the airspace user (AU) hours before the expected off-block time. The purpose of this model, when applied to one operational use case, is to provide the Network Manager (NM) and Air Navigation Service Providers (ANSPs) with additional information about the upcoming flights and a prediction of the demand of airspace that improves the current methods based on the FPs issued by the AUs and on historical data.

To validate the use case and expected benefits of the model, we interviewed potential target users, developed a static mock-up to demonstrate how the associated tool could be integrated in the current workflow, and eventually collected target users' feedback on the developed mock-up.

The process is summarised as follows:

1. Interviews to target users
2. Definition of user needs and requirements
3. Redesign of strategic planning, enhanced by the proposed model
4. Design of HMI (Human Machine Interface) mock-up
5. Analysis of data to be visualised into the HMI mock-up
6. Feedback from target users

5. RESULTS

5.1 Use case application/Mock-up tool results

The scheme in Figure 17 represents how the planning process of the NM could be modified to include the information generated by the model.

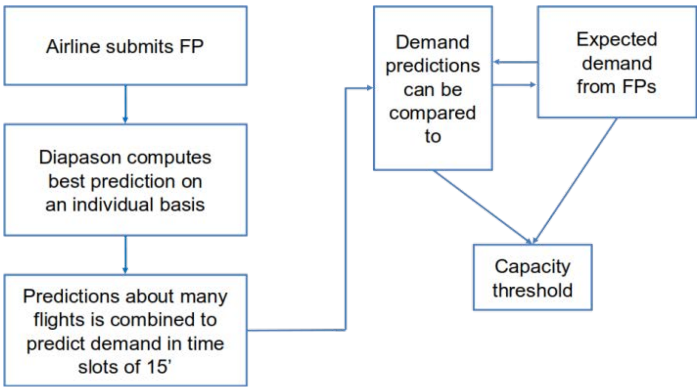

Figure 17: Schematic of the way the proposed tool predictions could be integrated in the planning process at NM level.

Every time an airline submits a FP hours before the EOBT, the proposed tool (called DIAPasON or Data-drIven approach for dynamic and Adaptive trajectory PredictiON) computes the best prediction of what the final FP will be.

While each prediction could be useful also on its own individually, the target users expressed a need of aggregate information, about all flights predicted to cross specific airspace sectors within a certain time interval. This prediction corresponds to the overall demand of traffic as a function of time in every given sector.

As soon as FPs become available, the predicted demand computed with our model can be compared to the expected demand calculated from the airline FPs. Both demands are to be compared with the capacity of the sectors at any given time of the day. The objective of the planning is to always keep the demand below the capacity threshold.

The main benefit occurs when the predicted and expected demands differ, and essentially when one of the two exceeds the capacity threshold. In this situation, the planner must choose between the model prediction and the expectation based on the FPs.

At this stage, the HMI mock-up is designed to display the flights exceeding the capacity threshold and for which there is a discrepancy between the model prediction and the expected FP.

As the model prediction comes with an indication of the prediction quality (in percentage), a different design option would be to decide a threshold over which only this prediction is considered.

To give a demonstration of how the model can be integrated in the tools for planning that are already in use at the pre-tactical level, we developed a static HMI mock-up, which was used to collect feedback from target users. The mock-up is meant to capture the benefit to current planning processes, focusing on the role a new tool might play. The look & feel simulates an interactive tool, and it was implemented using an off-the-shelf prototyping software (i.e. Figma).

To design the role and the mock-up look&feel, we first designed a storyboard, describing:

- User input
- System reaction
- HMI sketch

We took 6 months of data from 01/02/2018 until 30/09/2018, which include 26369 individual flights, with focus on the flights connecting the two main Spanish airports, LEMD and LEBL, with a limited number of European airports, LPPT, LFPG, EGLL, and LIRF. To understand the extent to which the model prediction differs from the FP data 4-8 hours before EOBT, we plotted the trajectories on maps, as illustrated in the following Figure 18.

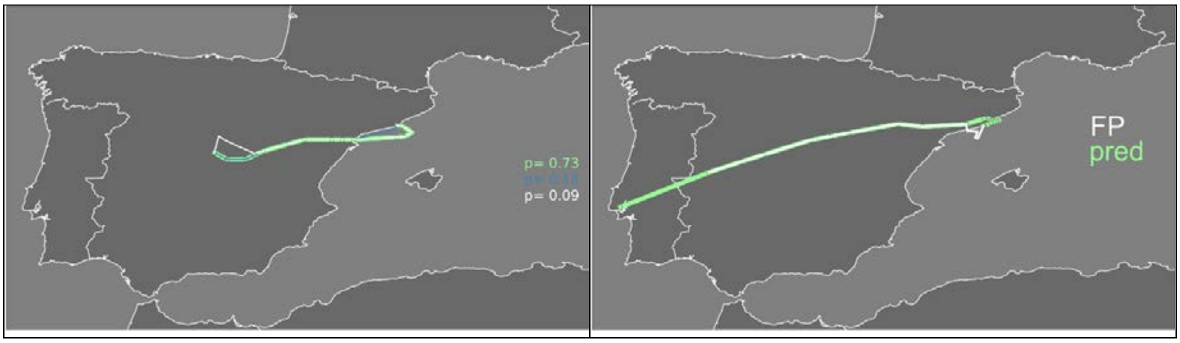

Figure 18: (left) flight #2328616 MAD - BCN on 20/06/2018 with 3 alternative predictions from the model with decreasing likelihood of being accurate. (right) submitted FP for flight #2326321 BCN - LIS on 02/02/2018 (white line with open circles) and corresponding predicted trajectory (green).

This illustrates how, compared to the FP submitted by the AUs 8 and 4 hours before EOBT, respectively, the model prediction at the same time points leads to a more accurate estimate of the last FP before operations. Figure 18 also depicts a problem encountered in the majority of the trajectories selected at this stage: in particular, despite being more accurate, the predictions of the model differ from the FP only in the regions immediately surrounding the TMAs (Terminal Manoeuvring Areas), while the two coincide in most of the en-route phase. This difference is only of limited benefit for the target users, as it might be related to local needs emerged at contingency level (an issue on a runway, a change in local weather conditions, etc.), and therefore as a follow up we choose a different approach to select the flights to visualise on the map.

In our revised approach, we focus on one week dataset (25 – 31 May 2018) and we select only flights that exhibit significant differences in the en-route waypoints Figure 19 and Figure 20 below show some of the results obtained with this selection criterion. For these flights, the model may enable a better demand prediction in en-route sectors.

Figure 19: FP (white) and model prediction (blue) 4 hours before EOBT for flight #3229838 LIRF – LEBL.

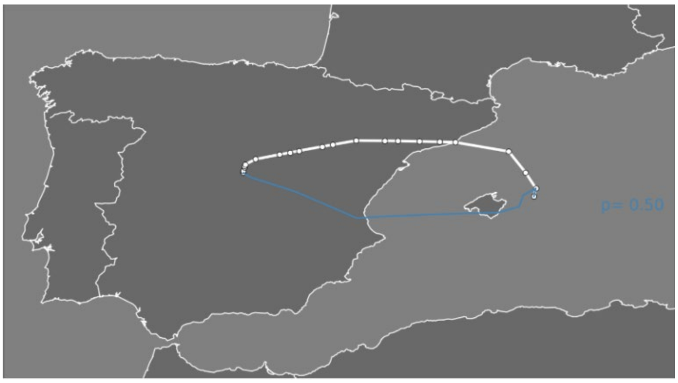

Figure 20: Same as Fig. 3 for flight #3229078 LEMD – LEMH.

The next step to develop the HMI mockup is to visualise the map of the Spanish en-route sectors of the Madrid, Barcelona and Sevilla ACCs (Area Control Centres). For these sectors, we study the occupancy demand and capacity as a function of time. In particular, we highlight in red the suffering sectors in which either the expected occupancy calculated with the FPs or the model-predicted occupancy (or both) exceed the declared threshold capacity of that sector at a given time. By selecting one such a sector, the user access to additional information, namely:

- The expected occupancy as a function of time compared to maximum capacity.
- The predicted occupancy as a function of time compared to maximum capacity.
- The list of flights expected to cross the sector in the time interval in which the demand exceeds the capacity.
- For these flights, the comparison of the trajectories in the FP and in the predictions, with their associated probability.

These data are meant to support the decision process of the target users at pre-tactical level as follows:

- By drawing attention on sectors that will be under stress in the course of the day.
- By enabling a more accurate estimate of the sectors’ occupancy than that obtained from the FPs.
- By showing how the sectors under stress may vary in the forecasts based on FPs and our model.
- By displaying the expected and predicted trajectories of flights that might overflow sectors close to the capacity limit.

A second round of interviews has been conducted among target users to obtain their feedback on the HMI mock-up (in terms of functionality), on the model, and on the way the information generated by the proposed model could be integrated in the existing tools currently adopted by air traffic controllers and the NM.

During the interviews, the HMI mock-up was presented to the target users and subsequently the following questions were asked to guide the discussion.

- What are your first impressions?
- What do you like/find useful in this tool?
- Would you change or add anything to the tool?

In general, the response was very positive. In the context of the development of an innovative tool to support the decision process at a pre-tactical level, the most relevant elements the interviewees appreciated include, among others:

- The graphical layout of the interface which resembles other tools currently adopted by Eurocontrol and ANSPs.
- The way the information is delivered was perceived as very clear.
- The actions that were mimicked in the HMI mock-up (such as the selection and visualisation of critical sectors or critical time intervals, the visualisation of individual flights, etc.) were perceived as intuitive to understand and to perform.
- The histograms with the aggregated data about the evolution of the sector occupancy in time were perceived as clear. The interviewees were very familiar with this way of conveying the information and they consider it fundamental to have a thorough view of how the demand of airspace will evolve in each sector. The possibility to directly compare between the expected and predicted air traffic load was considered very useful.
- The panel with the additional information about the reliability time of the airlines, i.e. the threshold in time after which, on average, a given airline is unlikely to change the FP, was found innovative and insightful.

The interviewed target users provided thorough advice on possible aspects to consider and explore in the further development of the tool:

- Attention should be paid to the possible reasons that trigger a change in FP: this could be related to the weather conditions, temporary needs of the company, regulations, and so on. The case of imposed regulations should be studied separately, as they force AUs to take a decision that normally they would not make. Therefore, it is interesting to isolate the situations in which the AUs actively take a decision from the cases in which they are subjected to a decision taken at ATM level.
- A useful information to include is the dynamical evolution of the sectorisation. This information would provide the users with elements to evaluate if the currently planned sectorisation is the best possible or if it is possible to adapt it to the forecasted traffic, for example merging two sectors that are both predicted with a limited load. It would be useful for the controller to visualise the consequences of this decision, namely by how much the traffic would increase on the merged sector, for how long the new configuration could be sustainable, etc.

- Target users consider useful to have the possibility to dynamically change the size of the time window at which to look at when studying the overall traffic load on a specific sector over time. In particular, at ATCO level it is common to visualise 20-minutes or 60-minutes slots. Sometimes, in particularly trafficked situations, it could be useful to visualise shorter time slots of 5-10 minutes.
- The interviewees confirmed that the tool is most useful in predicting variations in the en-route phase of the flights. This is because variations in the TMA are most often connected to local needs at airport level and consequently lack the regularity that is necessary to have reliable predictions.
- The future tool could integrate data-based advice to the users on how to react to a foreseen critical situation, for example by showing and comparing the impact of different decisions, such as: imposing a regulation on one or several flights, opening a new sector, collapsing two sectors, etc.
- The future tool should include the vertical dimension, which is considered a fundamental information to optimise the air space management.
- An intriguing development of the tool to improve its efficacy at airport/TMA level is to include the temporal dimension and a precise timing of the arrivals. This could help avoid congestion at airport level.

5.2 Predictive Model results

In this Section we present a summary of the validation performed to the predictive model.

The objective is to show the differences in occupancy counts per sectors between the real data in the planning phase and the output provided by our model.

It is important to note that for the validation of the model presented in this section, the time and altitude were estimated (so that we had a 4D trajectory), while in the results presented in section 3.1, it was only considered the 2D prediction of the waypoints.

The first step was to extract the information from the Network Manager in order to obtain the number of occupancy counts based on the information of the flight plan just before the EOBT (Estimated Off-Block Time) of the flight. The second step was to extract the output from our model using the same time windows, that is, fifteen minutes width sliding fifteen minutes, as showed in Figure 21.

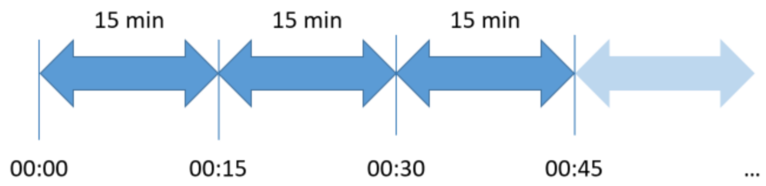

Figure 21. Distribution of times windows.

The third step was to compare the real data, flight plan before EOBT, with the computation of occupancy counts extracted from the algorithm. It is key to highlight that our model provides two different outputs: data that are just what would be predicted if the flight plans were completely reliable (and so the knowledge from the week before), and data with the prediction model. Both cases are provided in two different timestamps: eight and four hours before EOBT.

The comparison aforementioned was carried out for six different days from summer and winter season of 2018: 18th, 20th and 23rd of June, and 19th, 21st and 24th of November (Monday, Wednesday and Saturday), and for two different sectors: LECMTLL and LECMASU. A summary of the results are presented in Figure 22, Figure 23, Figure 24, Figure 25 and Figure 26 , where the light blue line is the real data, "fp" stands for flight plan (trusting in the reliability of the flight plan), "pred" corresponds to the output with the model, and DT4 and DT8 are the two different timestamps described.

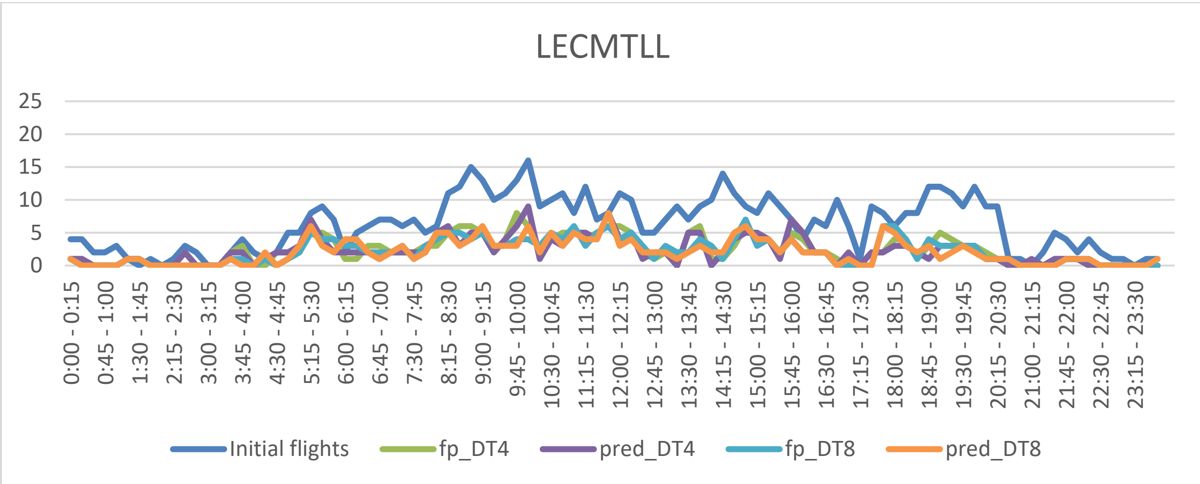

Figure 22. Comparison for 18th of June in LECMTLL sector.

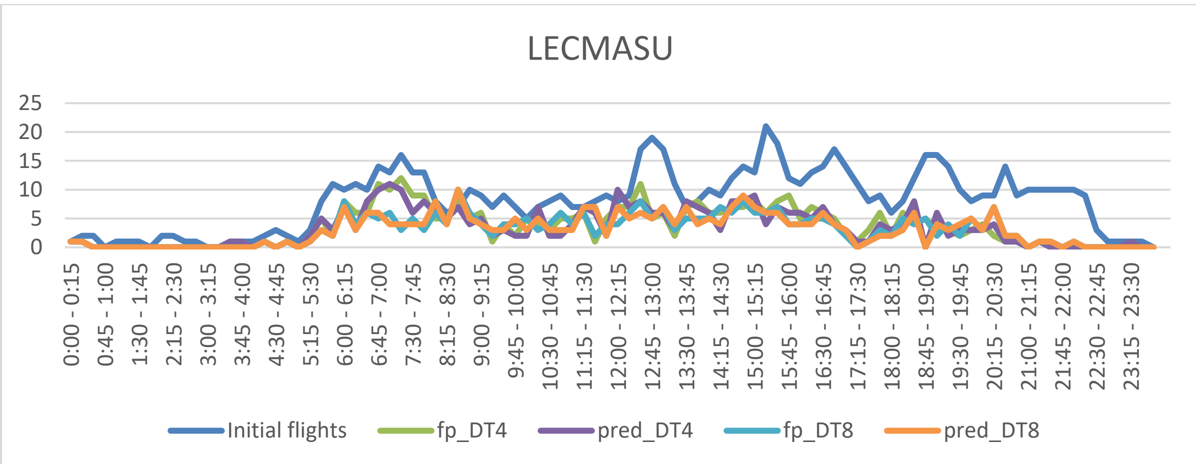

Figure 23. Comparison for 18th of June in LECMASU sector.

Figure 22 and Figure 23 show the comparison between the reality and the forecast for 18th of June 2018 and for two different sectors: LECMTLL and LECMASU.

In both cases, the trend of the occupancy counts is captured by the forecast, but it is interesting to underline that the behaviour of the prediction is better in the case of LECMASU than LECMTLL which is a sector with most of the flights in evolution, instead of in en-route phase, more typical for LECAMSU sector. Moreover, zooming in to a specific period, as seen in Figure 24 , it can be said that, in general, the prediction 4 hours before the EOBT is better than the one 8 hours before.

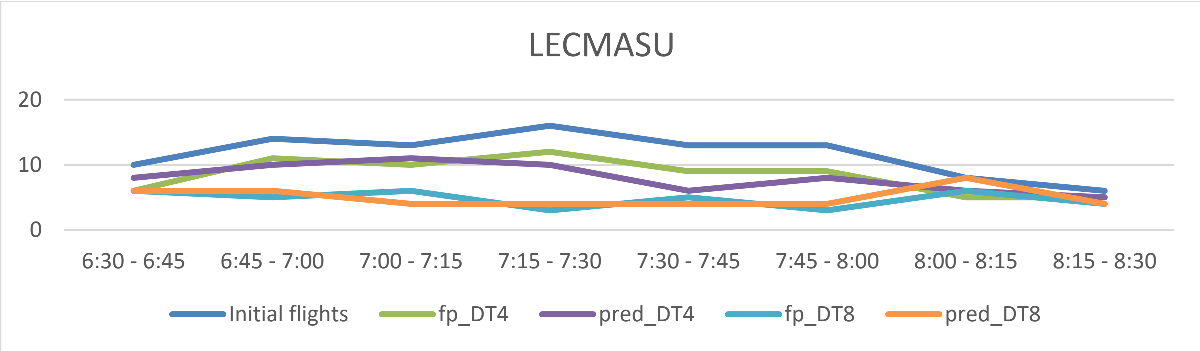

Figure 24. Comparison between DT4 and DT8.

Regarding the day of the week, there are no important differences, and the trend of the occupancy counts is also captured, as it can be seen in Figure 25.

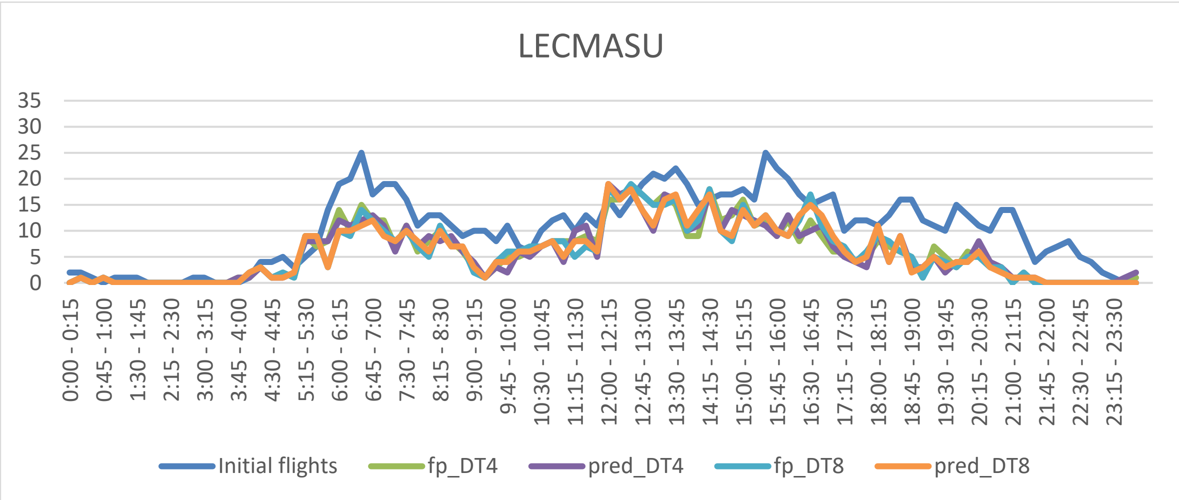

Figure 25. Comparison for 23rd of June in LECMASU sector.

However, for winter season the difference between forecast and reality is higher than in summer season, as it can be seen in Figure 26, which can be explained by the uncertainty induced by bad weather.

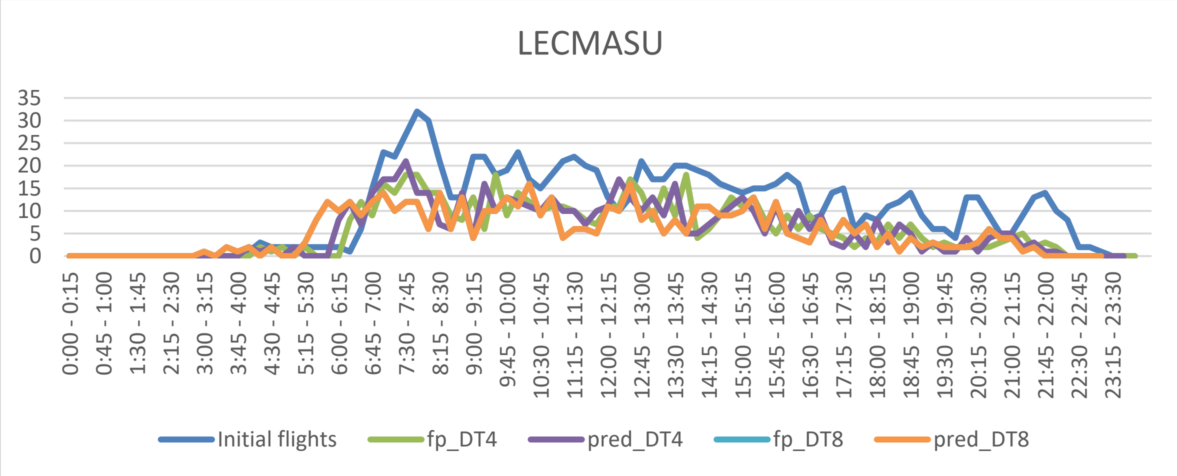

Figure 26. Comparison for 24th of November in LECMASU sector.

6. CONCLUSIONS

Our study focuses on the need of the ATM system to develop tools and methodologies that are able to support traffic and trajectory management functions. For these activities, trajectory and traffic prediction is key, in particular within the context of Trajectory-Based Operations (TBO).

While there are previous research addressing these matters, we present a different approach. In particular, the study aims at analysing patterns of flight plan evolution for individual flights, and extract patterns and feature which can be applied in a wide number of operational contexts where this information is available. The main result of the study is the development of a methodology for TP and traffic forecasting in a pre-tactical phase (from a few days to a few hours before the operations, when a only limited number of flight plans are available). This can be adjusted to different time scales (planning horizons), considering the level of predictability of each of them and the specific use case to where it should be applied. These results have been explored with support of operational staff to maximize the benefits in pre-tactical phase.

Hence, we aimed at developing a methodology for Trajectory Prediction and traffic forecasting in a pre-tactical time horizon (covering from one to six days prior to operation), period in which few flight plans are available.

As a result of the work conducted, the study has obtained a Trajectory Prediction framework with the following characteristics:

- Data-driven, as the methodology is based on data analysis and its interpretation.
- Dynamic, as it can be adjusted to different planning horizons.
- Adaptive, as it the methodology can be enhanced through the inclusion of new tactical data.

- Airspace User oriented, as the framework is adapted to the characteristics and strategies of different AUs.

Both the actual specific implementation based on operational Spanish data and the overall methodological framework allowing extension to any similar context of operations are considered sufficiently usable and having reached the targeted TRL4 maturity. In particular, the implementation for Spanish data is considered a candidate for inclusion in operational decision-making support tools.

The Trajectory Prediction Framework has been developed in both a high resolution and low-resolution scenario:

- For the high-resolution scenario, a predictive model was developed using actual high-quality operational data from the Spanish ANSP, ENAIRE.
  Results of the predictive model derived in the study were analysed in different time horizons to conclude that the lowest accuracy is found in $\Delta t = 4$ and not in $\Delta t = 8$. This can probably be explained with the fact that not all the considered flights submit flight plans with the anticipation of $\Delta t = 8$ every day, so the prediction accuracies for different Δt are computed on slightly different samples. The main outcome is that the model significantly enhances the prediction accuracy for "very variable" flights, while for very regular flights the default choice and the prediction are usually the same.
  The prediction accuracy of the model was also computed for different airlines, concluding that in most of the airlines the prediction accuracy increases as Δt decreases, being similar for mainly are airlines and over 80% in most of the cases.
- For the low-resolution scenario, the predictive model was developed using DDR data instead, to cover the ECAC area. In order to make this scenario comparable to the high-resolution one, the correspondence between both sources of data was identified. The model, as in the high-resolution case, has two main functionalities: predict if the trajectory will change, predict the final trajectory (and its probability). The performance on low-resolution scenario is - quite predictably - lower than the high-resolution one.

On the other hand, digging on the usability and feedback from operational TP end users, the purpose of this predictive model is to provide the NM and ANSPs with additional information about the upcoming flights and a prediction of the demand of airspace that improves the current methods based on the FPs issued by the AUs and on historical data.

For this reason a series of interviews with potential target users were conducted and a static mock-up to demonstrate how the proposed tool could be integrated in the current workflow was developed. The most relevant elements the interviewees appreciated include, among others:

- The graphical layout of the interface
- The way the information is delivered was perceived as very clear.
- The actions that were mimicked in the HMI mock-up were perceived as intuitive to understand and to perform.
- The histograms with the aggregated data about the evolution of the sector occupancy in time were perceived as clear.
- The panel with the additional information was found innovative and insightful.

7. FUTURE WORKS AND LEASSONS LEARNED

To continue with the work already done in our study, two main aspects need be addressed:

- A refinement of the predictive model itself to obtain better accuracy in the low-resolution scenario, though the use of more reliable data sources to cover ECAC area.
- A refinement of the tool to present the results of the predictive model. In this sense, target users interviewed, proposed the following:
  - ✓ Attention should be paid to the possible reasons that trigger a change in FP.
  - ✓ A useful information to include is the dynamical evolution of the sectorisation.
  - ✓ Target users consider useful to have the possibility to dynamically change the size of the time window at which to look at when studying the overall traffic load on a specific sector over time.
  - ✓ The interviewees confirmed that the tool is most useful in predicting variations in the en-route phase of the flights.
  - ✓ The future tool could integrate data-based advice to the users on how to react to a foreseen critical situation.
  - ✓ The future tool should include the vertical dimension, which is considered a fundamental information to optimise the air space management.
  - ✓ An intriguing development of the tool to improve its efficacy at airport/TMA level is to include the temporal dimension and a precise timing of the arrivals.

The first lesson learned in our study is related to the use of DDR data to perform data-driven analysis based on flight plan information, as this source of information has shown to not be useful in this purpose given the lack of data on the flight plan updates. For this reason, for further works on this field, different sources of information at ECAC level should be used to obtain more accurate results. The study was able to demonstrate the importance of having high-quality operational information, such as the dataset used in the high-resolution scenario.

However, initial expectations were that, even only in the high-resolution scenario, predictions of flight plan behaviour (planned trajectories) would imply a larger accuracy when apply to an actual scenario, such as those described in the results section. The potential of such information is observed in a non-constant way, despite a very wide set of factors for predictability was addressed. This implies that this approach for TP is not applicable to all cases as implemented in our model. The use case needs to be carefully chosen to extract a maximum benefit (i.e., specific time advance, or specific shifts to be applied). The possibility to consider not just individual flights factors but repeated patterns in aggregated demand is considered to be a potential enhancement, as it would incorporate “hidden” policies or behaviours of interest for global TP/demand forecast.

An additional lesson, not unknown but definitively highlighted in the study, is how positive the input from operational staff is when applying methodologies to actual operations. The operational staff guidance and vision brings a lot of practical value to projects with a certain maturity level, such as the proposed model and tool.

EVALUATING AIRPORT AND AIRLINE SERVICE QUALITY: A STRUCTURAL EQUATION MODELING APPROACH

Claudia Muñoz Hoyos
Profesor, Universidad de Antioquia, Colombia
Henry Laniado Rodas
Profesor, Universidad EAFIT, Colombia

ABSTRACT

A new scale for assessing traveler experience in air trips is proposed. Here, passenger experience is measured through travelers' perception of service quality, considering it as a chain of services. The new scale is called air travel service quality (ATSQ). It considers three service quality stages: departure airport service, airline service, and arrival airport service.

This research applies the ATSQ scale to examine service quality in domestic travels in a Colombian context. Given that traveler's experience plays a crucial role in determining passenger satisfaction, a structural equation model was applied to examine the relationship between service quality stages, customer satisfaction, and behavioral intentions. Adding the passengers' perception of the arrival airport to the integrated service quality measurement is considering one of the main contributions of this study. The finding of this research confirmed that all three stages of air travel service have a significant, positive effect on passenger satisfaction. The scale found in this research should provide useful information for developing effective operational and marketing strategies for the air travel market. In this way, airports and airlines could better understand how traveler's perception of service quality may affect each choice related to which departure airport, airline, and arrival airport combination to choose from.

1. INTRODUCTION

In the air transportation industry, airlines and airports enjoy high revenues when traveler satisfaction increases because when travelers are satisfied, they are more likely to repeat their purchase. Airports and airlines recognize the necessity of studying traveler's satisfaction and identifying service quality indicators for improving the travel experience (Bogicevic, Yang, Bilgihan, & Bujisic, 2013). Some studies of airlines and the airport industry have found a significant relationship between perceived service quality and passengers' satisfaction (Park, 2010; Hussain, Al Nasser & Hussain, 2014; Al-Refaie et al., 2014; Prentice & Kadan, 2019).

Therefore, in the air transportation market, traveler's satisfaction plays an essential role in assessing service quality and its influence on loyalty (Park, Robertson, & Wu, 2005).

Different instruments have been developed to assess service quality. Parasuraman et al. (1988) proposed a model to measure service quality that included five dimensions known as tangibles, reliability, responsiveness, assurance, and empathy. The instrument was called the SERVQUAL scale. Cronin & Taylor (1992) instead developed the SERVPERF scale, which measures service quality based on customer's perceptions. Cronin & Taylor (1994) found that the SERVPERF instrument explains more of the overall variance in the measure of service quality than the SERVQUAL scale.

Bezerra & Gomes (2015)suggested that future works should be focused on integrated service quality, by including dimensions related to airline and airport service quality because they share a significant area of overlap. Airports act as the first and last contact point for air travelers, and Kirk et al. (2014) found that negative airport experience can influence future travel plans. Ekiz, Hussain, & Bavik (2006) tried to integrate service quality in two stages and developed a new instrument called AIRQUAL scale. This instrument measures airline service quality perception, by including a dimension related to the departure airport. AIRQUAL identified five dimensions of service quality: airline tangibles, terminal tangibles, personnel, empathy, and image. AIRQUAL scale has been widely applied to national and international travels (Nadiri et al., 2008; Suki, 2014; Ali, Lal Dey & Filieri, 2015; Alotaibi, 2015; Mohamed & Rani, 2016; Farooq et al., 2018).

Despite AIRQUAL applications in the air transportation industry, it might not be suitable for measuring overall traveler's experience through travel service quality measurement due to the different features of service quality related to the airline, departure airport, and arrival airport. This research attempts to extend previous works by incorporating traveler's experience with arrival airport into the perceived service quality measurement of the air travel.

This research contributes to the air travel experience literature in three aspects: first, by adding the traveler's perception of arrival airport to the integral service quality measurement. Second, by developing an assessment tool for evaluating traveler's experience in air travel, called here air travel service quality (ATSQ) instrument (Munoz, Laniado, & Córdoba, 2019). Finally, by investigating the relationship between service quality in its different service stages and satisfaction, as well as the effect of traveler's satisfaction on future intention.

2. HYPOTHESIS DEVELOPMENT

This study proposes a new instrument that measures air traveler's experience through passenger's perceptions of service quality of their recent air travel. The proposed theoretical model consists of dimensions related to the departure airport, airline, and arrival airport. This study proposes following six hypotheses:

H1: Perceived quality related to airline tangibles will have a significant positive effect on traveler´s satisfaction.
H2: Perceived quality related to airline staff will have a significant positive effect on traveler's satisfaction
H3: Perceived airline empathy will have a significant positive effect on traveler's satisfaction.
H4: Perceived quality related to the departure airport will have a significant positive effect on traveler's satisfaction.
H5: Perceived quality related to the arrival airport will have a significant positive effect on traveler´s satisfaction.
H6: Traveler's satisfaction will have a significant positive effect on brand loyalty.

3. RESEARCH INSTRUMENT AND DATA ANALYSIS

The objective of this study is to measure air traveler's experience through service quality perception, by focusing on the Colombian domestic flights. The survey questions were based on air traveler's service quality perceptions. The questionnaire was divided into five sections. The first and second sections contained demographic and the latest travel information, respectively. Third survey component had questions about service quality perception; some questions were based on the AIRQUAL scale (Ekiz, Hussain & Bavik, 2006).

The traveler's satisfaction model in air transportation was assessed, by using the structural equation modeling SEM with latent variables. The aim of constructing an SEM was to test whether the five dimensions of air transportation service quality have a significant influence on traveler's satisfaction. Besides, the supposition of whether traveler's satisfaction leads to traveler's loyalty was assessed.

The confirmatory factor analysis (CFA) was performed to confirm the measurement model and to assess the degree to which the measured variables represent the number of constructs. By using a maximum likelihood estimation method, 58 items were subjected to a CFA with a seven-factor measurement model. The results of the CFA in Table 1 show that composite reliability (CR) ranged from 0.85 to 0.97. These values were all greater than the recommended threshold of 0.70 suggested by Hair et al. (2014), implying that multiple items for each factor are internally consistent and reliable.

The average variance extracted (AVE) was used to assess convergent validity. AVE ranged from 0.53 to 0.82, exceeding the recommended threshold value of 0.5 (Hair et al.,2014), which means that more than one-half of the variances observed in the items were explained by their hypothesized constructs. Therefore, the data has good convergent validity.

Statements	**Composite reliability (CR)**	**Average Variance Extracted (AVE)**
Airline Tangibles	**0.95**	**0.76**
Airline Staff	**0.97**	**0.78**
Airline Empathy	**0.85**	**0.53**
Departure Airport Tangibles	**0.96**	**0.61**
Arrival Airport Tangibles	**0.96**	**0.66**
Satisfaction	**0.92**	**0.62**
Loyalty	**0.95**	**0.82**
Goodness-of-fit: $\chi 2/df = 2.7$, CFI = 0.9, RMSEA = 0.075		

Tabla 1 – Confirmatory factor analysis results

A detailed examination of Table 2 shows that airline tangibles (β=0.127; t-value=2.581; p<0.05) have a significant positive effect on traveler's satisfaction. Thus, hypothesis H1 is supported. Table 2 also reveals that airline staff (β=0.166; t-value=3.427; p<0.001) have a significant effect on traveler´s satisfaction, which means that H2 is supported. Similarly, the findings of this study also support H3, which proposes the significant influence of airline empathy (β=0.480; t-value=8.455; p<0.001) on traveler's satisfaction. Furthermore, a high perception of service quality related to departure airport tangibles has a significant positive effect on traveler's satisfaction (β=0.203; t-value=4.088; p<0.001), supporting hypothesis H4. It can also be noted that the arrival airport tangibles has a significant relationship with traveler satisfaction (β=0.237; t-value=4.818; p<0.001). Lastly, H6 hypothesized that there is a relationship between satisfaction and traveler loyalty. The results shown in Table 2 support this hypothesis (β=0.786; t-value=17.89; p<0.001).

Hypothesis	**Endogenous variable**	**Exogenous variable**	**Standardized estimate**	**t-value**	**Result**
H1	Satisfaction	Airline Tangibles	0.127	2.581**	Supported
H2	Satisfaction	Airline Staff	0.166	3.427*	Supported
H3	Satisfaction	Airline Empathy	0.480	8.455*	Supported
H4	Satisfaction	Departure Airport Tangibles	0.203	4.088*	Supported
H5	Satisfaction	Arrival Airport Tangibles	0.237	4.818*	Supported
H6	Loyalty	Satisfaction	0.786	17.890*	Supported
*Notes: *p<0.001; **p<0.05*					

Tabla 2 – Standardized estimates of the air travel experience model

4. DISCUSSION AND CONCLUSION

Empirical outputs via SEM demonstrated that service quality perception is a multidimensional construct, which includes service quality of departure airport, airline service quality, and service quality of arrival airport. The scale developed here is both reliable and valid. Therefore, this study contributes to the literature on air traveler's experience assessment through the validation of the ATSQ instrument (Munoz et al., 2019). This research extends on the current air traveler's experience literature to examine the effect of service quality on traveler's satisfaction and, in turn, the relationship between traveler's satisfaction and traveler's behavioral intention.

All the hypotheses formulated in this study were tested. One of the main results is that traveler's satisfaction is affected by service quality dimensions, here called airline tangibles, airline staff, airline empathy, departure airport tangibles, and arrival airport tangibles. The results of this paper indicate that departure airport tangibles, arrival airport tangibles, and airline empathy factors are the most influential constructs in terms of traveler's satisfaction. In this regard, this research finding coincides with previous studies (Nadiri et al., 2008; Mohamed and Rani, 2016; Farooq et al., 2018) due to fact that the departure airport tangibles significantly affect traveler's satisfaction.

The present study also supports previous empirical findings, where the traveler's satisfaction is an important prerequisite of traveler's loyalty (Gures et al., 2014; Hussain et al., 2014; Leong et al., 2015; Kos Koklic et al., 2017). Therefore, this study contributes to traveler's loyalty literature due to the fact that loyalty is characterized by repurchase intention and word-of-mouth communications. Hence, airline and airport management should try to keep service quality at a high level in order to increase traveler's satisfaction.

RESUMEN

La presencia de ciclistas circulando individualmente o en grupo es un fenómeno habitual en las carreteras convencionales españolas. El uso compartido de estas carreteras por bicicletas y vehículos motorizados implica su interacción, pudiendo modificar la seguridad y la funcionalidad de las vías. Este efecto puede ser mayor en carreteras convencionales estrechas, donde las bicicletas deben circular por el carril, y los motorizados realizan una invasión mayor del carril opuesto durante el adelantamiento, implicando maniobras potencialmente peligrosas y una mayor duración del adelantamiento.

La microsimulación del tráfico es una excelente herramienta para analizar la funcionalidad del tráfico y la seguridad en carreteras convencionales, pero los modelos actuales no consideran a los ciclistas en este ámbito, y mucho menos su interacción con los motorizados.

En este estudio, a partir de observaciones del fenómeno, se ha adaptado un modelo, que ya consideraba vehículos motorizados en carreteras convencionales, a la circulación de bicicletas y a la interacción entre estos dos usuarios. El modelo ha sido calibrado y validado con datos reales recogidos mediante bicicletas instrumentadas y observaciones naturalísticas en una carretera convencional estrecha considerando 7 configuraciones distintas de grupos de ciclistas, variando el número de ciclistas y su configuración en línea o paralelo. La calibración se ha realizado en dos pasos, el primero a nivel microscópico con datos de adelantamientos, y el segundo, a nivel macroscópico con datos de medidas de desempeño del tramo. La duración del adelantamiento se ha considerado una variable clave para calibrar la longitud equivalente de cada grupo de ciclistas.

Los resultados confirman la reducción en la funcionalidad causada por la presencia de ciclistas, y apuntan a que se necesitan nuevas medidas de desempeño y/o la reformulación de las existentes, de modo que incorporen el efecto del tráfico ciclista sobre la funcionalidad del tráfico y la seguridad en estas carreteras.

1. INTRODUCCIÓN

La circulación de ciclistas por carreteras convencionales es un fenómeno frecuente en la actualidad. La gran mayoría de ciclistas que se observan por carretera son ciclistas deportivos que circulan de manera individual o bien forman parte de un grupo. En 2019 el número de ciclistas y clubes federados en España fue de 74768 y de 3878 respectivamente (Ministerio de Cultura y Deporte, 2020). Al mismo tiempo que ha aumentado el número de ciclistas en las carreteras también lo ha hecho el número de accidentes con ciclistas involucrados. En 2019 se registraron en España 7837 accidentes con ciclistas implicados, aunque la mayor parte se produjo en vías urbanas (72%), en vías interurbanas se registró el 60% de las víctimas mortales. De hecho, en 2019 murieron 48 ciclistas en vías interurbanas, 5 más que en 2018 (Dirección General de Tráfico, 2019). Estos datos apuntan a la necesidad de investigar las interacciones entre ciclistas y vehículos motorizados en estas vías, y a definir medidas que aumenten su seguridad.

Las carreteras convencionales suponen el 90% de la red de carreteras en España (Dirección General de Tráfico, 2019). Estas carreteras han sido diseñadas teniendo en cuenta solamente a los vehículos motorizados, y la mayoría de ellas no dispone de arcenes suficientemente anchos ni de ninguna infraestructura diseñada para la circulación de ciclistas. En la Diputació de València un 68% de las carreteras convencionales disponen de arcén inexistente o impracticable, presentando un ancho de vía menor de 7 m (Ministerio de Fomento, 2019), y muchas de ellas presentan una elevada presencia ciclista. Un estudio realizado por la Universitat de València, junto con las fundaciones Ponle Freno y AXA, a partir de datos de accidentes con ciclistas entre 2008 y 2013 en España facilitados por la Dirección General de Tráfico, concluyó que el 78% de los accidentes se produjeron en carreteras con arcén inexistente o impracticable (Universitat de València, 2016), demostrando que muchas de las carreteras en las que interaccionan vehículos a motor y bicicletas son secundarias, con arcén estrecho o nulo. En este tipo de carreteras el adelantamiento a ciclistas supone una mayor invasión del sentido opuesto y más maniobras iniciadas desde el seguimiento, pudiendo crear situaciones más peligrosas.

En España la circulación de ciclistas y su interacción con los vehículos a motor viene regulada por el Reglamento General de Circulación (Ministerio del Interior, 2003). En este Reglamento se permite la circulación de las bicicletas por el arcén o por el lado derecho de la calzada cuando el arcén es intransitable, y se les permite circular como máximo dos en paralelo si existe suficiente visibilidad. También se regula el adelantamiento a ciclistas exigiendo una distancia mínima de 1,5 metros.

El uso compartido de las carreteras por bicicletas y vehículos motorizados implica su interacción, pudiendo modificar no solamente la seguridad, sino también la funcionalidad del tráfico en estas vías. En España la funcionalidad del tráfico se determina mediante la metodología del Highway Capacity Manual (HCM) (Transportation Research Board, 2016).

El HCM determina el nivel de servicio que ofrece una carretera basándose en tres medidas de desempeño: el porcentaje de tiempo en cola, la velocidad media de recorrido del tramo y la velocidad en flujo libre. Para carreteras estrechas con una intensidad de tráfico motorizado relativamente baja, el porcentaje de tiempo en cola es la principal medida de desempeño que caracteriza la funcionalidad del tráfico. Sin embargo, la metodología descrita en el HCM solamente tiene en cuenta a los vehículos motorizados. En carreteras convencionales la presencia de ciclistas supone un obstáculo para los vehículos a motor, debido a la diferencia de velocidades que existe entre ellos, siendo la posibilidad de adelantamiento esencial para no penalizar la funcionalidad del tráfico. En vías estrechas el adelantamiento requiere la prácticamente total ocupación del sentido opuesto, y en muchos casos obliga a realizar un seguimiento del grupo de ciclistas previo a su adelantamiento. Esto implica que tanto el deseo, como la posibilidad de adelantamiento a bicicletas, sean mayores que entre vehículos motorizados, para una misma carretera. Por tanto, es necesario analizar en detalle la interacción entre bicicletas y vehículos motorizados en estas vías para evaluar el efecto de la presencia de tráfico ciclista tanto en la seguridad como en la funcionalidad del tráfico.

En los últimos años se han realizado numerosos estudios sobre la interacción de bicicletas y vehículos motorizados en entorno interurbano. La mayoría de ellos están enfocados a la seguridad durante el adelantamiento, centrándose en el análisis de la separación lateral y la velocidad durante la maniobra de adelantamiento y el tipo de maniobra realizada, como los realizados por Llorca et al. (2017), Bianchi Piccinini et al. (2018) y Farah et al. (2019).

Recientemente un estudio realizado por Feizi et al (2021) recogió datos de separaciones laterales utilizando una bicicleta instrumentada en distintos tipos de carreteras de Estados Unidos; una de sus conclusiones fue que en carreteras anchas con arcenes las separaciones laterales eran mayores. En España la circulación de grupos de ciclistas es una realidad que debe de tenerse en cuenta. Sin embargo, pocos estudios han considerado la circulación de ciclistas en grupos, solamente García et al. (2019) y López et al. (2020) realizaron un estudio considerando grupos de hasta 3 y 10 ciclistas respectivamente. En el presente estudio se consideran grupos de ciclistas circulando en línea y en paralelo.

A partir de observaciones en campo se pueden obtener medidas que permiten caracterizar la seguridad y la funcionalidad del tráfico en carreteras convencionales. Sin embargo, las observaciones no cubren todo el rango de demandas de tráfico existentes, y no es posible obtener algunas medidas de desempeño mediante observación directa del fenómeno. La microsimulación del tráfico es una herramienta que permite simular escenarios geométricos y de tráfico diferentes a los observados, y obtener medidas de desempeño difícilmente medibles en campo como el tiempo de demora acumulada de los vehículos. En la actualidad existen diferentes programas de simulación del tráfico, pero ninguno de ellos permite simular la interacción entre bicicletas y vehículos a motor en entornos interurbanos. En este estudio se ha utilizado el sofware de simulación de tráfico Aimsun Next (Aimsun, 2020).

Aimsun Next dispone de un módulo que permite simular adelantamientos entre vehículos motorizados en carreteras convencionales desarrollado por Llorca et al. (2015), y que fue calibrado y validado con observaciones en campo. En este estudio se pretende incorporar a las bicicletas como un nuevo usuario en este modelo, con sus respectivas características, considerando la interacción con los vehículos motorizados y la circulación de grupos en línea y en paralelo.

El adelantamiento a grupos ciclistas presenta algunas particularidades que deben adaptarse al modelo existente para vehículos motorizados. El modelo debe de representar la realidad, considerando las interacciones entre motorizados pero incorporando a las bicicletas, por tanto, los parámetros que rigen las interacciones entre motorizados deben adaptarse sin variar el comportamiento entre ellos.

Las principales limitaciones del modelo actual son la imposibilidad de simular la invasión parcial del carril opuesto durante el adelantamiento y la no consideración de anchos de vía ni de vehículos. Para superar estas limitaciones se ha modificado el modelo, calibrando las longitudes equivalentes de los grupos de bicicletas de manera que las duraciones de los adelantamientos coincidan con las observadas, incorporando así el efecto de invasiones parciales del carril opuesto, y la configuración del grupo de ciclistas.

Se consideran diferentes longitudes para grupos circulando en línea o en paralelo, considerando el diferente ancho de cada grupo de ciclistas.

Este estudio es la continuación de Moll et al. (2021), donde se calibró y validó el modelo considerando ciclistas; sin embargo, solo fueron analizados ciclistas circulando en paralelo. Dado que la presencia de grupos ciclistas en línea también es muy habitual, este estudio se centra en la influencia de esta configuración y en la comparativa de las mismas con el objetivo de analizar la seguridad y la funcionalidad del tráfico en estas vías.

2. OBJETIVOS E HIPÓTESIS

El objetivo principal de esta investigación es analizar el efecto que tiene la presencia de tráfico ciclista en la seguridad y la funcionalidad del tráfico en carreteras convencionales mediante el uso de un microsimulador de tráfico, considerando a los grupos de ciclistas circulando en línea y en paralelo. Para ello se desarrollaron dos metodologías de tomas de datos en campo que permitieron obtener los datos necesarios para adaptar, calibrar y validar un modelo de microsimulación de tráfico que incorpore a estos usuarios, su comportamiento y sus interacciones.

Las hipótesis de partida consideradas son las siguientes:
La presencia de ciclistas reduce la velocidad media de recorrido de los vehículos motorizados.

- A mayor número de ciclistas que forman el grupo mayor será su afección sobre la funcionalidad y la seguridad.
- Cuando los ciclistas circulan en línea su afección es mayor que cuando lo hacen en paralelo.
- El uso de microsimulación del tráfico permite obtener medidas de desempeño difícilmente medibles en campo.

3. METODOLOGÍA

Para llevar a cabo este estudio se han diseñado y realizado dos tipos de tomas de datos reales en campo; por una parte, se han instrumentado bicicletas con la finalidad de obtener datos relativos a la maniobra de adelantamiento a nivel microscópico, y por otra, se han realizado tomas de datos en la entrada y salida del tramo de estudio para obtener medidas de desempeño a nivel macroscópico.

Una vez recogidos y analizados todos los datos, tanto a nivel microscópico como macroscópico, se modela el fenómeno en el microsimulador de tráfico, y se calibra y valida con los datos observados en campo, considerando la circulación de los grupos de ciclistas en línea y en paralelo.

Con el modelo de microsimulación se obtendrán las medidas de desempeño consideradas en el HCM y otras que caractericen el efecto de la presencia de ciclistas, y se verificará la validez del modelo para simular carreteras convencionales estrechas con tráfico motorizado y ciclista.

3.1 Tramo de estudio

El tramo de estudio está situado en el sur de València, en la carretera CV-502, entre los PK1+315 y PK3+500. En este tramo se realizaron diversos aforos y se comprobó una elevada presencia de tráfico ciclista, tanto en días laborables como festivos, ya que se trata de un tramo habitual en los recorridos de los clubes ciclistas. La Fig. 1 muestra la ubicación del tramo y sus características geométricas.

Fig. 1 - Localización y características del tramo de estudio.

Se trata de un tramo de carretera convencional sin arcén, con un ancho de carril de 3.5 m, una IMD de 3544 veh/día y un porcentaje de vehículos pesados de 2.07% (Diputació de València, 2020). El tramo de estudio discurre paralelo a la playa, y la pendiente es prácticamente nula en todo el tramo.

La longitud del tramo es de 2185 m, y la velocidad límite es de 70 km/h. Se trata de un tramo homogéneo, sin entradas ni salidas intermedias de vehículos. Para poder modelar el tramo en el simulador de tráfico se ha realizado un estudio determinando las características geométricas del tramo, tales como líneas continuas, velocidades límite y señalización viaria.

Estos datos se han tomado en los dos sentidos de circulación, y son necesarios para incorporar el tramo en el simulador de tráfico correctamente.

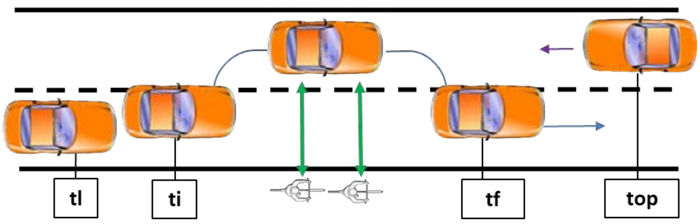
3.2 Datos a nivel microscópico

Para modelar correctamente las interacciones entre vehículos motorizados y ciclistas es necesario conocer en detalle la maniobra de adelantamiento, ya que esta es la interacción más importante que se produce entre ellos. Para estudiar esta maniobra se ha diseñado una metodología de toma de datos basada en la circulación, por el tramo de estudio, de bicicletas instrumentadas que permitan registrar datos durante las maniobras de adelantamiento. La instrumentación detallada de las bicicletas puede consultarse en Moll et al. (2021), y puede verse en la Fig. 2.

Los ciclistas recorrieron el tramo en las siete configuraciones de grupo mostradas en la Fig. 2. Los ciclistas que participaron en las pruebas tenían experiencia en el ciclismo de carretera, y circularon libremente manteniendo la configuración del grupo indicada. Para la realización de las pruebas los ciclistas llevaron ropa deportiva adecuada y casco, ya que su uso en obligatorio en carretera.

Fig. 2 - Bicicleta instrumentada y configuraciones estudiadas.

En la reducción de los datos registrados con las bicicletas instrumentadas se obtuvo la línea temporal de cada adelantamiento. Se define la duración del adelantamiento como el tiempo desde que el vehículo inicia la maniobra hasta que la termina regresando a su posición natural en el carril de circulación, en la Fig. 3 corresponde con tf-ti. La duración del adelantamiento es la principal variable utilizada para calibrar las maniobras de adelantamiento a nivel microscópico.



tl: tiempo de llegada a las bicicletas; ti: tiempo de inicio de la maniobra; tf: tiempo fin de la maniobra; top: tiempo en que se observa el opuesto.

Fig. 3 - Línea temporal de la maniobra de adelantamiento.

3.3 Datos a nivel macroscópico

La metodología de toma de datos a nivel macroscópico o de sección consiste en realizar grabaciones desde una posición estática a la entrada y salida del tramo, con la finalidad de registrar en estos puntos el tiempo de paso de cada usuario y su tipología. En el caso de agrupaciones de ciclistas también se registra el número de ciclistas que componen el grupo y su configuración en línea o en paralelo. Todas estas grabaciones se realizaron con videocámaras de alta definición colocadas de forma estratégica de manera que se consiguieron grabaciones en las que se distingue perfectamente las variables de estudio sin ser advertidas por los usuarios, no afectando así a su comportamiento. La Fig. 4 muestra la metodología utilizada y las variables registradas en estas tomas de datos.

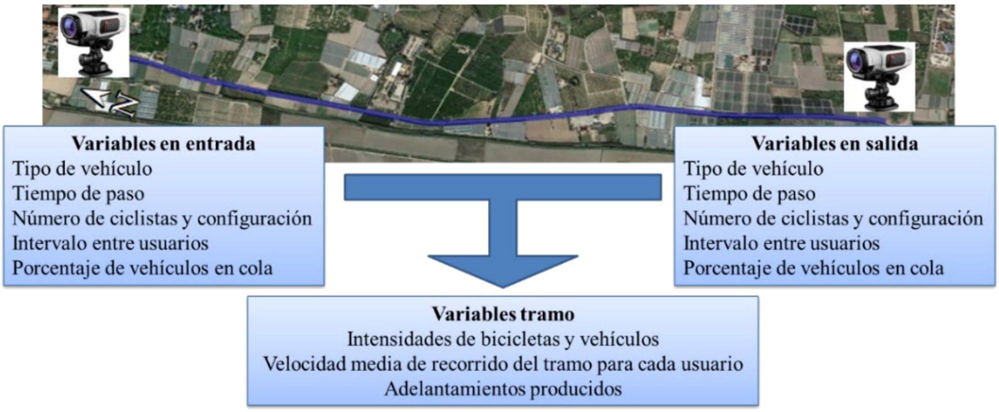


Fig. 4 - Toma de datos y variables registradas a nivel macroscópico en el tramo de estudio.

La reducción de datos se realizó mediante el software de procesamiento de vídeos Kinovea, obteniéndose las siguientes variables:

- El tiempo de recorrido del tramo de cada usuario.
- La velocidad media de recorrido de cada usuario.
- Intervalos de tiempo entre usuarios en entrada y salida.
- Porcentaje de usuarios en cola a la entrada y a la salida del tramo. Se considera que un vehículo circula en cola si el intervalo con su predecesor es menor de 3 s, siguiendo el criterio del HCM (Transportation Research Board, 2016).

A partir de estos datos se calcularon las intensidades en periodos de 15 minutos, tanto de bicicletas como de vehículos motorizados. Estas intensidades se calcularon con ventanas deslizantes de 5 minutos, y para cada valor se obtuvo la intensidad horaria equivalente. Para las bicicletas se tuvo en cuenta su agrupamiento, registrando el número de ciclistas que formaban el grupo y su configuración en línea o en paralelo. Estas intensidades horarias equivalentes proporcionaron los escenarios de tráfico necesarios para calibrar y validar el modelo de microsimulación.

3.4 Modelo de microsimulación

En este estudio se utilizó el software Aimsun Next, en su versión Aimsun Next 20. Esta versión incorpora una mejora que permite adelantar a vehículos más lentos incluso con línea continua (Aimsun, 2020), esta novedad permite representar la realidad más fielmente, ya que la normativa española permite adelantar a bicicletas en línea continua si existe suficiente visibilidad según el Reglamento General de Circulación (Ministerio del Interior, 2003).

Aimsun Next dispone de un módulo de adelantamiento en carreteras convencionales desarrollado por Llorca et al. (2015). En este estudio se adapta el modelo existente a la circulación de bicicletas y motorizados y a su interacción, y se calibra y valida con datos observados. La metodología de desarrollo del modelo de microsimulación, y la calibración y validación se puede consultar en Moll et al. (2021).

4. RESULTADOS Y DISCUSIÓN

4.1 Resultados de la toma de datos a nivel microscópico

Mediante la metodología de toma de datos a nivel microscópico se han recopilado un número elevado de variables relacionadas con la maniobra de adelantamiento entre vehículos a motor y bicicletas. Para calibrar el modelo de microsimulación solamente se utilizaron los datos de las duraciones de la maniobra de adelantamiento a los diferentes grupos de ciclistas que recorrieron el tramo en las configuraciones indicadas.

En la Tabla 1 se recogen los datos registrados de velocidades del vehículo adelantante, separaciones laterales y duraciones del adelantamiento a los distintos grupos de ciclistas. Se observa que los resultados de las velocidades del vehículo adelantante durante el adelantamiento fueron similares para todas las configuraciones de ciclistas estudiadas. En cuanto a las separaciones laterales durante el adelantamiento, cuando los ciclistas circularon en línea se registraron separaciones mayores, y en todos los casos, las separaciones laterales medias respetaron la distancia mínima exigida de 1.5 metros.

Configuración	Observaciones		Velocidad (km/h)		Separación (m)		Duración (s)	
	N	%	Media	Desv.	Media	Desv.	Media	Desv.
Individual (1)	37	16%	65.60	15.66	1.88	0.455	5.65	1.65
2 en línea (2L)	41	18%	66.39	19.35	1.78	0.461	6.71	2.11
2 en paralelo (2P)	42	19%	62.48	13.94	1.60	0.458	6.17	1.99
4 en línea (4L)	36	16%	68.46	13.55	1.91	0.42	8.58	2.22
4 en paralelo (4P)	31	14%	63.03	14.84	1.67	0.32	6.84	2.00
10 en línea (10L)	16	7%	62.06	9.72	1.99	0.39	9.44	2.22
10 en paralelo (10P)	22	10%	64.68	12.75	1.83	0.51	7.59	1.97
Total	225	100%	64.85	14.91	1.79	0.45	7.03	2.30

Tabla 1 - Número de adelantamientos registrados y datos de velocidad del adelantante, separación lateral y duración del adelantamiento según configuración del grupo de ciclistas adelantado.

4.2 Resultados de la toma de datos a nivel macroscópico

Se tomaron datos a la entrada y salida del tramo un día laborable por la mañana, iniciando a las 9:15 y con una duración poco mayor de 3 horas. Los datos se redujeron y analizaron en los dos sentidos de circulación. En la Fig. 9 se muestran las bicicletas y los vehículos motorizados ligeros acumulados registrados en cada sentido de circulación durante el periodo de toma de datos.

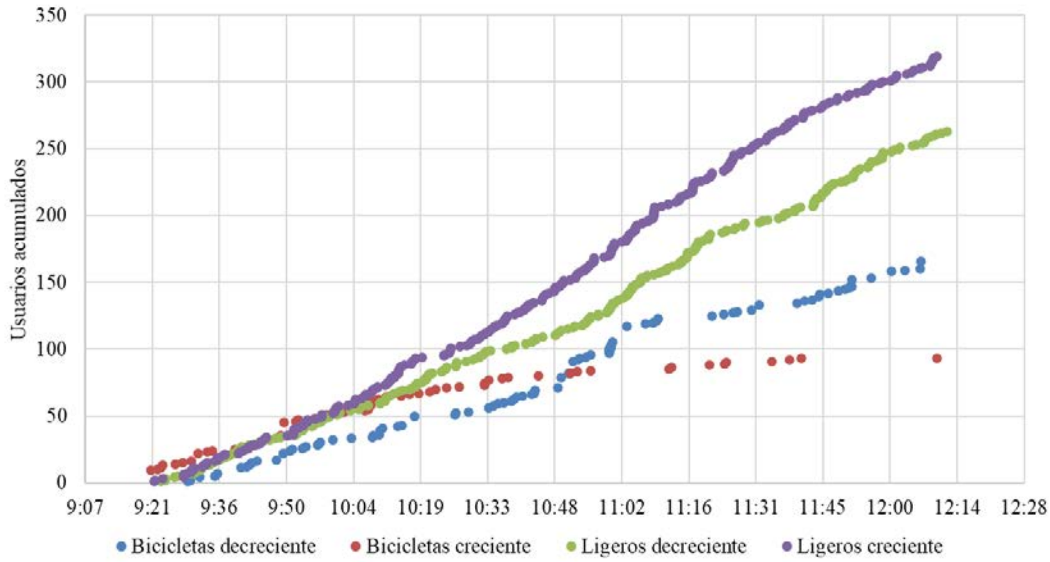

Fig. 9 - Bicicletas y ligeros acumulados registrados durante el periodo de estudio en cada sentido.

A partir de estas observaciones se decidió realizar el estudio en el sentido decreciente del tramo, ya que fue el sentido con mayor número de ciclistas observados. Se obtuvieron los escenarios de tráfico horario equivalente, a partir de las observaciones cada 15 minutos (Fig. 10).

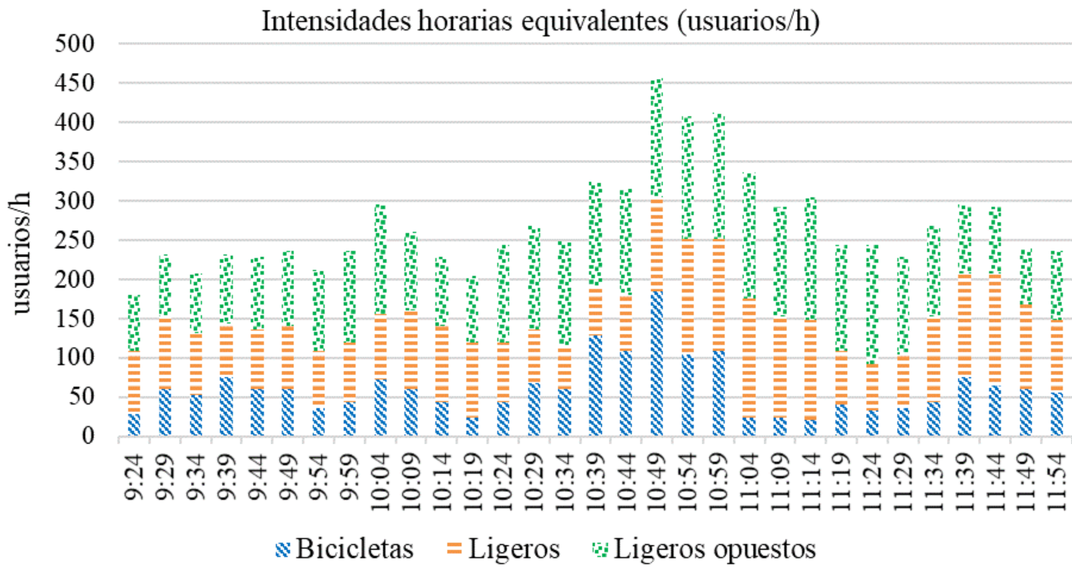

Fig. 10 - Intensidades horarias equivalentes de usuarios en sentido decreciente.

A partir de los datos observados en inicio y fin del tramo se obtuvieron las distribuciones de velocidades medias de recorrido de bicicletas y vehículos ligeros. Estos datos de velocidades son necesarios para definir las velocidades de los usuarios en Aimsun, y para calibrar y validar los resultados de las simulaciones.

Los datos de velocidades de bicicletas circulando individualmente y en pelotón se compararon mediante un análisis ANOVA y los resultados indicaron que no existe diferencia estadísticamente significativa entre las medias de las velocidades medias de recorrido de estos dos grupos ($F=0.09$, $p=0.7591$). Por tanto, a la hora de analizar las velocidades medias de recorrido de ciclistas individuales y en grupo, se consideran todos los datos conjuntamente, ya que todos ellos circulan a la misma velocidad.

La distribución de velocidades medias de recorrido de los ciclistas presentó un valor promedio de 29.52 km/h y una desviación de 4.45 km/h. Las velocidades de los ciclistas presentaron poca dispersión debido a que el tramo no presenta prácticamente pendiente, y los ciclistas observados eran semiprofesionales con una forma física desarrollada. Los 263 vehículos ligeros que se registraron presentaron una velocidad media de recorrido con un valor promedio de 62.08 km/h y una desviación de 8.21 km/h.

Se seleccionaron los escenarios para calibrar el modelo en Aimsun Next y para validarlo a partir de los datos de intensidades horarias observadas (Fig. 10). Para calibrar el modelo se utilizaron los escenarios de demanda máxima y mínima de bicicletas, y un tercer escenario de demanda media, con sus correspondientes demandas de ligeros en el mismo sentido de circulación y en sentido opuesto. Una vez calibrado el modelo se validó considerando cuatro escenarios de demanda diferentes a los utilizados en la calibración. Para calibrar y validar el modelo se consideraron los grupos de ciclistas circulando en línea y en paralelo.

Intensidades (usuarios/h)	Calmin	Calmed	Calmax	Val1	Val2	Val3	Val4
Ligeros	128	144	120	76	64	136	108
Ligeros opuestos	156	160	152	136	156	88	84
1	12	36	40	24	16	24	20
2P/2L	4	12	8	16	0	16	0
4P/4L	0	0	4	0	4	4	8
10P/10L	0	4	12	8	0	0	0
Total ciclistas	20	100	192	136	32	72	52

Tabla 2 - Escenarios de tráfico utilizados para calibración y validación (usuarios/h).

4.3 Resultados del modelo de microsimulación

4.3.1 Calibración del modelo

Se realizaron varios procesos de calibración del modelo, variando en cada uno de ellos los parámetros necesarios. En la Tabla 3 se muestran los resultados de los principales parámetros después del proceso de calibración. Se calibraron las longitudes de los grupos de ciclistas para conseguir las mismas duraciones de los adelantamientos obtenidas en las simulaciones y en las observaciones de campo. El resto de los parámetros del modelo se revisó con detalle, y se intentó variar mínimamente los valores originales para no afectar a la interacción entre motorizados, ya que en el modelo resultante los vehículos motorizados también deben de interaccionar entre sí de manera correcta.

Segmento					
	Diferencia de velocidades para adelantar en línea continua (km/h) = 20 km/h				
	Longitud tramos generación de colas (m) = 350 m				
Usuarios					
	Longitudes	Individual = 4 m;	2P = 6 m;	4P = 10 m;	10P = 16 m
	equivalentes (m):		2L = 11 m;	4L = 28 m;	10L = 35 m
	Velocidad máxima deseada Ligeros = media 78 km/h (Desv. 10 km/h)				
	Velocidad máxima deseada bicicletas = media 30 km/h (Desv. 2 km/h)				
Experimento					
	Demora entre adelantamientos simultáneos (s) = 0 s				
	Número de adelantamientos simultáneos permitidos = 5				
	Rango máximo en la cola para desear adelantar = 2				
	Umbral de tiempo hasta fin de tramo (s) = 5 s				

Tabla 3 - Valores de los principales parámetros calibrados.

El proceso de calibración se inició analizando los datos a nivel microscópico obtenidos de las maniobras de adelantamiento a los diferentes grupos de ciclistas en el simulador.

En esta fase se calibraron las longitudes equivalentes de cada grupo de ciclistas mostradas en la Tabla 3, de manera que no existieran diferencias estadísticamente significativas entre las duraciones de los adelantamientos obtenidas en los escenarios de calibración y las observadas en campo. Los resultados de la prueba ANOVA mostrados en la Tabla 4 muestran que para todos los casos el *p-valor* es mayor de 0.05, por tanto, las medias de los valores simulados y observados de las duraciones no presentaron diferencias estadísticamente significativas con un nivel de confianza del 95%. Para cada escenario de calibración se comparó una a una las distribuciones de duraciones obtenidas de las simulaciones con las observadas para cada grupo de ciclistas mediante la prueba de Kologorov-Smirnov (K-S). En total se realizaron 15 pruebas K-S, solamente para un ciclista individual se obtuvieron valores de $p < 0.05$, indicando en todos los otros casos que no existía una diferencia estadísticamente significativa entre las dos distribuciones comparadas con un nivel de confianza del 95%.

Grupos de ciclistas	Calmin			Calmed			Calmax			Resultados ANOVA	
	N	Media	Desv.	N	Media	Desv.	N	Media	Desv.	F	*p*-valor
1	148	5.88	1.46	192	5.74	1.57	190	5.56	1.54	1.22	0.303
2L	45	6.89	1.82	35	6.34	1.81	41	6.71	2.11	0.51	0.673
2P	45	6.18	1.93	81	6.20	1.64	73	6.06	1.55	0.10	0.961
4L	-	-	-	-	-	-	51	8.31	2.15	0.32	0.571
4P	-	-	-	-	-	-	40	6.65	1.66	0.19	0.665
10L	-	-	-	51	9.25	2.29	86	9.30	2.19	0.04	0.960
10P	-	-	-	69	7.31	1.73	103	7.14	1.62	0.71	0.495

Tabla 4 - Resultados estadísticos de las duraciones de los adelantamientos (s) según la configuración del grupo de ciclistas.

En la segunda parte de la calibración se obtuvieron los valores de los parámetros que minimizaban las diferencias entre los valores observados y simulados de las variables a nivel macroscópico. Se calibraron las velocidades medias de recorrido, los intervalos de tiempo entre usuarios y el porcentaje de vehículos en cola a la entrada y salida del tramo para los tres escenarios. Los resultados del proceso de calibración a nivel macroscópico pueden consultarse en Moll et al. (2021).

A la vista de los resultados del proceso de calibración, se considera que el modelo está calibrado y funciona correctamente, tanto a nivel microscópico, observando las maniobras de adelantamiento en detalle, como a nivel macroscópico o de sección.

4.3.2 Validación del modelo

El modelo se validó en cuatro escenarios de tráfico diferentes a los utilizados en la calibración, y mostrados en la Tabla 2. El proceso de validación se realizó a nivel macroscópico, comparando los resultados de las simulaciones con las observaciones en campo de las velocidades medias de recorrido, y el intervalo de tiempo entre vehículos y los porcentajes de vehículos en cola a la entrada y salida del tramo.
El proceso de validación y los resultados obtenidos se pueden consultar en Moll et al. (2021).

Después de los procesos de calibración y validación, el modelo está listo para ser utilizado para calcular las variables necesarias para analizar la afección que el tráfico ciclista puede tener sobre la seguridad y la funcionalidad del tráfico en carreteras convencionales estrechas considerando los grupos de ciclistas circulando en línea y en paralelo.

4.4 Análisis de la seguridad y la funcionalidad del tráfico

En este apartado se analizan los resultados de las simulaciones de los tres escenarios utilizados para calibrar el modelo de microsimulación. Estos tres escenarios han sido simulados considerando a los grupos de ciclistas circulando en línea y en paralelo.

A partir de las observaciones en campo realizadas mediante las bicicletas instrumentadas se obtuvieron las distribuciones de las duraciones del adelantamiento considerando diferentes agrupaciones de ciclistas. En la Fig. 11 se puede observar como la tendencia fue que a mayor número de ciclistas formando el grupo, se registraron mayores duraciones, y para grupos formados por el mismo número de ciclistas se registraron mayores duraciones cuando circulaban en línea que cuando lo hicieron en paralelo. Mayores duraciones del adelantamiento implican mayores tiempos en el carril opuesto, generando un mayor riesgo de exposición a colisión frontal con los vehículos opuestos.

En el tramo de carretera convencional estrecha donde se desarrolló el estudio, la mayoría de los grupos ciclistas observados circulaban en paralelo, esta configuración presentó duraciones menores del adelantamiento y por tanto una menor exposición al riesgo para los conductores. Estas observaciones difieren de la opinión de los conductores que realizaron las encuestas del estudio realizado por López et al., 2019, donde la mayoría de los conductores encuestados prefirieron que los ciclistas circulen en línea.

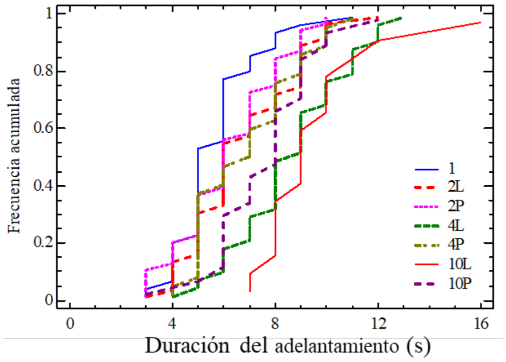

Fig. 11 - Distribuciones de las duraciones del adelantamiento (s) a los diferentes grupos de ciclistas obtenidas en campo.

En la Fig. 12 se muestran las distribuciones de velocidades medias de recorrido de los vehículos ligeros resultantes de las simulaciones de los seis escenarios de calibración.

Se observa que la velocidad media de recorrido del tramo se redujo a medida que aumentaba la demanda de ciclistas. Se realizó la prueba de Kruskal-Wallis para comparar las medianas de las distribuciones, ya que los datos no provienen de distribuciones normales, los resultados mostraron que existe una diferencia estadísticamente significativa entre las medianas con un nivel de confianza del 95%. Sin embargo, las medianas y las distribuciones de las velocidades considerando los escenarios de demanda máxima y media no mostraron diferencias estadísticamente significativas con una significancia del 5%. Esto indica que, a partir de un cierto nivel de tráfico ciclista cercano a la demanda media observada, el efecto sobre la velocidad media de recorrido de los vehículos ligeros es menor, a medida que aumenta el volumen de ciclistas. Las medianas entre línea y paralelo no presentaron diferencias estadísticamente significativas en la prueba de Bonferroni para los tres escenarios de tráfico.

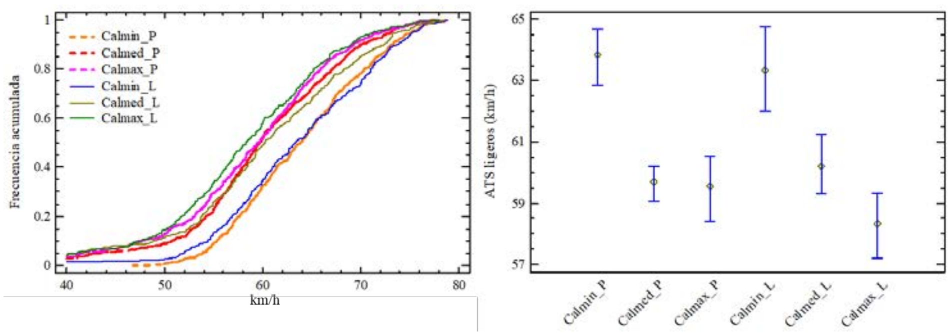

Fig. 12 - Distribuciones de las velocidades medias de recorrido de los vehículos ligeros (km/h) (izquierda) y medianas e intervalos del 95% de confianza (derecha) obtenidas en las simulaciones de los escenarios de calibración.

Otra variable que sirve para caracterizar la seguridad y la funcionalidad del tráfico es el número de adelantamientos realizados por vehículo en el tramo. En la Fig. 13 izquierda se pueden observar las distribuciones del número medio de adelantamientos por vehículo obtenidos de las 15 simulaciones para los seis escenarios simulados. Es evidente que a mayor volumen de ciclistas circulando en el tramo se realizan más maniobras de adelantamiento.

Los resultados de la prueba ANOVA constataron las diferencias entre las medias de los escenarios simulados ($F=116.65$, $p<0.05$). Sin embargo, para los escenarios simulados, no se observaron diferencias estadísticamente significativas entre las medias de los adelantamientos registrados considerando las configuraciones de los grupos de ciclistas en línea y en paralelo (Fig. 13 derecha).

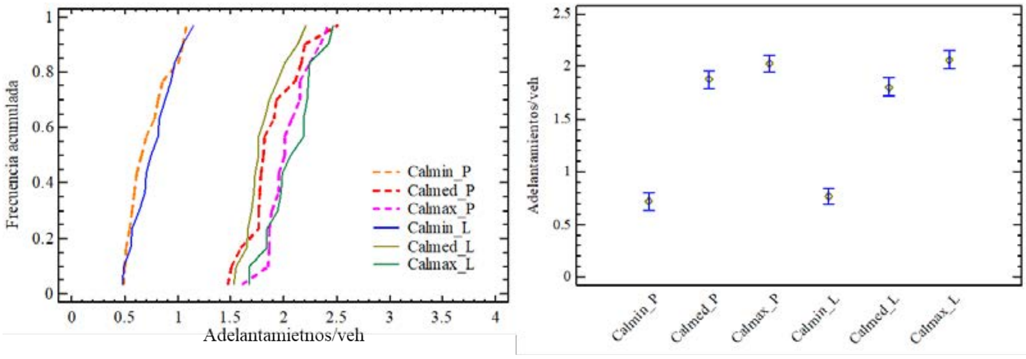

Fig. 13 - Distribuciones de los adelantamientos realizados por vehículo (izquierda) y media e intervalos LSD de Fisher (derecha) obtenidos en las simulaciones de los escenarios de calibración para los grupos circulando en línea y en paralelo.

En la Fig. 14 se han representado los valores del tiempo de demora acumulada de los vehículos ligeros obtenidos en las 15 replicaciones de cada escenario de calibración. Se puede observar como el tiempo de demora aumentó al incrementar el tráfico ciclista.

También se observa que, al aumentar la demanda de ciclistas, el tiempo de demora presentó una mayor dispersión. Esta mayor dispersión se debe a que al simular escenarios con una elevada demanda ciclista existen vehículos que se encuentran con más ciclistas y otros con menos, y su tiempo de demora depende del número de ciclistas con los que interaccione. La prueba ANOVA ($F=63.37$, $p<0.05$) indicó que las medias de las seis distribuciones de tiempo de demora presentaron diferencias estadísticamente significativas con un nivel del 5% de significación. Cuando los grupos circularon en línea, la media del tiempo de demora de los vehículos motorizados no presentó diferencias estadísticamente significativas respecto a la configuración en paralelo, sin embargo, los valores de la demora media y las dispersiones fueron ligeramente mayores para las configuraciones en línea debido a la mayor longitud de los grupos (Fig. 14 derecha). Esta diferencia, a pesar de no ser significativa en los escenarios simulados, va aumentando a medida que aumenta la demanda ciclista, poniendo de manifiesto que la configuración del grupo de ciclistas tiene mayor importancia cuando el tráfico es elevado.

El tiempo de demora acumulada de los vehículos ligeros es una variable difícil de medir en campo, en este estudio se ha obtenido mediante el uso del modelo de microsimulación, poniendo en valor el uso de esta metodología para obtener variables que pueden caracterizar la seguridad y la funcionalidad del tráfico.

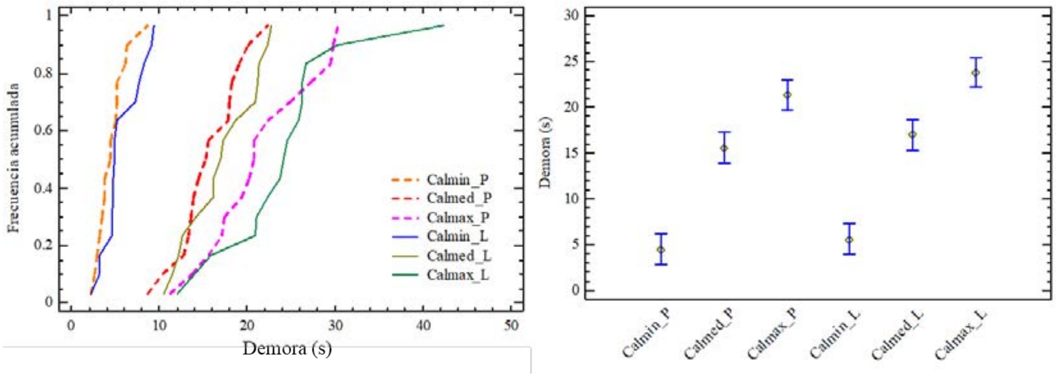

Fig. 14 - Distribuciones de las demoras acumuladas (izquierda) y media e intervalos LSD de Fisher (derecha) obtenidos en las simulaciones de los escenarios de calibración para los grupos circulando en línea y en paralelo.

Otra medida de desempeño analizada en este estudio fue el porcentaje de vehículos en cola (VC) a la entrada y a la salida del tramo de estudio. Esta variable se calculó en los escenarios considerando la demanda mínima, media y máxima de ciclistas registrados. En la Tabla 7 se pueden observar los valores calculados del porcentaje de vehículos en cola. Para cada escenario, la variación entre el inicio y el final del tramo no es muy significativa, presentando valores muy similares en los dos puntos para los tres escenarios analizados. Si se observa la variación entre escenarios, sí se aprecian más diferencias.

El escenario con demanda mínima de bicicletas presentó valores del porcentaje de vehículos en cola menores, cercanos al 20%, mientras que los escenarios con demandas media y máxima presentaron valores más elevados alrededor del 30%.

Por tanto, la presencia de tráfico ciclista aumentó el valor del porcentaje de vehículos en cola en carreteras convencionales estrechas. Los resultados obtenidos considerando a los grupos de ciclistas circulando en línea y en paralelo fueron muy similares, no presentando diferencias estadísticamente significativas entre las dos configuraciones.

	Inicio del tramo	Fin del tramo
Escenario	VC Sim.	VC Sim.
Calmin	18.80%	19.10%
Calmed	32.40%	28.20%
Calmax	29.40%	28.90%

Tabla 5 - Resultados estadísticos para el porcentaje de vehículos en cola (VC) en los escenarios de calibración.

Las diferencias entre las configuraciones en línea y en paralelo de los grupos de ciclistas en los niveles de tráfico analizados no fueron significativas para ninguna de las variables analizadas. Sin embargo, la configuración en la que circulan los grupos tiene más influencia sobre el tiempo de demora a medida que aumenta el volumen de ciclistas en el tramo. Como líneas futuras de investigación se propone simular escenarios de tráfico diseñados aumentando tanto la demanda ciclista como motorizada.

5. CONCLUSIONES

La presencia de ciclistas en carreteras convencionales no solamente afecta a la seguridad en estas vías, sino también a la funcionalidad del tráfico. Esta afección es especialmente acusada en carreteras convencionales estrechas, con arcén nulo o impracticable, donde los ciclistas deben de circular por el carril y los vehículos realizan adelantamientos con una mayor invasión del sentido opuesto y una mayor duración.

En este estudio se han tomado datos de campo en un tramo de carretera convencional sin arcén mediante dos metodologías distintas. Por una parte, se han recogido datos a nivel microscópico utilizando bicicletas instrumentadas. Se ha observado que la circulación de ciclistas por el tramo ha aumentado el número de maniobras de adelantamiento necesarias generando un mayor riesgo de colisión frontal con los opuestos y de alcance con las bicicletas. Uno de los principales resultados han sido las duraciones de los adelantamientos a los diferentes grupos de ciclistas considerados en el experimento. Estas duraciones fueron mayores a medida que había más ciclistas en el grupo, y en cuanto a su configuración, para un grupo formado por el mismo número de ciclistas, la duración del adelantamiento fue mayor cuando circulaban en línea que cuando lo hacían en paralelo.

La segunda metodología utilizada consistió en realizar grabaciones naturalísticas en los extremos del tramo de estudio, obteniendo los diferentes escenarios de tráfico utilizados para calibrar y validar el modelo de microsimulación, y para analizar la funcionalidad.

A partir de las observaciones en campo, se ha adaptado, calibrado y validado un modelo de microsimulación del tráfico que permite simular adelantamientos en carreteras convencionales, de manera que se represente el comportamiento de vehículos motorizados, bicicletas, y sus interacciones. Se ha utilizado el programa Aimsun Next 20. En el modelo de microsimulación se han calibrado las longitudes equivalentes de cada grupo de ciclistas para obtener duraciones de los adelantamientos similares a las observadas, representando así la invasión parcial del carril opuesto y la configuración del grupo de ciclistas. El uso de modelos de microsimulación del tráfico, debidamente calibrados y validados, permite estudiar el efecto de los ciclistas sobre determinadas medidas de desempeño que caracterizan la seguridad y la funcionalidad del tráfico. También permite obtener algunas medidas difíciles de registrar en campo, como el tiempo de demora acumulada de los vehículos ligeros.

Se han simulado seis escenarios considerando la demanda de ciclistas mínima, media y máxima observadas y considerando los grupos circulando en línea y en paralelo. Los resultados obtenidos muestran que al aumentar el volumen de ciclistas la velocidad media de recorrido de los vehículos ligeros disminuye, y el número de adelantamientos realizados por vehículo y el tiempo de demora acumulada aumentan.

El aumento de la presencia de ciclistas también aumentó el porcentaje de usuarios en cola en los extremos del tramo. Para los niveles de tráfico analizados en este estudio no se observaron diferencias estadísticamente significativas entre las configuraciones en línea y en paralelo de los grupos de ciclistas para ninguna de las variables analizadas. Sin embargo, al aumentar el volumen de tráfico, tanto ciclista como motorizado, puede que la configuración de los grupos si influya en los resultados, debido a la mayor longitud de los grupos al circular en línea. Este estudio se propone como futura línea de investigación.

La microsimulación del tráfico es una herramienta que puede ser explotada con diferentes fines, pudiendo simular medidas y escenarios obteniendo resultados de una manera rápida y económica. Uno de estos fines es la simulación de escenarios variando la demanda, tanto de motorizados como de ciclistas, y analizar cómo afecta a las diferentes medidas de desempeño esta variación. Por otra parte, se puede estudiar el efecto de medidas tomadas sobre el tráfico o la propia carretera, como reducciones de la velocidad límite o la incorporación de apartaderos que faciliten la maniobra de adelantamiento a los ciclistas. El uso de la microsimulación del tráfico puede ayudar a las Administraciones a integrar a las bicicletas y a los vehículos motorizados en las carreteras de una manera más segura y eficiente.

AGRADECIMIENTOS

Este estudio forma parte del proyecto de investigación Bike2lane "Mejora de la seguridad y operación de carreteras convencionales con ciclistas" con referencia (TRA 2016-8089-R) subvencionado por el Ministerio de Ciencia e Innovación. Este estudio también ha sido realizado gracias a la Agencia Estatal de Investigación "Ayudas para contratos predoctorales para la formación de doctores 2017" (BES-2017-080474).

Las tomas de datos en campo fueron realizadas gracias a la cooperación de la Dirección General de Tráfico y al Àrea de Carreteres de la Diputació de València.

Finalmente, los autores quieren agradecer a Aimsun SLU su colaboración en el desarrollo del estudio.

Luis Miguel Romero Pérez
Grupo de Ing. e Infr. De los Transportes, Universidad de Sevilla, España

RESUMEN

El Plan Director de la Bicicleta aprobado en 2007 para Sevilla, consiguió impulsar el uso de la misma hasta alcanzar un 6% de reparto modal. En el Programa de la Bicicleta Sevilla 2020 el Ayuntamiento se propuso como objetivo alcanzar al menos un 15% de reparto modal en 2020 en este modo. Para alcanzar esa cifra, es necesaria la promoción, con actuaciones no solo sobre la infraestructura, sino también con medidas de concienciación e información, con el fin de transmitir la idea de la bicicleta como un modelo eficiente y moderno, que puede mejorar la habitabilidad de la ciudad y la calidad de vida de sus ciudadanos. Este trabajo pretende aportar dicha visión por medio del mapa esquemático Metro-Bici, presentado en un formato similar al de un modelo de líneas del modo de transporte público (metro), con el fin de hacer más atractiva la idea de la bicicleta como modo de transporte.

Para su diseño, se han actualizado los datos de movilidad disponibles de tal forma que se consigan obtener volúmenes de demanda parecidos a los observados en las diferentes vías que conforman la infraestructura de la bicicleta, mediante un proceso de optimización y ajuste. A esto le ha seguido un posterior análisis de la demanda para concluir con un mapa esquemático de la red de bicicleta, en el que se define un conjunto de líneas, sintetizando las rutas principales obtenidas, presentando la bicicleta como un modo de transporte moderno y eficiente. Con la creación de estas líneas no solo se aspira atraer a la población hacia el modo de transporte en estudio, sino que también pretende identificar y jerarquizar corredores en función de su demanda con el fin de priorizar las posibles futuras actuaciones sobre la infraestructura.

1. INTRODUCCIÓN

Para conseguir mejorar el modo de transporte de la bicicleta es necesario analizar por un lado el comportamiento actual de sus usuarios y casi más importante, las causas que motivan el rechazo de los usuarios de los otros modos a usarla como modo de transporte para sus desplazamientos. Para ello, se han realizado una serie de encuestas que permiten identificar al tipo de usuario que hacen uso de esta infraestructura y a su vez, se decide encuestar a peatones con el fin de determinar si éstos utilizan la bicicleta asiduamente, y en caso negativo conocer el motivo.

Las encuestas de las que se dispone han sido realizadas por varias promociones del Máster en Ingeniería de Caminos, Canales y Puertos al cursar la asignatura de Planificación del Transporte de la Universidad de Sevilla, siendo la distribución del número de encuestas la siguiente:

- 555 encuestas a usuarios de bicicleta realizadas en el curso 2016/17.
- 350 encuestas a usuarios de bicicleta realizadas en el curso 2018/19.
- 293 encuestas a peatones realizadas en el curso 2018/19.

El cuestionario de las encuestas dirigidas a los usuarios en bicicleta se basa en el modelo propio de encuestas de SIBUS, 2015, con el objeto de contrastar el perfil de los usuarios y validar las encuestas.

Las modificaciones realizadas sobre las encuestas originales buscan la eliminación de los posibles sesgos que pudieran darse, así como destacar información relevante como la duración de los viajes, los pares Origen-Destino, e incluso se incluye un apartado de mejora de la infraestructura asociada a la bicicleta en Sevilla.

En cuanto a la encuesta de peatones, se busca obtener la frecuencia de uso de bicicleta, así como los motivos de su no uso si corresponde.

En García Sánchez, 2019 se presentan los modelos de encuestas utilizados y los resultados pormenorizados del análisis de las encuestas, presentando aquí las conclusiones de dicho análisis:

- Del proceso de encuestación a peatones se extrae que el 10% de los encuestados afirma no saber utilizar la bicicleta existiendo una relación estadísticamente significativa con el sexo, pues casi el 75% de estos eran mujeres. Esto puede influir en el hecho de que en el proceso de encuestación a usuarios de bicicleta tan solo el 35% eran mujeres.

- La edad es otro factor importante a comparar con otras variables, como por ejemplo el tipo de bicicleta, las cuales presentan una relación estadísticamente significativa, por lo tanto, los grupos de edad más jóvenes presentan mayor proporción de uso de la bicicleta de alquiler. En el caso de analizar los tiempos de viajes en función de la edad, se obtiene una significación estadística, de tal forma que a medida que avanza la edad, los tiempos de viajes por lo general tienden a ser superiores.

- Siguiendo con la dinámica anterior, se analizan los tiempos de viajes donde se observa como los viajes realizados con bicicleta de alquiler son relativamente más cortos, obteniendo una asociación significativa entre el tipo de bicicleta empleada y el tiempo de trayecto.

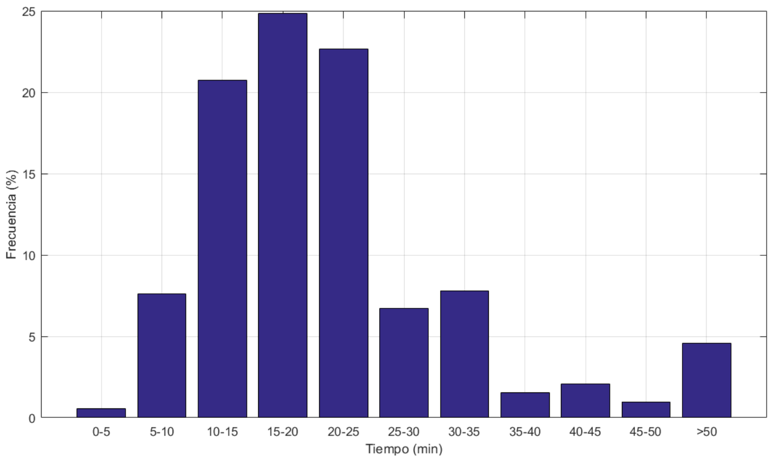

Figura 1. Histograma de viajes en distancia (km) extraído de encuestas

- De todo el proceso de encuestación cabe destacar la importancia, dada su implicación en el proceso de ajuste de la matriz, de:
  - Histograma unitario de viajes en distancias, mostrado en la Figura 1.
  - El motivo de viajes de los encuestados, donde el 75% de los viajes recogidos eran por movilidad obligada

2. PROPUESTA DE POLÍTICA DE PROMOCIÓN DE LA BICICLETA

Son de sobra conocidos algunos aspectos positivos del uso de la bicicleta, no solo para el usuario, sino también para la ciudad, así como ciertos inconvenientes que puedan derivar en rechazo a este modo de transporte, y, por tanto, los que habrá que trabajar para hacer más llamativa la bicicleta.

En cuanto al individuo, PROBICI,2010, el uso de la bicicleta aporta como ventajas:

- Autonomía, flexibilidad y accesibilidad: a diferencia del transporte público, la bicicleta está disponible en cualquier momento, ofrece un servicio puerta a puerta y no está sujeta a horarios ni rutas fijas. El individuo que la utilice goza de una libertad similar a la que ofrece el transporte privado.

- Fiabilidad y económica: dado que el sistema de transporte asociado a la bicicleta no está congestionado, los tiempos de viajes se mantienen y son fácilmente predecibles, a diferencia del transporte privado. Además, esta requiere una menor inversión no sólo inicial, sino también de mantenimiento frente al automóvil.

- Eficacia: en distancias cortas, la bicicleta es más competitiva que el transporte público o privado.

- Para viajes menores de los 2 km la bicicleta presenta mayor competitividad que el automóvil, siendo un factor primordial el aparcamiento disponible. Para distancias menores que la presentada, los tiempos de viajes en ambos modos son parecidos, presentando la bicicleta mayor eficiencia a la hora de aparcar dada su ligereza y pequeñas dimensiones con respecto al automóvil.

- Para viajes menores de los 5 km, la bicicleta es más competitiva que el transporte público, pues como se ha comentado esta presenta mayor autonomía y flexibilidad. Para distancias mayores, el transporte público presenta ventajas, siendo lo óptimo la intermodalidad (situación win-win o de ganancia mutua).

Analizando las encuestas realizadas, en particular el histograma en distancias mostrado en la Figura 1, aproximadamente el 25% de los viajes están por debajo de los 3 km y el 54% de los viajes menor de los 5 km de distancia, mostrando eficiencia hasta los 7km de distancia.

Conociendo que la mitad de los trayectos urbanos en vehículo privado en España están por debajo de los 5 km, se puede establecer la bicicleta como una buena opción para realizar estos trayectos.

A pesar de estas ventajas, también se encuentran inconvenientes que general rechazo al uso de la bicicleta. Teniendo en cuenta diferente bibliografía, PROBICI, 2010 Civinet, 2015 y las encuestas realizadas a peatones, las razones que llevan a un individuo a no optar por este modo son:

- Condiciones climáticas
- Pendientes pronunciadas en el trayecto
- Incomodidad a la hora del transporte de mercancía o niños
- Preocupación por el robo

La bicicleta, no solo presenta beneficios para el usuario que la utiliza, sino que también presenta ventajas para el resto de la población, y, por tanto, para la ciudad, si y solo si esta es capaz de aumentar su reparto modal atacando al de los vehículos motorizados, es decir, solo si se da una transferencia de demanda de vehículos privados a la bicicleta.

Estas son:

- Menor tasa de sedentarismo, lo que conlleva un aumento de la salud de la población.
- Menos contaminación (de agua, suelo y atmosférica) y ruido, lo que aumenta el bienestar social.

- Humanización, pues facilita el contacto interpersonal
- Mayor seguridad vial, pues se reduce el tráfico motorizado.
- Mayor disponibilidad de recursos al reducir el consumo de petróleo.
- Menor impacto sobre el territorio y mayor eficiencia, pues la bicicleta requiere menor ocupación del suelo urbano, además de menor mantenimiento, menor inversión inicial y apenas requiere gastos policiales, lo que conlleva a su vez un ahorro económico.

De aquí se extrae que la bicicleta es un modo de transporte bastante favorable y necesario teniendo en cuenta las situaciones desfavorables debido al tráfico motorizado que se están alcanzando en algunas ciudades españolas.

2.1 Promoción de la bicicleta: mapa esquemático

En esta comunicación se presenta una propuesta concreta para la promoción de la bicicleta, particularizada para la ciudad de Sevilla pero extensible para cualquier otra ciudad: la generación de un mapa esquemático de la red bici, con un diseño atrayente que presenta la bicicleta como un modo *moderno* y *eficiente*. Con este plano se pretende por un lado presentar una imagen del transporte en bicicleta como una opción moderna, de ahí su semejanza en el diseño a un plano de líneas de un sistema metro urbano. Por otro lado, se quiere mostrar que es un modo eficiente, que conecta los puntos más importantes de la ciudad en un tiempo competitivo con el de los otros modos.

Para la realización del plano, se contemplan las siguientes fases:

- *Determinación de puntos de interés*. Establecer puntos de interés en un mapa guía de líneas, ayuda a los usuarios a localizar rápidamente su destino. Estos puntos o lugares de interés se refieren a estaciones de metro, estación de autobuses y cercanías, los cuales permiten la intermodalidad, zonas de gran interés turístico y centros comerciales (para incentivar el uso de la bicicleta para viajes no obligados), siendo muy importante la localización del servicio de bicicleta pública más cercano a dichos puntos.

- *Elección de arcos principales.* En la realización del mapa esquemático es necesario estipular una serie de arcos principales, así como la localización de grandes centroides de atracción y generación.

Esta necesidad reside en el deber de establecer un conjunto de líneas del modo de transporte de la bicicleta con el fin de hacer atractivo el uso de la misma por medio de líneas simples y directas uniendo los principales orígenes destinos. Para conseguir esto, se seleccionan aquellos arcos que presenten mayor volumen de usuarios, el cual se ha obtenido gracias a la asignación realizada en el apartado 4.4, que serían aquellos arcos con un volumen mayor a 4900 usuarios Estos arcos deben formar parte de las líneas principales a desarrollar en el siguiente apartado, ayudándose a su vez de otras líneas de menor volumen.

- *Elección de las líneas o rutas principales.* El proceso de creación de las líneas principales de desplazamiento en bicicleta se ha realizado por medio de un estudio simplificado de la demanda asociada a cada par. Para ello, ha sido necesario desarrollar la modelización completa de la demanda de los usuarios, así como el modelo de red de los carriles bici de la ciudad de Sevilla. En el apartado 3 se resume la macrosimulación desarrollada.

3. MACROSIMULACIÓN DEL MODO DE TRANSPORTE BICICLETA EN SEVILLA

Para poder realizar la macrosimulación del modo de transporte “bicicleta” en Sevilla, uno de los datos previos más importante es la matriz Origen-Destino, que muestra el volumen de usuarios que viajan entre cada par de Origen y Destino.

En este apartado, se presenta la matriz OD en la que se basa el presente trabajo y el proceso de ajuste de la misma con el fin de obtener resultados que muestren la realidad de la forma más fidedigna posible.

3.1 Matriz OD base

La matriz OD de la que se parte es la matriz de movilidad global de Sevilla (EDM07), la cual agrupa todos los viajes de los diferentes modos de transporte que se dan en la ciudad en un día medio, basado en la encuesta de movilidad llevada a cabo en 2007.

Dado que esta matriz recoge todos los modos es necesario extraer de la misma la correspondiente a las bicicletas. El reparto de bicicleta estimada en el 2010 es del 6%, Ayto. de Sevilla, 2010. A falta de información para una mejor distribución, puede suponerse como matriz OD de partida para el modo bicicleta la resultante de imponer un reparto modal uniforme en todas las zonas de transporte, obteniéndose:

$$T_{bici} = 0.06 \cdot T_{global} \qquad (1)$$

Pero las hipótesis planteadas anteriormente presentan una deficiencia principal, aparte del desfase temporal de la misma, y es que la matriz global representa viajes realizados en otros modos como es el privado y el transporte público, que presentan características muy diferentes a los realizados en bicicleta. Un usuario que utiliza la bicicleta está condicionado por el tiempo de viaje, trayectos demasiado largos pierden interés, como se puede observar en el histograma de viajes en distancia extraído de las encuestas.

Esto significa que el reparto modal del modo en estudio no se produce de la misma forma que el transporte público o el privado.

La matriz global se estimó hace más de 10 años, y se ha observado como en general ha aumentado el número total de viajes en bicicleta desde el estudio de movilidad de 2010 que establece el reparto de la bicicleta en un 6%; por ello, se decide actualizar la matriz para que el número total de viajes sea representativo del actual.

3.2 Ajuste de la Matriz OD

3.2.1 Elección del criterio de ajuste de la matriz

Para modificar la matriz, se opta por implementar un método de ajuste de matriz, incluyendo información adicional de conteos de tráfico en arcos de la red y una serie de restricciones.

El objetivo de este proceso es disminuir la discrepancia con los volúmenes observados mientras se controla la distorsión de la matriz.

Como criterio de optimalidad en el proceso de ajuste de la matriz, se utiliza el de la máxima entropía o de mínima información, donde se busca extraer una matriz de viajes nueva a partir de una base. Bajo este criterio la función de distancia utilizada para medir la diferencia, tanto entre los aforos y los volúmenes modelados como entre la matriz resultante y la previa, es la función de entropía relativa, Van Zuylen y Willumsen, 1980 , Cascetta, 1980.

A lo largo del proceso de estimación de la demanda, se establece la hipótesis de que el mecanismo que utilizan los usuarios para escoger ruta es el minimizar su coste generalizado (que en el modo de transporte de la bicicleta básicamente se basa en la distancia de los recorridos). Esto es debido a que el fenómeno de la congestión todavía no es apreciable, y se supone que no tienen incidencia en la selección de ruta.

Por otro lado, la aplicación de máxima entropía tiene en cuenta una matriz de referencia, y el problema formulado tiene múltiples soluciones, siendo importante para el resultado final la solución inicial de partida. Se considera que los aforos no son fuentes de información creíble, puesto que se establece que estos no contienen suficiente información para la estimación, por ello, una buena decisión sería incluirlo en la función objetivo, puesto que los flujos en el modelo incluidos como restricción son de obligado cumplimiento:

$$Minimizar\ Z(\boldsymbol{g},\boldsymbol{v}) = \gamma_1 \sum_{p\in\boldsymbol{\mathcal{P}}} \left(g_p \left(log\left(\frac{g_p}{\bar{g}_p}\right) - 1 \right) \right) + \gamma_2 \sum_{a\in\bar{\boldsymbol{\mathcal{A}}}} \left(v_a \left(log\left(\frac{v_a}{\bar{v}_a}\right) - 1 \right) \right) \quad (2)$$

siendo g la matriz Origen-Destino con el flujo viajes para cada par origen-destino ordenada en formato vectorial, $\boldsymbol{v}$ el vector de flujos o volúmenes en los arcos, $\boldsymbol{\mathcal{P}}$ y $\bar{\boldsymbol{\mathcal{A}}}$ los conjuntos de pares Origen-Destino y de arcos aforados en la red, respectivamente.

A pesar de lo anterior, y dado el reducido número de puntos de aforo de los que se dispone, se deciden incluir como restricción por simplicidad.

$$Minimizar_{T,v}\, Z = \sum_{p\in\boldsymbol{\mathcal{P}}} g_p \left(log\left(\frac{g_p}{\overline{g_p}}\right) - 1 \right) \tag{3}$$

donde g_p es el flujo de viajes correspondiente al par p de los O/D

3.2.2 Restricciones del ajuste

Para realizar el ajuste de la matriz, se decide incluir una serie de restricciones que permitan obtener una mejor distribución de los viajes totales estimados en la matriz OD. Una posible alternativa es imponer un modelo físico, como el modelo gravitatorio o el de radiación, para explicar la demanda de este modo de transporte, infiriendo los parámetros del modelo de modo que se ajusten lo más posible a los datos de la realidad. Sin embargo, estos modelos se definen por semejanza a fenómenos físicos que poco tienen que ver con los mecanismos que tienen los viajeros para decidir si realizan determinados viajes y qué modo utilizarían para ello. En este trabajo se opta por imponer una serie de condiciones matemáticas que debería verificar una matriz de demanda, que resuman la información real conocida del modo de transporte, evitando así formular una serie de hipótesis sobre el comportamiento de los usuarios difíciles de validar. El concepto de restricción está asociado a una condición de obligado cumplimiento, es por ello, que se debe discutir la conveniencia de incluir o no cada posible restricción en el proceso final de ajuste. La información disponible para la definición de este conjunto de restricciones es la siguiente:

- Aforos.
- Histograma unitario de distancia del trayecto.
- Población.
- Usos del suelo (Catastro).
- Empresas de >50 empleados.
- Universidades

3.2.2.1 Aforos

Se dispone de la información de 10 Eco-contadores localizados a lo largo de la red ciclista de Sevilla. Estos dispositivos cuentan, almacenan y transfieren permanentemente el número de ciclistas que circulan sobre ellos. Esta información es controlada por la Gerencia de Urbanismo de Sevilla. Hay información disponible en datos diarios y también en tramos horarios. Esta información es relevante para completar el ajuste de la matriz, apareciendo los datos de flujo conocidos en arcos en la función objetivo.

Para el ajuste de la matriz se utilizarán los datos de los eco-contadores disponibles en la Gerencia de Urbanismo de Sevilla pertenecientes a un día que sea representativo y lo suficientemente próximo a la fecha actual, una vez eliminados los registros pertenecientes a fines de semana y festivos, así como los pertenecientes a los meses de verano. se decide escoger la media de los valores como volumen aforado para cada uno de los eco-contadores de los que se dispone información. Dado que se buscan valores representativos, se deciden despreciar los días en los que se obtiene una bajada significativa de los volúmenes causados por ejemplo por la existencia de precipitaciones.

En cuanto a la formulación del ajuste de la matriz, la restricción asociada a los aforos será tal que relacione los pares origen-destino con el aforo, de tal forma que quede registrado todos los pares OD que transiten por cada uno de los aforos disponibles.

$$\boldsymbol{v} = \boldsymbol{\Gamma}^T \cdot \boldsymbol{g} \qquad \forall a \epsilon \overline{\boldsymbol{\mathcal{A}}} \tag{4}$$

Donde $\boldsymbol{g}$ es la matriz de viajes ordenada en formato vectorial, $\boldsymbol{v}$ es vector con los volúmenes de los aforados en los eco-contadores y Γ^T la matriz de incidencia que relaciona los Pares Origen-Destino con los arcos aforados, en la que el elemento Γ_p a es 1 si la ruta mínima del par p contiene el arco a, 0 en otro caso.

La asignación de rutas mínimas empleada conlleva una asignación de tráfico lineal, limitándose a un único cálculo de la matriz de incidencia Γ (aforos-pares OD, constante por no considerarse la congestión) y una multiplicación de matrices que equivale a la suma de los pares que utilizan un arco determinado.

3.2.2.2 Histograma de viajes

Con un número razonable de encuestas, sí puede extraerse información cualitativa y cuantitativa sobre la disponibilidad de los usuarios a realizar o no un determinado viaje atendiendo a una información transversal a todos los pares en función del coste generalizado, como puede ser la distancia o el tiempo de viaje, aunque no sean encuestas suficientes para estimar una matriz OD.

De la idea anterior se extrae el histograma distancia-frecuencia de viajes, el cual recoge el número de viajes realizados según el tiempo o distancia de viaje. Esta información es bastante valiosa, puesto que puedo afectar al reparto modal de tal forma que, dependiendo de la distancia de viajes, ese par OD puede ser más o menos atractivo para ser realizado en bicicleta u otro medio de transporte.

El histograma de viajes que se ha obtenido de las encuestas es el mostrado en la Figura 1.
Al definir los intervalos del histograma de viajes, se extrae de las encuestas la proporción de viajes observados pertenecientes a cada uno de estos intervalos; es decir, para cada intervalo b del conjunto de intervalos $\boldsymbol{\mathcal{B}}$ se obtiene una proporción P_b respecto al total de viajes realizados en bicicleta.

Por tanto se puede establecer una restricción en la que la suma de los viajes de aquellos pares incluidos en un intervalo dado, se corresponda al total de viajes correspondientes a dicho intervalo. Esta restricción se puede expresar de forma matricial sin más que definir la matriz de incidencia Δ histograma-pares Origen-Destino, Ortiz 2017, que relaciona los pares OD con su intervalo en el histograma.

$$\sum_{p \in P(b)} g_p = P_b \cdot T \qquad \forall b \epsilon \boldsymbol{\mathcal{B}} \tag{5}$$

$$\Delta_b \cdot \boldsymbol{g} = P_b \cdot T \qquad \forall b \epsilon \boldsymbol{\mathcal{B}} \tag{6}$$

Donde el subíndice en la matriz índica que se trata de la fila b. Esto significa que el modelo debe de cumplir que los viajes de la asignación para cada intervalo definido en el histograma deben coincidir con las proporciones obtenidas de las encuestas mostrada en el histograma, Figura 1.

3.2.2.3 Población

La población es un factor importante a la hora de generación de viajes, por ello, se decide introducir como restricción en el modelo de ajuste. Ante la ausencia de información para la obtención de modelo de Generación – Atracción, se decide asumir que los viajes generados por cada TAZ están proporcionalmente relacionados con su población.

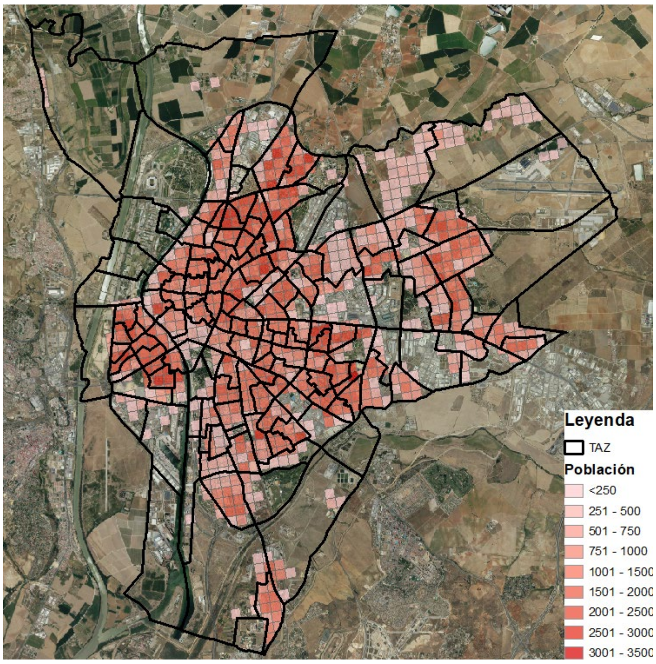

Figura 2. Distribución zonal de la Población 2017

Para imponer la restricción ha sido necesario contabilizar el total de la población y el % de población en cada una de las TAZs que intervienen en el modo de la bicicleta, Xpob. Se puede definir una matriz de incidencia **Θ** Orígenes - pares OD, que relaciona los pares OD con su origen, de tal forma:

$$\boldsymbol{\Theta} \cdot \boldsymbol{g} = \boldsymbol{X}_{pob} \cdot T \tag{7}$$

3.2.2.4 Número de empresas >50 empleados y Universidades

De las encuestas realizadas, se observa como uno de los principales motivos del uso de la bicicleta es el desplazamiento al trabajo, por lo que se decide introducir una restricción relacionada con el número de empresas y los asalariados de las mismas asociadas a cada TAZ. Los apartados anteriores trataban de actuar sobre la generación de viajes, pero en este caso, afectará a la atracción de los mismos. Con el número de empresas con más de 50 asalariados se busca relacionar el uso de la bicicleta con factores socioeconómicos.

Esta restricción se impone según los establecimientos que se encuentran dentro de cada una de estas TAZs, y, más tarde, se ponderan sus valores de atracción teniendo en cuenta los asalariados, obteniendo finalmente una proporción para cada TAZ.

En el ajuste, se impone la restricción por columnas, de tal forma que la atracción de viajes de una zona j sea proporcional a los establecimientos y el total de asalariados de la zona $\left(P_{emp,j} = \frac{A_j}{\sum A_k}\right)$, siendo P_{emp} la proporción, A el número de asalariados (o coeficiente de diferenciación) y j la TAZ en estudio.

$$\sum_{p/D(p)=j} g_p = P_{emp,j} \cdot T \qquad \forall j \epsilon \mathcal{D} \tag{8}$$

Siendo $\mathcal{D}$ el conjunto de destinos, que de nuevo coincide con $\boldsymbol{\mathcal{Z}}$ al considerar todas las zonas de transporte como posible Origen/Destino de viajes.

Para expresar esta restricción en formato matricial, se define la matriz de incidencia $\boldsymbol{\Phi}$ Destinos - pares OD, que relaciona los pares OD con sus destinos, de tal forma:

$$\Phi \cdot g = P_{emp} \cdot T \tag{9}$$

Como en el caso anterior, otro de los motivos principales que llevan al usuario a utilizar la bicicleta es por necesidad de desplazamiento hacia el centro de estudio, por tanto, se decide afectar la atracción de viajes con la inclusión de las diferentes facultades y centros universitarios existentes en Sevilla. Se extraen las diferentes facultades existentes en Sevilla y se asocian a los centroides que definen el modelo. Dada su similitud con la restricción anterior, y a fin de simplificar el ajuste de la matriz, se decide introducir la información de las universidades en la restricción de atracción que versa sobre los asalariados de las empresas de más de 50 empleados.

3.2.3 Algoritmo de ajuste

El proceso de ajuste que finalmente se propone se define en la expresión (10). Consiste en un problema de optimización en el que se minimiza una función objetivo que mide la distancia con respecto a una matriz previa $\bar{g}$ y las restricciones anteriormente comentadas.

La función de distancia finalmente adoptada para la función objetivo es la de la entropía relativa, que como puede verse sin más que desarrollar en serie en torno la matriz previa, es una función intermedia entre el error absoluto y el relativo. A este sistema es necesario incluir una última restricción en la cual se establece la obligatoriedad de que todos los volúmenes entre cada par OD sea positivo ($g \geq 0$), pues no tiene sentido físico un flujo de viajeros negativo. Con esta configuración, y dado que las restricciones impuestas son todas lineales, puede utilizarse como algoritmo de resolución el algoritmo de equilibrado iterativo, Bregman, 1967. Finalmente, se obtiene la siguiente formulación basada en la minimización de la función objetivo, sujeta a las restricciones anteriormente mencionadas:

$$Minimizar_{T,v}\ Z = \sum_{p \in P} g_p \left(log\left(\frac{g_p}{\bar{g}_p}\right) - 1 \right) \tag{10}$$

$s.a \quad \boldsymbol{v} = \boldsymbol{\Gamma}^T \cdot \boldsymbol{g} \quad \forall a \in \mathcal{A}$ Restricción Aforos

$\boldsymbol{\Delta}_b \cdot \boldsymbol{g} = P_b \cdot T$ Restricción Histograma

$\boldsymbol{\Theta} \cdot \boldsymbol{g} = \boldsymbol{X}_{pob} \cdot T$ Restricción Población

$\boldsymbol{\Phi} \cdot \boldsymbol{g} = \boldsymbol{P}_{emp} \cdot T$ Restricción Empresas

$g_p \geq 0 \quad \forall p \in \mathcal{P}$ Volúmenes reales

En la Figura se muestra la diferencia entre la matriz ajustada y la matriz base. Se destacan los valores de máxima diferencia, los cuales llegan hasta los 630 usuarios en algunos pares.

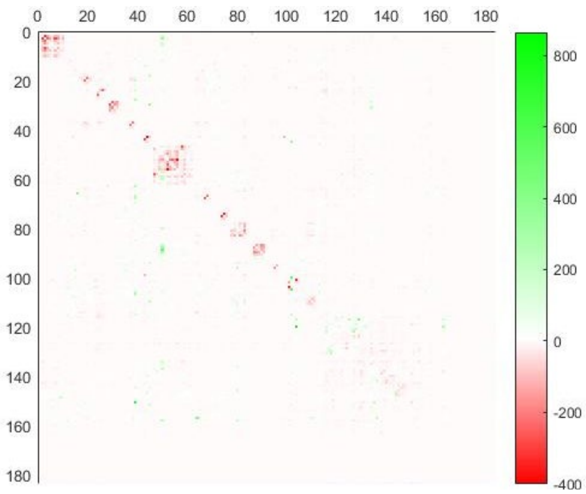

Figura 3. Diferencia entre matrices

En cuanto al histograma de viajes obtenidos, se aprecia como cumple perfectamente la restricción impuesta.

	0-1.25	1.25-2.5	2.5-3.75	3.75-5	5-6.25	6.25-7.5	7.5-11.25	11.25-15	15-30
Histograma encuesta	,555%	7,772%	21,207%	25,427%	23,206%	6,884%	11,658%	1,665%	1,888%
Histoframa Matriz Ajustada	,555%	7,772%	21,207%	25,427%	23,206%	6,884%	11,658%	1,665%	1,888%
Histograma Matriz 6% Actualizada	11,128%	27,277%	16,731%	8,732%	8,556%	6,398%	15,413%	5,525%	,501%

Figura 4. Histogramas extraídos de encuestas, de la matriz ajustada y la del 6% actualizada

4. DISEÑO DEL MAPA ESQUEMÁTICO.

Finalmente, esta tarea ha consistido en un proceso estético por el cual se busca llamar la atención de los potenciales usuarios de tal forma que vean la movilidad en bicicleta de una forma sencilla, con el fin de incitar al cambio de modo. Para conseguir esto se han llevado a cabo las siguientes acciones:

- Inclusión de los puntos de interés ya sea por medio de iconos o imágenes de sitios de interés turístico.
- Ubicación de estaciones Sevici cerca de los puntos de interés comentados.
- Identificación de las principales vías de tránsito, recogidas en la figura 5.
- Rectificación y esquematización del trazado.

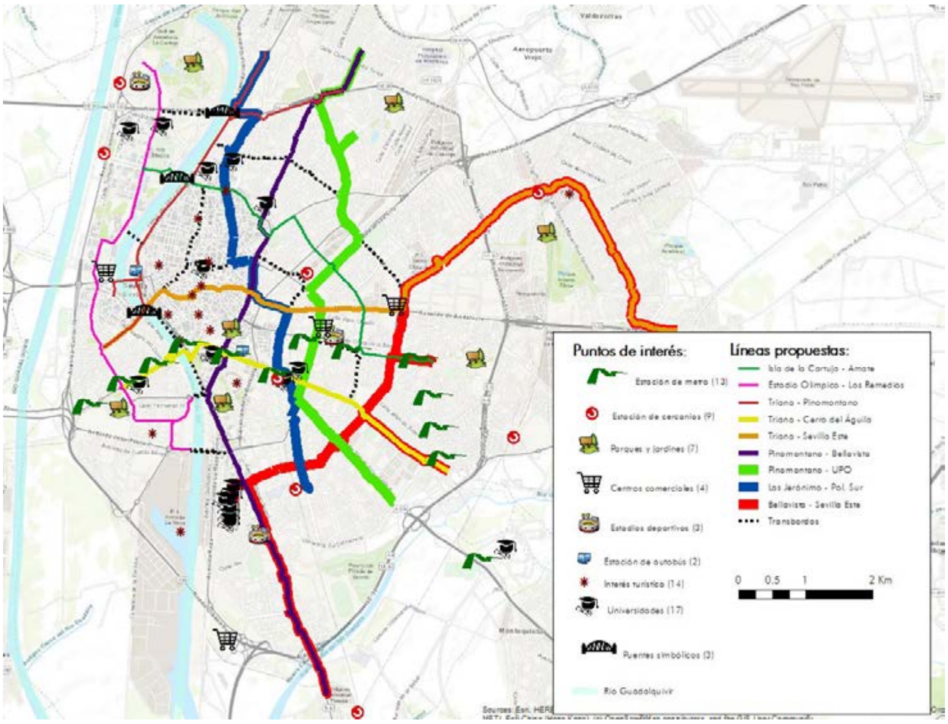

Figura 5. Trazado real de las líneas propuestas para incluir en el plano esquemático

Además, se decide no incluir información sobre el tiempo y distancia de recorrido asignado a cada uno de los arcos que componen las líneas, con el fin de evitar crear rechazo al individuo, pues la distancia y tiempo se relaciona con el esfuerzo físico que el individuo estima que debe realizar, y estos son las principales barreras que llevan a gran parte de la población a rechazar este modo de transporte. En la figura 6 se aprecia un recorte del plano resultante, diseñado a semejanza de un plano de Metro con recorridos idealizados como líneas rectas que unen los puntos de interés.

Figura 6. Fragmento del diseño final del plano esquemático de líneas de Metro-Bici Sevilla.

AGRADECIMIENTOS

El autor L. M. Romero desea agradecer expresamente el esfuerzo y la entrega de todos los alumnos que participaron en el proceso de encuestación mientras cursaban la asignatura Planificación del Transporte del Master de Ingeniería de Caminos, Canales y Puertos de la Universidad de Sevilla.

ANALYSIS OF REAL EXPERIENCES USING DIFFERENT SIZED BIKE SHARING SCHEMES IN IRISH CITIES

Pilar Jiménez
Department of Civil Engineering, Technical University of Cartagena, Cartagena, Spain
Maria Nogal
Faculty of Civil Engineering and Geosciences, Delft University of Technology, Netherlands

ABSTRACT

The first Irish public Bike Sharing Scheme (BSS) was launched in Dublin in 2009. Dublinbikes has been internationally recognised as one of the most successful bike-sharing rental schemes in the world. For this reason, among others, the cities of Cork, Limerick and Galway launched their own BSSs at the end of 2014.

The objective of this paper is to compare the performance of the four BSSs during the first two years of implementation in each Irish city according to endogenous factors, such as the physical design of the schemes, and exogenous factors, such as city size and population density. In terms of population, Limerick and Galway are small cities, Cork is a medium-sized city and Dublin is a large city. In consequence, the results cover the main relevant aspects of BSSs according to the size of the scheme, pointing out similarities and differences among BSS of different sizes. The main findings indicate that the number of daily rentals per bike is a good metric from the point of view of the transport operator. However, a higher density of bikes, stations and docking points does not imply greater usage, whereas the size of the deployment area could be a key factor in improving bike usage. Finally, a synopsis of the essential aspects to consider when designing a BSS deployment based on types of users in small cities is provided.

1. INTRODUCTION

The expansion of Bike Sharing Schemes (BSSs) across the world accelerated when the third generation of such schemes emerged. The third generation of BSSs refers to Information

Technology (IT)- based systems which apply computer technology tools to the operation of the schemes, such as electronic locks, telecommunications systems, smart cards, mobile phones or on-board computers. Moving around the city by bicycle has several advantages; for example, it reduces carbon footprints, reduces car use, provides a last-mile connector mode of transport or develops tourism. These are some of the main reasons why BSSs have grown exponentially around the world (see DeMaio, 2009; Shaheen & Guzman, 2011 or Midgley, 2011 for more detail).

Following this general trend, the first Irish public BSS (Dublinbikes) was launched in Dublin in 2009. Dublinbikes has been internationally recognised as one of the most successful bike-sharing rental schemes in the world, surpassing initial predictions and reaching one million journeys 11 months after its launch. Twenty months later, the two-million mark was attained (according to the reports of the Dublin BSS website: www.dublinbikes.ie). Besides the several advantages cited above, Dublinbike's success inspired the cities of Cork, Limerick, and Galway to launch their BSSs at the end of 2014. These four Irish cities: Dublin, Cork, Limerick and Galway, are the cities under study in this paper.

Recent works have addressed the multi-city scenario of BSSs. BSSs in European cities (for example, London, Barcelona, Paris or Dublin) and North-American cities (Denver, Chicago, Washington D.C. and Miami, among others) are compared to try to understand aspects such as the diffusion patterns of BSSs, considering the characteristics of cities and operator models, learning processes and future developments (see Parkes et al, 2013; Austwick et al, 2013; Sarkar et al, 2015). A global view of bike-sharing characteristics based on data analysed from 38 systems located in Europe, the Middle East, Asia, Australasia and America can be found in the research conducted by O'Brien et al (2014). In this study, the BSSs are characterised on a city level, comparing them in terms of system size, daily usage and compactness, to eventually build a hierarchy of cities sharing similar characteristics. Besides this, Chardon et al (2017) provide a comparison of 75 BSSs, mainly in Europe and North America, using the metric of trips per bike per day.

These studies have attempted to compare very different BSSs, and their main common results are; (i) BSSs are attractive and adaptable urban-mobility systems that are showing rapid development and expansion; (ii) there are a good number of quantitative factors characteristic to BSSs that are easily measurable, however, it is difficult to provide a benchmark to determine the success of BSSs, even when they have no explicit or measurable target; and (iii) the success of a BSS surviving over time depends on policy-makers' goals or other external inputs, such as inclusion within an effective public transport system.

In relation to the lack of a measurable target for some BSSs and their survival over time, this paper aims at pointing out similarities and differences arising from the different sizes of BSSs, mainly in small cities. It generates an open discussion about what the target users of a BSS should be according to the size of the city and its characteristics, in order to achieve a successful BSS that could be maintained over time. Moreover, whether BSS performance in one city could be extrapolated to another city with similar characteristics will be analysed.

Insights on these issues will be obtained from the study of real BSSs in the same country; Ireland. Specifically, the BSS of a large city, Dublin, during the 2009-2011 period; the BSS of a medium-sized city, Cork, during the 2015-2016 period and; the BSSs of two small cities, Limerick and Galway, during 2015-2016 will be analysed, corresponding to the first two years of their implementation in all the cases.

The paper compares how each BSS has performed according to the following differentiating factors: scheme size and density of bikes, stations and docking points (endogenous items) and city size and population density (exogenous items). These observed quantitative factors facilitate a simple comparison of many BSSs to understand each BSS in general terms. From this general perspective, it will be easier to conduct future detailed research.

This paper is structured as follows. Section 2 briefly describes the characteristics of the four Irish cities under study and their BSSs. In Section 3, data analyses focused on the density of bikes, stations and docking points of each BSS and their usage are shown, to finish with a discussion about the relevant issues found. Finally, in Section 4, some conclusions and possible future works are provided.

2. LITERATURE REVIEW AND CHARACTERISTICS OF THE BIKE SHARING SCHEMES STUDIED

2.1 Literature review

Several articles can be found about Irish BSSs; mainly about the Dublin BSS due to its success. For example, O'Neill and Caulfield (2012) analysed the mobility patterns of Dublinbikes during the first stage of the system, and Jiménez et al. (2016) focused on understanding the use of the bike stations according to user mobility patterns in 2015. Murphy and Usher (2015) studied the Dublin BSS from a social point of view, to find out the socioeconomic characteristics of the users, the impact of this mode of transport on modal choice and on driver awareness of cyclists. Caulfield (2014) investigates whether the pro-cycling policies (e.g., bicycle-purchasing schemes, reducing speed limits and the construction of segregated cycle lanes) to promote cycling applied by Dublin Council had an impact on cycling rates during the years after their implementation. Apart from these, this scheme has been researched from an economic point of view by Bullock et al (2017), whose paper places the benefits of BSSs in the economic context of private individual benefits and public good benefits, and they examine the relative value of these benefits and their impact on the spatial functioning of the city. Lawson et al (2013) have looked at the issue from a safety point of view, identifying and analysing the factors influencing cyclists' safety experiences in an urban, signalled multi-modal transportation network in their paper.

With regard to Cork, Limerick and Galway, a Technical Feasibility Study was conducted on the introduction BSSs in these regional cities, which is very useful for understanding the basis of these systems (Jacobs, 2011). Apart from this study, little more can be found about the BSSs of these three cities. Caulfield et al (2017) and McBain and Caulfield (2018) examine the trends of the bike-sharing scheme in the city of Cork, and an MNL Regression model is proposed to predict variations in the journey times of different bike trips based on spatial variables such as bike station location, distance from the city centre and type of services (shops, restaurants, public transport) along the route.

The effectiveness of the BSSs in Limerick and Galway based on station turnover ratios are described by Jiménez et al (2018). Regarding Galway BSS, Maher et al (2016) work with user surveys and stakeholder interviews to understand the beginning of the scheme (from January 2015 to September 2015); and O'Regan et al (2016) analyse the use of a smartphone application to collect rich trip and mode share data from the Limerick BSS to propose a methodology based on current feasibility studies to expand the existing schemes to other neighbourhoods.

Little research can be found related to BSSs developed in small cities. From a multi-city scenario, Audikana et al. (2017) study the Swiss experience with small BSSs spread across different cities to find out about the opportunities and challenges of BSSs in small cities. Among their different conclusions, the authors point out that more research is needed to ensure levels of success similar to medium-sized and large cities, and that partnership, communication and accountability are critical aspects to achieving successful small BSSs.

Thus, the findings of this paper could help to improve BSS performance in small cities, which usually enjoy ease of pedestrian and cycle movement.

2.2 Characteristics of the Irish bike-sharing schemes studied

The main characteristics of each Irish BSS (Dublin, Cork, Limerick and Galway) are described in this section.

Dublinbikes, is a public bicycle rental scheme which has operated in Dublin city since September 2009. At its launch, the scheme used 450 bicycles with 40 stations spread across Dublin city centre. Its acceptance was very positive during the first months. Therefore, in 2010, a mini-extension was made with 4 stations and 100 more bikes. Thus, during its first stage, Dublin Bikes consisted of 44 bicycle stations and 550 bicycles, with an estimated deployment area of 8.75 km^2; approximately 7.5% of the total area of the city (see Figure 1a). The subsequent extensions counted on up to 101 bike stations and 1,500 bikes (www.dublinbikes.ie), which increased this scheme to 20 km^2; about 17% of the total metropolitan area. In order to compare results at the same level as other cities; that is, after two years of the BSS implementation, the data collected from Dublin are related to the year 2011, considering the data of the first period of the scheme.

Figure 1b shows the deployment area of the scheme, the location of the 44 bike stations, the third-level campus located in the area, i.e., Trinity College Dublin, and the defined attraction area of the city. The attraction area includes numerous banks, offices, shopping centres, museums, tourist attractions, restaurants, cafés, clubs, hotels, pedestrian areas and green areas. That is to say, the attraction area has been defined by the high density of services offered. Most of the bike stations are located within the attraction area. They give access to businesses, shops, restaurants, tourist attractions and services, except the northern part of the system, which serves a more residential area.

The deployment area of 2.5 km per 3.5 km provides an appropriate distance to cross the city by bicycle with an average travel time of 12 minutes.

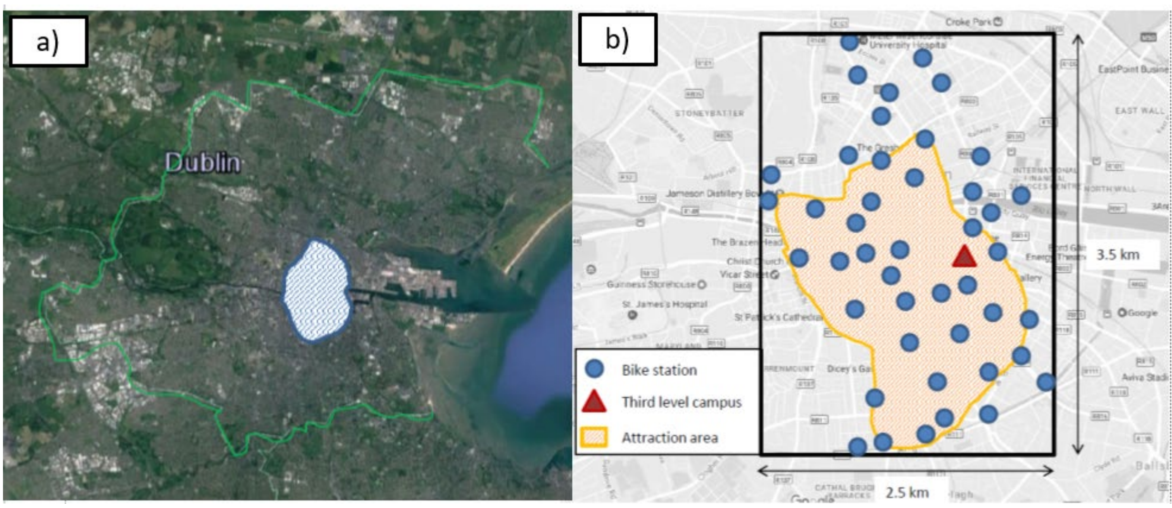

Fig. 1 – a) Dublinbikes deployment area in 2011. b) Detail of Dublinbikes extension in 2011. Source: Google maps. Digital globe 2016.

Cork's *Coca-Cola Zero Bikes* has operated in the city since December 2014. At its launch, the scheme used 330 bicycles with 31 stations spread across Cork city centre. It is estimated that the area occupied by this scheme is 2.5 km^2; approximately 6.5% of the total area of the city (Figure 2a), which is very similar to the first stage of the Dublin BSS.

Figure 2b shows the deployment area of the scheme in the main part of the Cork city centre (on the island between the two river channels), the location of the 31 bike stations and the third-level campus located in the southwestern part of the area, University College Cork. Most of the bike stations are located within the attraction area. Therefore, they give access to businesses, shops, restaurants, tourist attractions and services, but the scheme is enlarged to the Northeast to give access to the train station, and to the Southwest to cover the university, typically associated with higher BSS demand. The extension of this deployment area of 2.5 km per 1 km also provides the appropriate distance to cross the city by bicycle with an average travel time of 7 minutes; probably shorter distances than the Dublin scheme, but still efficient for bicycles.

Fig. 2 – a) Cork Bikes extension in 2016. b) Detail of Cork Bikes extension in 2016. Source: Google maps. Digital globe 2016.

Limerick's *Coca-Cola Zero Bikes* has operated in the city since December 2014, like the Cork BSS. The scheme uses 215 bicycles with 22 stations spread across Limerick city centre.

It is estimated that the area occupied by this scheme is 3 km^2; approximately 10% of the total area of the city, and the largest area of the four Irish cities at the beginning of their BSS implementation (Figure 3a). The deployment area of the Limerick scheme, the city centre, is shown in Figure 3b, together with the location of the 22 bike stations. Most of the bike stations are located within the attraction area. They give access to businesses, shops, restaurants and tourist attractions, although the scheme has some bike stations near to residential neighbourhoods in the East and Southwest. The extension of this deployment area of 1.5 km per 2 km is within the limit of an appropriate distance to go by bicycle. This means that to ride 2 km across the city takes 8 minutes with an average speed of 15 km/h (comfortable speed), whereas walking these 2 km across the city takes 24 min (average speed of 5 km/h for pedestrians). Generally, half an hour is the maximum time commuters will consider walking. Thus, it can be said that a distance of 2 km is the lower limit for the use of bicycles because distances lower than 2 km are also comfortable to walk, and people would not have to change their mode of transport. Note that this BSS does not cover the demand of the University of Limerick, located about 6 km from the city centre towards the East.

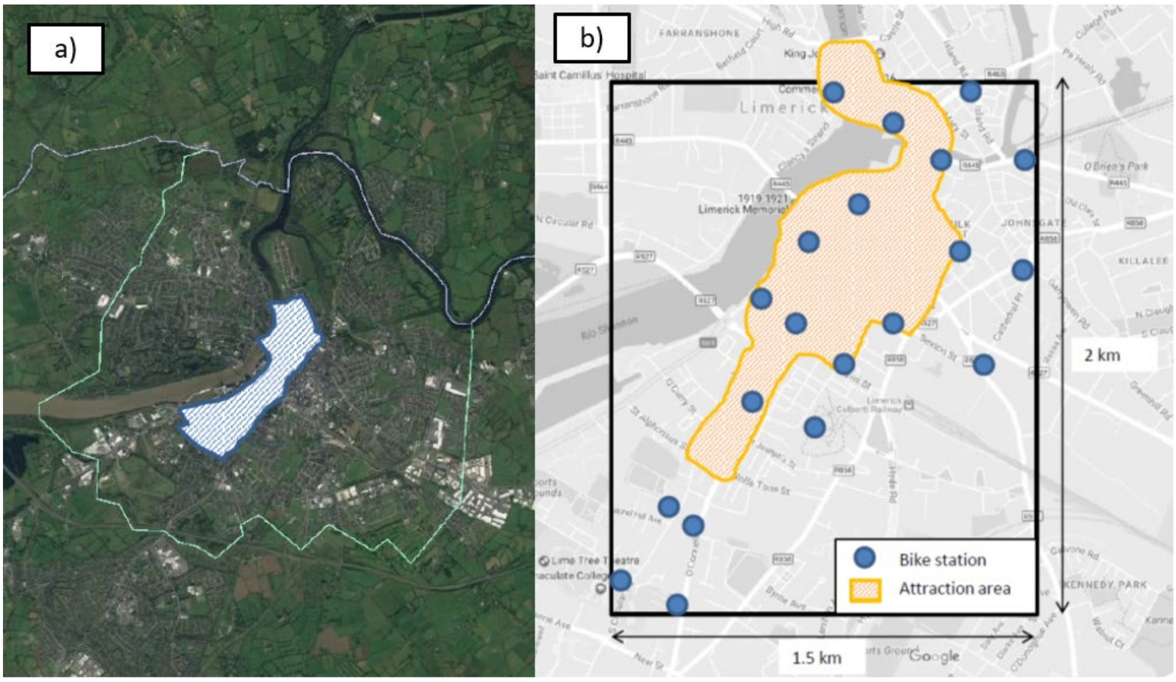

Fig. 3 – a) Limerick Bikes extension in 2016. b) Detail of Limerick Bikes extension in 2016. Source: Google maps. Digital globe 2016.

Galway's *Coca-Cola Zero Bikes* has also operated in the city since November 2014. The scheme uses 195 bicycles with 15 stations spread across Galway city centre. It is estimated that the area occupied by this scheme is 1.2 km^2; approximately 2% of the total area of the city, the lowest value among the four cities (Figure 4a). The deployment area of the Galway scheme, as well as the city centre, is shown in Figure 4b, together with the location of the 15 bike stations. Most of the bike stations are located within the attraction area. This means they give access to businesses, shops, restaurants and tourist attractions. Related to the third-level campus, the location of a bike station near the Galway Technical Institute (lower left corner) and the lack of them near the National University of Ireland - Galway (upper left red point in Figure 4b) stand out because universities are a source of potential bike-sharing users. On the other hand, the extension of this deployment area of 1 km per 1.2 km is also remarkable because the possible distance covered by bicycle (an average travel time of 5 min from extreme to extreme) can also be done by walking; thus, people might not be encouraged to use bicycles in the same way as in Limerick.

Note that in these specific cities, university campuses are relevant to understanding current and future BSS usage because (i) the scheme is used by students, faculty and staff members to access the university, (most of them combine bicycles with the train if they live in the outskirts), (ii) the bike stations related to these universities become part of the general scheme of the city, (iii) the universities are tourist attractions, especially in Dublin and Cork, and (iv) the students living on university campuses use bikes to move around the city.

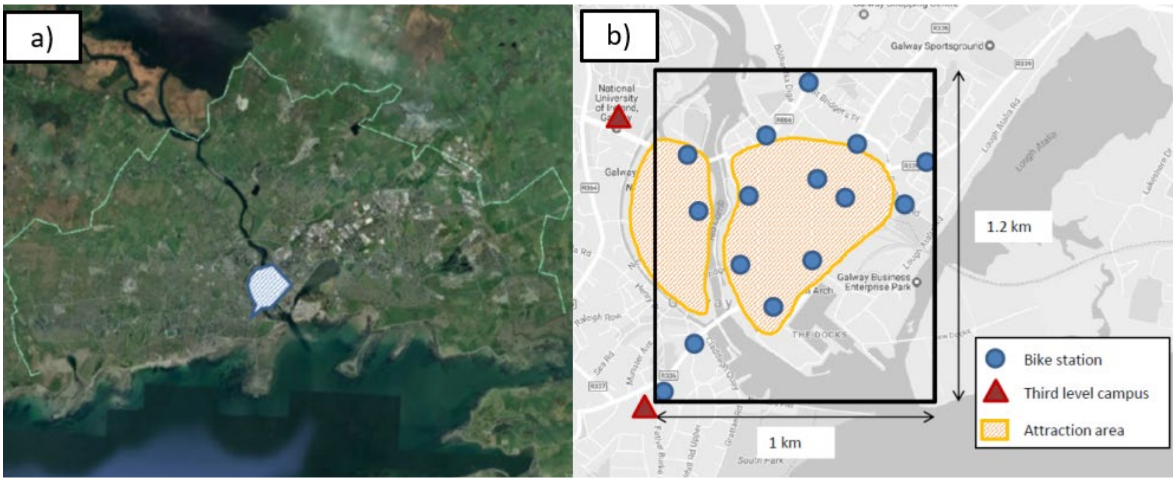

Fig. 4 – a) Galway Bikes extension in 2016. b) Detail of Galway Bikes extension in 2016. Source: Google maps. Digital globe 2016.

Table 1 provides data about population density, potential BSS users (considering that citizens between 20 and 39 years old are the main target group for bicycle usage on a daily basis), the area of the city occupied by the scheme and the number of bikes, stations and docking points of each BSS for each city. From this table two aspects are highlighted: (i) Dublin, Cork and Limerick have greater population density than Galway, and (ii) the percentage of the city area with bike stations during the first stage in all the cities could be considered to be similar, except for Galway. Galway has a low value with 2.4% of the area with bike stations; 5 points below the percentage of the first stage of *Dublinbikes*, and 8 points below the Limerick BSS. Both issues are important because they could affect the usage of the system in each city.

	Dublin 2011	Cork 2016	Limerick 2016	Galway 2016
Population (inhabitants)	527, 612	125, 657	94, 192	78, 888
Area of the city (km^2)	116.58	38.59	28.38	50.00
Population density (inh/km^2)	4, 526	3, 256	3, 319	1, 578
Main potential BSS users (20-39 years old)	208, 489	44, 561	26, 033	30, 693
% main potential BSS users over the total population	39	35	28	39
Area of the city with bike stations (km^2)	8.75	2.50	3.00	1.20
% area of the city with the bike stations over all area	7.51	6.48	10.57	2.4
BSS basic data				
Number of bikes	550	330	215	195
Number of stations	44	31	22	15
Number of docking points	1, 145	574	406	250

3. DATA ANALYSIS

3.1. Research context

This paper focuses on a multi-city scenario (most of them small to medium-sized) within a country to identify similarities and differences among the different sizes of BSSs. Also, the role of BSS target users in relation to a city's size and its characteristics are investigated to see what makes a BSS successful over time. Moreover, the question about whether the BSS performance of a consolidated scheme, such as *Dublinbikes*, could be extrapolated to other schemes with similar characteristics except city size, will be analysed.

To achieve these objectives, the European research study, Optimising Bike Sharing in European Cities – A Handbook (OBIS, Büttner et al 2011) has been taken as a reference. Its main objective is to encourage the implementation and optimisation of BSSs all over Europe and worldwide. This project collects relevant information about more than 50 BSSs from different European countries. Data are analysed and the results presented according to city size, providing a good overview and guidance for cities with similar conditions.

Therefore, according to their population and the definition of the OBIS project, Limerick and Galway are small cities because their population is between 20,000 and 100,000 inhabitants, Cork is a medium-sized city because its population is between 100,000 and 500,000 inhabitants and Dublin is a large city with a population greater than 500,000 inhabitants (Table 1).

Furthermore, the OBIS document gathers factors influencing BSSs, which are divided into endogenous and exogenous factors. This classification is used as the guide to select the factors analysed in this paper.

Regarding endogenous factors, only the physical design of the schemes (size and density) is analysed because it is the main differentiating factor among the BSSs involved. The rest of the endogenous items are similar for the four BSSs. All the services are available all year round, 7 days a week, from 5 am to 00.30 am, though a bike can be returned to available stands at any time of day or night.

They all offer two types of registration; annual subscription and 3-Day subscription for occasional short-term use or for visitors to the cities. Thus, all stations are equipped for Annual Card and 3-Day Ticket users because the hardware and technology consist of card-based access in each station. The first 30 minutes of each hire is free. For longer hires, a charge is applied.

With reference to exogenous factors, city size is the most relevant. The other exogenous factors such as climate, topology, economy and policy exhibit secondary importance. In fact, climate is not a key factor because the weather is similar in all four cities.

They have a mild oceanic climate with abundant rainfall and a lack of extreme temperatures. Thus, the use of bicycles is typical of warm cities with regular use all year and a slight fall in winter and summer (according to the description of the OBIS document). In relation to general geographical factors, all the cities have a main river and/or river channels, they are not hilly, the bikes are integrated into the traffic flow (except in Dublin, where there are a few segregated cycle lanes), and the core of the bicycle scheme is located in the main attraction area of the city (with several businesses, restaurants, shops, tourist attractions and services).

Thus, the cities depart from a similar starting point in terms of local conditions. However, the size of the deployment area and its extension into residential areas or university campuses are different in each city, and these will be the aspects to compare and explain.

In particular, the density of the bikes, stations and docking points of each BSS related to the population, the entire city area and the city area with bike stations, together with other ratios regarding the docking points are analysed. These figures provide a general view of the scale of bicycle-sharing network coverage (relatively dense), allowing comparison with average European values (according to the OBIS document), which are helpful in understanding the possible relationship between BSS coverage scale and the usage and development of the schemes. With regard to BSS usage, the data are divided according to the type of user (annual or occasional).

An estimation of the degree of success of a BBS will depend on the point of view of the stakeholders. In this case, the point of view is the transport company's, based on the usage and efficiency of the systems, which is understood as the number of daily rentals per bike.

The aggregated data used in this study allows for the estimation of the degree of success from this perspective. The larger the values, the more successful the system is. This criterion is widely used because it is an easily comparable measure. Besides, it is of interest to identify possible patterns in the usage data of the first years of BSS implementation in the four cities and to find specific characteristics of BSSs in small cities.

3.2. Dataset description

The dataset has been obtained by open sources and previously published manuscripts. The data related to Dublinbikes are obtained through the reports available on its website (www.dublinbikes.ie), and in the cases of Cork, Limerick and Galway BSSs, from the reports available on the common website (www.bikeshare.ie). In addition, the provided data from Caulfield et al (2017) and McBain and Caulfield (2018) are consulted to complete Cork bike information, whereas for the BSSs of Limerick and Galway, data from Jiménez et al (2018) are also used.

The proposed approach is not data intensive. Thus, it is easily scalable by adding new cities, and allows a good picture of the main BBS characteristics without overwhelming the analyst with an overly extensive list of indicators.

3.3. BSS infrastructure

In order to compare the four BSSs, the density of bikes, stations and docking points of each BSS are calculated. Table 2 provides the main results in relation to the density of each bike, station and docking point over the population, over the entire area of the city and over the deployment area of the scheme. The ratios regarding docking points based on the figures of Table 1 are also analysed.

	Dublin 2011	Cork 2016	Limerick 2016	Galway 2016
Bike/station/ docking point density over population				
Number of bikes / 10, 000 inhabitants	10	26	23	25
Number of stations / 10, 000 inhabitants	0.8	2.5	2.3	1.9
Number of docking points / 10, 000 inhabitants	22	46	43	32
Bike/station/ docking point density over the whole city area				
Bike density (unit/km^2)	4.72	8.55	7.58	3.9
Station density (unit/km^2)	0.38	0.80	0.78	0.30
Docking point density (unit/km^2)	9.82	14.87	14.31	5.00
Bike/station/ docking point density over the city area with bike stations				
Bike density (unit/km^2)	62.86	132.00	71.67	162.50
Station density (unit/km^2)	5.03	12.40	7.33	12.50
Docking point density (unit/km^2)	130.86	229.60	135.33	208.33
Ratios regarding docking points				
Number of docking points / bike	2.1	1.7	1.9	1.3
Average number of docking points / station	26	18	18	17
Standard deviation of docking points / station	5.5	6.6	4.5	3.8

Table 2 –Scheme size and density of bikes/stations/docking points of BSSs for each Irish city studied.

In relation to the density of bike/station/docking points over the population, the Cork, Limerick and Galway BSSs (the medium-sized and the two small-sized, respectively) have approximately double the value than the Dublin BSS This means that they provide more physical components per inhabitants. The figures of these three cities are also higher than the average values indicated in the BSS key figures of the OBIS sample (14.8 bikes per 10,000 inhabitants and 1.5 stations per 10,000 inhabitants), whereas Dublinbikes is below these references.

When comparing the schemes according to city area or the deployment area of the BSSs, two aspects are highlighted. The first one is that Cork and Limerick’s ratios of bike/station/docking point density over the entire city area stand out above the rest, and the second one is that the ratios of bike/station/docking point density over the deployment area of the BSSs are similar between Cork and Galway, and, in turn, higher than Dublin and Limerick’s.

Ratios of docking points show that each bike has roughly two docking points. However, the ratio in Galway is close to one; the minimum value required to be able to operate. However, it corresponds to the figure in the OBIS document (1.2) for this item in small cities.

Concerning the capacity of the stations, the Dublin bike stations are bigger than the bike stations in the other cities; that is, they have more docking points. Interestingly, the capacity data are opposed to the sample given in the OBIS project, where results show an average of 9.5 docking points per station for large cities and 23.5 and 22.9 docking points per station for medium-sized and small cities, respectively.

3.4. BSS usage

Regarding the usage data shown in Table 3, three aspects are highlighted.

The first feature is the large number of trips in Dublin; four times greater than Cork, thirty-five times greater than Limerick and almost seventy-seven times greater than Galway. This figure is closely related to the number of users; that is, there are four times more users in Dublin than in Cork, and about twenty times more than in Limerick and Galway.

The second aspect to point out is the share of annual and occasional users. Dublin and Galway BSSs have a large number of tourists since occasional users are 40% of the total. However, the Limerick BSS has high annual user demand, with these users making up 90% of the total. Similarly, regarding the total number of trips during the two first years of implementation, the average number of daily trips is greater in Dublin, and this value decreases according to the size of the BSS.

The third point to highlight is related to the daily rental ratio per bike. Specifically, the low values in Limerick and Galway show practically no daily use of bikes.

This indicates that the trips and users are insufficient to keep a steady level of usage throughout the year, and use is concentrated over several months in spring and autumn. Thus, neither of these systems are considered to be efficient in terms of the regular usage of the scheme.

	Dublin 2009-2011	Cork 2015-2016	Limerick 2015-2016	Galway 2015-2016
Total number of trips	2, 500, 000	518, 000	71, 595	32, 460
Total number of users	62, 000	N.A.	3, 230	2, 743
% Annual users	60	N.A.	90	64
% Occasional users	40	N.A.	10	36
Average daily trips	3, 425	710	98	44
Daily rental per bike	6.2	2.2	0.5	0.2
Average number of trips per user (all types of users)	40	N.A.	22	12

Table 3- Usage of each BSS studied. (N.A. – Not available)

3.5. Discussion

Dublinbikes, a large city scheme, has been well received by society. Proof of this is the second enlargement of the system in 2014. Some of the main reasons are (i) Dublin's high population density, 4,526 inh./km2 in 2011 (see Table 1), and (ii) the size of the deployment area of the BSS; that is, the extension area where the bike trips are efficient and can be combined with trips on foot and by car to access work or when enjoying leisure activities.

Additionally, other characteristics and practical measures such as the percentage of young population, cycling facilities, 30 km/h zones, communication campaigns and council favour, have supported its development. However, the values of the density of bikes, stations and docking points over the population and the entire city area are lower than the values of the other three cities and the reference values of the OBIS document.

Related to Cork, a medium-sized city, when comparing the data of trips and population with the data of trips and population in Dublin in 2011, the same proportion is shown. Thus, the same trend experienced by Dublin could be expected there. Some of the main reasons for achieving these numbers of trips and users could be the city's population density and the deployment area of the BSS. Indeed, this area is within the limit of efficient bike trips; that is, an area of 2.5 km^2 providing appropriate distances to cross the city by bicycle with an average travel time of 7 minutes (in an area smaller than 2.5-3.0 km^2, the possible routes are also appropriate for walking, and the impact of the scheme might be lower due to the low level of usage).

Usage is reinforced with the university connection, which provide an important group of system users. Note that neither Limerick nor Galway have bike stations near their university campuses.

The findings of this paper show that usage in Galway and Limerick is lower than in the other Irish schemes, with average daily bike rental near zero (Table 3). One possible strategy to increase this usage could be to expand the scheme.

This coverage growth could result in an upturn in usage numbers. Considering that both cities have small deployment areas in the schemes, a modal shift from pedestrians to cyclists is complicated. Moreover, a large group of potential demand, the staff and students of the universities, are outside of both BSSs. However, the cities have different characteristics.

Limerick has similar population density to Cork, whereas Galway has lower population density than the other cities. The type of users in each city is also different. This indicates that the development of each BSS for the short-term should be addressed from different perspectives according to the characteristics of each target group.

The main outcomes of the analysis based on real experiences could be summarised as follows:

- Only data from Dublinbikes could be partially comparable to the Cork scheme (medium-sized city), according to the ratio of number of trips and population, which have the same proportion. Moreover, deployment areas have a large enough extension to encourage bike usage, being close to the university.

- The number of daily rentals per bike is the most objective indicator of success in relation to usage from the perspective of the transport operator. Thus, the schemes of Dublin and Cork have good performance, whereas Limerick and Galway show a value below 1 (some bikes are unused each day).

- A higher density of bikes, stations or docking points does not imply greater usage; whereas the size of the deployment area could be a key factor in improving bike usage.

- BSS performance in small cities should not be compared with the BSSs of large cities by means of only quantitative data.

The identification of a successful BSS is indeed a difficult issue to solve because each city is conditioned by many aspects such as the characteristics of the surrounding area, the initial scenario of implementation and operational management. Moreover, the success of a system cannot be based only on a single ratio (e.g., number of daily rentals per bike) despite its good performance. In fact, the success of a BSS will depend on the desired goals of the council or the promoting body of the project in the short and long term and on the indirect benefits expected. That is, assessing whether a BSS is successful or not will depend on *what* and *who* it is for. Therefore, and according to the obtained results, the question to answer is how to improve the performance of BSSs in small cities. To answer this question, some considerations were analysed, from which Figure 5 emerges.

Figure 5 shows a synopsis of key aspects and recommended questions to consider before designing a BSS deployment or when improvements are desired after a few years of working. The identification of city characteristics from the point of view of the offer available is the first analysis to carry out; that is, to identify the attraction areas of the city such as business areas, third-level campuses, shopping areas, outdoor leisure and indoor zones and museums and areas of cultural activities. Next, the generation areas are also determined, such as residential and tourist accommodation areas, to consider that all attraction areas become generation areas when they are the origin of the trip.

Geographical barriers are also described to discover uncomfortable paths, inaccessible areas or critical points in bicycle trips. Space syntax would be a useful tool for this purpose. At the same time, the potential users, residents and/or tourists are also identified, in addition to the definition of the attraction and generation areas involved with each one (right upper corner of Figure 5). For example, the main attraction areas for residents are the business areas and third-level campuses because they make these trips on a daily basis, although they also visit the rest of the identified attraction areas during their leisure time. However, tourists are usually interested in visiting all types of leisure areas and places with cultural activities.

Once all these elements have been identified according to the target user of the BSS, some questions should be considered to design an adequate deployment area able to attract users and make the BSS profitable. As the lower part of Figure 5 shows, if the main target users are residents, the key is the extension of the deployment area to make bicycle trips efficient; that is, there will be sufficient bicycle stations to link residential areas with attraction areas. Moreover, the distance should be far enough to make the trip by bike worthwhile.

This type of user guarantees a steady level of usage, although detailed studies on seasonality and student mobility patterns should be developed to continue improving the scheme. If the target users are tourists, becoming aware of the seasonality of their visits is essential to understanding the usage of the system, as might be Galway's case in the first stage. In this case, the deployment area would be less important because tourists usually make circular trips, enjoying the city while stopping for sightseeing and shopping, so they use the BSS in a different way than residents. Finally, if the BSS covers both types of users, in addition to the two previous questions, it is important to identify possible overlapping between resident and tourist attraction areas to be able to take advantage of this overlapping and make the BSS more profitable. Obviously, these are general considerations that help in initiating the layout of a BSS in small cities. They should be complemented with specific studies for each city.

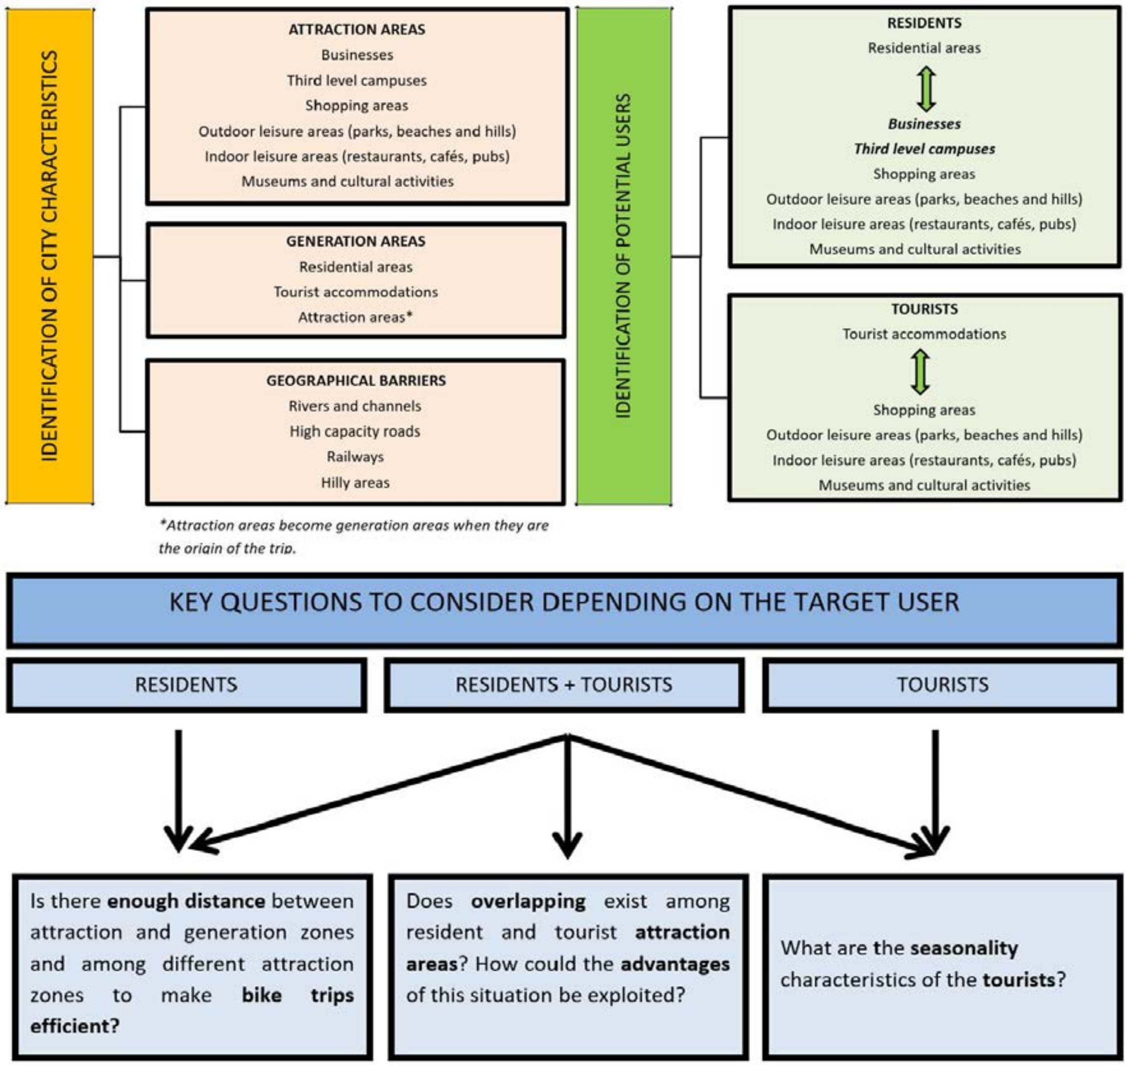

Fig. 5 – Synopsis of key questions to consider when designing a BSS deployment area in small cities.

4. CONCLUSIONS

A BSS in Dublin (large city), a BSS in Cork (medium-sized city), and two BSSs in Limerick and Galway (small cities) have been analysed during their first two years of implementation to try to understand how the size of the city and its scheme could affect the usage of each BSS.

The number of daily rentals per bike is a good metric from the point of view of the transport operator. However, a higher density of bikes, stations or docking points does not imply greater usage, whereas the size of the deployment area could be a key factor in improving bike usage.

In general terms, the development and operation of BSSs in medium-sized to large cities are usually satisfactory because of the high population density, the several groups of interest and the suitable distance covered by bicycle trips. In contrast, the usage level of BSSs in small cities is different from large cities because the deployment area is usually inefficient for bicycle trips and the management of potential users is not adequate. Thus, based on these current experiences, to extrapolate general results from the BSSs of large cities to schemes in small cities would not be recommendable.

Improving BSS performance, mainly in small cities, requires the identification of the city's characteristics from the point of view of the offer available, attraction and generation areas, along with possible geographical barriers and the identification of the potential users, residents and tourists. All these elements could help to guide the initial design or new measures to put into practice to improve BSS performance in the short term.

In fact, studying the first two years of BSS implementation in small cities is very helpful to be able to understand the mobility patterns of users and how to manage a BSS to obtain successful operation in the future. Developing a BSS depending on the characteristics of the main group of users registered during the studied period, i.e., annual or occasional users, to achieve the desired results in the short term, and then expanding the system to other types of users if desired, is recommended. Thus, studies on each group of specific users and how to adapt BSSs to them in small cities will be the next topic to research in order to improve the knowledge in this area and to be able to adapt better schemes to achieve efficient and profitable results. For these studies, not only the identified critical issues should be considered, but also how to improve cycling infrastructure, new 30 km/h zones or communication campaigns for the development and operation of small BSSs.

RESUMEN

En los últimos tiempos ha cobrado fuerza en las ciudades españolas la necesidad de contar con una red de carril bici con gran parte de su recorrido segregado del resto del tráfico. En paralelo, la pandemia de COVID-19 iniciada en 2020 provocó el interés de muchos municipios por crear redes provisionales de carril bici segregadas, mediante obras que se limitaban a alterar la señalización del viario. Para ambas situaciones -planificación de una red definitiva o una red provisional- se desarrolla un método de planificación rápida basado en herramientas GIS que consiste en analizar el conjunto de vías urbanas consolidadas, recabando datos de parámetros como la geometría transversal y longitudinal, la existencia de aparcamientos o la definición del tráfico en su sección tipo. A partir de los datos se obtiene el conjunto de calles que están en condiciones de ser modificadas para introducir en ellas un carril bici sin alterar el esquema circulatorio previo. El método se aplica a la zona centro de la ciudad de Gijón, España.

1. INTRODUCCIÓN

Las ventajas del empleo de la bicicleta como medio de transporte urbano son harto conocidas, y alcanzan la sostenibilidad ambiental o la repercusión positiva en la salud de los ciudadanos, por citar algunas (Frank et al., 2006; Gotschi, 2011; Mueller et al., 2018). Pese a ello, España ha mostrado una fuerte reticencia a la bicicleta como vehículo urbano. Así, el Eurobarómetro sobre la actitud de los europeos hacia la movilidad urbana (European Union, 2013) preguntaba la frecuencia con la que se empleaba la bicicleta, y España estaba en las últimas posiciones (sólo por delante de Chipre y Malta) con un 4% de los ciudadanos que reconocían el uso diario de la bicicleta (lejos del 43% de los Países Bajos, y de la media europea, que se situaba en el 12%).

Del mismo modo, en el Eurobarómetro sobre calidad del transporte (European Union, 2014) a la pregunta “En un día normal, ¿qué modo de transporte utiliza con más frecuencia?” el 8% de los europeos citaba la bicicleta por el 3% de los españoles, y lejos por tanto de neerlandeses (36%), daneses (23%) o húngaros (Plasencia-Lozano, 2021).

Sin embargo, en los últimos años se han puesto en marcha políticas y proyectos que incrementan el número de carriles bici con el propósito de cambiar el paradigma tradicional de la movilidad urbana, que situaba al coche particular en el centro durante décadas. No en vano, los informes del Observatorio de la movilidad urbana (Monzón de Cáceres, López García de Léaniz, Del Cuvillo, Julio Castillo, y Sánchez Sacristán, n.d.) muestran un incremento significativo de las infraestructuras ciclistas construidas en España (Tabla 1): Sevilla fue la primera gran ciudad en plantear una red amplia, tras el Plan Director de la Bicicleta del 2007 (Morales Carballo, 2011); en ciudades como Madrid, Barcelona o Alicante el incremento ha sido significativo desde el 2012, mientras que los casos de Málaga, Granada o Tarragona prueban que aún hay ciudades reticentes al cambio.

Tabla 1 – Longitud (km) y densidad (km /millón de habitantes) de los carriles bici construidos en algunas ciudades españolas. Incluyen todo tipo de carriles concebidos para bicicletas, incluyendo calles compartidas. Fuente: Observatorio de la Movilidad Metropolitana

En paralelo, la irrupción de la COVID-19 ha provocado profundos cambios en la movilidad de nuestras ciudades (Awad-Núñez, Julio, Moya-Gómez, Gomez, y Sastre González, 2021).

Los nuevos hábitos de transporte indican una tendencia decreciente del uso del transporte público, y un aumento en la movilidad en vehículos individuales, especialmente bicicletas o patinetes, que ha provocado la construcción de nuevos carriles bici en todo el mundo. No en vano, durante la pandemia, las más diversas ciudades realizaron modificaciones en el uso del espacio público (con mayor o menor éxito) para implantar redes de carriles bici provisionales (Soengas, 2020): en ocasiones, la actuación se limitaba a introducir alguna señal vertical y a disponer señalización horizontal, pintando sobre la propia calzada o acera (Abad, 2020). Aparentemente, no había un trabajo previo de planificación.

Figura 1 – Carriles bici provisionales construidos en diversas ciudades durante la pandemia: Oviedo (Abad, 2020), Vigo (Vila, 2020), Barcelona (Blanchar, 2020) y Berlín (Redacción).

La planificación en detalle de una red de carril bici, dentro de una estrategia amplia de movilidad es una tarea compleja que implica muchas horas de trabajo. El espacio público en los centros urbanos suele ser escaso y por ello la introducción de una nueva malla de transportes (el carril bici) implica la reducción o eliminación de alguno de los usos existentes. En tiempos recientes, se han desarrollado métodos para poder realizar determinar con eficacia una red (Koh y Wong, 2013; Winters, Davidson, Kao, y Teschke, 2011), entre los que destacan aquellos derivados del método BLOS (Bicycle Level of Service) desarrollado por el Transportation Research Board, que evalúan las condiciones de las vías urbanas para incorporar un espacio ciclista (Terh y Cao, 2018).

En paralelo, las herramientas GIS están revolucionando la planificación gracias a la capacidad que ofrecen para plasmar información diversa en relación a una realidad territorial.

En esa línea, creemos interesante desarrollar una metodología rápida de planificación que pueda ser usada tanto para realizar una primera evaluación de red, dentro de un proceso prolongado de planificación integral de la movilidad urbana, como para determinar con rapidez la viabilidad o no de poder implantar una red de carril bici de forma provisional sin afectar especialmente a los esquemas de circulación de vehículos privados. Esta metodología se realizará con herramientas GIS, a partir de datos públicos y de otros datos recabados en trabajo de campo.

El propósito será, por tanto, evaluar si las condiciones geométricas del conjunto de calles permitirán introducir un carril bici en ella sin afectar al esquema de circulación ya existente.

Aquellos ayuntamientos que deseen introducir una red provisional mediante la inserción de señalización vertical y horizontal pueden encontrar útil este método para analizar si puede plasmarse con rapidez una red válida que no afecte al esquema circulatorio; aquellos consultores que están realizando un plan de movilidad pueden encontrar válido el método para determinar, a priori, qué conjunto de calles son las idóneas para intervenir en ellas introduciendo un nuevo carril bici.

El método desarrollado se aplica a la zona centro de Gijón, ciudad de tamaño medio situada en el norte de España, donde la red de carril bici se encuentra aún poco desarrollada pese a que ya hay planes para ampliarla (Ayuntamiento de Gijón, 2021).

Figura 2 – Ubicación de Gijón y área de estudio.

2. MÉTODO

El método desarrollado se basa en la recopilación de datos y en el uso posterior de una herramienta GIS para tratarlos y analizarlos.

En primer lugar, se seleccionan una serie de guías de diseño y publicaciones de referencia relacionados con la planificación y diseño de carriles bici. Las publicaciones de referencia son: el Manual CROW (2011), el Cycle Infrastructure Design del Department for Transports (2020); Focus on cycling, de Copenhague (2013); Cycle concepts, de Dinamarca (Andersen et al., 2012); el manual Sustrans (2015); las recomendaciones incluidas en el Plan Andaluz de Bicicleta 2014-2020 (2014); y las Recomendaciones para el proyecto y diseño de viario urbano del Ministerio de Fomento de España (2000). En ellos se buscan los valores recomendados para los siguientes parámetros: pendiente máxima de la calle; anchura necesaria para un carril bici adosado al viario al mismo nivel; velocidad máxima del tráfico rodado en la calle; tipo de pavimento; idoneidad o no de coexistencia de la bicicleta en calles peatonales. Los valores obtenidos serán cotejados con los valores reales de las calles incluidas en la zona de estudio, y permitirán determinar qué tramos viales cumplen con criterios teóricos.

En paralelo, se determina el valor mínimo que pueden tener las distintas bandas de las distintas zonas: aparcamiento y calzadas; para ello se emplea como referencia las recomendaciones para el proyecto y diseño de viario urbano del Ministerio de Fomento de España. Con estos valores se podrá determinar qué espacios actuales pueden ser sustituidos por carriles bici futuros sin modificar el esquema de circulación existente: esta será la premisa mínima que debe cumplir la red de carril bici resultante. Para realizar el análisis se emplea el software libre QGIS, que permite introducir el viario junto con los valores reales y realizar así el estudio de cada tramo de calle. Finalmente, se analiza el viario resultante, y se extraen conclusiones.

3. RESULTADOS

3.1. Datos procedentes de documentos técnicos

En primer lugar se realiza la comparación de los valores otorgados por los documentos técnicos utilizados a los diferentes parámetros (Tabla 2). Se observa que la pendiente máxima admisible suele establecerse en el 5%. Con respecto al tipo de pavimento, se consideran adecuadas las superficies suaves como las mezclas bituminosas o incluso el hormigón, y se desaconseja el empleo de adoquines.

En cuanto a la anchura adecuada para un carril bici adosado a una vía con tráfico, sin separación física, se ha buscado información para dos casos: carril bidireccional y carril unidireccional.

La opción de disponer un carril bici bidireccional adosado a uno de los sentidos es desechada porque las publicaciones analizadas lo desaconsejan o ni siquiera lo consideran.

En cuanto a la opción de disponer un carril bici unidireccional adosado a cada uno de los sentidos, se establece que el valor mínimo es de 1,5 m, con lo cual el total de la calzada a ocupar sea de 3,0 m. Otro parámetro importante para la seguridad de circulación es la velocidad máxima admisible de la circulación rodada de la calle cuando no existe una separación física clara. En general, los manuales no recomiendan un carril bici adosado en calles donde se circule a más de 50 km/h, y se decide que esa velocidad sea el límite máximo admisible. En calles con una mayor velocidad de circulación admisible sí se podría introducir el carril bici igualmente, pero tendría que limitarse la velocidad a 50 km/h.

Finalmente, se evalúa la posibilidad de incluir bicicletas en calles peatonales. En los documentos técnicos consultados no se recomienda cuando hay bastante afluencia de peatones. En Gijón no hay aforo de peatones: por ello se decide no utilizar las calles peatonales dentro de la malla.

PARÁMETRO		CROW	Cycle Infrastructure Design	Focus on cycling	Cycling concepts	Sustrans	Plan Andaluz de Bicicleta	Recomendaciones para el proyecto y diseño de viario urbano

	Caso de un carril bici unidireccional	Mínimo 1,5 m; adecuado 2,0 m; máximo 2,5 m	Mínimo 1,5 m; adecuado 2 m	Mínimo 1,6 m; adecuado 2,2 m	Mínimo 1,5 m	Mínimo 1,5 m; adecuado 2 m	Mínimo 1,5 m; adecuado 1,8 m	Mínimo 1,8 m; adecuado 2 m
Velocidad del tráfico rodado en la calle en un carril bici al mismo nivel		Prohibido en vías > 70 km/h. Poco recomendable en vías > 50 km/h	Prohibido en vías > 50 mph. Poco recomendable en vías > 30 mph. Precaución en vías > 20 mph	-	Prohibido en vías > 55 km/h. Poco recomendable en vías > 35 km/h	Prohibido en vías > 40 mph	Prohibido en vías > 50 km/h	-
Tipo de pavimento		Asfalto bien; hormigón adecuado; adoquines mal	Asfalto bien; adoquines mal	Asfalto bien; adoquines mal	Asfalto bien; adoquines mal	Asfalto obligatorio en rampas	Asfalto bien; adoquines mal	Asfalto bien; adoquines mal
Calles peatonales. Espacio compartido con el peatón.		Sólo si hay menos de 100 peatones por hora y por metro	Hasta 300 peatones por hora, en calle de 3 m	-	Desaconseja el uso mixto en general	-	-	-
Calles peatonales. Espacio compartido con el peatón.		Sólo si hay menos de 100 peatones por hora y por metro	Hasta 300 peatones por hora, en calle de 3 m	-	Desaconseja el uso mixto en general	-	-	-

Tabla 2 – Parámetros obtenidos en los documentos técnicos consultados.

3.2. Anchuras mínimas de las franjas de espacio viario. Árbol de decisión

Una vez cuantificados los valores adecuados para los parámetros se determinan las anchuras mínimas que presentan las distintas franjas de espacio viario ocupado por los vehículos.

Para ello se toman los valores mínimos establecidos por las Recomendaciones del Ministerio de Fomento, como documento de referencia en España (Tabla 3). Gracias a ello, podrá decidirse qué espacios de tipo calzada o aparcamiento pueden ser sustituidos por sendos carriles bici unidireccionales.

Espacio	Ancho (m)
Carril bici unidireccional. Un carril de 1,5 m por cada sentido	3 m
Aparcamiento en línea	2 m
Aparcamiento oblicuo 30° (más restrictivo que oblicuo 45° o 60 °)	3,6 m
Calzada	3 m

Tabla 3 – Anchura mínima de los diferentes espacios urbanos.

A partir de esos datos se establece un árbol de decisión (Figura 3). Se establece que la modificación menos contundente es la sustitución de un carril de calzada por dos carriles bici unidireccionales, siempre y cuando uno de los sentidos de la calle tenga más de un carril.

Con ello se logra no alterar el sistema de circulación existente y tampoco disminuyen las plazas de aparcamiento ofertadas. Una modificación que altera algo más el *statu quo* de la calle sería eliminar plazas de aparcamiento. Se tiene así que una calle con dos líneas de aparcamiento puede ver sustituidas dichas líneas por dos carriles bici unidireccionales.

Asimismo, una fila de aparcamiento oblicuo puede ser sustituida también por dos carriles bici.

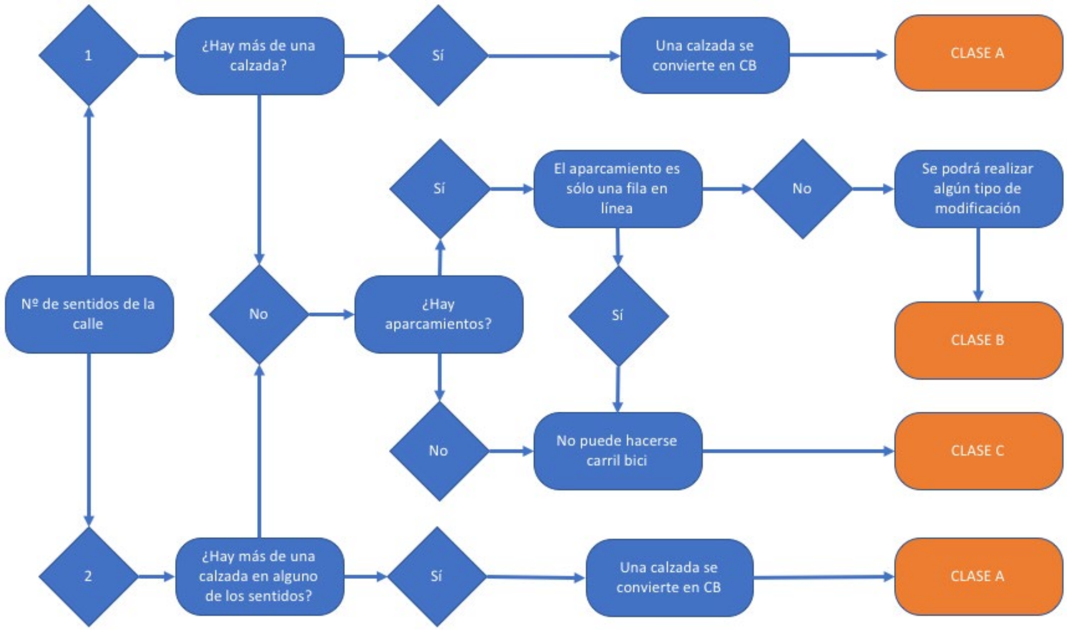

Figura 3 – Árbol de decisión.

3.3. Análisis con QGIS

Como consecuencia de los pasos anteriores, se generan una serie de capas en QGIS que recogen los distintos parámetros. Las pendientes de la zona de estudio son adecuadas para la circulación en bici, salvo en la zona sur. En relación a los pavimentos, sólo se aprecian adoquines en el conjunto de calles de la península de Cimavilla, así como algunas vías en la zona central y occidental presentan adoquines. Del mismo modo, se ha comprobado que todas las calles del ámbito tienen limitada la velocidad máxima permitida a 50 km/h; por tanto este parámetro lo cumple todo el conjunto. Por último, se han determinado el conjunto de calles de tipo A, B y C en función de lo definido en el apartado anterior. Se puede comprobar que la mayor parte de las vías de la zona occidental son C, mientras que en la mitad oriental son de clase B. Las vías tipo A quedan reducidas a algunos tramos puntuales.

Figura 4 – Datos de pendientes, tipo de pavimento, velocidad máxima permitida y tipos de calles (A, B o C, en función del árbol de decisión citado).

A partir de estos resultados se establece una clasificación de vías (tipos 1, 2 y 3; Tabla 4) y se determina el conjunto de vías aptas para trazar la red de carriles bici (Figura 5). Se observa que en el ámbito no hay calles tipo 2. El esquema resultante pone de manifiesto que sería factible realizar una ampliación notable del carril bici en la zona este; asimismo, podría realizarse una conexión con la zona oeste. Además, se comprueba que es inviable introducir un carril bici adecuado en la zona central de la ciudad sin modificar el esquema de circulación de la ciudad.

Tipo	Descripción	Detalle
Tipo 1	Vías idóneas para la circulación en bicicleta	Pendiente menor a 5 % y pavimento bituminoso y velocidad máxima de 50 km/h y ser de tipo A o B
Tipo 2	Vías a las que se puede incorporar un carril bici segregado, pero incómodas para el ciclista por incumplir un criterio (pendiente excesiva o pavimento inadecuado)	Pendiente menor a 5 %, o pavimento adoquinado, y velocidad máxima de 50 km/h y ser de tipo A o B
Tipo 3	Vías a las que no se puede incorporar un carril bici sin modificar el esquema de circulación actual. Vías a las que se puede incorporar un carril bici, pero son excesivamente incómodas por tener pendiente excesiva y pavimento inadecuado	Tipo C. Tipo A y B con pendientes iguales o mayores a 5 % y pavimento adoquinado

Tabla 4 – Tipos de calles, en función de la idoneidad o no para albergar un carril bici

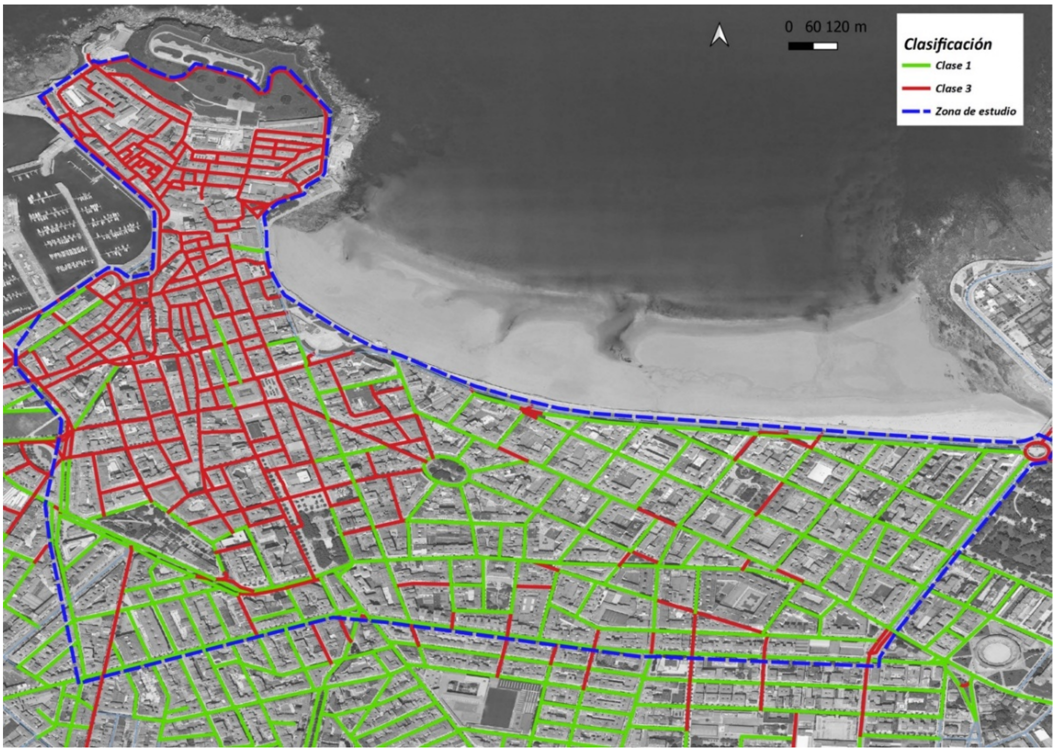

Figura 5 – Vías en las que se podría insertar un carril bici

4. DISCUSIÓN Y CONCLUSIÓN

Los nuevos paradigmas de movilidad en los núcleos urbanos, aceleradas por la pandemia asociada a la COVID-19, han provocado un interés creciente de las ciudades hacia la planificación de redes de carril bici segregado del tráfico rodado, provisionales o permanentes. Este texto propone un método de evaluación rápida de las condiciones actuales del viario urbano que permite determinar con facilidad qué vías son aptas para introducir en ellas un carril bici segregado, de doble sentido, adosado a los carriles de circulación.

El análisis de diversos documentos técnicos de referencia ha permitido establecer las condiciones mínimas requeridas por un carril bici segregado de doble sentido en un entorno urbano: una pendiente menor a un 5%; una anchura de 3 m; una velocidad máxima de 50 km/h en los carriles de tráfico rodado aledaños; un pavimento suave (hormigón o mezcla bituminosa). Se ha observado que, en general, hay notables similitudes entre ellos a la hora de determinar los valores recomendados y no recomendados de los parámetros.

Además, a partir del estudio de las anchuras mínimas de carriles bici, bandas de aparcamiento y carriles de circulación, se ha generado un árbol de decisión que permite determinar la aptitud de una calle para ser reconfigurada con el propósito de introducir en ella un carril bici, y que por tanto es otro de los resultados de esta investigación. El criterio tomado ha sido el de sustituir bandas de aparcamiento o carriles de circulación (cuando hay más de uno en alguno de los sentidos) por un carril bici de doble sentido.

El método desarrollado se ha aplicado en la zona centro de Gijón. Los resultados han permitido mostrar su aplicabilidad para la planificación futura de carriles bici en centros urbanos, donde las calles suelen ser más estrechas que en las periferias y los aparcamientos escasean, y para la generación de mallas provisionales como las surgidas durante la pandemia, consiguiendo así aumentar el espacio público destinado a la bicicleta. Del mismo modo, el método podría aplicarse para otros propósitos, como el aumento de la superficie de espacio público destinado al peatón.

Los resultados particulares de Gijón permiten también caracterizar el carril bici ya existente. Así, se ha comprobado que el carril bici actual discurre por calles particularmente anchas (de Clase A, según el método empleado), con pendientes inferiores al 2 % y con una velocidad de tráfico rodado limitada a 50 km/h. Es decir, el viario por donde discurre el carril bici es idóneo para albergarlo, según nuestra investigación.

En relación con la malla obtenida tras la aplicación del método en Gijón, se observa que un número relevante de calles analizadas sí podría albergar un carril bici segregado, y por ello podría ser sencillo realizar una ampliación provisional o permanente de la actual malla urbana para las bicicletas.

También se observa un posible recorrido de unión entre el Este y el Oeste de la ciudad que podrían completar la red de carril bici y prolongarlo a las zonas aledañas. En la zona más céntrica se acumulan calles que no permitirían introducir el carril bici sin realizar un estudio detallado que comprendiera el estudio de la presencia de garajes y accesos rodados a determinados negocios (talleres, aparcamientos de pago…) para redefinir el sistema circulatorio actual, y sin un estudio geométrico particular de cada vía. El método, así, ha permitido restringir la necesidad de realizar dicho estudio detallado a menos de la mitad de las calles del ámbito, con el consiguiente ahorro en tiempo.

En vista a futuros estudios sobre redes de carril bici en centros urbanos, podrían tenerse en cuenta algunos parámetros adicionales como las servidumbres citadas (garajes, talleres, etc.), el porcentaje de vehículos pesados que circulan por cada calle, que podría afectar al confort de los ciclistas en el caso de ser muy elevado, los radios de giro en las intersecciones (muy importantes para los ciclistas), etc. Otra investigación futura que se desprende de ésta es la aplicación de este mismo método en otras ciudades de tamaño similar a Gijón para realizar una comparación de los parámetros obtenidos en cada una de ellas, de este modo, se podrá caracterizar cada una de las ciudades y encontrar similitudes entre ellas.

AGRADECIMIENTOS

Este estudio se desarrolla en el marco del proyecto de investigación SV-20-GIJÓN-1-21 financiado por el IUTA (Universidad de Oviedo) y el Ayuntamiento de Gijón. Los autores desean reconocer la labor del Dr. Juan Sevilla (Universidad de Oviedo) y de Jorge Muriel (Taksee Imbric) por su ayuda durante la investigación.

CONDITIONING FACTORS FOR BIKE SHARING SUCCESSFUL EVOLUTION. THE CASE OF BICIMAD

Raky Julio
TRANSyT – Centro de Investigación del Transporte, Universidad Politécnica de Madrid
Andrés Monzon
Catedrático Departamento de Ingeniería Civil - Transportes, Universidad Politécnica de Madrid

ABSTRACT

Bike sharing systems (BSS) have gained great acceptance in many cities arround the world. Since the deployment of the first system, many cities promote the public bike not only as a sustainable mode of transportation, but also as a way to make visible the use of bicycles in urban environments. Four generations of BSS with great advances in between are recognized. BiciMAD in Madrid is one example of the last generation. A system deployed in mid-2014 with 1,560 bicycles and 123 stations.

During the early stage, TRANSyT-UPM conducted a series of studies to identify the intention of use, before the system deployment, and the user satisfaction and the relation between the use intention and real adoption, after the deployment. Since the last study in 2016, the system experienced some substantial changes and improvements in order to subsist.

Now that the system has reached its maturity, we conducted a survey in May of 2019, to study the evolution in the user satisfaction with the main factors that conditioned the success of BiciMAD. We asked subscribers, occasional users and non-users about their satisfaction with the elements of the system obtaining over 6,500 valid responses.

First, we compare the results obtained in previous surveys (2015 and 2016) with the latest, in order to identify changes in user profile and the conditioning factors for bike-sharing use.

Our results suggest that there are external and internal characteristics of the system that made it successful. For instance, the electric pedaling assistance is an attribute positively valuated that make user consider the streets slope unimportant. Also, the system had achieved some important goals, such as reduce the total trips in private car of the subscribers and not deterring users from walking.

1. INTRODUCTION

The phenomenon of urbanization, driven by the continuous rise in the population moving to cities, is prompting public authorities to pay more attention to the design, operation and management of urban transportation systems (Banister, 2005; Goldman & Gorham, 2006).

Therefore, transportation professionals and researchers are devoting efforts to promote sustainable travel alternatives, such as foster the use of public transport, and active modes such as walking and cycling, both affordable options to counter the negative effects of private car usage.

In this line, one popular strategy implemented among many cities since the early years of the 21^{st} century is the installation of public bike-sharing systems (PBSS) (Fishman et al., 2013). Bike-sharing systems have enjoyed a widespread acceptance around the world. Since the deployment of the first system, many cities have promoted public bikes not only as a sustainable mode of transportation, but also as a way to give bicycles visibility as a practical mode of transport in urban environments. This popularization phenomenon is so called the "*renaissance of bike-sharing systems*" (Pucher et al., 2011 ;Shaheen et al., 2010), especially in Europe, East Asia and North America.
PBSS have gained popularity in cities at the time they did in scientific literature. The research on PBSS could be divided in three research lines: the history and evolution of bike-sharing systems and the suitability of their implementation, functioning and governance; PBSS integration in the transport network; and user satisfaction.

With this work, we aim to combine the study of the evolution of a bike sharing system, at the time we intend to identify the key elements that made BiciMAD a successful system and would enhance the user satisfaction. This is done by comparing the results of a series of surveys (2015, 2016 and 2019) on some special attributes of the user profile and the factors that influence the use of bicycles, as well as performing an Importance Performance Analysis (IPA) and applying the Three-Factor theory (3FT) to identify the key elements of the system.

2. LITERATURE REVIEW

Bike-sharing is a relatively new concept, since the implementation of the first system in the Netherlands in 1965. Since, the systems evolution could be divided in four generations. The first generation, "white bikes" consisted of unlocked bicycles randomly located throughout the city. The bicycles were painted in one bright color. They could be picked up and left anywhere in the city, and their use was free of charge. In most of the cases where this scheme was implemented, bikes were vandalized and the attempts were not successful. The second generation of BSS, the coin-deposit system, was introduced in the 1990s. In this generation, the system was properly organized by a transportation authority and some features were introduced in order to avoid the first generation problems.

These systems were characterized by the particular, strong construction and bright color of the bicycles. The designated docking stations where bicycles were borrowed and returned were also a special characteristic, and the fact that a payment was required for using the bikes (DeMaio, 2009).

These systems were mainly introduced in north European countries such as Denmark and the Netherlands (Bachand-Marleau et al., 2012). In addition to the second generation, the third incorporated transaction kiosks that allowed for identification of users that deter the misuse the bicycles. These introductions succeeded in reducing theft rates as users were subject to penalties if they failed to return the bicycles to the stations. The latest generation of BSS is the demand responsive (Shaheen et al., 2010). The main innovations include the solar powered stations, the use of mobile apps and smart carts, and the incentives for automatic redistribution of bicycles.

User satisfaction is one success determinant of a provided service. The greater the increase in satisfaction, the more likely it is that the user will continue to be a client of the service (Anderson & Sullivan, 1993; Boulding et al., 1993; Yi, 1991). With this consideration, there has been an increase in the analysis of the perceived quality of BSS and the keys to its success. Manzi & Saibene, (2017) investigate the reliability of PBSS customer satisfaction surveys and the potential of emerging technology to improve transportation systems.. Kim et al., (2017) evaluate policy strategies for optimal PBS implementation. Alvarez-Valdes et al., (2016) investigate the impact of bicycle distribution imbalances across stations on user perceptions of service quality, which is one of the attributes considered in this study as station occupancy/bicycle availability. According to Albiński et al., (2018), several factors affect the performance of a bike-sharing scheme, but the two that have the biggest impact on customer satisfaction are bike accessibility and pricing.. (Médard de Chardon et al., 2017) conduct a comprehensive analysis of 75 PBSS to identify the determinants of success in terms of number of uses per day, while (Eren & Uz, 2020) analyse external factors such as weather, land use, PT connection and the influence of safety on bike-sharing demand.

Finally, Morton's (2018) assessment identifies how the PBSS in London will maintain or attract new customers by improving service quality.

3. DATA AND METHODOLOGY

3.1 Case study

Madrid is the capital city of Spain. It has 3.27 million inhabitants (2019) and traditionally was not considered a "cycling city" (Muñoz et al., 2013). Some special characteristics, such as the lack of extensive cycling infrastructure, their inhabitants' mobility behavior and the hilly topography (differences in elevation of up to 200 m) make it less attractive for cyclists than other European "cycling capitals". However, there is a positive movement by cycling collectives and public authorities to foster cycling. The implementation of BiciMAD.

Madrid was the first to introduce a city-center-wide large bike-sharing fleet of pedal-assisted bicycles in Western countries (Munkácsy & Monzón, 2018). As well as the development of segregated cycling infrastructure – 282 km in 2018 (MITECO, 2020) –, the prioritization of roads in the city center for cyclists and pedestrians and active campaign strategies for raising awareness of the benefits of cycling are encouraging people to cycle.

BiciMAD, Madrid's public bike-sharing system, was implemented in 2014. BiciMAD was originally deployed in the inner and denser districts of Madrid with approximately 15,000 to 30,000 inhabitants per km2. At that time the system had 123 stations and 1,560 bicycles; the system has now grown to 258 stations, 2,964 bicycles and over 60,000 subscribers.

BiciMAD was a pioneer of demand-responsive systems (Munkácsy & Monzón, 2017). Its general configuration is:

- The first city-wide bike-sharing system with electric pedal-assisted bicycles only (pedelecs)
- The whole fleet is GPS tracked
- Minimum fee per use of €0.50, including the 30 first minutes
- User-based redistribution, rewarding users by applying a discount of €0.10 for taking a bike from a full station and €0.10 for returning it at an empty station.
- User interface fully supported by online mobile applications and solar-powered totems at the stations.
- Occasional user scheme, with a €4 per hour pay-by-use fee structure.

The general characteristics of BiciMAD subscribers (Ayuntamiento de Madrid, 2017) are:

- 35% woman, 65% men
- 40% between 30 and 40 years old, 25% between 20 and 30 years old
- 85% have a university degree, 13% general certificate of education or vocational studies, and 2% primary or secondary studies

3.2 Data collection

This research is based on data collected in a series of surveys. The first conducted in 2014, with 1859 responses, the second in 2015 with 430 responses, the third in 2016 with 336 and the fourth and last in 2019 with 5540 valid responses. The first one at an early stage, before the system deployment to evaluate the intention of use, the second, on year after, as part of a before-and-after panel survey and the third to explore the effects of pedelec-sharing on travel patterns, and the fourth to evaluate the system maturity and evolution.

The latest survey was specially tailored to evaluate the influence of specific service attributes performance and influence over overall satisfaction. The attributes were selected ad-hoc, considering the system particularities as recommended in the literature (De Oña & De Oña, 2015).

A hybrid methodology was applied to achieve a representative sample to the four surveys. The method combines the advantages of personal intercept interviews and online questionnaires to fulfil the basic requirements of a survey, namely good data quality, representativeness and minimal costs (Monzon et al., 2020).

3.3 Methodology

The first part of this study, is a comparative analysis of the results obtained with three of the four surveys. The results of the 2014 *ex-ante* survey are dismissed, as the questions posed were exclusive for this stage and do not allow further comparison. Therefore, we use only the results of the 2015, 2016 and 2019 surveys.

For the comparative analysis, we will address only the responses given by the subscribers, as they are more frequent users and compose the BiciMAD system orientation, rather than occasional leisure usage.

To study the relationship between the cycling experience of the respondents and the assessment of the factors that influence the use of bicycles the different aspects of use were distinguished.

- Frequency of use. We have distinguished 6 discrete scales of frequency of use of the bike. Respondents had to choose between whether they used the bike to commute daily, sometimes a week, once a week, sometimes a month, sometimes or never. These categories have been summarized for ease of interpretation in the results section.
- Reasons for use. The reasons for use have been analyzed from two close perspectives but not matching:
- By forced mobility or not: we understand by forced mobility that whose motive is a permanent and systematic daily activity such as work or study. The rest of reasons (leisure, sports, personal affairs, shopping, others) are not required mobility.

The subjective factors that influence the use of the bicycle have been selected after a extensive review of the literature (Fernández-Heredia and Monzón, 2010). The factors have been valued by respondents on a semantic Likert scale graduated in 6 levels to judge the degree of importance between nothing, very little, little, something, very important or fundamental.

4. RESULTS

4.1 Sociodemographic evolution

Regarding the socio-demographic characteristics of the users, it is possible to observe that the gender distribution remains equal since the system deployment, with men slightly overrepresented with an average of 64% versus 36% of woman.

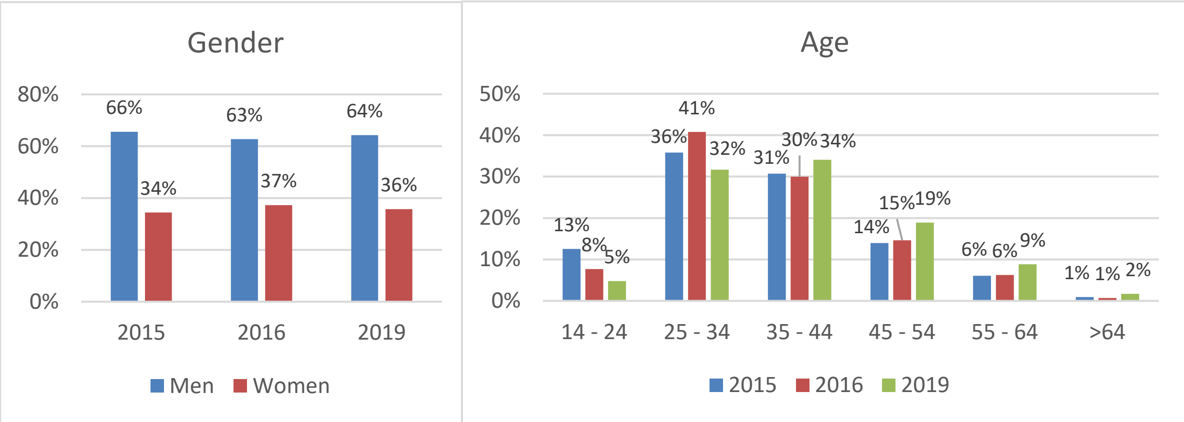

Figure 1. Gender and age evolution of BiciMAD subscribers

It is also possible to observe in figure 1, the aging of BiciMAD users, as all the intervals have increased in percentage on intervals over the 35 years and reduced on the lower intervals, from 14 to 34 years old.

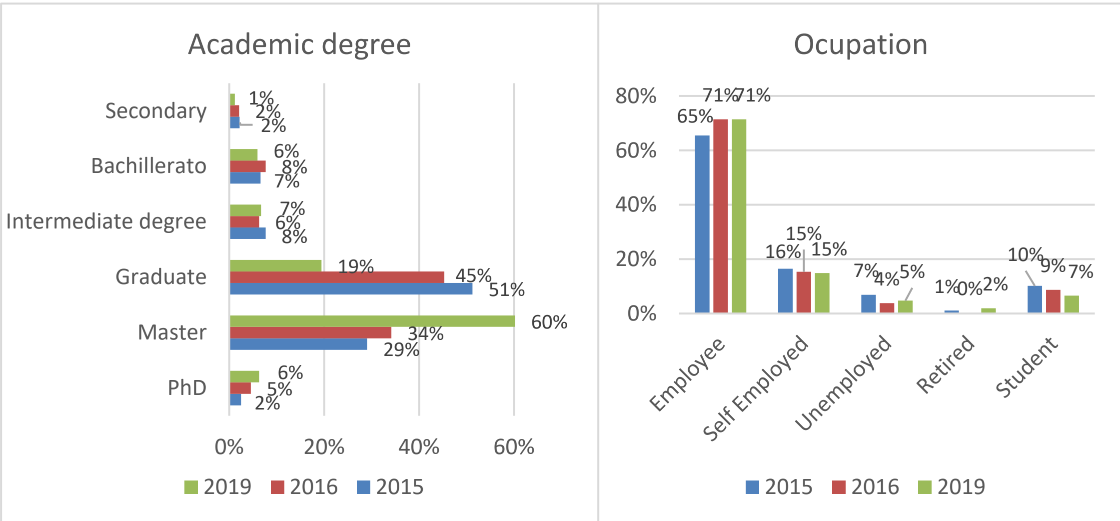

Figure 2. Academic degree and occupation evolution of BiciMAD subscribers

Regarding the academic degree, it is possible to observe that the average user of BiciMAD is becoming more educated. Especially if we concentrate in the difference between graduate, master and PhD. In 2015 and 2016 the majority of the sample was graduate, while in 2019 60% has a Master. This change could be explained with the introduction of the Bologna

Process, in which many careers demanded professionals to have a Master degree. The proportions of occupations remain steady. 85% of BiciMAD users have an income, either as employees or self-employed. It is noticeable that the percentage of students slightly decreased, while the retired slightly increased. Coherent with the aging of the user profile.

4.2 External factors evolution

We evaluate some external factors, general in the bicycle usage. This attributes are considered as a the more influential for the general cyclist.

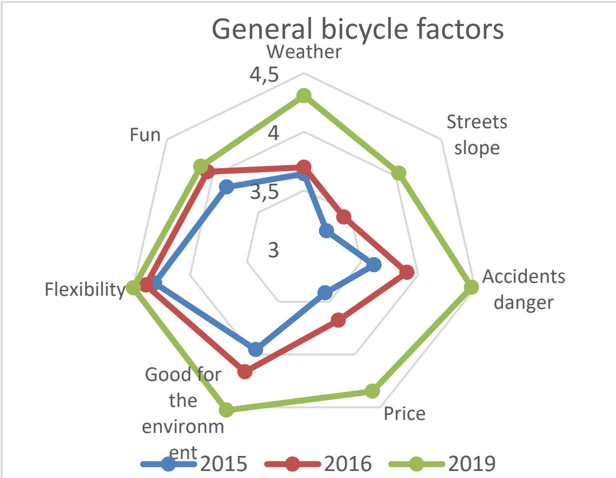

Figure 3. Evolution of factor importance

In general, subscribers of BiciMAD pose higher importance to all the attributes in 2019, compared with the results of previous years. Moreover, most of the factors have proportional increase along the years. That is to say, that factors such as the street slope remain as the less important. This might be conditioned due that BiciMAD is a fully electric BSS, then the effort needed for cycling using the service is less than a normal bicycle, therefore in Madrid, street slopes are not important.

The most important factors reported in the three surveys are “flexibility”, “good for the environment” and the “accident danger”. The first received the highest score for importance.

The absence of attachments for the use of BiciMAD, such as the storage, helmet and parking space make one of the most flexible modes for transportation in the city center of Madrid.

The good environmental perception of cycling is an important factor for subscribers, this factor could foster the use of bicycle and the promotion of the service in this sense could increase the use frequency.

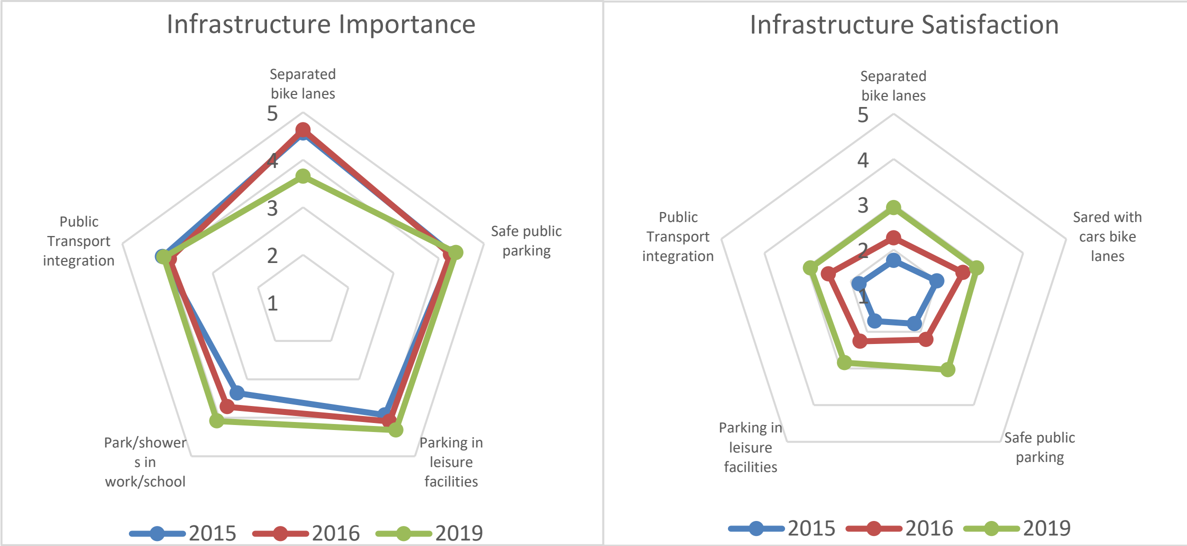

Figure 4. Evolution of infrastructure importance and satisfaction

In general, subscribers assign higher importance than satisfaction to Madrid cycling infrastructures. Regarding the importance, the "separated bike lanes" and the "safe public parking" are the infrastructures that receive more importance from subscribers. Moreover, BiciMAD do not require private parking places, users recognize that it is important for the general use of bicycle among all the years when surveys were conducted. Regarding the separated bike lanes, there is a clear change in the importance assigned to this infrastructure.

We consider that as cyclist are more familiar with sharing space with motorized vehicles, at the time there are more separated bike lanes than when the two first surveys were conducted. Therefore, this attribute is less important that at the beginning of the service introduction. It is possible to observe that the parking and showers at work and study places are gaining in importance, this is probably due to the popularization of cycling, then users demand better conditions on the facilities they regularly use.

There is a steady increase in satisfaction with all the infrastructures along the years. This might be due to a combination of familiarity with the bicycle usage, and the improvements in this regard.

4.2 Changes in use frequency and travel patterns

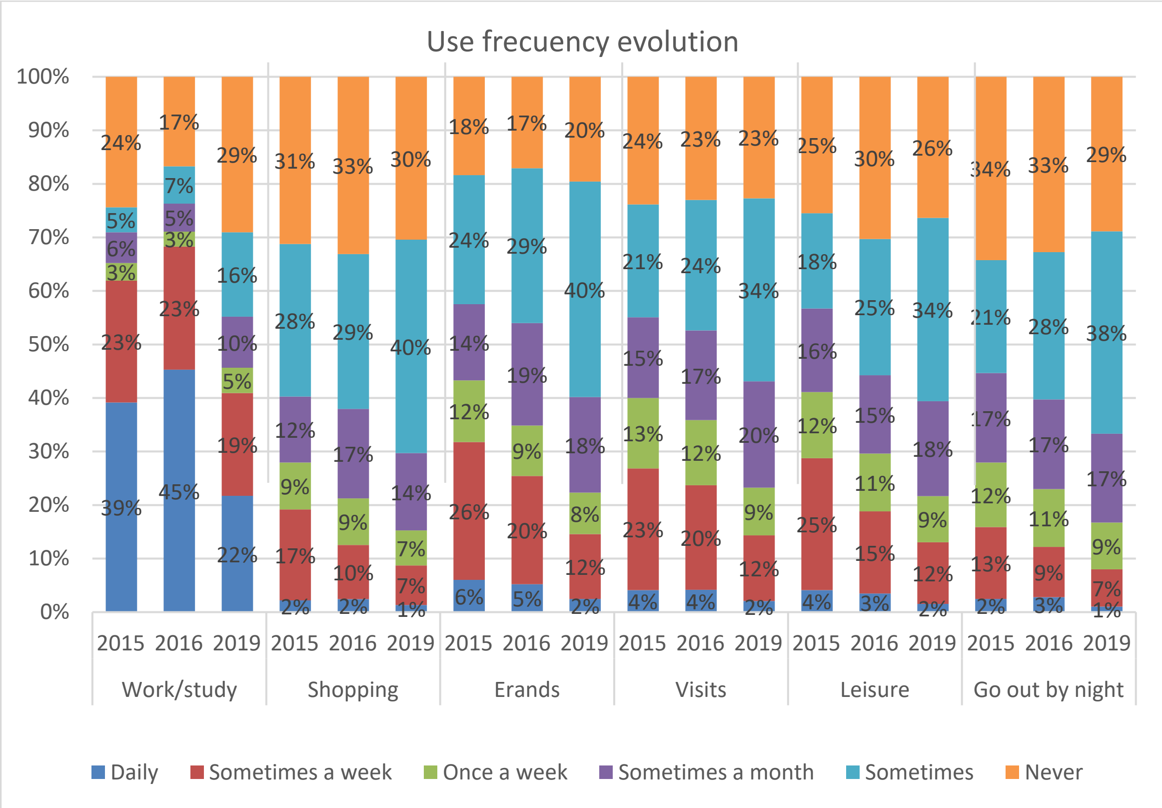

Figure 5. Evolution of use frequency

The frequency of use has reduced in general for all the purposes. It is notorious that the most intensive use categories have reduced significantly when, especially when it comes to the *daily* and *sometimes a week* frequency. If we focus on the work/study purposes, the percentage of daily use drops from 45% to 22%. The *sometimes a week* use for shopping reduces constantly all the years, from 17% in 2015 to 7% in 2019. Similar drops in use frequency could be observed for errands (26% in 2015 to 12% 2019), for visits (23% in 2015 to 12% in 2019), leisure (25% in 2015 to 12% in 2019) and go out by night (13% in 2015 to 7% in 2019).

The category that increases the most among the trip purposes is *sometimes*. It is worth of further studies to investigate the possible reasons for the drop in frequency of use, as well as to analyze the evolution of the number of subscribers

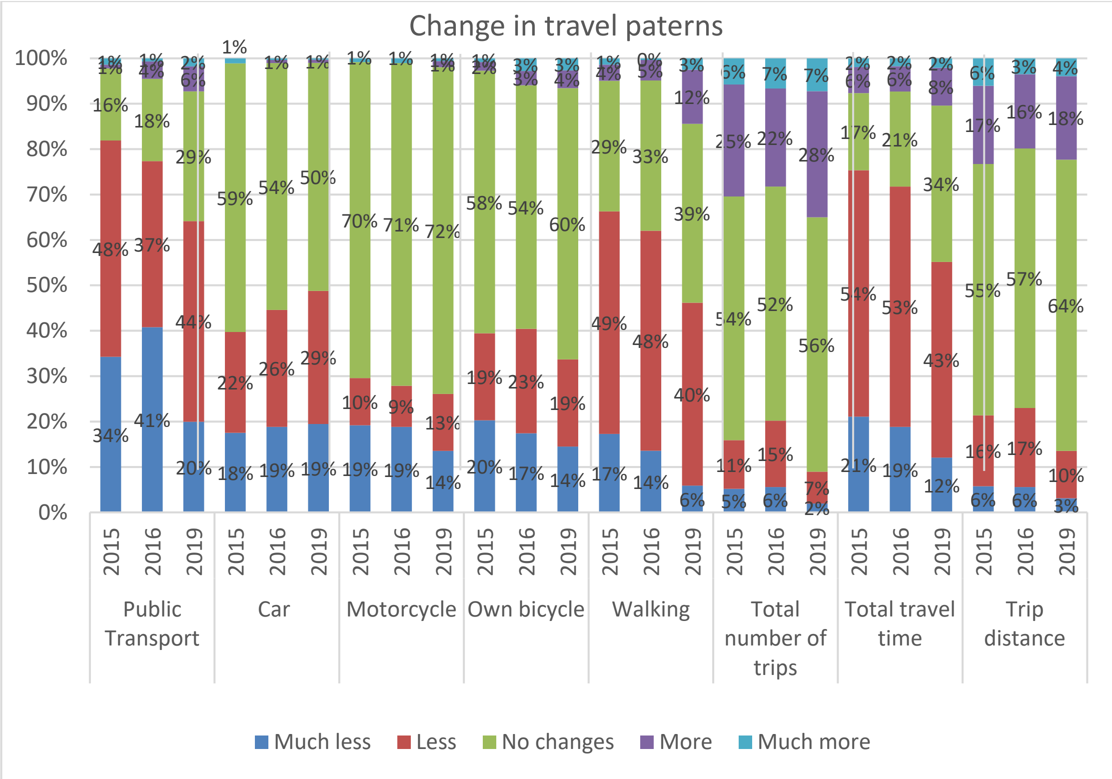

Figure 9. Evolution in travel patterns since the BiciMAD deployment

The respondents claim that they reduced their usage of public transport, this is possible to observe on a steady tendency since 2015 to 2019, if we focus on the values of much less and less putted together. This could be considered as a drawback of the BSS, as the purpose is not to take users out of the public transport, but from private vehicles, especially from the car.

In this regard, it is possible to observe that car usage also decreased from a 40% in 2015, up to a 48% in 2019, if we put together the values of *less* and *much less* together. A positive outcome of the implementation of the BSS.

There is a slightly increase in the use of the private bicycle, from around the 3% in 2015 to 7% in 2019. This positive effect is also compensated with the drop from 39% in 2015 to the 33% in 2019.

It is also positive that the walking passed from a 66% of reduction in 2015 to 46% in 2019. This is an indicator that the fee per use is effective when deterring the subscribers to take a bicycle that they could do walking. Indeed, it is possible to observe that from 2014 and 2015, the percentage of users that walk more since they subscribed to BiciMAD passed form around 5% to 15%.

Since 2015, less subscribers declare that the total travel time have reduced. A similar result with the trip distance, that almost remain steady since 2015.

4. CONCLUSIONS

As a result of the comparative analysis, it is possible to observe that there is significate change in some attributes and related with the user profile, perception of cycling factors and service use behavior and mobility patterns. This could be considered as conditioning factors for the evolution of BiciMAD system.

The profile of the user remains steady in most of the attributes, except the age and the academic degree, where is possible to observe the ageing of the subscribers, as well as possible effects of the Bologna Program, as there is a higher percentage of users with a master degree.

Pedelec bicycles are an influential factor of success. Due to this feature, the users assign little importance to the slopes of the streets in Madrid.
It is worthy to study the possible reasons for drop in use frequency, and if this is related with the number of daily use, and overall system performance in terms of Trips per Day per Bike (TDB) (Médard de Chardon et al., 2017). It is possible as well that user's perception of the use intensity would be due to the familiarity with the system, then their perception of use intensity is less than the reality. To conduct this verifications, it would be worthy to analyze the data of use intensity and number of subscribers in the system, as the administration claim that this values have stabilized in nearly 8 TDB and the number of subscribers is nearly 63,000.

The system has double effect over cycling, as it is possible to observe an increase in use of private bicycles, maybe because more users realize that it is possible to move by bicycle in Madrid, then are encouraged to start using it. At the same time, it reduces the usage on others, possibly because the convenience of BiciMAD, as there is no need of storage, maintenance, and other issues related to a bicycle ownership.
BiciMAD achieved the goal of not deter subscribers from walking, or at least reduce the number of users that stopped in 2015, that was much higher than in 2019.

Based on the results of this study, we identify a research gap, on the reasons conditioning the decrease in use frequency and its relationship with the above mentioned factors and the data from the service administration. This future research line could be conducted by performing and ordered logistic regression to understand the influence of each common variable among the three waves of surveys with the use frequency.

ACKNOWLEDGMENT

RESUMEN

El comportamiento de los ciclistas es esencial a la hora de evaluar la seguridad vial de una carretera convencional con una alta demanda ciclista y, especialmente, a la hora de proponer mejoras en este tipo de carretera. Para su análisis, una de las principales variables es la Percepción Subjetiva de Riesgo (PSR) que manifiestan los ciclistas ante determinadas configuraciones de la infraestructura, ya que esta puede condicionar su manera de circular.

En este estudio se presenta una nueva metodología para obtener datos de PSR de ciclistas, basada en encuestas y en realidad virtual. Para ello, se ha preparado una sala con el siguiente equipamiento: una bicicleta sobre un rodillo de entrenamiento, unas gafas de realidad virtual y un video wall. En estas instalaciones, 26 ciclistas, con diferente experiencia en circulación por carretera, han recorrido 10 tramos de carretera convencional con diferentes infraestructuras ciclistas, con las correspondientes intersecciones, que fueron previamente grabadas con cámaras 360º.

Durante cada recorrido, los ciclistas manifestaron su PSR para cada uno de los elementos que componían los diferentes tramos recorridos, valorando el riesgo de 1 a 5. Asimismo, valoraron en una escala de 1 a 7 el grado de inmersión al realizar los recorridos con las gafas de realidad virtual (sistema inmersivo) y con la video wall (sistema semi-inmersivo).

Los resultados del estudio han permitido identificar qué elementos de la carretera y configuraciones de esta son considerados más y menos peligrosos por los ciclistas, así como las diferencias que hay entre ciclistas dependiendo de su grado de experiencia en la circulación por carretera. Estos resultados serán la base para valorar el potencial impacto de posibles medidas de seguridad vial en su comportamiento y su percepción del riesgo.

1. INTRODUCCIÓN

De acuerdo con el Anuario Estadístico de Accidentes 2019 de la DGT, en 2019 fallecieron 48 ciclistas en vías interurbanas y 2363 resultaron heridos en accidentes de tráfico siendo el 90% de ellos hombres. Esta cifra que ha ido aumentando progresivamente en los últimos años, a diferencia de lo que ocurre con los accidentes con vehículos motorizados que ha disminuido progresivamente. De los 2530 accidentes con víctimas con bicicletas involucradas, 567 se produjeron debido a infracciones de los conductores, mientras que en 1023 no se produjo ninguna infracción. Por lo que es posible que una de las causas sea la infraestructura.

Este aumento en la siniestralidad relacionada con la bicicleta está relacionado con un aumento también en su utilización. De hecho, de acuerdo con el barómetro de la bicicleta en España de 2019, desarrollado por GESOP para la DGT, alrededor de 9 millones de españoles utiliza la bicicleta semanalmente y más de 4 millones la utiliza alguna vez en los desplazamientos por trabajo o estudios.

Por todo ello, es importante considerar la circulación ciclista a la hora de evaluar la seguridad vial de una carretera convencional con presencia de bicicletas, así como en el momento de implementar medidas para la mejora de su seguridad. El desafío es conocer el comportamiento que los ciclistas tienen en la carretera y este aspecto está íntimamente relacionado con el riesgo que perciben al circular por ella, representado por su Percepción Subjetiva de riesgo (PSR).

Para el análisis del comportamiento de los ciclistas en carretera pueden utilizarse metodologías de toma de datos basadas en grabaciones desde cámaras fijas (Silvano, 2015), en el uso de bicicletas instrumentalizadas (López et al., 2020) o incluso de simuladores de conducción (Thorslund y Lindström, 2020). Sin embargo, con cámaras únicamente se obtienen datos del comportamiento ciclista en una localización concreta y no se dispone de información sobre la percepción del riesgo de los ciclistas. En el caso de las bicicletas instrumentalizadas puede disponerse del dato de la percepción subjetiva del riesgo de los voluntarios que las conducen, pero la muestra es reducida. Esta metodología es más idónea para el análisis del comportamiento de los conductores que interaccionan con la bicicleta.

Mientras que, en el caso de los simuladores de conducción, generalmente los escenarios son reducidos por la carga que supone su modelización. Por ello, para llegar a una mayor muestra y aumentar la casuística, se recurre, en ocasiones, a las encuestas, muy utilizadas en la planificación para conocer las preferencias de los usuarios.

En este sentido, Monsere et al. (2012) evaluaron el nivel de aceptación de una nueva infraestructura ciclista tanto de ciclistas, como también de peatones y de conductores de vehículos motorizados.

Posteriormente, McNeil et al. (2015) utilizaron esta misma metodología para analizar el grado de comodidad que sentirían los ciclistas al circular por infraestructuras ciclistas con diferentes elementos de separación con el tráfico motorizado, mostrando estas configuraciones en imágenes de escenarios simulados. Por su parte, Ng et al. (2017) centraron su investigación, basada en una encuesta, en el grado de seguridad declarado por ciclistas ante imágenes de diferentes configuraciones de intersecciones no señalizadas y con diferentes maniobras. Los resultados de estas encuestas, aunque con una alta participación, son aplicables a una población muy limitada y podrían no ser extrapolables a otros países por la diferencia de comportamiento y de percepción del riesgo y comodidad de los usuarios de diferentes países e, incluso, regiones.

En España, López et al. (2019) llevaron a cabo una encuesta online sobre hábitos, situaciones de riesgo, cumplimiento de la normativa y percepción de los ciclistas ante diferentes medidas de seguridad vial y diferentes diseños de la infraestructura, tanto en cuanto a sección transversal como diseño de intersecciones. En este caso, la encuesta también estuvo basada en imágenes, algunas fotografías de ubicaciones reales y otras simuladas.

Los resultados de estas encuestas al referirse a imágenes aisladas reflejan la percepción del riesgo mostrada por los ciclistas teniendo en cuenta más su experiencia anterior que el riesgo que pudieran suponerles las configuraciones reales.

El objetivo del estudio que se presenta es el desarrollo de una nueva metodología basada en entrevistas a voluntarios durante la realización de una serie de recorridos en una bicicleta de carretera sobre una bancada mientras visualizan los recorridos con gafas de realidad virtual y en PowerWall, mostrando así una percepción del riesgo que se ajusta más a la realidad.

2. METODOLOGÍA

2.1 Selección de los tramos

El objetivo de la investigación es analizar la percepción del riesgo de los ciclistas ante diferentes configuraciones de la infraestructura ciclista en carreteras convencionales, incluyendo el tronco de las carreteras, así como también las intersecciones. Por ello, la selección de los tramos sobre los que realizar las entrevistas a los voluntarios se basó en identificar tramos de carretera con conocida afluencia ciclista en la provincia de Valencia, con diferentes diseños de sección transversal y equipamiento próximos a intersecciones. Además, teniendo en cuenta que cada voluntario realizaría 10 recorridos y que el tiempo máximo del total no debería superar los 15 minutos, en la selección de los tramos se consideró la necesidad de que cada recorrido pudiera realizarse en no más de 1.5 minutos.

Teniendo en cuenta estas consideraciones, se seleccionaron para el análisis seis glorietas y dos intersecciones, para analizar la percepción del riesgo en ellas y en los tramos de carretera que en ellas concurren. A continuación, se muestra un análisis somero de cada uno de los recorridos seleccionados.

2.1.1 Glorieta CV-333 / CV-25

La glorieta en la que confluyen la CV-333 y la CV-25 dispone de un único carril en su anillo central y seis entradas/salidas, tres de ellas se corresponden con las vías citadas, una corresponde a una vía acondicionada para tráfico de vehículos motorizados circulando a baja velocidad y dos corresponden a vías de menor entidad, teniendo una de ellas un carril bici paralelo.

En su entorno se han seleccionado dos recorridos (Figura 1):

- R1.1: comienza en el carril bici segregado paralelo a la CV-25, cruza la intersección por el paso ciclista habilitado en la rama sur y se incorpora a la vía de tráfico mixto, para continuar hacia el norte.
- R1.2: comienza por la vía de servicio paralela a la CV-25, se incorpora a la glorieta por la entrada de vehículos motorizados y realiza la glorieta completa para incorporarse a la rama sur de la CV-333.

Fig. 1 – Recorridos R1.1 y R1.2

2.1.2 Glorieta CV-25

La glorieta en la que confluyen la CV-25 y el acceso al municipio de Olocau dispone de dos carriles en su anillo central y cuatro entradas/salidas, dos de ellas se corresponden con la CV-25, una con la entrada al municipio de Olocau y otra con una con un camino.

En su entorno se han seleccionado dos recorridos (Figura 2):

- R2.1: comienza desde el oeste por el carril bici adosado a la CV-25 (separado por bordillos y bolardos), cruza la glorieta por el cruce diseñado para tal efecto y continua por el carril bici hacia el norte.
- R2.2: transcurre desde el oeste hacia el norte por la CV-25, circulando por el arcén de la calzada de la carretera e incorporándose a la glorieta junto con el tráfico motorizado.

Fig. 2 – Recorridos R2.1 y R2.2

2.1.3 Glorieta e intersección T CV-333 / Urb. Torre Porta Coeli

El tramo seleccionado está delimitado por una glorieta y una intersección en T. La glorieta dispone de un único carril central y cinco entradas/salidas, dos se corresponden a la CV-333, una al acceso a la Urbanización Torre Porta Coeli y dos a vías de menor entidad. Por su parte, la intersección en T, canalizada y con carriles centrales de espera, constituye el acceso sur a la citada urbanización.

En su entorno se han seleccionado dos recorridos (Figura 3):

- R3.1: comienza en la vía de tráfico a la altura de la glorieta, cruza la misma por el cruce diseñado para ello y se incorpora al carril bici segregado, circulando hacia el sur hasta llegar a la intersección, que cruza por el cruce habilitado para ciclistas.
- R3.2: comienza en el acceso de la glorieta correspondiente a la vía de tráfico mixto, realiza la glorieta por el anillo de la misma en convivencia con el tráfico motorizado, para continuar por el arcén de la CV-333 y girar a la derecha en la intersección.

Fig. 3 – Recorridos R3.1 y R3.2

2.1.4 Glorieta CV-310 / CV-305 y glorieta CV-310 / Urbanización Mont Ros

El tramo está delimitado por dos glorietas. La glorieta situada más al norte une las carreteras CV-310 y CV-310, disponiendo de dos carriles en su anillo central y 4 vías confluyentes, dos de ellas se corresponden con la CV-310, en la que en su rama norte se dispone de una vía de servicio paralela y en la sur un arcén coloreado, una con la CV-305 y otra con una vía de menor entidad.

En su entorno se han seleccionado dos recorridos (Figura 4):

- R4.1: comienza al sur de la glorieta norte, transcurre por el arcén coloreado que finaliza en dicha glorieta y la cruza en convivencia con el tráfico motorizado.
- R4.2: comienza al norte de la glorieta norte, en la vía de servicio, se incorpora a la glorieta para atravesarla junto con el tráfico motorizado, se incorpora al arcén coloreado de la rama sur de la CV-310, que finaliza unos metros antes de llegar a la glorieta, volviendo a mezclarse con el tráfico motorizado para atravesar la glorieta sur.

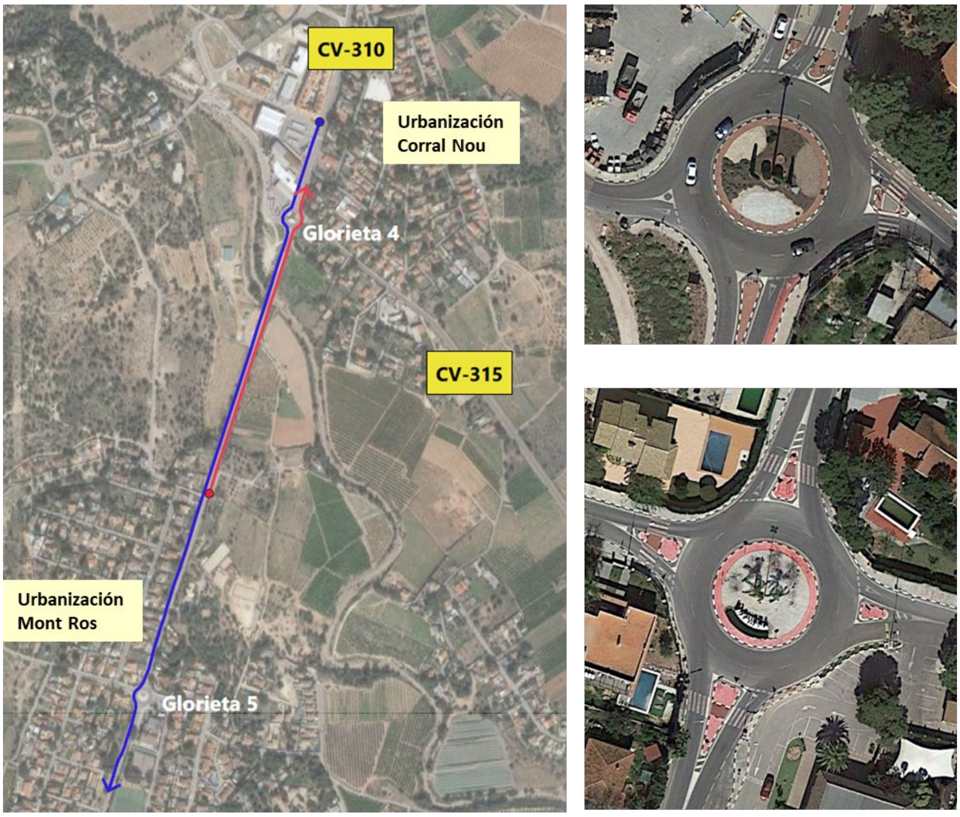

Fig. 4 – Recorridos R4.1 y R4.2

2.1.5 Glorieta CV-315 / CV-305 e intersección CV-305 / Urbanización Bonanza

El tramo está delimitado por la glorieta que une las carreteras CV-315 y la CV-305 y la intersección que da acceso a la Urbanización Bonanza desde la CV-305. La glorieta dispone de dos carriles en su anillo central y cuatro patas, tres de ellas se corresponden con las carreteras que une y una con el acceso a una urbanización, mientras que la intersección en T da acceso desde la CV-305 a la Urbanización Bonanza, siendo canalizada y con carriles centrales de espera.

Entre ellas, se han seleccionado dos recorridos (Figura 5):

- R5.1: comienza al este de la intersección, circulando por el arcén coloreado, cruza la intersección, donde el ciclista tiene prioridad de paso, y se dirige a la glorieta, en cuyo acceso el arcén coloreado para a carril bici segregado, para volver a convertirse en arcén coloreado al norte de la glorieta.
- R5.2: comienza al norte de la glorieta, circulando por arcén coloreado, atraviesa la glorieta por un carril bici segregado, que se convierte de nuevo en arcén coloreado al sur de la misma.

Fig. 5 – Recorridos R5.1 y R5.2

2.2 Grabación de los recorridos

Los 10 recorridos seleccionados fueron grabados con una bicicleta instrumentada, equipada con una cámara Nikon KeyMission 360, que cuenta con dos objetivos ultra gran angular a cada lado de la cámara, que se combinan para crear el entorno 360º (Figura 6).

Fig. 6 – Cámara Nikon KeyMission 360

A pesar de que la cámara ya cuenta con una función de reducción de la vibración, fue necesario utilizar un estabilizador tras comprobar en el primer recorrido que los movimientos de la cámara recogidos en el vídeo no permitían una visualización adecuada para la realización de las pruebas, especialmente con las gafas de realidad virtual.

El estabilizador utilizado fue el G360 Panoramic Camera Gimbal (Figura 7) que tiene un sistema de cuatro contrapesos verticales que garantiza un vídeo estable. Este estabilizador hace que la cámara gane altura con lo que colocado en el manillar queda a la altura del punto de vista del ciclista, dando una mayor sensación de inmersión en su reproducción.

Fig. 7 – Estabilizador G360 Panoramic Camera Gimbal

2.3 Preparación de la sala

Para la realización de los recorridos por parte de los voluntarios, el Instituto de Investigación e Innovación en Bioingeniería habilitó una sala insonorizada, permitiendo así que la sensación de inmersión fuera mayor. La sala contaba con los siguientes equipos (Figura 8):

- PowerWall: sistema semi-inmersivo que consta de dos proyectores de vídeo Mirage HD3 (Christie Digital Systems USA Inc, Cypress, CA, USA), que proporciona una pantalla estereoscópica de 2 metros de alto por 6 metros de largo.
- Gafas de realidad virtual: unas gafas de HTC Vive Pro Head Mounted Display (HMD), suponiendo un sistema totalmente inmersivo.
- Bicicleta de carretera sobre una bancada, de forma que los voluntarios pudieran pedalear durante los recorridos, llegando incluso a poder girar la rueda delantera.

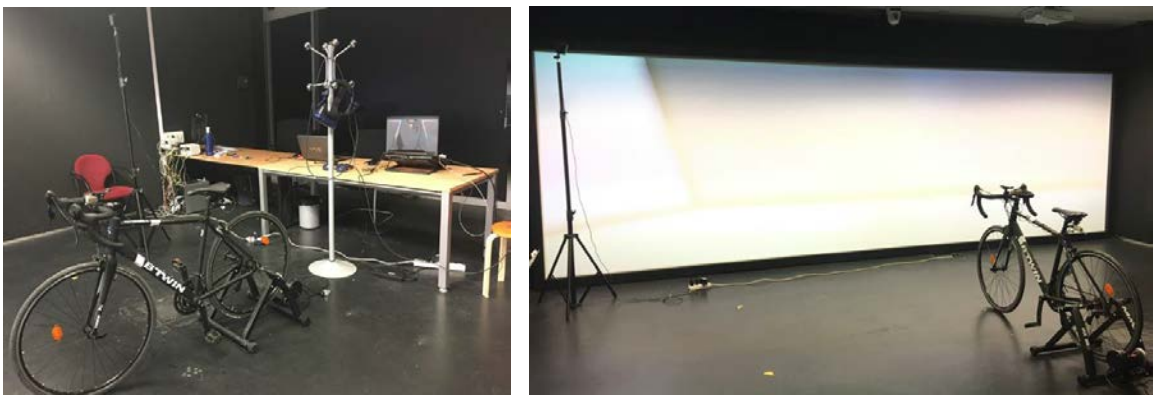

Fig. 8 – Sala habilitada para la realización de las pruebas

El hecho de que los voluntarios puedan pedalear y girar el manillar y la rueda delantera proporciona una inmersión mayor en el escenario.

Si bien es cierto que la velocidad de pedaleo puede no corresponderse con la velocidad del ciclista del vídeo, la diferencia se estima en ± 5 km/h, por lo que no es excesivamente perceptible.

2.4 Recorridos de los voluntarios

Para la realización de las pruebas, se solicitó la colaboración de diferentes asociaciones ciclistas de la provincia de Valencia. Asimismo, se dio difusión de las pruebas por las redes sociales del grupo de investigación, de la Escuela y de la Universidad. Con todo ello, se obtuvo la colaboración de 31 voluntarios, de los cuales 4 eran mujeres y 27 eran hombres.

De ellos, durante la realización de las pruebas, cuatro hombres y una mujer sufrieron episodios de mareo que les impidió realizar los recorridos adecuadamente, con lo que sus datos no han sido contabilizados en el análisis.

De esta forma, se dispone únicamente de 26 voluntarios, contando solo con 3 mujeres. En función de su experiencia en ciclismo por carretera se observaron 3 perfiles diferenciados (Figura 9):

- Ciclistas semiprofesionales con alta experiencia en ciclismo deportivo por carretera y un alto número de kilómetros recorridos semanalmente. Todos ellos son hombres.
- Cicloturismo. Son ciclistas con un alto número de kilómetros recorridos semanalmente, pero, generalmente, no por carreteras con un elevado tráfico vehicular. Todas ellas mujeres.
- Ciclismo urbano/montaña. Ciclistas que utilizan la bicicleta de forma habitual pero no por carretera.

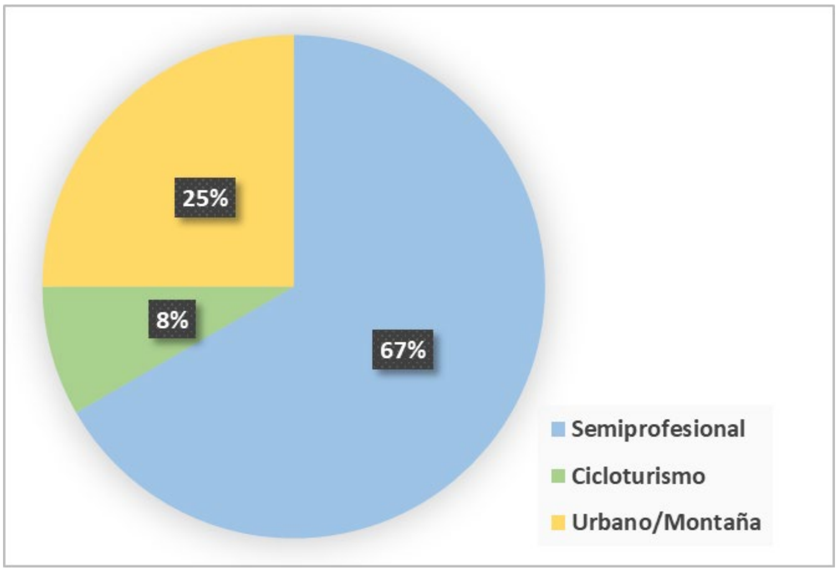

Fig. 9 – Distribución de voluntarios en función de su experiencia

Los voluntarios que completaron todos los recorridos realizaron 10 recorridos, cinco de ellas con el vídeo proyectado en el PowerWall y cinco con las gafas de realidad virtual.

La distribución de los recorridos entre estos dos sistemas de visualización entre los diferentes voluntarios se realizó de forma aleatoria, así como también el orden en el que fueron visualizados. Finalmente, el número de veces que fue visualizado cada uno de los recorridos fue el que se muestra en la Tabla 1.

Recorridos	Gafas Realidad Virtual	PowerWall
R1.1	11	15
R1.2	16	10
R2.1	15	11
R2.2	12	14
R3.1	14	12
R3.2	15	11
R4.1	11	15
R4.2	14	12
R5.1	10	16
R5.2	12	14

Tabla 1 – Visualización de cada recorrido en función del sistema

A cada uno de los voluntarios se les realizó una serie de preguntas antes de comenzar las pruebas, al finalizar cada recorrido y al finalizar las pruebas:

- Previo a los recorridos. Los datos recogidos se referían a sus datos personales:
    - Nombre
    - Experiencia en ciclismo por carretera (años)
    - Kilómetros recorridos semanalmente
    - Formación o experiencia en seguridad vial y/o tráfico
- Al finalizar cada recorrido:
    - Valoración de la seguridad de la intersección (1 más segura – 5 menos segura)
    - Valoración de la seguridad del tramo (1 más seguro – 5 menos seguro)
    - Percepción de la realidad (1 menos real – 7 más real)
- Al finalizar todos los recorridos:
    - En general, ¿prefiere usted el uso del carril bici o de la calzada?
        - Carril bici en todo momento
        - Carril bici solo cuando voy solo
        - Carril bici solo cuando voy en pelotón
        - El carril bici en ningún momento
        - Ninguna de las anteriores

- Valoración de la sensación de mareo con las gafas de realidad virtual (1 menos mareo – 5 más mareo)
- Valoración de la sensación de mareo con el PowerWall (1 menos mareo – 5 más mareo)

Adicionalmente, la mayor parte de los ciclistas, durante la realización de los recorridos comentaban su percepción del riesgo de los elementos que consideraban de mayor riesgo.

Aunque inicialmente no se había contemplado esta posibilidad, la información facilitada por los ciclistas, especialmente por los más experimentados fue muy valiosa.

3. ANÁLISIS Y DISCUSIÓN

A lo largo de este apartado se analizan diferentes aspectos, comenzando con aspectos relacionados con el comportamiento ciclista, como son la percepción subjetiva del riesgo declarada por los ciclistas y la preferencia de uso de los carriles bici, para continuar con la comparativa entre ambos sistemas en cuanto a sensación de mareo y a grado de inmersión.

3.1 Percepción subjetiva del riesgo

La percepción del peligro que tienen los ciclistas sobre una infraestructura puede animarlos a circular por ella o todo lo contrario, es lo que se denomina la Percepción Subjetiva del Riesgo (PSR). Esta depende de cada persona, pero a la hora de realizar una encuesta, depende también de como se muestre la infraestructura. En el caso del presente estudio, se han utilizado dos sistemas: un sistema semi-inmersivo, como es el PowerWall, y las gafas de realidad virtual, que suponen, en principio, una inmersión mayor.

En la Figura 10 se muestran los resultados de la PSR para cada una de las glorietas de los recorridos realizados, contabilizando tanto las visualizaciones con PowerWall como con gafas de realidad virtual. Como puede observarse, las glorietas con una mayor PSR son por las que han circulado en el recorrido R2.1, en el R5.2 y en el R4.2. La glorieta del R2.1 se encontraba en obras en el momento de llevar a cabo las grabaciones, siendo esta la causa principal del aumento del PSR, según comentaron la mayor parte de los ciclistas.

En el R5.2 los ciclistas circulan por arcén coloreado que, al aproximarse a la glorieta, pasa a ser un carril segregado, realizando el cruce por uno de los ramales. Los ciclistas indicaron como uno de los problemas la falta de visibilidad, así como la falta de claridad en quien tiene la preferencia de paso.

En el R4.2, los ciclistas indicaron como principales problemas la proximidad de las entradas a la glorieta, la alta intensidad de tráfico y la ausencia de arcén.

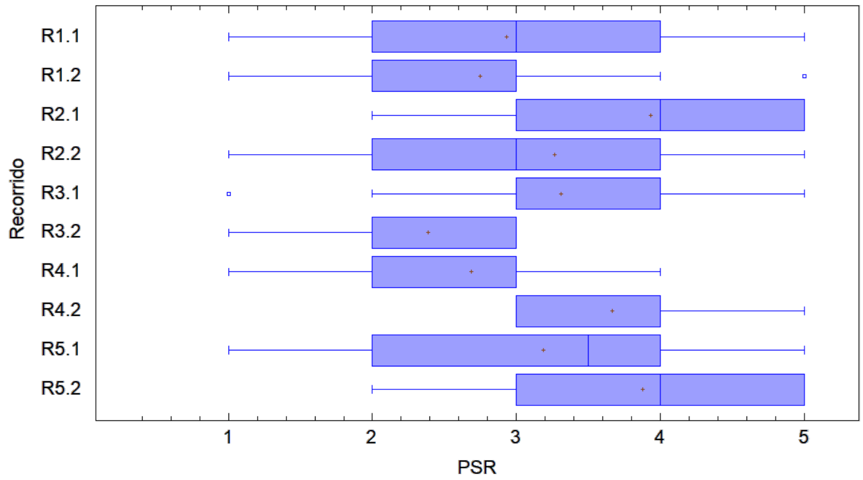

Fig. 10 – PSR de las glorietas analizadas

Estos resultados, como se ha mencionado, están basados en la PSR indicada por los ciclistas que realizaron las pruebas tanto con el PowerWall como con las gafas de realidad virtual.

En la Figura 11, se muestran los resultados distinguiendo según el sistema utilizado para la visualización. Como puede observarse, la percepción del riesgo varía según el sistema utilizado. De hecho, en la mayor parte de los casos la PSR es mayor al realizar la visualización con el PowerWall que con las gafas de realidad virtual. Únicamente en los recorridos R2.1, R3.2 y R4.1 la PSR es mayor con las gafas de realidad virtual. En todo caso, la variabilidad es alta y los valores medios no varían sustancialmente entre un sistema y otro.

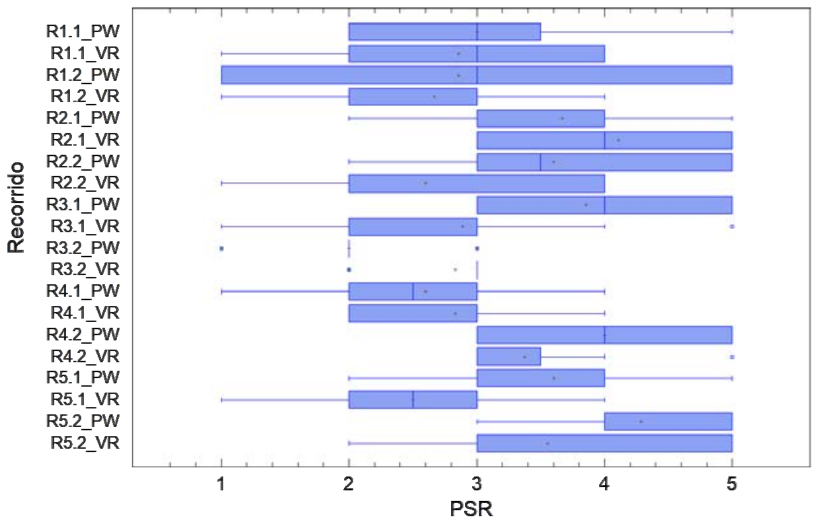

Fig. 11 – PSR de las glorietas analizadas según el sistema de visualización

Además de las glorietas, los ciclistas también valoraron los tramos por los que circularon.

Sin embargo, no sería adecuado establecer un valor de PCR por recorrido, ya que dentro de un mismo recorrido los voluntarios indicaron elementos que podrían hacer aumentar su percepción del riesgo y otros que les aportaban seguridad, siendo estos similares a los identificados en las encuestas de López-Maldonado et al. (2019).

Los principales elementos que son decisivos a la hora de valorar un tramo de carril bici segregado como más o menos peligros desde el punto de vista de los ciclistas son:

- Falta de mantenimiento de la infraestructura, tanto por el estado del firme como por el estado de la vegetación, que reduce la visibilidad, especialmente en las proximidades de los cruces.
- Falta de señalización, indicando la preferencia en los cruces.
- Entradas y salidas al carril bici mal diseñadas. Los ciclistas deportivos alcanzar una velocidad relativamente alta y, al circular en pelotón, si tienen que reducir la velocidad para incorporarse o salir de un carril bici, pueden producirse caídas.

En el caso de la circulación por calzada, los elementos que suponen una mayor influencia en la percepción del riesgo son:

- Anchura del arcén.
- Estado del pavimento del arcén, así como la invasión del arcén por parte de la vegetación.
- Color del arcén. En general, los ciclistas consideran más seguros los arcenes coloreados, siempre y cuando tengan un ancho suficiente, ya que, en caso de no tenerlo, los vehículos motorizados no dejan suficiente distancia lateral con el ciclista. Este resultado es similar al observado en las encuestas realizadas por López-Maldonado et al (2019). Sin embargo, en el caso de las encuestas online, únicamente dispusieron de porcentajes de valoraciones de los encuestados, sin los comentarios adicionales de los que se dispone después de este proyecto, en el que la conclusión es que la PSR depende del ancho del arcén coloreado.
- Las barreras de seguridad metálicas. Estas barreras son la causa de heridas en las piernas de los ciclistas.
- Los elementos situados en los márgenes. En los márgenes con acequias adosadas a la carretera o con desniveles, la PSR aumenta considerablemente ante la posibilidad de una caída.

Además de estos elementos relacionados con la infraestructura y su equipamiento, los ciclistas indicaron que el elemento que más hacía aumentar su percepción del riesgo son los vehículos motorizados. De hecho, algunos de ellos destacaron que al hacer algunos de los recorridos se sentían seguros porque en ese momento no había una alta intensidad de vehículos motorizados, pero que su PSR aumentaría al aumentar el tráfico.

3.2 Preferencia de uso del carril bici

Al finalizar todos los recorridos, se les preguntó a los voluntarios si, en general, prefieren el carril bici o la calzada. Como puede verse en la figura 12, la mayor parte de ellos indicaron que prefieren el carril bici en todo momento. Sin embargo, puntualizaron que siempre y cuando el carril bici sea suficientemente ancho y las entradas y las salidas estén adecuadamente diseñadas. Para ello, deben estar libres de bolardos u otro obstáculo y que las embocaduras sean amplias y sin curvas de bajo radio.

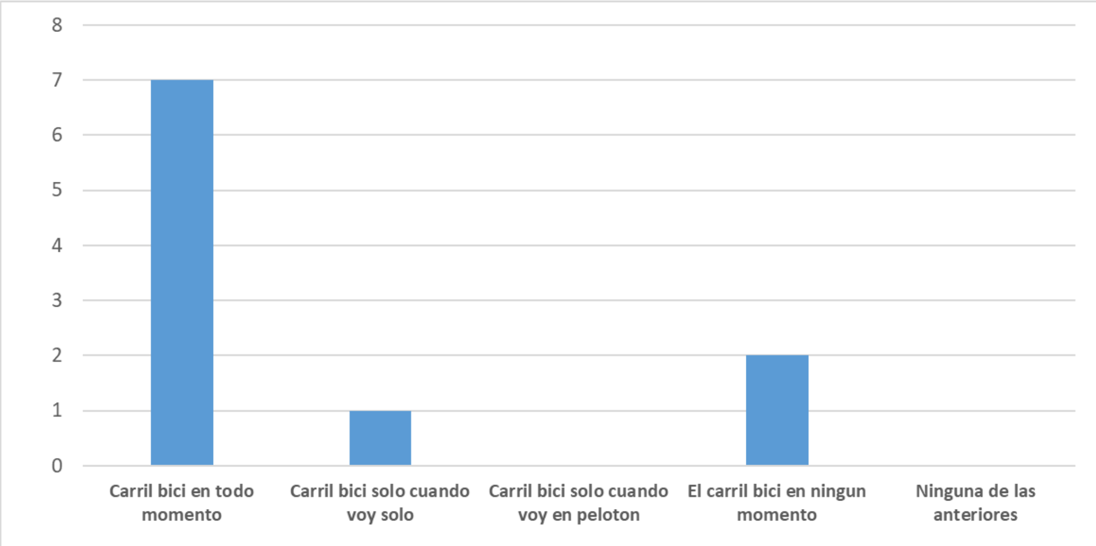

Fig. 12 – Preferencia de carril bici

En la encuesta realizada por López-Maldonado et al. (2019), los ciclistas indicaron que para circular en grupo un 45.6% prefería realizarlo por el arcén. Tras el presente estudio, podemos concluir que los ciclistas en grupo optarían por ir por carril bici si este estuviera adecuadamente diseñado y mantenido.

3.3 Comparativa entre sistemas

Para llevar a cabo la comparativa entre ambos sistemas, se establecen como principales parámetros el grado de inmersión y la sensación de mareo.

Como se ha indicado anteriormente, cuatro hombres y una mujer tuvieron que interrumpir las pruebas a causa del mareo. La edad de la mujer y de uno de los hombres era inferior a 35 años, mientras que los otros tres hombres tenían una edad superior a los 60 años. Todos ellos visualizaron los primeros recorridos con las gafas de realidad virtual. Este es un primer indicador de que la sensación de mareo es mayor en las gafas de realidad virtual que con el PowerWall.

Al resto de los participantes, al finalizar las pruebas se les solicitó que valoraran la sensación de mareo con cada uno de los sistemas (1 menos mareo – 5 más mareo).

La Figura 13 muestra como las respuestas fueron similares, siendo un poco mayor la sensación de mareo en el caso de las gafas de realidad virtual.

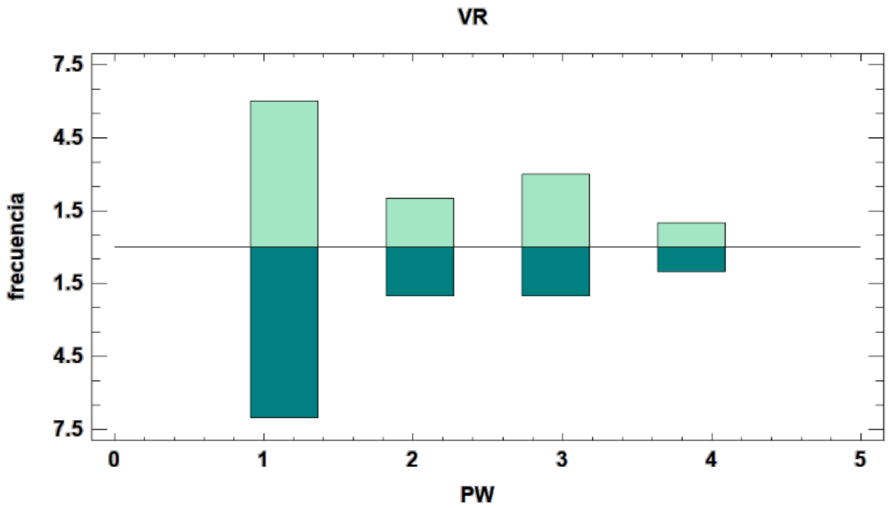

Fig. 13 – Sensación de mareo que producen las gafas de realidad virtual (VR) y la PowerWall (PW)

Adicionalmente, al finalizar cada recorrido, los voluntarios indicaron el grado de realidad de la experiencia que acababan de vivir con un rango de 1 (menos real) a 7 (más real). Como se muestra en la Figura 14, las gafas de realidad virtual presentan un grado de inmersión mayor que el sistema PowerWall, especialmente porque los voluntarios pueden girar la cabeza y contemplar todo el escenario y porque la calidad de la imagen es mayor.

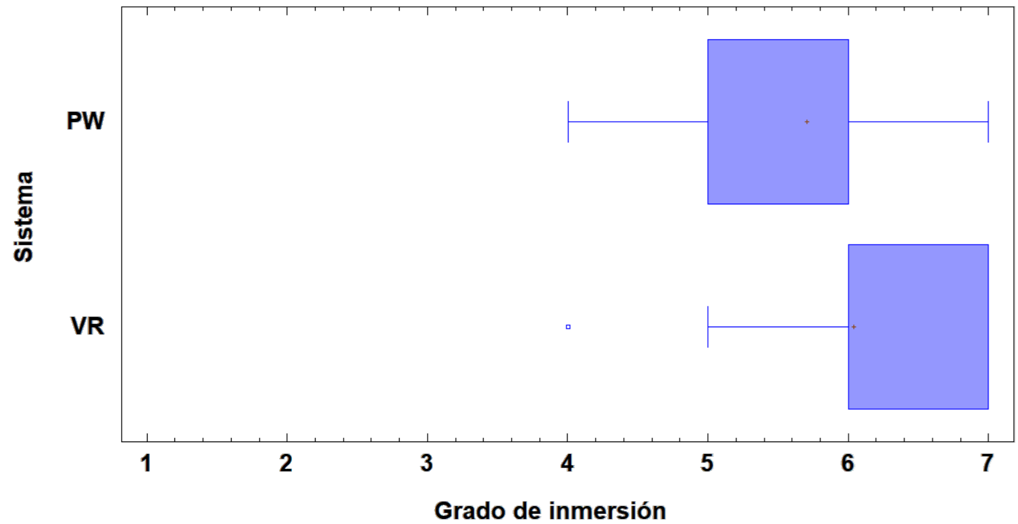

Fig. 14 – Grado de inmersión de las gafas de realidad virtual (VR) y la PowerWall (PW)

4. CONCLUSIONES

La circulación ciclista, especialmente deportiva, en las carreteras convencionales ha aumentado considerablemente en los últimos años, lo que ha supuesto un aumento progresivo de la accidentalidad. A pesar de las actuaciones que se han ido realizando, la accidentalidad relacionada con los vehículos motorizados ha disminuido, pero no la accidentalidad de las bicicletas. Por ello, es necesario estudiar los factores que suponen un mayor riesgo para este tipo de usuarios.

Existen diferentes alternativas para realizar estos estudios, siendo la más extendida las encuestas online por el alto número de participantes que puede alcanzarse. Sin embargo, esta metodología se basa principalmente en mostrar imágenes, sobre las que los encuestados deben valorar el nivel de riesgo de una infraestructura o un elemento de la misma. Al tratarse únicamente de imágenes la percepción del riesgo no es comparable a la real, sino que se basa principalmente en la experiencia de la persona que responde.

Por ello, en este estudio se ha desarrollado una nueva metodología para estudiar la percepción del riesgo que los ciclistas experimentan ante ciertos diseños de las carreteras por las que circulan y su equipamiento. Esta metodología consiste en el recorrido de varios tramos de carretera sobre una bicicleta instalada en un rodillo de entrenamiento, visualizando los recorridos en una PowerWall y con gafas de realidad virtual, en una sala adecuadamente insonorizada.

Tras la realización de los recorridos, los voluntarios indicaron su Percepción Subjetiva del Riesgo (PSR) tanto de los tramos por los que circularon como de las intersecciones que en ellos se encontraban, valorando el riesgo de los mismo de 1 a 5. De esta forma, se han identificado las intersecciones y los tramos que suponen un mayor riesgo para los ciclistas.

Sin embargo, el resultado más importante ha consistido en los comentarios de los propios ciclistas mientras realizaban los recorridos, identificando los elementos que consideraban como un mayor riesgo para su seguridad. Entre ellos destacan, en el caso de los carriles bici segregados, la falta de mantenimiento de la infraestructura, la falta de señalización y el inadecuado diseño de las entradas y salidas del carril bici. Mientras que, en el caso de los recorridos realizados por la calzada, los elementos que aumentan el riesgo según los ciclistas son una anchura reducida de los arcenes, especialmente si estos son coloreados, el estado del pavimento del arcén, las barreras de seguridad metálicas y el diseño de los márgenes (acequias y desniveles). Aunque todos coinciden en que el mayor riesgo es el comportamiento de los conductores de vehículos motorizados.

Adicionalmente, se les preguntó a los voluntarios sobre su preferencia a la hora de circular por el carril bici o por la calzada, concluyendo que prefieren en su mayoría por el carril bici, siempre y cuando este esté adecuadamente mantenido, su anchura sea suficiente y, sobre todo, que las entradas y salidas estén libres de obstáculos y no supongan una reducción considerable de la velocidad para los pelotones, ya que en ese caso la probabilidad de caídas es alta.

Finalmente, se han comparado ambos sistemas de visualización, tanto en cuanto al grado de inmersión como en cuanto a sensación de mareo. Mientras que el grado de inmersión es mayor en el caso de las gafas de realidad virtual, gracias a su imagen envolvente y a la calidad de la misma, la sensación de mareo también es mayor en ellas. Sin embargo, la mayor parte de los voluntarios realizaron las pruebas sin sufrir una sensación de mareo significativa.

Estos resultados muestran esta nueva metodología basada en la realización de entrevistas a voluntarios circulando con gafas de realidad virtual como una buena opción para identificar los elementos que suponen un mayor riesgo para los ciclistas al circular por carreteras convencionales. Con ello, aumentando la muestra se podría llegar a valorar el potencial impacto que algunas medidas de seguridad vial tienen en el comportamiento de los ciclistas y en su percepción del riesgo.

AGRADECIMIENTOS

El presente estudio forma parte del proyecto “Bike2Lane - Mejora de la seguridad vial y operación de carreteas convencionales con ciclistas” con referencia TRA2016-8089-R, subvencionado por el Ministerio de Economía, Industria y Competitividad dentro del Plan Estatal de Investigación, Desarrollo e Innovación Orientada a los Retos de la sociedad, en el marco del Plan Estatal de Investigación Científica y Técnica y de Innovación 2013-2016.

ABSTRACT

Rental bikes are popular in many urban areas to help people expand their mobility. It is important to make the rental bicycle usable and available to the general public at the appropriate time and place. Inevitably, providing the city with a steady supply of rental bicycles becomes a major concern. The most important aspect is the estimation of the number of bicycles required in each bicycle sharing station at any given hour. This paper gives an examination of human mobility as indicated by bicycle renting information of the bike sharing system. In this paper, we proposed a new approach for forecasting the bike inflow and outflow from one station to another during certain time slots. Our method analyses human mobility pattern by two steps: (1) Using Tuckers tensor decomposition to create a 3D tensor to model human mobility and extract latent temporal and spatial characteristics of various stations and time slots. (2) to use a Long-Short Term Memory

Neural Network to model the relationship between mobility patterns and the derived latent spatial and temporal features in order to predict bike flow between stations. The main contribution of this study that with the extracted latent characteristics through Tuckers factorization we improve the accuracy of prediction by 16% and decrease the amount of training data that used in prediction. Also, a root mean squared error of prediction is 1,5 bike.

We compare our model with baseline models as historical average, ARMA, the feed-forward neural network, and KNN. The proposed method showed the best results

1. INTRODUCTION

Public bike rental systems have become popular in recent years. People increase attention to bicycles because of their flexibility, low cost, and benefit for health. The list of cities, that provides public bike-sharing systems are still growing. A bike-sharing world guide can be found from the following link www.bikesharingmap.com.

For the ideal execution of such frameworks, there must be (a) the likelihood of finding a bike when the client needs to start the ride, (b) the likelihood of leaving the bike at the client's destination, and (c) the distribution of bike stations around the city.

To avoid overgrowing the structure, there are two different ways to solve these problems: firstly, inform the client in advance about where to get or leave bicycles, and improve the redistribution of bicycles from entire stations to empty ones.

In this study, we developed a solution to these problems by analysing cyclical mobility models, which we then used to predict hourly the number of bicycles available at stations by predicting inflow and outflow between stations. These predictions will be made by the current bike rental systems; increase user satisfaction with the system. Knowing the established patterns that follow people can lead to optimization of the bike sharing system, forcing the operator to predict in advance overcrowding or shortage of bicycles at precise stations and optimize their redistribution according to the situation.

The understanding of human mobility and find traveling patterns of passengers is crucial for public transportation systems, taxi providers, and bike renting companies because predicting it accurately can increase citizens living conditions and increase profit of transportation companies. The transportation-related works published in different fields, such as sociology, urban planning, computer science and other areas. In this section, some studies on human mobility discussed.

Many machine-learning algorithms were used to predict the demand for bicycles. Jia et.al (2019) used a Gaussian mixture model for the bike-sharing system clustering to group stations by migration trends, then apply the gradient boosting regression tree to predict renting traffic. Sathishkumar et.al. (2020) applied the data mining technique to predict hourly rental bike demand and found that Gradient Boosting Machine showed the highest and best result. Graph structured information was added to deep learning models in the study of Yang et.al. (2020) to short term forecasting of travel demand. Feng et.al. (2017) analysed the future availability of bicycles at cycle stations using instant analysis of a Markov chain model with continuous time and time-dependent metrics. A random forest model applied in work of Huang et.al. (2013) to predict the demand of bikes, and then authors applied the hub-firs-route-second bike repositioning technique to redistribute bikes.

Raviv et. al. (2013) analyses bike-sharing systems imbalances caused by various levels of attractiveness and generation of station-level trips. Systems and Lacker (2013) and Garcia-Palomares (2012) provides efficient bike redistribution strategies to reduce bike distribution imbalance. With a similar goal of introducing a more balanced system, other studies by Khatri (2015) modeled demand or developed models that optimize the location of stations. Wergin and Buehler (2018) have focused on the GPS analysis of casual cyclists' routes. Artificial neural networks have been widely used in several fields of transportation engineering. The work of Polson and Sokolov (2017) found the fact that the deep learning architecture can capture spatio-temporal effects and deep learning provides accurate short-term traffic flow predictions. The temporal relationship is significant in the task of a forecasting time series. LSTM is a time series prediction algorithm that designed to merge short-term and long-term time information with good forecasting performance.

Zhao et al. (2015) proposed an LSTM model in which the two measurements straightforwardly shown to the spatial-temporal association with inspect the spatio-temporal connections in busy time gridlock transfer. The work of Yu et al. (2017) proposed a combined deep LSTM approach that uses deep LSTM to reenact normal traffic from case in exceptional conditions. Ma et al. (2015) used another deep LSTM on far off microwave sensor information to catch non-linear traffic elements.

2. METHODS

In this work, to predict the demand of bikes, first, we modelled human mobility patterns using tensor decomposition, and then this pattern was used to estimate the number of bikes to be taken and returned to stations. We compress all historical bike trip data to the 3-dimensional tensor to reduce the amount of input data for training model as shown in Fig.1. We use tensor to extract mobility patterns. Only this pattern is used to train model. Also, for training the model we use last month's trip information and weather condition information. This section describes the tensor model, a model for prediction, and input parameters to the model.

2.1 Tensor model

According to the study of Kolda and Bader (2009) tensor is an array with more than three-dimension. A higher order tensor decomposition used to compress a volume of data or to find some dependencies between data. Tensor decomposition is widely used in graphical analysis, numerical analysis, computer vision, data mining, neuroscience, etc. In this article, we propose to simulate the movement of a bicycle between different stations using a three-dimensional tensor $\mathcal{H} \in \mathbb{R}^{N \times N \times L}$, as shown in Figure 1.a. The first tensor dimension $\mathcal{H}$ means the identifiers of the source cycling stations, the second dimension means the N identifiers of the destination stations, and the third dimension means the L time intervals.

Each element of the tensor $\mathcal{H}$ (i, j, l) stores an average amount of trips from station i to station j over a period of time l. With this tensor model, we extract the latent spatial characteristics of each source station, destination station, and the latent temporal characteristics of each time slot using the Tucker decomposition.

The Tucker is a higher-order principal component analysis technique (PCA). In each dimension, it decomposes a tensor into a base tensor multiplied by a matrix. In our case, we decompose the tensor $\mathcal{H}$ into three matrices $o \in \mathbb{R}^{N\times P}$, $Sd \in \mathbb{R}^{Q\times N}$, $T \in \mathbb{R}^{L\times R}$ and the base tensor $G \in \mathbb{R}^{P\times Q\times R}$, as shown in Fig. 1. In terms of a mathematical formula, this relationship can be written as in equation (1):

$$\mathcal{H} \approx G \times {}_1So \times {}_2Sd \times {}_3T \quad (1)$$

The feature vector indicating the characteristics of origin station i is the row i of matrix So after tensor factorization. The feature vector indicating the characteristics of destination station j is the same, the row j of matrix Sd, Sd_j. T_k is a feature vector that indicates the quality of the time gap k. The degree of cooperation between different components of So, Sd, and T is specified by each element of the core tensor G.

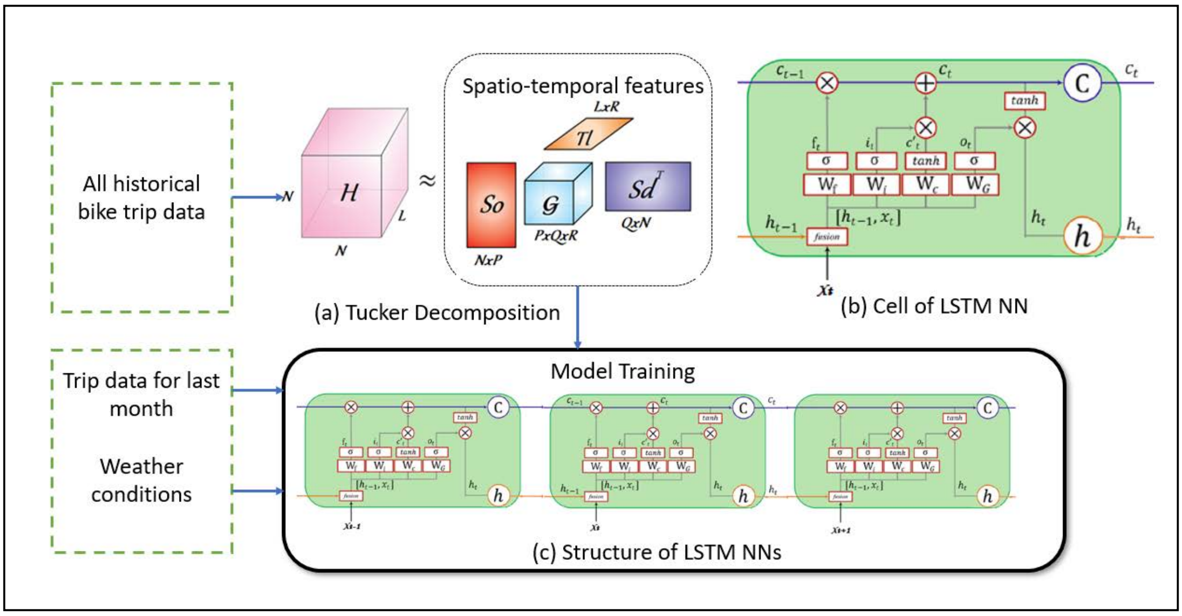

Fig. 1 – Illustrations of LSTM NN and its inputs.

The volumes of outflow $x_{oj:k}$ and inflow $x_{lj:k}$ of a station i at time gap k are under on their hidden spatial features So_i, Sd_j, latent temporal features T_k , and their previous values, $x_{oi:k-1}$, $x_{li:k-1}$ respectively. This is verified using the PC algorithm in the work of Guo and Karimi (2017). To see this dependency, we draw the values of the matrix T when P, Q, R is equal to 1 (Fig. 2). According to the graph, we have two maximum points at time slot (8-9) in morning rush hour, and at time slot (17-18) in evening rush hour. In addition, there is a minimum number of bike riders in the early morning. Likewise, the sum of all bikes taken from one station is high correlated with So matrix. Correlation coefficient is 0.806. It means that these values can be used to estimate the demand for bikes.

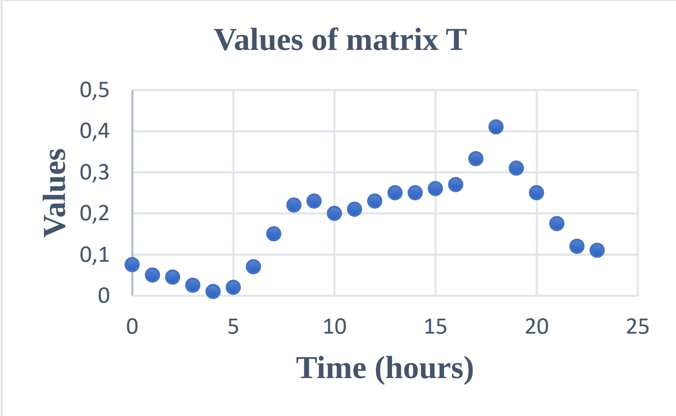

Fig. 2 – Values of matrix after tensor decomposition

2.2 Model Inputs

Anticipating the inflow and outflow of groups in each the bicycle sharing station is exceptionally testing, influenced by the accompanying three complex components:
Spatial conditions. The inflow of one station is influenced by outflows of another close-by stations. In like manner, the outflow of one station would influence the inflows of other stations.

Temporal conditions. The flow of groups in a station is influenced by ongoing time stretches, both all over. For example, a traffic flow happening at 8 am will influence that of 9 am.

Moreover, traffic conditions during morning times of heavy traffic might be comparable on successive workdays, rehashing like clockwork. Moreover, morning heavy traffic times can continually occur later when winter comes. At a time when temperatures constantly drop and the sun rises later, people rise later and later.

External conditions. Some external variables, such as climatic conditions and circumstances, can dramatically alter the flow of groups in different locations in a city. There spatial conditions and worldly conditions are separated from Tucker decomposition. The external impact is very troublesome. The traveler streams can be influenced by different outside elements, for example, climate and occasions. To investigate the impacts of these variables, Liu et al (2019) looked at traveler streams under various conditions. The precipitation information got for the examination records the evaluation of precipitation. Creator contrasted with a typical day, occasion, and end of the week have an obvious impact on the traveler streams. For example, on the off chance that a hefty downpour is seen on Monday, we will at that point contrast it and the information of past Monday to guarantee that they have similar qualities. To see is there some closeness in non-weekend days we look at them.

We found that the use of bicycles does not generally rely upon workday or end of the week data. At last, non-weekend day data, season of the day, and grade of precipitation is included as info boundaries for the demonstrating. Ashqar et.al. (2019) investigated climate conditions on bicycle checks and found that mugginess, season of-day, and temperature are noteworthy indicators of bicycle tallies. These boundaries were taken as an outer impact for forecast.

For metadata (for example, day of the week, hour of the day, and rainfall estimates), the insertion procedure is used to plan irreducible qualities in 3D vectors. It should be noted that the provisioning suite and the test suite are processed using the same bounds. At this point, the model itself can learn the data, which improves the accuracy of the predictions.

3. RESULTS AND DISCUSSION

The methodology given in this paper is trained and tested on public data available on web site https://www.citibikenyc.com/system-data. There can be found information about all CitiBike New York users' trips and annual monthly reports from May 2013. The data used in work contain records from 1st January 2017 to 31st December 2017 and January 2018. We use all data for 2017 to build 3D tensor and used data of January 2018 to test and train the model. From January 2018, we chose the last 10 days as the testing set and the left samples as the training set. In this case, the time period for traffic aggregation for forecasting is 1 hour. It's worth noting that if the chosen time interval is too short, the forecast would be incorrect and meaningless. Furthermore, short-term flows are often trivial, making the prediction approach difficult to use. We used the Min-Max normalization technique to scale the passenger traffic data in the range [-1, 1] for both the training and test sets. During estimation, the normalized predicted values are scaled and compared to the actual performance.

The results of the proposed method are compared with the following baseline models:

Historical average: We use the average historical supervision at the same time gap, the average of the past week's bike flow at the same time gap is set as the prediction outcome.
ARMA: Autoregressive moving-average model - is the mathematical model used for the forecasting and analysis of stationary time series data in statistics. The ARMA model combines two simpler time series models - the autoregressive (AR) model and the moving average (MA) model. The ARMA(p, q) model, where p and q are numbers showing the order of the model, a time series {Xt} is generating by next process:

$$X_t = c + \varepsilon_t + \sum_{i=1}^{p} \alpha_i X_{t-i} + \sum_{j=1}^{q} \beta_j \varepsilon_{t-j}, \quad (2)$$

Where c is a constant, ε_t is white noise, that is, a sequence of identically and independent normally distributed random variables, with zero mean, and $\alpha_1, \dots, \alpha_p$ and $\beta_1, \dots, \beta_q$ – autoregressive coefficients and moving average coefficients.

This model can be explained as a linear multiple regression model, in which the previous values of the dependent variable itself go as illustrative variables and moving averages of white noise elements go as the regression remaining.

FFNN: The dynamic nonlinear relationship between different variables can be captured by a feedforward neural network. We use the passenger flow in recent tree adjacent time intervals to reflect temporal dependencies in FFNN. (i.e. $[x_{t-1}, x_{t-2}, x_{t-3}]$).

KNN: K-nearest neighbours' algorithm, k-NN - a metric algorithm for automatic classification of items or regression. In our case, the object is given an average value based on the k objects closest to it, whose values are already known, using the regression method. In this article, we use a value of 4 for k..

The study's efficiency metrics are as follows: Root Mean Square Error (RMSE), , Mean Absolute Error (MAE), Symmetric Mean Absolute Percent Error (SMAPE), and Mean Relative Error (MRE).

The proposed methodology is assessed using RMSE, SMAPE, MRE, and MAE. The outcomes are shown in Table 1.

Performance metrics	HA	ARMA	FFNN	KNN	LSTM	LSTM ST
SMAPE	92.5	88.	48.1	46.4	46.1	44.2
RMSE	3.3	3.1	2.5	2.4	2.4	1.5
MAE	2.1	1.9	1.5	1.5	1.5	1.2
MRE	72.8	66.8	65.7	61.9	59.2	47.6

Table 1- Performance comparison

Different variation models were checked and compared to the baseline outcome to assess the forecast accuracy of the models in terms of RMSE, SMAPE, MRE, and MAE. Table 1 shows that using only the average bike flow over the previous time period (Historical average) results in a lower forecast.. Autoregressive models show better result than just calculating average. The accuracy remarkably improved when we apply FFNN, KNN and LSTM NN models. If we compare results of FFNN, KNN and LSTM NN, LSTM NN is better than other models, because LSTM NN model best suits for time series forecasting problem.

Models FFNN, KNN, LSTM accuracy approximately the same, the error in the number of bikes is about 2 or 3. But after applying the Tucker decomposition result error decreased to 1 or 2 bikes. That is good enough to help a bike managements system to improve the availability of bikes and docks in stations. The Tensor model increased forecasting accuracy for RMSE metric to 15 % from 2.43 to 1.53

4.CONCLUSION

We proposed a method for forecasting spatial-temporal bike mobility patterns, namely the inflow and outflow of bicycles from one station to another during a time gap. Our approach consists of two stages: (1) using a 3D tensor to model human mobility and recovering hidden spatial and temporal characteristics such as origin and destination stations and timeframes through tensor factorization; and (2) determining a connection between mobility patterns and recovering hidden features using a Long-Short Term Memory Neural Network for human mobility forecasting. We conduct a study of bicycle trips in New York City in order to validate the proposed technique. The results showed that the recover hidden features effectively identify attributes of timespans and spatio - temporal features with a strong correlation coefficient with bicycle sharing station inflow and outflow. The proposed method for extracting hidden characteristics can be applied to existing models to increase precision (MAE error is reduced by 16 percent).

By picking up from past historical bike rent data and past weather information, the proposed LSTM model with Tucker decomposition results can foresee the interest in bikes at a particular time. Considering the estimate, we can make the proposal for bike associations about how to scatter the bikes expressly to each station to satisfy the need of customers similarly as saving a silly cost of keeping bikes. The use of the proposed model will be a useful answer for both the bike renting organizations and the bike riders

ABSTRACT

People face different barriers when choosing to commute by bike. The predominance of these barriers in users' perception could explain the low cyclability rates present in many cities. An investigation of cyclists' perceptions is developed using the data set obtained through a survey made to individuals from Quito, Ecuador. This study is aimed to evaluate the perception of a group of individuals about barriers to bike use, in particular, assesses how perception varies according to the available information and the different profiles. Using ordered probit models, the study compares the overall evaluation of bike acceptance before and after making individuals reflect on the importance of certain variables (e. g. lack of bike infrastructure, city temperatures, etc.). The main results show that to improve bike use acceptance, enhancing multimodality or providing facilities like electric bikes must be considered. The results also demonstrated a high heterogeneity of individuals' perceptions caused by their socio-demographic characteristics and the environmental context.

1. INTRODUCTION

Nowadays cities face major environmental, socio-economic, and transport challenges, whereby, the importance of promoting non-motorized modes of transport such as the bicycle, is recognized. Bike transportation offers many important benefits at environmental, health, social interaction, and urban mobility levels. However, despite its wide advantages, regular bike use is still not broadly accepted in many cities, especially in Latin America (Gutiérrez, Hurtubia, & Ortúzar, 2020; Keeling, 2013). The unconcern in integrating the bicycle in urban mobility has caused several challenges including identifying the most effective ways to spend the resources, usually limited, allocated to its promotion. Commonly, bike mobility planning is focused primarily on solving the service from a technical perspective (e.g. proposing the fastest routes or with lower agency costs). However, several authors conclude that to achieve a positive bike assessment and its acceptance among users, the system must also comply with other subjective aspects that respond to individuals' needs (Cepeda

Zorrilla, Hodgson, & Jopson, 2018; Heinen, Maat, & van Wee, 2011; Jakovcevic, Franco, Visona Dalla Pozza, & Ledesma, 2016).

From this perspective, in contexts with low rates of bike use, it seems reasonable to focus on identifying the weakest points of the system to work and invest in them, reducing the risk of investing in solving other aspects that will not necessarily motivate people to commute by bike (Dell'Olio, Ibeas, & Cecín, 2010).

This study aims is to identify the barriers that influence individuals around bike use, as well as obtaining the comparative weights of each of these variables. Previous studies have proven that *Ordered Probit Models* are satisfactory for the analysis of categorized or non-quantitative ordered choices and replies (Dell'Olio, Ibeas, De Oña, & De Oña, 2018c). The contribution is a model that identifies and ranks the perceived barriers of bike use, therefore, this research pretends to better understand citizens' needs to facilitate better bike mobility planning.

This work is divided into several parts. First, a brief contextualization of the problem is presented. Afterward, the methodology, the collected data, and some results are discussed. And to finish, the main conclusions are presented.

2. LITERATURE REVIEW

2.1 Choice to commute or not by bicycle

Studies conclude that bike commute decision is highly complex since it can be influenced by both objective and subjective factors (Konstantinidou & Spyropoulou, 2017; Muñoz, Monzon, & Lois, 2013). This section describes the role of psychological factors, such as attitudes and perception towards bike use in its acceptance among individuals. These factors are related to travel motivations, socio-economic, journey, and environmental characteristics, among others (Cepeda Zorrilla et al., 2018; Majumdar & Mitra, 2013).

Likewise, other authors conclude that these aspects are not necessarily equally perceived by all individuals or have the same weight in the overall perception of the service (Dell'Olio et al., 2010; Weinstein, 2000). Therefore, the importance of understanding the relationship between individuals' perception towards bike use and their different profiles is recognized (Dell'Olio et al., 2010; Dell'Olio, Ibeas, De Oña, & De Oña, 2018b; Garrido, De Oña, & De Oña, 2014).

The literature suggests that aspects such as the *weather conditions* incluiding the *temperature, rain or wind* (Fernández-Heredia, Monzón, & Jara-Díaz, 2014; Freitas & Maciel, 2017; Heinen, Maat, & van Wee, 2011; Helbich, Böcker, & Dijst, 2014), *long-distance travels* (Corcoran, Li, Rohde, Charles-Edwards, & Mateo-Babiano, 2014; Fernández-Heredia et al., 2014; Heinen, Maat, & Van Wee, 2011; Konstantinidou &

Spyropoulou, 2017), *lack of well-connected and high-quality cycle-path networks* (Buehler & Pucher, 2012; De Sousa, Sanches, & Ferreira, 2014a; Fernández-Heredia et al., 2014; Gutiérrez et al., 2020; Konstantinidou & Spyropoulou, 2017), the *perception of risk* (Fernández-Heredia et al., 2014; Gutiérrez et al., 2020), *traffic insecurity* (Branion-Calles, Nelson, Fuller, Gauvin, & Winters, 2019; Muñoz et al., 2013), *topography* (De Sousa, Sanches, & Ferreira, 2014b; Fernández-Heredia et al., 2014; Majumdar & Mitra, 2013), *physical abilities* (Branion-Calles et al., 2019; Freitas & Maciel, 2017; Majumdar & Mitra, 2013), *insecurity against crime and vandalism* (Eren & Uz, 2019), and the *personal appearance* (Iwińska, Blicharska, Pierotti, Tainio, & de Nazelle, 2018) affect bike commutes and reduce the frequency of trips.

Wide studies have investigated barriers to cycling, however, this number is limited when identifying the weight of each variable in individuals' perception (Handy, van Wee, & Kroesen, 2014; Porter, Suhrbier, & Schwartz, 1999). Dell'Olio, 2010 among others authors (Dell'Olio et al., 2010; Garrido et al., 2014; Weinstein, 2000) have estimated the different influence that each attribute's perception exerts on users' global assessment, focusing mainly on public transport (PT) services, however, the implemented methods are found suitable to the present study.

2.2 Service Quality and User Satisfaction

Service Quality (SQ) has been widely studied since Parasuraman, Zeithaml, & Berry (1985) first introduced it, defining SQ as the difference between both, the expected and the perceived quality of service. User perceived quality has been shown to have a positive effect on user satisfaction with transport services (Braun et al., 2016; J. De Oña, De Oña, Diez-Mesa, Eboli, & Mazzulla, 2016; Rocío De Oña, 2013). However, evidence suggests that although users perceive a good quality of service, taking this indicator as a criterion of success could be precarious, hence, it cannot be used as the only reference when planning policies aimed at retaining customers and attracting new ones (J. De Oña et al., 2016; Dell'Olio, Ibeas, De Oña, & De Oña, 2018a; Fernández-Heredia et al., 2014).

Parasuraman et al. (1988) suggested that for the study of the SQ of transport services, their defining variables or attributes should be established, proposing a generic list of 22 attributes and dimensions applicable to any type of service. However, many authors criticized this generic list stating that the attributes must respond to each specific case (Babakus & Boller, 1992). Likewise, other evidence demonstrates that the predictive value of the model developed by Parasuraman et al. 1988 increased when the items were adapted to the study context (Carrillat, Jaramillo, & Mulki, 2007). The key then is to enlist the generic attributes but adding other aspects own of each specific context and service.

Diversity of methodologies and tools have been developed to evaluate SQ variation according to users' preferences. For example, *satisfaction surveys* allow researchers to associate quality perception to a type of user classifying them accordingly to their socio-economic and journey characteristics (Alonso, Barreda, dell'Olio, & Ibeas, 2018; Bordagaray, Ibeas, & Olio, 2012; Branion-Calles et al., 2019). Others studies establish this relationship by developing methodologies based on *structural equations* (J. De Oña, De Oña, Eboli, & Mazzulla, 2013; Rocio De Oña & De Oña, 2015; Dell'Olio, Ibeas, De Oña, & De Oña, 2018d) or the application of *decision trees*, the latter permits to generate models able to differentiate between different kinds of users (Rocío De Oña, 2013). Likewise, other not model-based methods have provided interesting results, such as *descriptive statistics* (Eboli & Mazzulla, 2011) or *neural networks* (Garrido et al., 2014).

Ordered probit models have proven to be a highly efficient and useful tool for modeling perceived quality (Alonso et al., 2018; Bordagaray et al., 2012; Dell'Olio et al., 2010, 2018c). This particular methodology allows ordered qualitative responses to be modeled, meaning that the *non-linearity* existing between the different replies can be considered (Dell'Olio et al., 2010, 2018c). Another key feature of the model is its ability to use interactions to incorporate systematic variations resulting from the socio-economic characteristics of the different users (Bordagaray et al., 2012), assuming that these factors follow a *statistical distribution*.

However, evidence on the combination between systematic and random variations in the same model, as well as the inclusion of attributes' importance within the modeling of bike use perception is limited (Porter et al., 1999). Therefore, using *ordered probit models,* the present research aims to fill this gap and complete the knowledge about bike use perception, by studying the *relative importance* of barriers to bike use in the general individuals' perception (Dell'Olio et al., 2018b).

3. METHODOLOGY

3.1 Description of the study area

The city of Quito has an area of 372 square kilometers and approximately 1.7 million people (INEC, 2017). Its particular allocation close to the equatorial line, its altitude, and its closeness to the Andes mountain range gives the city special climate conditions (spring relatively constant throughout the year), and a mostly irregular landscape with steep slopes (IGM, 1992). In 2011, inhabitants' global mobility rate was 2 trips per day, which is equivalent to almost 3.4 million daily trips. From these, the majority were made by public transport (62%), 20 % by private car, 15% by foot, and only 0.3% by bicycle (Metro de Quito, 2012). Since 2012, Quito has a Public Shared Bicycle Service (BiciQuito) and a 173 km long cycle path network of which only 32% are exclusively for bikes, the rest are shared spaces with pedestrians or motorized vehicles.

3.2 Data Collection

Data collection was conducted in the city of Quito, Ecuador. After a deep literature review aimed to identify psychological, socio-economic, environmental, and travel-related factors that could affect bike use, in particular, the barriers, a first draft of the survey was developed and presented to specific groups of individuals from the study area.

Afterward, considering this first stage's feedback, a second draft was designed and applied in a pilot survey tested to verify the clarity of the questionnaire and to ensure the proper capture of the information necessary for the model estimation. The final survey was applied via the web in the last week of January of 2021 and collected 422 completed forms. Figure 1 presents a flow chart of the process.

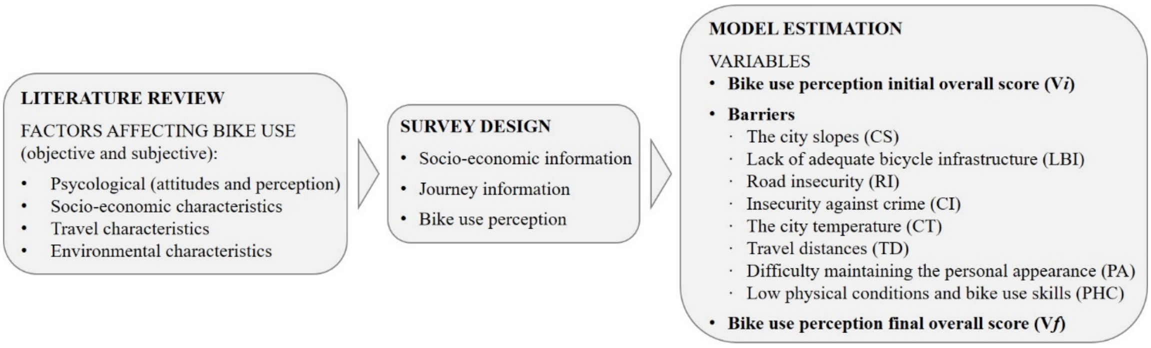

Figure 1 – Methodology flow chart

Survey design

The questionnaire consisted of two main segments. The first part collected information about the person's *socio-demographic* and *journey characteristics* (see Table 2). This information will permit respondents' stratification into different profiles. The second part enclosed bike use perception and consisted in asking an individual to give an opinion about a subjective aspect related to bike use, in this case, a barrier. This segment consisted of three questions.

The first obtained a first valuation of the bicycle as an option to commute, representing individuals' initial opinion based on the information they have, ergo, their understanding of the service through the personal experience. The second gets separate values for each of the previously defined variables (barriers). The third and final question was asked right after individuals valued each barrier and consisted in a second score of the overall perception of bike use. This second score is required to analyze any changes on the bicycle's global score once individuals have had the opportunity to analyze every aspect that makes up the system.

Namely, to check the degree by which they changed their opinion after the reflection made on each barrier that may be affecting bike use (Dell'Olio et al., 2010, 2018b).

The set of selected barriers was: city slopes (CS), lack of adequate bike infrastructure (LBI), road insecurity (RI), crime insecurity (CI), city temperature (CT), long travel distances (TD), difficulty in maintaining the personal appearance (PA), and insufficient physical conditions and cycling skills (PHC).

Using a 5-point Likert scale, participants were asked to rate the variables (see Table 1).

Question 1	***Do you agree that the bike, in your city, is a good option to commute?***								
			Strongly disagree	1	2	3	4	5	Totally agree
Question 2	***The following aspects could DEMOTIVATE bike use, how much do you think they influence?***								
	Variable		Very influential	1		→		5	Not influential
	CS	The city slopes							
	LBI	Lack of adequate bicycle lanes and parking slots							
	RI	Fear of having a traffic accident							
	CI	Insecurity against crime							
	CT	The temperature of the city (too cold, too hot)							
	TD	Travel distances							
	PA	Difficulty maintaining the personal appearance							
	PHC	Low physical conditions and abilities to bike use							
Question 3	***Do you consider the bicycle as a good option to commute in your city?***								
			Strongly disagree	1	2	3	4	5	Totally agree

Table 1 – Survey segment 2: Perception on bike use

3.3 Statistical Approach

The type of model was selected after collecting and analyzing the data. Since that, the dependent variables (initial and final overall bike use perception) are ordinal by nature, ordered probit models seemed to be suitable. Following the belief that latent and continuous variables cannot be measured discretely, thus the variable (bike use perception) is intended to be segmented into several options associating each one of them with a range value of the latent variable (in this case from 1 to 5). The key idea of this method first proposed McKelvey & Zavoina, (1975) is that allows to transform a continuous latent variable into an ordered, observed, and discrete reply, so when individuals select an option, are in fact selecting not a discrete value but rather the closest answer to their true perception, of bike use in this case (Alonso et al., 2018; Dell'Olio et al., 2010, 2018a, 2018c; Echaniz, Ho, Rodriguez, & dell'Olio, 2019).

Segement 2 of the survey regarding bike use perception was performed as follows:

1st. *Initial overall valuation* of bike use (V_i).

2nd. Scoring the eight variables previously identified as possible *barriers* to bike use.

3rd. A *second overall valuation* of bike use (V_f).

Two types of models were estimated for the different profiles of respondents. Both V_i and V_f were related separately to the variables identified as possible barriers to bike commute. The first model aims to identify which variables are unconsciously relevant when an

individual decides not to commute by bike, and the second, which variables would individuals consider as important after having more information about the service.
According to the literature a *probit ordered model* consists of a direct relationship between the dependent variable, in this case, bike use perception -initial (V_i) and final (V_f) scores-, and the independent variables (barriers) V_{ik}. A constant β_0 and an estimation error ε_i associated with individuals' heterogeneity complements the model (Dell'Olio et al., 2018c).

The models are based on the following mathematical expression:

$$Q_i^* = \beta_0 + \sum_{k=1}^{N} \beta_k \cdot V_{ik} + \varepsilon_i \qquad \text{with } k \in [1, 2, \dots, N] \tag{1}$$

$\mathbf{Q}_i$ represents the general evaluation of the person i; $\boldsymbol{\beta_0}$ the model constant; N the number of evaluated bike use aspects (barriers); β_k the coefficient of the variable *k (barrier)*; V_{ik} is the valuation made by each individual *i* of each variable *k*.

To fit the models Log Likelihood function was used:

$$\log L = \sum_{i=0}^{n} \quad \sum_{j=0}^{J} m_{ij}\, log\left[F\left(\mu_j - \beta'_{V_i}\right) - F\left(\mu_{j-1} - \beta'_{V_i}\right)\right] \tag{2}$$

Once the corresponding models were estimated for each individuals' categories, possible relationships between them were identified.

4. RESULTS AND DISCUSSION

4.1 Initial data analysis

First, the data set composed of 422 observations were analyzed to characterize individuals' profiles as shown in Table 2.

Variable	Category	Frequency	Percen
Sample		**422**	
Gender	Female	186	44%
	Male	236	56%
Age (years)	< 24	121	29%
	25 to 44	142	34%
	45 to 64	132	31%
	> 65	27	6%
Main occupation	Student	104	25%
	Dependent worker	87	21%
	Self-employed or independent worker	57	14%
	Home care	62	15%
	Unemployed	91	22%
	Retired/pensioner/other	21	5%
Household income	< 400 USD	75	18%
	400 - 800 USD	166	39%
	800 - 1.200 USD	135	32%
	> 1.200 USD	46	11%
Mode of transport	Walking	43	10%
	Bicycle	23	5%
	Public Transport (bus, BRT)	186	44%
	Private car	31	7%
	Motorcycle	14	3%
	Taxi / Service on demand (Uber, Cabify)	27	6%
	Teleworking / No commute	98	23%

Table 2 – Profile of respondents

As explained in subsection 3.3, the overall valuation of bike use was asked twice, the first (V_i) immediately before and the second (V_f) immediately after scoring each variable (barriers) separately (see Table 1). So, the difference between V_f and V_i will show if there were any changes in people's opinion concerning the first valuation. The results showed that around 60% of individuals changed their score, either positively or negatively (see Tables 3 and 4). When categorizing the surveyed according to the previously defined characteristics (22 categories), some differences could be identified (see Tables 3 and 4).

In all categories, the second valuation had a higher score than the first, generally double, except for two: *bike users* and private car users, from now on *car users* (see Tables 4 and 5). These results show that people tend to be more critical than they would be if they had more knowledge about the service, that is, ignorance or misinformation prevents them from evaluating it impartially. Seem to be that, in the initial valuation(V_i), individuals tend to perceive more negatively the barriers. In this case, these results can be explained by the lack of familiarity with bike use present in the majority of the inhabitants of the city of study (see Table 1). However, in other contexts where bike use for commuting is more positioned, the results would be different. Since previous findings suggest that an individual is more positive towards modes that are included in the daily mobility patterns compared to the modes that are not (Ton et al., 2020).

Regarding the ‘working' category, this second higher evaluation could be because respondents possibly realized those bike use barriers would not actually be as influential for cycling. Since evidence suggests that bike use is more prevalent in young people, for reasons such as the smaller technological gap compared to other ages, resulting in more openness to route planners or bike-sharing systems (Goodman, Sahlqvist, & Ogilvie, 2013). About the positive variation of PT users, this is not necessarily unexpected. It is in accordance with previous studies that conclude the clear tendency to change from PT to cycling. This could be because users may find PT to be a relatively inflexible (and sometimes unreliable) mode, therefore they would choose more flexible options such as the bicycle (Thorhauge, Kassahun, Cherchi, & Haustein, 2020). Furthermore, in many cities, PT service quality is poorly perceived (Cepeda Zorrilla et al., 2018; Mark & Heinrichs, 2019), so the bike can be seen as a better choice. A fact that, within the bad, could be seen as an opportunity to position it in the urban transport offer.

This knowledge is important, since policies aimed at improving certain factors may have little effect on people's opinion if aspects with an apparently greater weight than they actually do are prioritized. Therefore, any strategy seeking to increase bike use acceptance must first focus on knowing what are the aspects that really influence people's perception.

The difference between V_f and V_i is denoted below by δ_{value}.

$$\delta_{value} = V_f - V_i \tag{3}$$

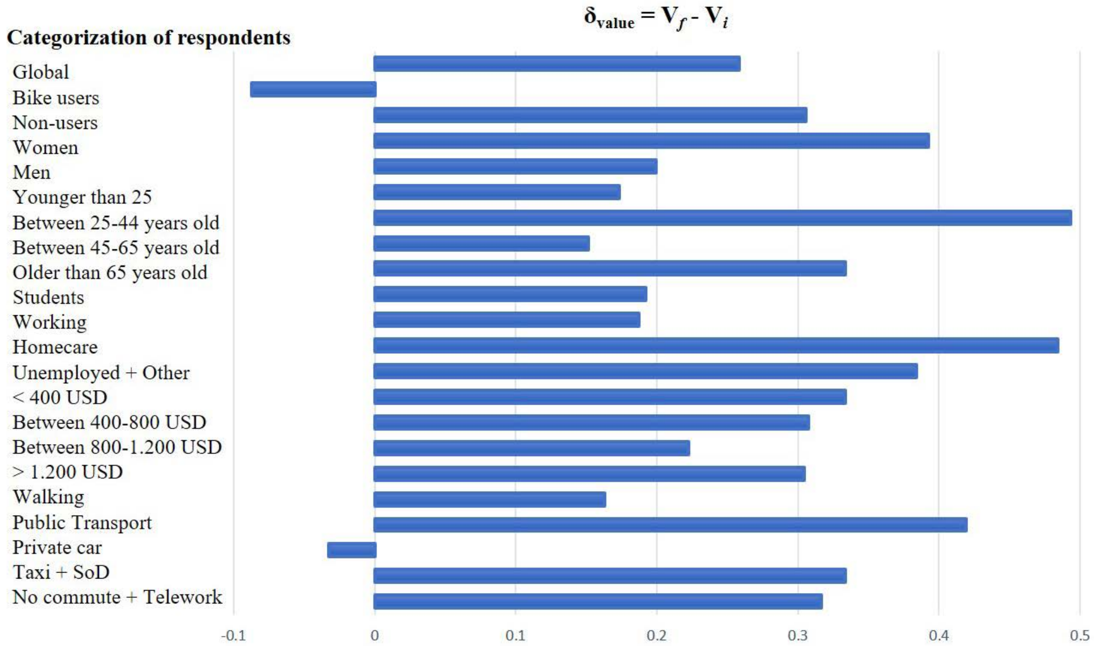

Table 3 – Variations on δ_{value} according to respondents' categorization

Given that bike use V_f trending was to change positively, this paper presents the *models* estimated for the two categories which did so negatively: *Bike users* and *car users*.

The negative change in bike users can be explained because in contexts with poor cycling facilities and lack of incentives, in short, non-friendly cycling mobility contexts, people who decide to commute by bike do so out of beliefs and not out of any kind of incentives (Iwińska et al., 2018; Jakovcevic et al., 2016). In other words, they are bike commuters 'no matter what', with which the reflection process may have made them focus on the weakest aspects of the system and therefore have been more critical. This agrees with previous studies concluding that bike use incentives work in the first stage, as a hitch for new users. However, if the aspects that users identified as barriers from the beginning are not improved, they will not find benefits in using it once the incentives are removed, and therefore, they will stop doing it (Jakovcevic et al., 2016). Therefore, it is important to prioritize the improvement of the weaknesses of the system if what is sought is the retention of users and the creation of habits.

4.2 Estimated models

Special statistical software STATA was used for its capability to estimate *ordered probit models* (Simons, 2018; StataCorp, 2017). These models were developed to work with the ordinal-natured dependent variables, in this case, V_i and V_f. Two models were developed: one for *bike users* and one for *car users*. The final data set enclosed 54 observations (23 bike users and 31 car users). Each respondent evaluated 10 variables. First, to track any data error, descriptive statics was performed. Said *data cleaning* examined mean, minimum, and maximum values of the variables (see Table 6).

Bike users						Private car users				
Variable	Mean	Std. Dev.	Min	Max	Obs	Mean	Std. Dev.	Min	Max	Obs
Bike_V*i*	4.3043	1.1455	1	5	23	3.4194	1.1482	1	5	31
CS	3.3043	1.5502	1	5	23	4.1290	1.2039	1	5	31
LBI	3.9565	1.2239	1	5	23	4.0323	1.1397	2	5	31
RI	4.1739	1.3702	1	5	23	4.5161	1.0286	1	5	31
CI	3.5652	1.3425	1	5	23	3.4839	1.1796	1	5	31
CT	4.0435	1.1862	1	5	23	4.2581	0.9650	1	5	31

PA	2.8261	1.3702	1	5	23	2.7419	1.3655	1	5	31
PHC	3.3478	1.5843	1	5	23	3.1935	1.4473	1	5	31
Bike_V*f*	4.2174	1.0853	1	5	23	3.3871	1.1159	1	5	31

Table 5 – Descriptive statistics of the variables

Comparing the models, conclusions can be drawn about how the mode of transport affects the variables' evaluation (see Table 7). The most representative changes in barriers' perception are described as follows.

The insecurity against crime (CI), barrier perceived by *bike users* as important at the beginning, in the second evaluation does not appear. This may be because, as previously stated, urban cyclists choose bike use by beliefs, therefore, CI may not be such an influential factor in their perception. On the other hand, regarding *car users*, CI went from having null importance to being the most influential barrier. This finding is interesting since it shows that the reflection process to which individuals were subjected indeed had an impact on their perception, since it may be that *car users* perceive CI as the most influential barrier and that is why they decide to commute by car and not tby bike.

Physical conditions and abilities to use the bike (PHC) have the same weight in *car users*' perception in both initial and final evaluations. However, regarding *bike users*, PHC has significantly higher importance on the second valuation (in the first did not appear), this could be explained because maybe in the reflection process individuals comprehended the realities they are exposed to when using the bike (e.g. tiredness).

Travel distances (TD) represents a heavy barrier from *bike users*' perspective since they introduced this aspect after the reflection process (in the initial valuation it did not appear). This may be because individuals could reflect on the times and reasons why they do not use the bike to commute, identifying TD as an influential barrier. TD could be improved by promoting multimodality. Likewise, it is not surprising that *car users* do not take TD into account in either of the two evaluations, this may be because they are not familiar with TD as a commute barrier, as they commute by car.

Table 6 – Ordered probit models of bike users and car users

To perform a complete analysis of the results, table 7 was developed. It shows each variable's contribution (by percentage) in each of the models. The parameters of the model where the dependent variable was V_i are represented by Θ_i, and in the case of V_f, by Θ_f (see Table 8). Θ_f - Θ_i is the difference in the contribution of each variable (Θ) between the models estimated for *bike users* and *car users*.

	Bike users			Private car

4. CONCLUSIONS

This paper presents the first findings of an ongoing research aimed to identify the aspects of bike use that may be preventing its acceptance among people carried out in the city of Quito, Ecuador. Prior to this study, there was uncertainty about whether if all the elements that make out bike use have the same impact on the overall valuation, whereby the method proposed by Dell'Olio et al. (2010) is useful in identifying the *relative importance* of the barriers to bike use.

Considering their approach, the present study was performed from two points of view: Firstly, know bike use perception from the information held a priori by individuals (V_i). Secondly, to immerse individuals in a process of *problem-analysis* (bike use acceptance as an option to commute) asking them to evaluate specific aspects of bike mobility to measure the relative importance of the variables (barriers) that could be influencing their overall perception. Immediately after this phase of meditation, individuals were asked for the second time to globally assess bike use (V_f).

The two proposed situations arose when seeking to meet two objectives: 1) to identify which variables have an unconscious impact on individuals and, 2) build up valuable information on where to direct the strategies and efforts that seek to improve the overall perception of bike use, focusing on those variables to which individuals seem to be more receptive. This study increases the knowledge about the perception towards bike use according to individuals' characteristics.

The research verifies the different bike use perceptions of a group of individuals before and after having reflected on each of the components of the system. The analysis according to individuals' categorization confirms that bike use perception varies depending in this case, of the mode of transport (*bike users* vs. *car users*). On the one hand, *bike users*' reflection causes a reduction in the weight they placed on aspects such as the importance of *maintaining the personal appearance* and *insecurity against crime*, resulting in increased importance placed on *travel distances*, and the *physical conditions and abilities to use the bike*, this latter being of null importance when the initial valuation was made. Regarding *car users*, aspects such as *city temperatures* fell in the second valuation, while *insecurity against crime*, which in the first evaluation was missed, in the second evaluation was highly influential. Therefore, the greatest impact on bike use perception will be achieved by, regarding *bike users*, enhancing multimodality, and the provision of facilities for bike use such as electric bikes. Whilst for *car users* should be by focusing on *safety*.

The results of this study evidence the importance that people's socio-demographic and journey characteristics have in the perception of a service, therefore, taking into account their needs should be a crucial factor to be considered when developing strategies that seek promoting bike use. Thus, mobility services will be able to meet demand requirements to, firstly, retain existing users and, secondly, attract new ones, especially from motorized modes. Therefore, in the future, bicycle mobility planning should be the product of collaboration between different mobility actors, especially integrating people's knowledge and perception, and not a product developed solely by experts and technicians.

Given that in cities with low rates of bike commute, the majority of the population is not familiar with the benefits of cycling as a means of transport. Therefore, dissemination strategies could focus on communicating the benefits of cycling as a fast, comfortable and reliable option, presenting it as a mode of transportation and not only as a recreational activity or a healthy lifestyle (Handy et al., 2014; Savan, Cohlmeyer, & Ledsham, 2017). This could be a key factor in changing the mindset towards its adoption as a regular mode of transportation. Short-term targeted campaigns can be an effective policy measure to expose these benefits and potentially engage new users in active mobility.

The application of the proposed methodology may provide planners and policymakers with valuable information for developing strategies aimed at different profiles of people, to improve bike use acceptance and attract new users. Nevertheless, it is important to bring up that this study serves as a first attempt to capture the bike use perception of a group of individuals in a city with a particular size, topography, and climate conditions. Further research should focus on studying the preferences of other sub-groups of people (e. g. males vs. females, students vs. working population, and so on), as well as in other cities with other characteristics where different results could be obtained related to the different contexts.

ABSTRACT

The social transformation caused by the COVID-19 pandemic may contribute to make cities healthier and more sustainable, with more space available for active modes of transport. This paper addresses people's willingness to go shopping by bike or kick-scooter and to transport lightweight goods in cities with low maturity for cycling and scooting. Data collection was based on a survey, applied in the two main urban areas of Brazil (São Paulo and Rio de Janeiro) and Portugal (Lisbon and Porto). The dataset was processed considering only two categories of respondents, that is, potential users and regular users. The results indicate that people are willing to transport lightweight goods by bike or kick-scooter, as long as the infrastructure is safe and comfortable. This research contributes to understanding mobility behavior changes and to identifying barriers to shopping by bike or kick-scooter. It also presents some recommendations for improving cycling and scooting use for shopping, which can be carried out by public authorities.

1. INTRODUCTION

The world is currently facing a new mobility paradigm driven by the impact of artificial intelligence, new cleaner energy sources and public health problems caused by the COVID-19 pandemic. These trends are changing the way people work, travel and purchase goods and services. Furthermore, the definition of sustainable mobility is broad and should cover the three pillars (social, environmental and economic), based on people’s need to have access to activities that facilitate their individual and societal development (Banister, 2008).

The reasons for using the car include convenience, time constraints, transporting heavy goods, picking up or bringing people, needing the car for the following trip and facing bad weather (Beckx et al., 2013; Mackett, 2001). The high car ownership rates, combined with a high percentage of short trips by car, has a negative influence not only on air quality, but also on living conditions in several cities (Soria-Lara et al., 2019).

The use of active modes of transport for this purpose becomes more difficult not only because of the weight of the load itself, but also because of the lack of safe and comfortable infrastructure (Félix et al., 2020), in addition to the lack of implementation of a public e-bike and e-scooter sharing systems in many places.

On the other hand, the COVID-19 pandemic is accelerating new lifestyles and the emergence of a new mobility scenario, in which public health and social distancing have become crucial challenges in transport policy and planning. In addition to mobility restrictions, the use of public transport has been limited and even discouraged in some places (Tian et al., 2020), having been identified as a vector for the spread of infection in dense populated areas (Buja et al., 2020). As demonstrated by the previous SARS pandemic, the fear of infection also discourages the use of public transport (Wang, 2014). As a consequence of that, the use of active modes of transport has also increased according to some studies (Abdullah et al., 2020; Bucsky, 2020; Haas et al., 2020).

Despite the ongoing vaccination for COVID-19, physical distancing may be necessary until 2022 (Kissler et al., 2020). Cities must adjust to that situation and compensate for some of the most negative long-term effects of the pandemic. The social changes prompted by the pandemic could be used to make cities healthier and more sustainable, with more space available for active modes of transport (Gutiérrez et al., 2020), which facilitates journeys by walking, cycling or scooting (Young & Whyte, 2020). In that scenario, this paper deals with the following research question: “are people willing to transport lightweight goods by bike or kick-scooter?”.

The paper focuses on the use of all types of bikes and kick-scooters (i.e., folding, electric, shared, rental, etc.) for personal shopping purposes by regular people (those working for a delivery company are not included). By actively promoting shopping by bike or kick-scooter, a new impetus can be given to improving and reinforcing sustainable shopping in cities. One possible contributor towards more efficient and environmentally friendly commercial transport is the use of bikes, especially cargo bikes (Nascimento et al., 2020; Schliwa et al., 2015), however, this paper does not deal with the feasibility of urban freight and city logistics. It also considers the hypothesis that part of the population can ride a bike and/or kick-scooter carrying some lightweight goods during their trips.

On the basis of a survey, a methodology was developed with the aim of characterizing the use of bike or kick-scooter for moving lightweight goods. The survey was applied to people of different age groups in the two main urban areas of Brazil (São Paulo and Rio de Janeiro) and Portugal (Lisbon and Porto). All those cities have low maturity for cycling (and also for scooting), meaning that they have: few cyclists (and even kick-scooter users), little infrastructure, no cycling (and/or scooting) culture (being considered unsafe and not respected), a car-oriented road design and a small modal share for active modes (Félix et al., 2017; Santos & Torres, 2020).

The main objectives of this paper are: (i) understand people's willingness to go shopping by bike or kick-scooter and to transport lightweight goods in cities with low cycling and scooting maturity, during the COVID-19 pandemic; and (ii) compare the results of the survey between regular users and potential users of bikes and kick-scooters.

The content of this paper is made up of this introduction plus other five sections. The second section presents the background and literature review. The third section deals with data collection and the fourth section presents the case study cities. The fifth section presents the results of the descriptive analysis, following the last section with the conclusions and future recommendations.

2. BACKGROUND AND LITERATURE REVIEW

Behavioral changes caused by the COVID-19 pandemic could be used to make cities healthier and more sustainable, with more space available for active modes of transport. Although it may not be easy to keep those habits over time, there is a clear window of opportunity available whereby temporary actions may inspire future policies (Gutiérrez et al., 2020).

Policy decision-makers, as well as the society in general, have a commitment to improve the quality of life in cities, air quality and public space, while ensuring equal accessibility in the urban context (Banister, 2008). The paradigm shift towards sustainable mobility is largely due to the transfer of fossil fuel-powered travel to electric vehicles; and from individual to collective transportation means and active modes, thus allowing short distances to be covered in the respective infrastructures (Moura et al., 2017; Santos & Torres, 2020).

Urban planning and transportation management policies must also be critically reviewed. The first actions taken during the COVID-19 pandemic sought to promote active modes and reduce the space allocated to private vehicles (Gutiérrez et al., 2020). However, the policies that will be implemented in the medium and long term are uncertain, as well as their impacts on active modes.

The benefits of active modes for urban mobility are well known for cities, including sustainability, equity, health, and quality of life. Increasing active mobility behavior, could help to address increasing rates of obesity, benefit physical and mental health, and reduce serious health problems associated with lack of exercise and air quality (Pérez et al., 2017; Sallis et al., 2004). However, changing the behavior of the population is a major challenge.

Planners and policymakers benefit from a greater understanding of available interventions to effectively promote cycling and scooting. In cities where cycling or scooting is starting to grow, as it is the case of the cities of this paper (i.e., São Paulo, Rio de Janeiro, Lisbon and Porto), little is known about who is cycling or scooting. Usually, in these cities, the attention of transportation agencies and mobility managers is not focused on active modes, so cyclists and kick-scooters users are not a priority. The resulting lack of useful data is also a problem because there is no basis upon which governments could justify investments in effective cycling and scooting infrastructure. Cities with low cycling maturity do not have historical experience with cycling, so it is necessary to better understand and inform urban planners about which strategic infrastructure investments should be made and programs to be implemented in order to leverage their participation and mature the culture of cycling (Félix et al., 2020).

The implementation and extension of segregated cycling networks and facilities are interventions that have a high chance to successfully induce cycling (Buehler & Pucher, 2012; Carr & Dill, 2003; Pucher & Buehler, 2006; Santos et al., 2013), and can also induce scooting. However, it was found that changes in travel behavior can also be associated with a change in life circumstances rather than a change in the external environment (Chatterjee et al., 2013), such as health problems, a job change, school or residence, etc. The built environment influences a lot the use of active modes, enabling or hindering cycling and scooting. Several authors have concentrated mainly on perceptions of risk in cycling and the provision of cycling facilities to overcome this barrier (Chataway et al., 2014; Götschi et al., 2018; McClintock & Cleary, 1996; Swiers et al., 2017; Vanparijs et al., 2015), and the perception of safety is possibly one of the most important factors influencing the decision to ride a bike or not (Félix et al., 2019; Fowler et al., 2017; Muñoz et al., 2016), and probably a kick-scooter as well.

In the case of bikes, for example, other barriers are related to the physical effort of cycling, which is related to the slope and cycling maturity of the city (Stinson & Bhat, 2003; Winters et al., 2010) and sweating (Engbers & Hendriksen, 2010). In order to overcome these common barriers, electric bicycles and kick-scooters, requiring less physical effort, have been promoted worldwide (Dill & Rose, 2012; Popovich et al., 2014). Enabling active modes through basic infrastructure may be a necessary first step for numerous cities with little or no infrastructure, but such an approach is likely to have only modest impacts on travel behavior. Furthermore, significant travel behavior changes may not be possible without policies and infrastructure levers that deter people from car driving, in order to increase active travel (Piatkowski et al., 2019).

In cities with few regular users of active modes, such as the case study cities, there is a large share of the population that prefer other commuting modes. Among them it is possible to distinguish potential users of active modes from those who are not able or willing to ride a bike (Félix et al., 2017) or a kick-scooter. There is a need to appropriately measure the relevant factors that determine whether people choose to ride (or not) a bike or kick-scooter, especially for shopping purpose.

The general assumption is that the factors that prevent people from cycling or scooting are caused by a combination of personal and external factors, which together constitute the perceived barriers to cycling or scooting and influence the expectations of potential users.

Some of these factors are subjective and others are objective. Some of the objective factors (for example, distance or slope) may be perceived differently among potential users, being a strong or irrelevant barrier to cycling or scooting. These factors vary over time and can potentially lead to a change in behavior in relation to the adoption of cycling or scooting.

Another assumption is that the paradigm shift reflects the behavioral change, in which perceived barriers are outweighed by perceived benefits (Kahneman & Tversky, 1979) and the resulting motivators and expectations lead to effective results. The influence of personal or external factors on decisions to ride a bike or a kick-scooter more often can change over time, especially during pandemic periods.

The current literature points out some recommendations for public authorities to improve cycling or scooting use for shopping, such as: (i) incite active modes by means of street design interventions (Barbarossa, 2020; De Vos, 2020); (ii) reduce the number of lanes on multi-lane streets to homogeneously expand the walking and cycling (or scooting) infrastructure in central business districts (Soria-Lara et al., 2019); (iii) define the total traffic restriction on selected streets with high retail activity in order to build an infrastructure for walking and cycling (or scooting) covering the entire traffic space (Soria-Lara et al., 2019); (iv) limit (free) car parking, as it is associated with a lower likelihood for cycling (Bueno et al., 2017) or scooting; and (v) provision of showers, lockers and parking for bikes (Bueno et al., 2017) and kick-scooters.

Based on the literature review, the main reason why people do not ride a bike or kick-scooter is the possibility of using the private vehicle for the same objective. Bike and kick-scooter sharing schemes, which are rapidly spreading in many cities, are also considered essential elements of urban transport policy. However, there may not be a significant cycling increase without dedicated cycling infrastructure (Félix et al., 2019; Pucher et al., 2010). Anyway, for those who do not have bike storage at home and thus are less likely to cycle (Fernández-Heredia et al., 2016), bike (or kick-scooter) sharing systems can be a practical option.

The literature points to many studies of urban freight and city logistics (mainly cargo bikes), considering mainly those people who work for a delivery company, which is not the focus of this paper. There are even fewer research studies focused on cities with low cycling and scooting development and maturity, which typically have sizeable non-users' population, and also potential users of bikes and kick-scooters. This is precisely the research gap that this paper intends to cover.

3. DATA COLLECTION

Data collection was based on a survey aimed at understanding respondents' current mobility patterns, attitudes towards urban cycling and scooting, willingness to change behavior, and some socio-demographic data. The survey is applicable to any city regardless of the level of maturity of cycling and scooting. All questions were closed-ended and are listed in the flowchart displayed in Figure 1.

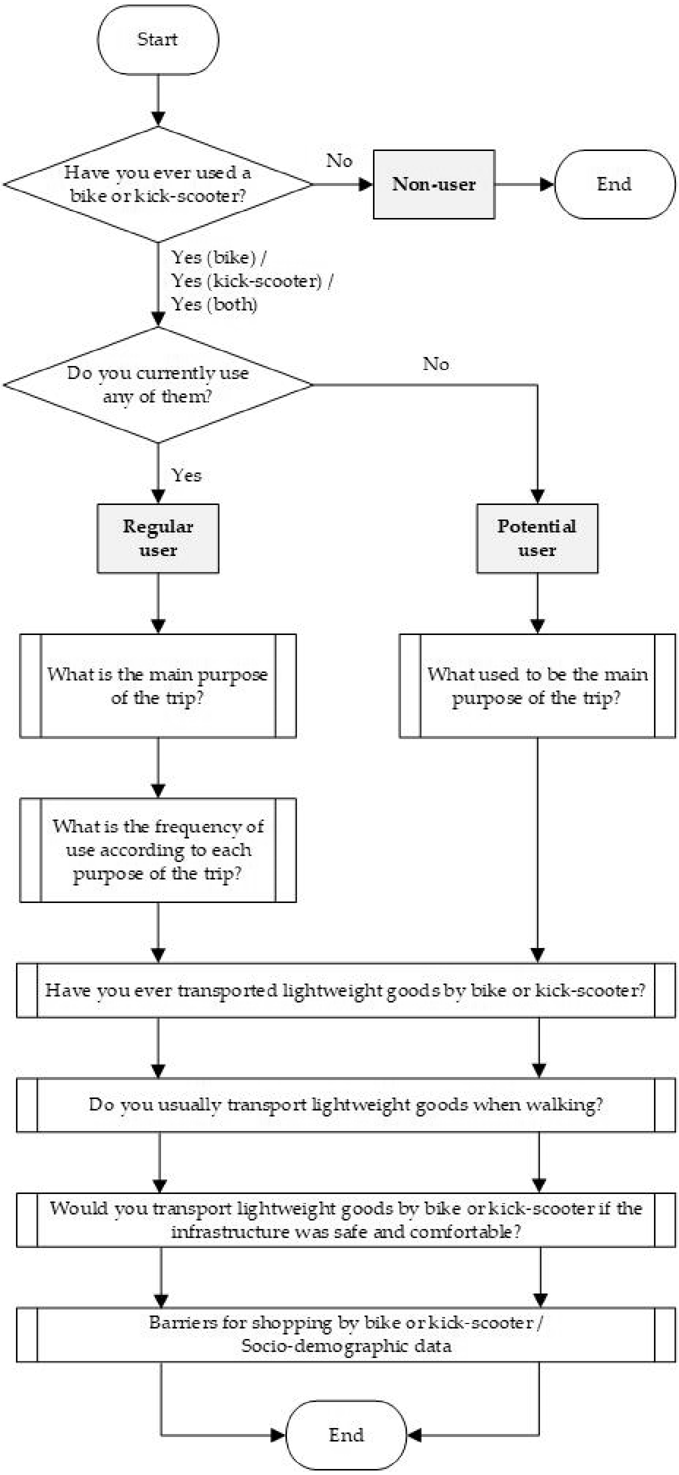

Figure 1 – Flowchart of data collection

It is worth mentioning that urban cyclists and kick-scooter users are not all the same, do not travel for the same reason or with the same frequency, or have the same needs (Christmas et al., 2010). Market segmentation has been used in transportation engineering for many years (Beirão & Sarsfield Cabral, 2007; Dallen, 2007; Jacques et al., 2013; Kassirer & Lagarde, 2010). To this end, the flowchart in this paper presents a categorization of the survey into smaller groups of similar individuals based on how they would likely respond to a particular marketing mix.

Respondents were categorized as “Non-users”, “Potential users” and “Regular users”, adapted after reviewing the literature (Kroesen & Handy, 2014; Bergström & Magnusson, 2003; Dill & McNeil, 2013; Félix et al., 2017), as follows: (i) Non-users: someone who has never ridden a bike or kick-scooter and has no particular interest in doing it; (ii) Potential users: someone who has ever ridden a bike or kick-scooter and would ride it again (or is willing to do so) if some conditions happen; and (iii) Regular users: someone who currently rides a bike or kick-scooter and should do so within the next month.

Different lines of inquiry were addressed to each group. The survey asked “Potential users” to recall their previous experiences when they used to ride a bike or kick-scooter, and “Regular users” to respond based on their current experience. The category of “Non-users” was not considered in the final dataset, as they have no particular interest in riding a bike or kick-scooter.

All questions were closed-ended, and all features were categorical. Regarding trip purpose, "Regular users" answered it for their current trips, while "Potential users" did it for the trips they would have made. Only "Regular users" had to answer what is the current frequency of use (i.e., “Sometimes”, “Once a week”, “2 to 3 times a week”, “Daily”), having to answer this question for each of the following four trip purposes: “Work or Study”, “Leisure”, “Shopping” and “Other”.

The next three questions were asked to the two categories of respondents in order to have a reference to test and validate the research question addressed in this paper (namely, are people willing to transport lightweight goods by bike or kick-scooter?). These three questions were “Yes/No” questions, involving: (i) “Have you ever transported lightweight goods by bike or kick-scooter?”; (ii) “Do you usually transport lightweight goods when walking?”; and (iii) “Would you transport lightweight goods by bike or kick-scooter if the infrastructure was safe and comfortable?”.

Finally, respondents had to answer a question to identify barriers for shopping by bike or kick-scooter in cities with low maturity for cycling and scooting (including the volume or cargo itself, etc.). They were also asked about some socio-demographic data (including gender and age).

4. CASE STUDY CITIES

The survey was applied to people of different age groups in the two main urban areas of Brazil (São Paulo and Rio de Janeiro) and Portugal (Lisbon and Porto). The two countries continue to be linked by a common language (Portuguese) and Portuguese-Brazilian ancestry, which facilitated the common application of the survey. These cities have important employment centers in their regions and have some differences related to urban morphology, transport infrastructure, modal share, etc. However, these cities have a low modal share for cycling (see Table 1) and scooting, as well as scarce infrastructure for active modes.

City	Cycling modal share	Reference
São Paulo (Brazil)	2.0%	Brand et al. (2019)
Rio de Janeiro (Brazil)	2.4%	Souza et al. (2017)
Lisbon (Portugal)	< 1%	Martinez & Viegas (2017)
Porto (Portugal)	< 1%	Costa et al. (2012)

Table 1 – Modal share for cycling in the case study cities

Cycling accounts for about 27% of trips in The Netherlands (Félix et al., 2019), unlike all cities in the case study that account for less than 3% of the participation in the cycling modal. Although information on the percentage of kick-scooter trips has not been found, it can be assumed that all cities have low development and maturity for the use of bikes and kick-scooters.

All cities in the case study face difficult challenges in adopting active modes for urban mobility: (i) low culture of cycling and scooting; (ii) little interest in collecting data on cycling or scooting; (iii) the general perception that cycling or scooting is neither safe nor respected; and (iv) car-oriented road projects.

On the one hand, the political choices that were made at the level of transport systems in these cities, were based on a bet on road infrastructure and the use of the car, in recent decades, with little significant investment in infrastructure and public transport services. The road infrastructure sector in these cities directly affects the accessibility of regions and the mobility of people and goods, contributing to access to work and income (Santos & Ribeiro, 2015, 2016a, 2018a) and road concessions have been the most strategic alternative feasible for maintaining roads at an appropriate level for traffic volumes (Santos, 2017; Santos et al., 2019; Santos & Picado-Santos, 2018, 2019; Santos & Ribeiro, 2018b). Traffic impact analysis is the key means to harmonize transport and land use planning (Santos & Gouvêa, 2012; Santos & Ribeiro, 2016b), but in these case study cities, such studies have only been used since the last few decades.

On the other hand, the conditions offered in these types of cities contribute to the individual's decision to ride (or not) a bike or kick-scooter, in a transitional way. Given that these cities do not have historical experience with cycling or scooting, it is necessary to better understand and inform city planners about what strategic infrastructure investments should be made and programs to be implemented in order to increase their participation in active modes, mature its culture, as well as encourage its use for shopping, which is the main objective of this paper.

5. DESCRIPTIVE ANALYSIS

Descriptive analysis was used to illustrate the basic characteristics of the dataset in this paper, providing simple graphical analysis and measurements. The survey was addressed to the residents, workers, students and visitors of the four cities already mentioned. As the survey was launched in different cities at the same time, no specific sampling methodology was used. The survey was distributed on social media and by university press advisory, with the title "Shopping by bike or kick-scooter in times of pandemic", and conducted in an online-only format, using the Google Forms. The survey was online in April and May 2020 and collected 294 responses. The representativeness of respondents and the three categories of population segmentation is shown in Figure 2.

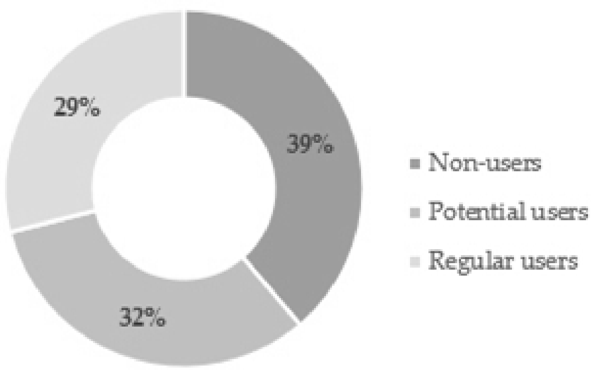

Figure 2 – Representativeness and categories of respondents (Note: 294 responses)

According to the representativeness and categories of the respondents, the category "Regular users" corresponds to 29%, which was expected in cities with low maturity for cycling and scooting. Then in second place it comes the category "Potential users" (32%), followed by the category "Non-users" (39%). In a low cycling and scooting maturity city, more non-users and potential users are expected, whereas in a high cycling and scooting maturity city, more regular users are expected (Félix et al., 2017). After the data cleaning process, the final dataset included only the categories "Regular users", as they are typically more proficient users, and also "Potential users", as they are willing but not convinced to ride a bike or a kick-scooter again if a number of conditions were fulfilled. The content of this dataset also confirms the initial hypothesis that part of the population can ride a bike and/or kick-scooter (around 61%).

Thus, the entire analysis from now on is based on the remaining 180 respondents, with almost half of them (53%) being “Potential users” and the remaining portion (47%) being “Regular users”.

The gender of respondents is shown in Figure 3, according to the category of respondents, as well as the grouping of these two categories.

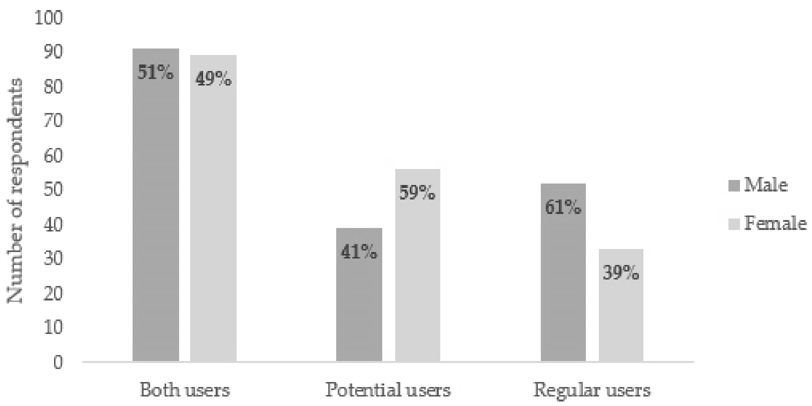

Figure 3 – Gender of the respondents

The gender of the respondents is well distributed among the sample (i.e., both users), in a total of 91 men (51%) and 89 women (49%). However, this distribution is not the same when analyzing the two categories of respondents. In the "Potential users" category, women represent the majority of the responses (59%), while in the "Regular users" category it was men who represented the majority of the responses (61%). These results are in line with the literature review, since among regular users, a higher percentage of men in countries with low maturity in cycling (and scooting) was expected (Garrard et al., 2008). The distribution of the age group of these respondents, as well as the grouping of these two categories, is shown in Figure 4.

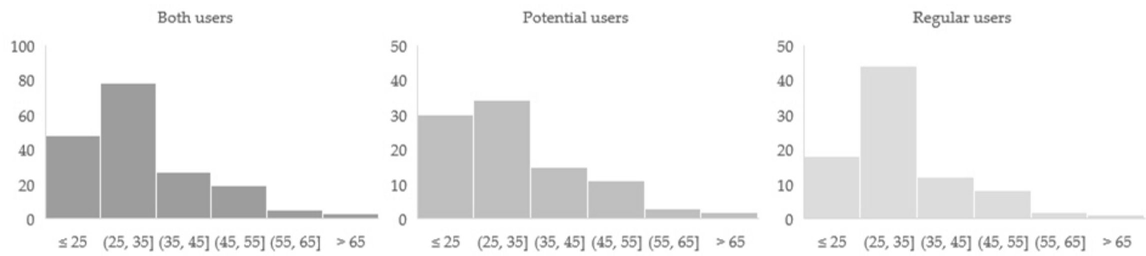

Figure 4 – Distribution of the age group

The distribution of the age group was similar in the two categories of respondents ("Potential users" and "Regular users"), as well as in the grouping of these categories (i.e., both users). In general, most respondents are between 25 and 35 years old, while a minority of respondents are over 55 years old.

The modal split is shown in Figure 5, according to the two categories of respondents.

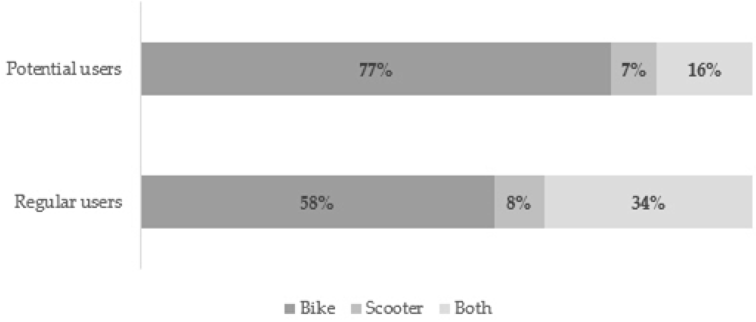

Figure 5 – Modal split according to the two categories of respondents

In the two categories of respondents considered, the modal split graph shows that the bike is the most used active means of transport, while the kick-scooter remains between 7% and 8%. However, it is observed that the use of both means (i.e., bike and kick-scooter) increases for the category "Regular users", which shows a better acceptance of these two means of transport.

The main travel purposes are shown in Figure 6, according to the two categories of respondents. As mentioned before, "Regular users" answered it for their current trips, while "Potential users" did it for the trips they would have made.

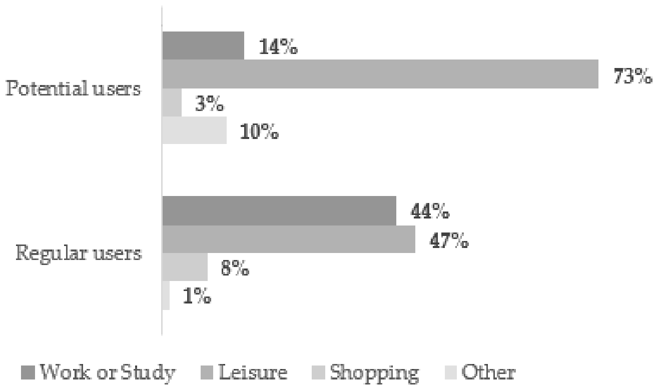

Figure 6 – Main travel purposes according to the two categories of respondents

According to the travel purposes graph, leisure was the most cited reason when analyzing the two categories of respondents. This reason is very high (73%) when analyzing the category "Potential users", followed by work or study (14%), shopping (3%), and other reasons (10%). On the other hand, the reason for leisure was the most cited among the category "Regular users" (47%), being very close to the reason for work or study (44%), which shows that these means of transport (bike and/or kick-scooter) are no longer used just for entertainment. In addition, its use for shopping is still relatively low (8%) but it also represents a growth trend (which meets the main objective of this paper).

Only "Regular users" had to answer what is the current frequency of use, having to answer this question for each of the four purposes of trip (“Work or Study”, “Leisure”, “Shopping” and “Other”), as shown in Figure 7.

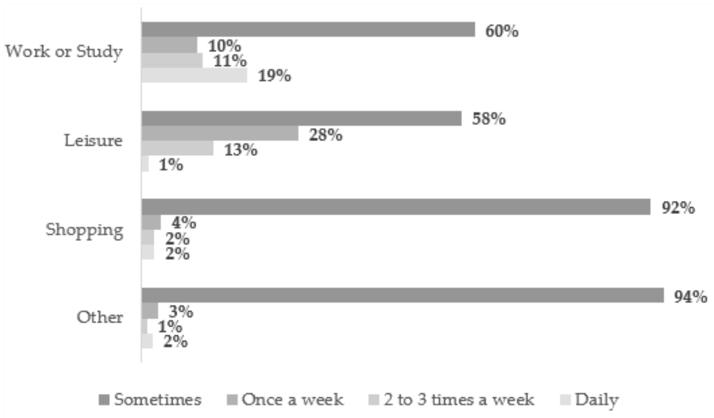

Figure 7 – Frequency of use according to each of the four purposes of trip (Note: applied only to the “Regular users” category)

The graph of the frequency of use according to each of the four purposes of trip shows that the “Regular users” often use active modes only sometimes, regardless of the four purposes of trip. It is worth mentioning that the reason for shopping is still not in use quite often, although a growth trend is expected in times of pandemic (especially in the medium- and long-term).

Some “Yes/No” questions were asked to the two categories to test and validate the research question addressed by this paper (namely, are people willing to transport lightweight goods by bike or kick-scooter?), as follows: (i) Q.1: “Have you ever transported lightweight goods by bike or kick-scooter?”; (ii) Q.2: “Do you usually transport lightweight goods when walking?”; and (iii) Q.3: “Would you transport lightweight goods by bike or kick-scooter if the infrastructure was safe and comfortable?”. The general results of these 3 questions are shown in Figure 8.

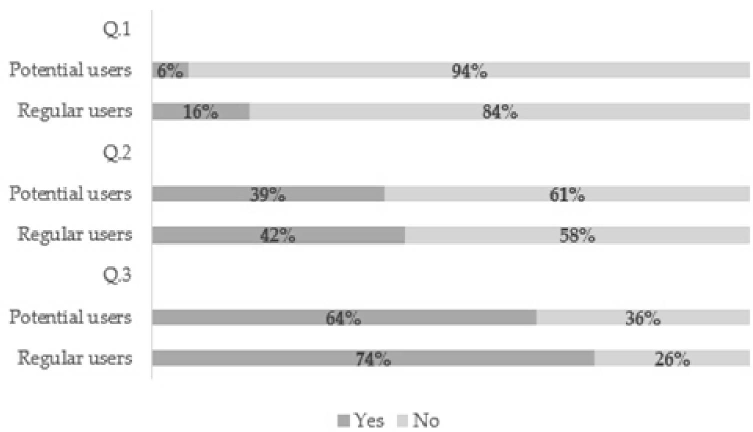

Figure 8 – General results of 3 questions to test and validate the research question

The general results of the 3 questions to test and validate the research question provide interesting results. When asked whether respondents have already transported lightweight goods by bike or kick-scooter (Q.1), both categories of respondents have mostly said "no", representing 94% for the category “Potential users” and 84% for the category “Regular users”. These results show that there is still a lot of work to be done to effectively promote active modes for shopping.

Then, when asked whether respondents usually transport lightweight goods when they walk (Q.2), the two categories of respondents have similar opinions, presenting an increase in the answers "yes" in relation to the previous question (Q.1). That is, 39% for the “Potential users” category and 42% for the “Regular users” category. It is worth mentioning that the figures are quite similar, even considering the “Potential users” (people who are willing but not convinced to ride a bike or a kick-scooter again), but who are willing to carry lightweights when walking.

Finally, when asked whether respondents would go shopping by bike or kick-scooter and transport lightweight goods if the infrastructure was safe and comfortable (Q.3), there was a significant share of the "yes" answer for both categories of respondents, representing 64% for the category “Potential users” and 74% for the category “Regular users”. Even “Potential users” would be willing to ride a bike or kick-scooter again (also for shopping purposes), if they had a safe and comfortable infrastructure, which is not common in cities with low cycling and scooting maturity. These results are in line with the literature review, indicating a high likelihood of changing mobility behavior (especially in times of pandemic). However, the change is conditioned to government interventions, such as the expansion of the cycling and scooting network and the implementation of public e-bike and e-scooter sharing systems.

Overall, the answer to the research question is “yes”, that is, people are willing to transport lightweight goods by bike or kick-scooter. Thus, the government interventions are a game-changer to start a city's progression towards higher levels of cycling and scooting maturity, and to meet the objectives of this paper, to transport lightweight goods by bike and kick-scooter if the infrastructure was safe and comfortable. This is essential, especially if they are implemented in cities with almost no cycling and scooting modal share, such as the case study cities.

To conclude, respondents answered a question to identify barriers for shopping by bike or kick-scooter in cities with low maturity for cycling and scooting. The main barrier declared by respondents was the volume or cargo itself. Other perceived barriers were: cycling or scooting in the traffic, living too far, motorists do not respect, not own a bike or kick-scooter, slope, arrive sweat, no safe route, no cycling or scooting network, taking more time, theft when parked outside, too hot or rainy, afraid of having an accident, do not ride for years, like driving a car, too dangerous, afraid of being robbed and physically unable.

6. CONCLUSIONS

This paper contributes to the understanding of the changing mobility behavior and the identification of barriers to go shopping by bike or kick-scooter in cities with low maturity in the use of these modes. In addition, it provides insight to the planning and definition of local policies and actions (hard and soft measures) that can potentially promote a modal shift for cycling and scooting in cities with low share of those modes.

The paper shows that people are willing to transport lightweight goods by bike or kick-scooter as long as the infrastructure is safe and comfortable enough. The main barrier for going shopping by bike or kick-scooter declared by respondents was the volume or cargo itself, while other perceived barriers include: cycling or scooting in the traffic, living too far, motorists do not respect, not own a bike or kick-scooter, etc.

Based on the literature review and the results of the descriptive analysis, the authors suggest additional recommendations to public authorities, with the aim to improve the use of bikes or kick-scooters for shopping purposes (especially in times of the COVID-19 pandemic), such as: (i) producing campaign to encourage car drivers for short shopping trips through active modes, especially bikes and kick-scooters; (ii) reducing distances and barriers for cyclists and kick-scooter users; (iii) fostering short travel policies; (iv) stimulating small- and medium-sized malls; and (v) avoiding planning large malls outside cities.

As a proposal for future studies, the research can be applied in different regions, for comparison purposes. In addition, the use of different machine learning techniques is expected to classify the use of active modes of transport to carry lightweight goods.

ACKNOWLEDGMENTS

The authors wish to thank the Spanish Ministry of Science and Innovation (MCI), the State Research Agency (AEI) and the European Regional Development Fund (FEDER), which have funded the project TI2018-095501-B-I00.

A STATED PREFERENCE SURVEY FOR EVALUATING PEDESTRIANS' EXPECTATIONS ON WALKWAYS

Maria Grazia Bellizzi
University of Calabria, Italy
Carmen Forciniti
University of Calabria, Italy

ABSTRACT

Pedestrian mobility is the oldest form of transport in urban areas. Due to the increase of private vehicles, transport planning has mainly focused on traffic congestion problems, neglecting pedestrian mobility and public transport. Given the current situation of pollution and climate change, walkability is again one of the most important transport modes to achieve urban sustainable mobility in the next future. As reported in the literature, city dwellers are willing to walk to carry out daily activities but complain about the lack of adequate pedestrian infrastructure. For promoting pedestrian mobility, the quality levels of pedestrian paths should be increased. Many researchers suggest methodologies for determining the pedestrian level of service. Among these, some studies consider both path physical characteristics and users' perception about the walkway. Investigating on users' perception represents a good strategy for implementing interventions aimed at increasing the quality of service. In addition to users' perception about the different characteristics of the pedestrian path, it is also necessary to take over the importance that users assign to each aspect.

This work proposes the design of a Stated Preferences survey and the analysis of the preliminary results. A questionnaire was addressed to a sample of 240 pedestrians on a walkway located in the University Campus of Rende (Italy). The aim is recording pedestrians' perception about the characteristics of the path and detecting the choices they would make in a hypothetical scenario. Then, the collected data has been analysed by means of a discrete choice model for assessing the weights assigned by pedestrians to each aspect included in the analysis.

The results have allowed the most relevant pedestrian path aspects for users to be identified. Just on these aspects it is necessary to intervene in order to make pedestrian paths increasingly attractive and to encourage users towards active mobility.

1. INTRODUCTION

Car traffic increasing undermines the quality of life in urban areas. Motorized traffic has grown so much that many important aspects of urban life are inhibited, so that the issue of sustainability has become a fundamental topic.

Promoting walking as an alternative to short trips made by car represents an important strategy to enact sustainability in more densely inhabited areas (Amoroso et al., 2012).

Benefits of increased walking include not only reductions in traffic congestion, air pollution and emissions, but also improvements in public and private health, community relations and positive sense of place, as well as improvements in economic and real estate performance (Hall Ram, 2018a). Walkability can be defined as the extent to which a built environment enables walking (Kelly et al., 2011) and is pedestrian friendly (Gebel et al., 2009; Moura et al., 2017). Some studies emphasize different environmental features that a pedestrian facility has to own, including areas being traversable, compact, safe, as well as the places have to be lively, enhancing sustainable transportation options, and encouraging outdoor exercise and leisure (Forsyth, 2015; Saelens and Handy, 2008; Hall and Ram, 2018b). In this context, it becomes fundamental to investigate on the direct users of the facilities about their perceptions and preferences concerning the service quality characterizing pedestrian environment. The use of pedestrian perceptions to explain the service quality has been less studied (Vallejo-Borda et al., 2020a). The relationship between pedestrian perceptions and service quality is still nascent (Bellizzi et al., 2019; Bivina and Parida, 2019; Jahan et al., 2020; Vallejo-Borda et al., 2020b). These studies are based on the collection of pedestrian perceptions in terms of rating expressed on evaluation scales.

On the other hand, some studies investigate pedestrian perceptions adopting the Stated Preferences (SP) approach, according to which actual or potential users are asked to rate or rank the attractiveness of existing or hypothetical streets (Adkins et al., 2012; Borst et al., 2008; Kaparias et al., 2012; Kelly et al., 2011; Lusk et al., 2018). The importance (utility) of the various service attributes is estimated based on the respondents' preferences. As an example, some of these studies found that wider sidewalks are generally preferred (Kim et al., 2011; Talavera-Garcia and Soria-Lara, 2015) and lateral separation from traffic increase streets' attractiveness (Adkins et al., 2012). The presence of trees is appreciated (Lusk et al., 2018; Talavera-Garcia and Soria-Lara, 2015). The existing literature confirms that the SP method is suitable for analysing pedestrian perceptions. SP scenarios are typically presented in text format showing attributes and their levels, but sometimes photos or videos are adopted (Kasrain et al., 2020).

This paper wants to provide a contribute in the literature of the studies proposing SP experiments for investigating on pedestrian preferences. For facilitating the users in expressing their opinions, we adopted also photos representing the characteristics of the alternative pedestrian environments proposed to the users to make a choice. After a deep study of the literature review, we selected four attributes to introduce in the SP experiment: width of the pedestrian path; pavement of the pedestrian path; equipment present along the pedestrian path; environment where the pedestrian path develops. Interesting findings emerge from the observations of the choice of the various alternatives made by the users. In order to synthetize the findings emerged from the analysis of the preferences expressed by the users, a Multinomial Logit (MNL) model was calibrated.

We found that the environment where the pedestrian path develops is the most important aspects for the users.

The rest of the paper is organized as follows: section 2 explains the design of the SP survey; section 3 describes the methodology and includes the data analysis and the calibration of the MNL model; in the last section the results are discussed and some final remarks are presented.

2. STATED PREFERENCE SURVEY DESIGN

The Stated-Preferences approach is a particular type of survey where two or more hypothetical scenarios are proposed to the interviewee. The interviewee is asked to choose the scenario they prefer most or to rank the scenarios according to their personal level of preference.

The SP survey planned in this work was referred to the detection of the perceived degree of comfort of a pedestrian path. The comfort attributes of a pedestrian path are countless. From the analysis of the literature, four most recurrent attributes have been identified:

- width of the pedestrian path;
- pavement of the pedestrian path;
- equipment present along the pedestrian path;
- environment where the pedestrian path develops.

Each attribute (or variable) varies on two levels or categories. Specifically, the categories relating to the width attribute are narrow path (pedestrians only) and wide path (interference with bicycles, scooters, hoverboards, authorized vehicles). The pavement can be traditional (asphalt, concrete, dirt path) or specific for pedestrian paths (coloured asphalt, rubber, beaten and/or stabilized ground). Along the route there may be more or less equipment, distinguishing between a poorly equipped path (lighting, baskets, benches) or an equipped path (lighting, waste baskets, benches and/or seats, beverage and food distributors, Wi-Fi and charging stations, protection from atmospheric agents).

The environment can be unpleasant (dirt, untreated green spaces, dilapidated building facades, scarce presence of commercial activities) or pleasant (clean, well-kept green spaces, decent building facades, presence of commercial activities).

After establishing the levels of each attribute, hypothetical scenarios were constructed. A scenario is given by a set of level attribute combinations. When all possible scenarios are considered, the survey project takes the name of Full Factorial Design. Specifically, we have considered 4 attributes at 2 levels, for which the Full Factorial Plan consists of 16 scenarios (2^4).
Often the Full Factorial Plan is too numerous or presents irrelevant scenarios, so a reduction in the total number of scenarios is implemented.

The Fractional Factorial Plan is a plan reduced through appropriate exclusions of scenarios in order to lose the least possible amount of information (variance explained) considering only the main effects of the attributes and neglecting some or all interactions. In our case, four scenarios have been eliminated, which correspond to cases in which we have traditional flooring and an equipped path. In fact, an equipped path is not compatible with an ordinary sidewalk with poor quality pavement. In total, twelve scenarios were included in the survey (Table 1).

Once the scenarios have been defined it is necessary to combine them in order to identify the set of choices. The scenarios were combined in pairs, obtaining 64 sets of choices. In this work, a set of choices has been named “card”.

Two combinations were discarded as one scenario was clearly better than the other, in order to avoid too expectable choices.

Scenario		Width	Pavement	Equipment	Environment
1	a	narrow	traditional	poorly equipped	pleasant
2	b	narrow	traditional	poorly equipped	unpleasant
5	c	narrow	specific	poorly equipped	pleasant
6	d	narrow	specific	poorly equipped	unpleasant
7	e	narrow	specific	equipped	pleasant
8	f	narrow	specific	equipped	unpleasant
9	g	wide	traditional	poorly equipped	pleasant
10	h	wide	traditional	poorly equipped	unpleasant
13	i	wide	specific	poorly equipped	pleasant
14	l	wide	specific	poorly equipped	unpleasant
15	m	wide	specific	equipped	pleasant
16	n	wide	specific	equipped	unpleasant

Table 1 – Fractional Factorial Plan

The interviewee had to administer a block consisting of 8 cards. For each card the interviewee was asked to choose one of the two scenarios. The interviewee's task was facilitated by the inclusion of images relating to the different categories of the attributes considered in the survey form (Figure 1).

Which of these alternatives would you choose?			
A ☐		B ☐	
Width **Narrow path** (pedestrians only)		Width **Wide path** (interference with bicycles, scooters, hoverboards, authorized vehicles)	Pavement **Specific for pedestrian paths** (coloured asphalt, rubber, beaten and/or stabilized ground)		Pavement **Traditional** (asphalt, concrete, dirt path)	
Equipment **Poorly equipped path** (lighting, waste baskets, benches)		Equipment **Poorly equipped path** (lighting, waste baskets, benches)	
Environment **Unpleasant** (dirt, untreated green spaces, dilapidated building facades, scarce presence of commercial activities)		Environment **Pleasant** (clean, well-kept green spaces, decent building facades, presence of commercial activities)

3. METHODOLOGY

3.1 Data analysis

The survey was carried out in November and December 2019 by interviewing a sample of 240 people along a pedestrian path located in the University Campus of Rende (Italy). The sample is divided almost equally between males (51%) and females (49%). As the survey was carried out on the University campus, most of the interviewees are students (99%) aged 25 or under.
The SP survey made up of 64 cards was divided into 8 blocks each containing 8 cards.

Each pedestrian interviewed answered only one block, so for each block we collected the answers of 30 respondents.

From the preliminary analysis of the data collected, it emerged that for each pair of scenarios where the possibility of choosing between pleasant and unpleasant environment appears, most of the pedestrians have chosen the scenario characterized by pleasant environment. As can be seen from the two bar diagrams in Figure 2, there are few (or even zero for card *ab*) pedestrians who, other things being equal, choose a path with an unpleasant environment.

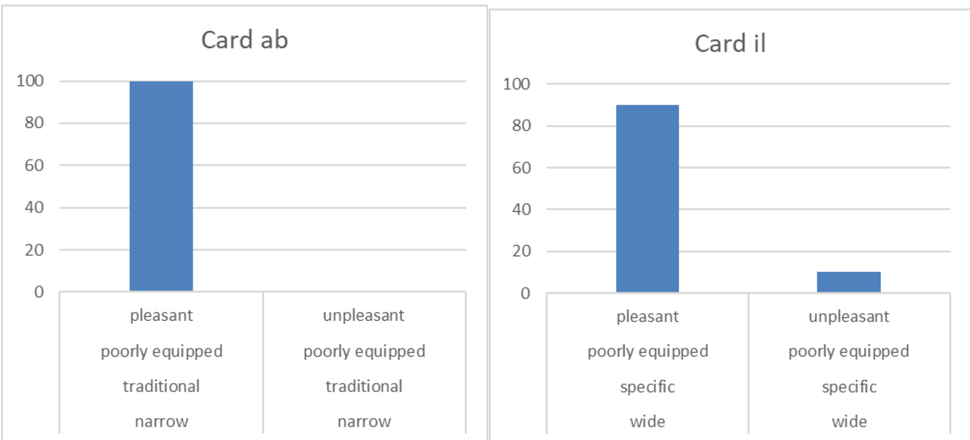

Fig. 2 – SP results: difference between pleasant and unpleasant environment

When comparing scenarios that also have other attributes that may vary in addition to the environment, most users continue to choose scenarios where the environment is pleasant.
For example, observing the card *ad* in Figure 3, it can be seen that the scenario with a pleasant environment and traditional pavement is chosen by 77% of pedestrians, while that with an unpleasant environment and specific pavement only by 23%. In the *af* card, the scenario with a pleasant environment, traditional flooring and poorly equipped path is chosen by 83% of the interviewees, while the scenario with specific flooring, equipped path and unpleasant environment is chosen only by the remaining 17%.

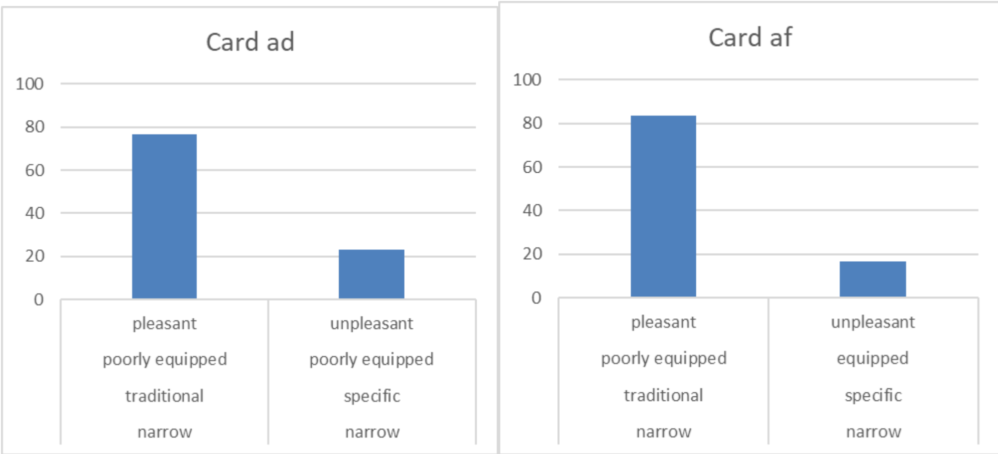

Fig. 3 – SP results: difference between pleasant and unpleasant environment in relation to other attributes

For the cards where two scenarios with the same characteristics are compared, except the pavement, the one preferred by most of the interviewed pedestrians is the scenario with specific pavement. For example, in card *ac* and card *gi* (Figure 4) the scenario with specific pavement was chosen by almost 80% of the interviewed pedestrians. The scenario with specific pavement is the most chosen one even when other attributes such as equipment and width are considered. For example, in Figure 5, in card *ai* the most chosen scenario is that with specific pavement (73%), even if the scenarios are different regarding the width. When the two scenarios differ also in terms of environment, as well as pavement, the most chosen scenario is always the one that presents the pleasant ambient alternative, regardless of the pavement. For example, in card *gl* in Figure 5, the most chosen scenario is the one in which there is traditional pavement and a pleasant environment (93%).

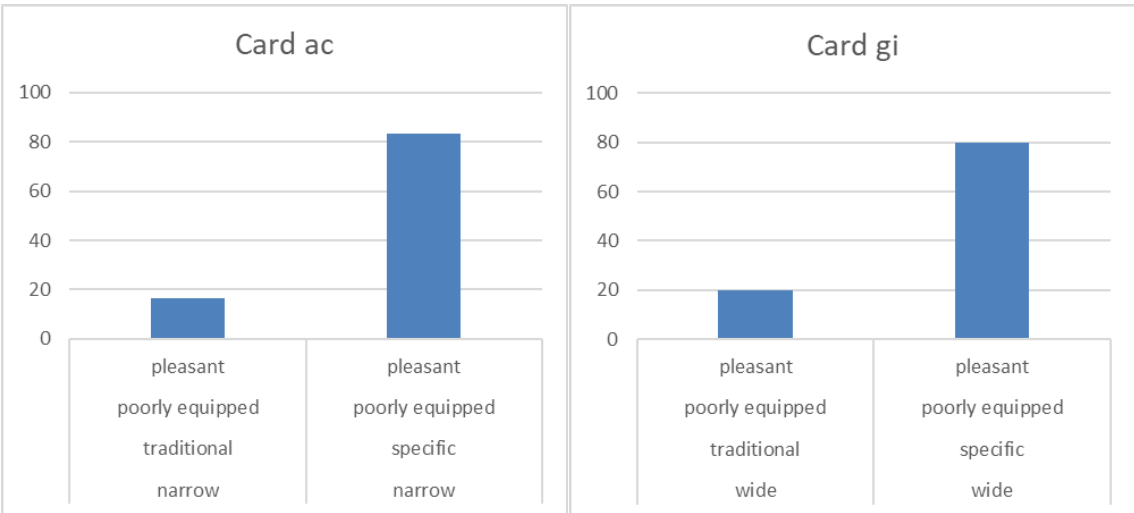

Fig. 4 – SP results: difference between traditional and specific pavement

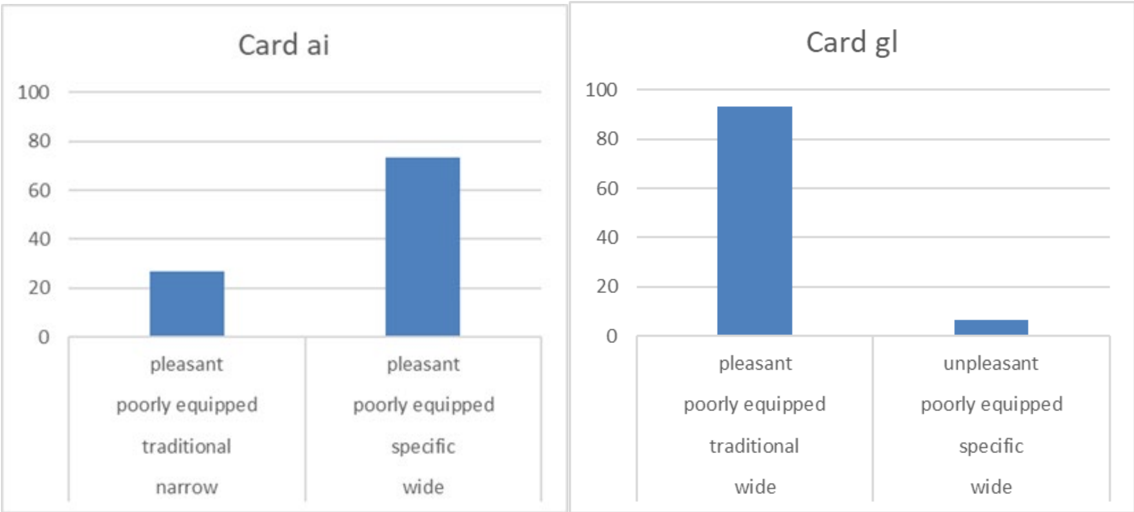

Fig. 5 – SP results: difference between traditional and specific pavement in relation to other attributes

By comparing scenarios with the same characteristics but different equipment (card *ce* in Figure 6), the equipped path is the one chosen by most of the interviewees (about 83%). The equipped path continues to be the most chosen one (80% of the respondents) when the environment is pleasant and when the pavement is specific, as reported in card *gm* (Figure 6). As can be seen from the graphs shown in Figure 7, the width of the path does not seem relevant with respect to the equipment attribute.

The width attribute is the one with the most variability. From the analysis of the results of the survey, it is clear that for some pairs of scenarios the most chosen scenario is the one with the wide path (card *ci* in Figure 8), for others the narrow path (card *ag* in Figure 8).

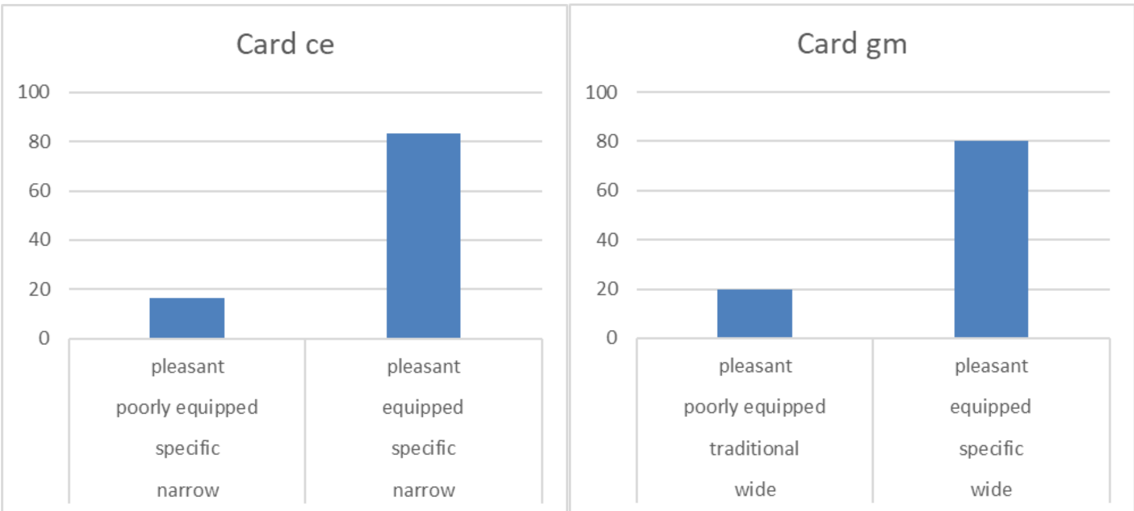

Fig. 6 – SP results: difference between poorly equipped and equipped path

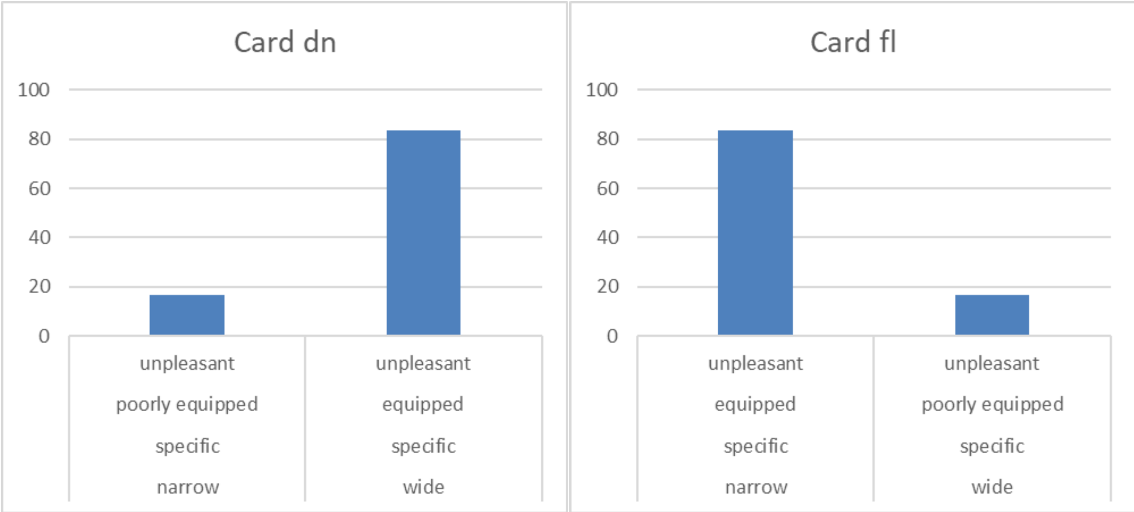

Fig. 7 – SP results: difference between poorly equipped and equipped paths in relation to other attributes

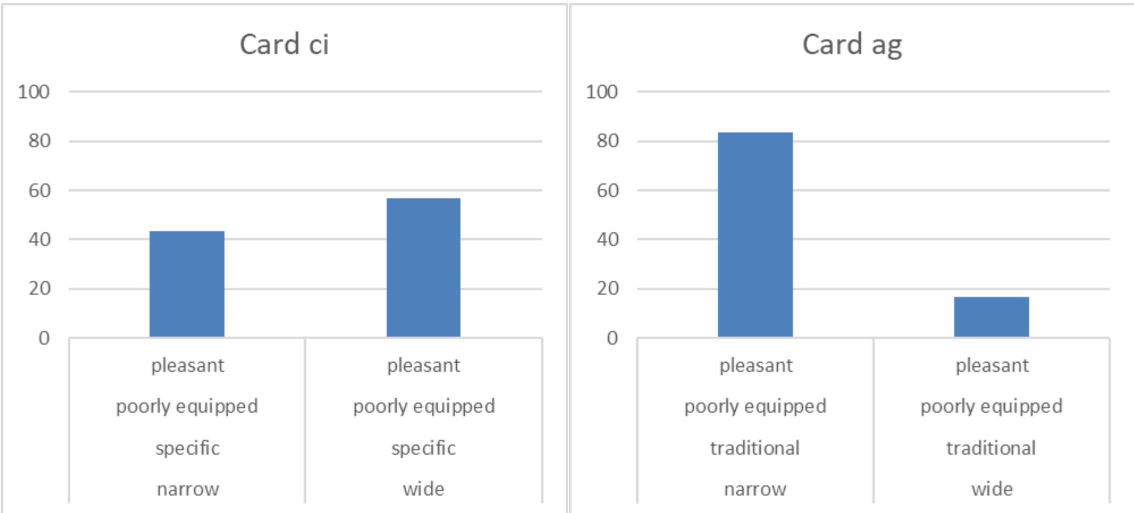

Fig. 8 – SP results: difference between narrow and wide path

Looking at the results related to the cards, where also other attributes vary, the width attribute seems to be the least relevant and the choice of scenario seems to be guided by the other variables.

From this preliminary statistical analysis, the environment where the walkway is located seems to be the most important aspect of evaluation for pedestrians.

3.2 Multinomial Logit model

A Multinomial Logit model (MNL) was calibrated for deriving the importance of each attribute in the pedestrians' evaluation. The four attributes (width, pavement, equipment and environment) were included in the model elaborated through NLogit software (Greene, 2016).

The results are reported in Table 2. The coefficients have the correct sign. Only the variable “width” is not statistically significant. The other three variables have a high statistical significance.

Variable	Standard coefficient		Error	z	Prob. |z|<Z*	Confidence interval	
Width	0.02365		0.07200	0.33	0.7425	-0.11747	0.16477
Pavement	0.60991	***	0.09706	6.28	0.000	0.41967	0.80015
Equipment	0.49662	***	0.09064	5.48	0.000	0.31897	0.67428
Environment	1.93261	***	0.09334	20.71	0.000	1.74968	2.11554
***, **, * ==> Significance at 1%, 5%, 10% level							

Table 2 – MNL output

The results of the model seem to confirm what was observed in the statistical analysis of the data. “Environment” is the variable with the highest coefficient. This means that, in this study, the environment of the walkway is the most important attribute for the pedestrians. “Pavement” and “equipment” variables are also relevant but the coefficients are lower.
In particular, the coefficient of “pavement” is higher than that of “equipment”. Even this result goes to confirm what observed analyzing the data. The variable “width” is not significant. This means that in this study the width of the path is not an important element in the pedestrians’ evaluation.

4. DISCUSSION AND CONCLUSIONS

The proposed analysis provides important points for discussion. “Environment” is the variable that most strongly affects the scenario selection in the set of choices. Among the variables included in the model, the environment can be considered as the most important aspect for pedestrians. This result is also amply confirmed by other studies in the literature (Motamed and Bitaraf, 2016; Vallejo-Borda et al., 2020b). In particular, “environment” is one of the most relevant attribute especially when its definition includes also the concept of security (Bivina and Parida, 2019).

The results also show that type of pavement has less importance than environment, but it still relevant in the evaluation of quality. In the literature, the pavement as structural element is poorly treated. Many studies consider the condition of the pavement in general as variable (Asadi-Shekari et al., 2013; Moura et al., 2017; Banerjee et al., 2018).

The variables that refer to the equipment along the walkway are often present in studies on the quality of pedestrian paths. As reported by Sarkar (2003), the presence of good furniture improves pedestrian comfort.

In the present study, the variable “width” does not result statistically significant. This means that having a more or less wide path does not influence the pedestrian’s evaluation. In other studies, instead, width is a significant variable (Kim et al. 2011; Talavera-Garcia and Soria-Lara, 2016). Streets with more lanes and streets where automobiles and bicycles are mixed have higher pedestrian numbers than pedestrian-only streets (Sung et al., 2015).

Regarding the methodology, the SP experiment seems to be suitable for simulating the pedestrians’ expectations on walkways. Considering hypothetical scenarios, respondents are faced with an unknown situation, so that their answers are not influenced by habit and knowledge of the path. In addition, the choice of including images representative of the different levels of the variables contributed to reducing any errors in understanding the question.

Ultimately, the results give indications regarding territorial and transport policies to be pursued in future years for increasing pedestrian mobility. Environment where the pedestrian path is inserted is the aspect needing more attention. It is clear that pedestrians prefer to walk in a pleasant and clean environment, with well-kept green spaces, decent building facades, presence of commercial activities. The objective has to avoid the production of an unpleasant environment, characterized by dirt, untreated green spaces, dilapidated building facades, lack of commercial activities.

The analysis provided satisfactory results, and in future studies it will be possible to continue to increase the proposed methodology. Other aspects could be included in the survey. As an example, an attribute relating to the presence of trees along the walkway could be inserted among the physical characteristics of the path. In fact, it was observed that pedestrians like to walk along tree-lined paths because the trees offer protection from the sun’s rays and heat.

Another potential important aspect could be the presence of restaurant and bar activities.

Other studies, in fact, have shown that the presence of these activities makes the walkway more pleasant for the pedestrian.

ABSTRACT

In the last few years, Machine Learning (ML) methods have acquired great popularity due to their success in numerous applications such as autonomous cars, image and voice recognition systems, automatic translation systems, etc. This success has led to an increase in the use of ML methods and the extension of their applications to areas such as transport planning.

One of the main tasks within transport planning is the analysis of transport demand. To do so, it is necessary to analyse the way in which users make their decisions about the trips they make and, therefore, be able to predict the number of passengers on the transport network in relation to respect to interventions made on the transport system. Consequently, transport policies and plans can be evaluated according to the behaviour of the passengers. Discrete choice models based on random utility maximization have been developed over the last four decades and currently they have acquired a high degree of sophistication, becoming the canonical tool for transport demand analysis. Nowadays, the use of ML methods could provide an alternative to discrete choice models, as they offer a high level of accuracy in their predictions. In addition, the analyst is relieved from the need of specifying the functional expressions for the utility functions beforehand.

A Python software package called PyKernelLogit was developed to apply a ML method called Kernel Logistic Regression (KLR) to the problem of predicting the transport demand. This package allows the user to specify a set of models using KLR and the estimation of those using a Penalized Maximum Likelihood Estimation procedure. Moreover, this tool also provides a set of indicators for goodness of fit and the application of model validation techniques. Finally, it allows to obtain the willingness to pay or value of time indicators commonly used in transport planning.

1. INTRODUCTION

The efficiency and reliability of any public transport system depends on the design, management and operation of its infrastructure. These factors have a direct impact on the economic activity of the population, on their fidelity, as well as on the environment (such as pollution). There are two main strategies for improving a public transport system. On the one hand, the reliability of the infrastructure and its operations has to be improved. On the other hand, it is necessary to define an offer of transport services which is oriented to its potential demand. To achieve the second objective, it is crucial to analyse the transport demand, i.e. it is necessary to analyse the way in which passengers choose their mode of transport and thus predict the number of passengers in the transport network. Therefore, policies and plans can be established and evaluated according to the needs of the passengers.

Traditionally, process-driven models are used to predict passenger behaviour. Discrete choice models based on random utility theory describe how a rational-decision maker chooses an alternative within a set of options depending on the characteristics of each of them and the specific peculiarities of each decision-maker. The choice process involves some latent (unobservable) functions known as *utility functions*, which measure the interest of each alternative for a decision-maker. Random utility theory supposes that any decision-maker would choose the alternative that maximizes his or her utility. The utility associated with each alternative is composed of two parts: A deterministic part (also called the *systematic part*) which depends on the attribute vector of the alternative; and a *stochastic part*, whose probability distribution determines the resulting model. The Multinomial Logit (MNL) model is the most widespread example and assumes an extreme value Gumbel distribution. These models are generally estimated using a Maximum Likelihood Estimation (MLE) methodology that allows an asymptotic distribution of the estimators to be determined and to test assumptions about the value of the parameters.

The continuous technological evolution has allowed the development of new intelligent systems and Internet of Things (IoT) devices which automatically gather information about passengers on the transport system. Consequently, the amount of information used by these models has significantly increased, and the models are becoming more complex. For this reason, there is a need for new alternatives that complement the classical demand modelling methods, which are based on Random Utility Models (RUM). In this context of massive data acquisition, new models are needed, such as data-driven models. These models build relationships between input and output data, without worrying too much about the underlying processes, using statistical and Machine Learning (ML) techniques.

In the last years, the transport community has been evaluating new proposals to predict the passenger behaviour which are based on ML. Preliminary studies have revealed a significantly higher predictive performance of ML methods, which encourages further research. In ML, the *radial basis function kernel*, or RBF kernel, is a popular kernel function used in various kernel-based machine learning algorithms, such as support vector machine (SVM) classification. The combination of MNL models with radial basis functions is known in the ML community as Kernel Logistic Regression (KLR) (Zhu & Hastie, 2005). Martín-Baos et al. (2021) propose to use the KLR method as a way to specify non-parametric utilities in RUM. In KLR the parameter estimation problem is based on a Penalized Maximum Likelihood Estimation (PMLE) in which the goodness of fit criterion balances empirical risk and complexity. The main advantage of the KLR method over the RUM is that it does not require the modeler to specify a functional expression of the utilities in advance, being enough to choose certain hyperparameters such as the kernel function.

At the present moment, there are several packages for different programming languages which allows to estimate a wide variety of RUM models, such as logit models. Nonetheless, these packages do not allow to estimate discrete choice models based on KLR. In this work a Python package for estimating discrete choice models based on RUM and KLR is described. In order to avoid re-codifying functions that already exist in other software packages, it has been decided to take as a baseline a current open source package for estimating a wide variety of RUM models and to use it as a basis for aggregating the KLR models. Furthermore, it is sought to implement in this library some functions to estimate some indicators such as the Willingness to Pay or the Value of Time. The developed software package has been called PyKernelLogit.

2. RELATED WORKS

Discrete choice models based on Random Utility Theory have dominated travel behaviour research during the last decades (M. Ben-Akiva & Bierlaire, 1999; M. E. Ben-Akiva et al., 1985; McFadden, 1978; Train, 2003). For this reason, during the last years, a large number of software packages have emerged to estimate this type of discrete choice of models. These tools are usually based on the estimation of logit models and their variants, such as Nested Logit models and more recently Mixed Logit Models, among others. The following lines describe the most popular software packages which are currently available for practitioners.

2.1. Biogeme

Biogeme (Bierlaire, 2020) is an open source multi-platform package which is specially designed to estimate discrete choice models. Nonetheless, it can also be used for the estimation of general parametric models using the maximum likelihood procedure. Biogeme has been developed by Michel Bierlaire, which is a professor in the Transportation and Mobility Laboratory at the Ecole Polytechnique Fédérale de Lausanne, Switzerland.

The last version of the Biogeme package, which is called PandasBiogeme, was released in the year 2018. This version was coded mainly in Python 3 and relies on the Pandas Data Analysis Library for data management. The most compute-intensive software parts were coded in C++, for the sake of efficiency. This package can be easily installed using the Python Package Index (PIP) package manager.

Biogeme allows to define the utility functions using traditional mathematical operations which makes the utility specification very straightforward. It also uses a dictionary to describe the availability conditions of each alternative, i.e. supports datasets where the choice set may vary across observations. Biogeme supports a wide range of choice models, which are listed in Table 1. Biogeme also allows to calculate some economic indicators which are relevant in the context of discrete choice models, such as willingness to pay, value of time, market shares, revenues, and elasticities using a simulation technique which is called *stratified random sampling*. Finally, this package also allows to estimate models with latent variables, i.e. variables that are not directly observed but can be inferred from other observed variables.

2.2. PyLogit

PyLogit (Brathwaite & Walker, 2018) is a Python package intended to be used for performing maximum likelihood estimation of conditional logit models and other similar discrete choice models. This package can be installed using the PIP or Anaconda python package managers and the source codes are available in a GitHub repository.

PyLogit takes as input a long format dataset, which is composed of one row per individual per available alternative. The main advantage of the long format dataset is that it allows to calculate the utility functions $V_{ij} = x_{ij}\beta_i$ directly using a matrix dot product. PyLogit also supports different choice sets per individuals and model specifications admit alternative specific attributes, subset specific attributes or generic attributes.

An important difference between PyLogit and other packages, such as PythonBiogeme or mlogit, is the need to pre-calculate all variables to be used in the model. In other words, PyLogit does not perform variable creation, it only focuses on the model estimation using previously pre-computed variables. Hence, the user must define all the variables to be used in the model before executing the estimation procedure. Once the variables have been defined, the model can be specified and estimated. The specification of the utility functions is less intuitive than in PandasBiogeme because they are defined using a list for each variable indicating the alternatives which are affected by that variable. PyLogit also supports a wide range of choice models which are listed in Table 1.

2.3. ChoiceModels

ChoiceModels (Urban Data Science Toolkit, n.d.) is a Python package used for discrete choice modeling, as part of the Urban Data Science Toolkit, an open source portfolio developed and maintained by Berkeley Urban Analytics Lab.

This library integrates several open source packages such as PyLogit. ChoiceModels is a kind of wrapper that allows to manage in an easy way the data before applying the choice model. In addition, this package also provides a tool for Monte Carlo simulation of choices given the probability distributions from fitted models. However, its main limitation is that it only integrates Multinomial Logit Models, losing the other powerful models which are provided by PyLogit.

2.4. mlogit

mlogit (Croissant, 2019) is a R package which allows to estimate random utility discrete choice models using maximum likelihood procedure. The package can be installed directly in R from the CRAN package repository.

In mlogit the utility functions are written using an extended model of the R *Formula* package, which allows to write these expressions using a notation which is similar to the one used in ChoiceModels with Patsy, making it very intuitive. It allows to define alternative specific variables with specific and generic coefficients and individual specific variables on the utility function. Nevertheless, one of the major limitations of this package is that it does not integrate support for varying choice sets over individuals.

2.5. Other alternatives

There are also other alternatives for discrete choice modeling. However, they have not been analysed in detail because they are not open source, free to use or widely popular between practitioners. Kenneth E. Train personal webpage contains several Matlab, R and Gauss codes for estimating Mixed Logit models. It should be highlighted the software piece called *Mixed Logit Estimation by Hierarchical Bayes* which was coded in Matlab to elaborate Chapter 12 of Train (2003). Finally, there are also some proprietary and commercial packages which can be used for discrete choice model estimation problems, such as nlogit, Stata, SPSS, etc.

2.6. Comparative of the different packages

To summarise the different software packages, Table 1 compares the discrete choice models which can be estimated by each of the different software packages and Table 2 summarises the key features of each alternative.

Supported models \ Package	Biogeme	PyLogit	ChoiceModels	mlogit
Multinomial Logit	✓	✓	✓	✓
Probit	✓ (only binary)	✗	✗	✓
Nested Logit	✓	✓	✗	✓
Cross-Nested Logit	✓	✗	✗	✗
Multivariate Extreme Value	✓	✗	✗	✗
Models with nonlinear utility functions	✓	✗	✗	✗
Models designed for panel data	✓	✗	✗	✗
Heteroscedastic models	✓	✗	✗	✗
Multinomial Clog-log	✗	✓	✗	✗
Multinomial Scobit	✗	✓	✗	✗
Multinomial Uneven Logit	✗	✓	✗	✗
Multinomial Asymmetric Logit	✗	✓	✗	✗
Mixed Logit	✓	✓	✗	✗

Table 1 – Discrete choice models that can be estimated by each package

Package	Programming Language	Active?	Open Source?	Data preprocessing	Different choice sets per individual?	Allows to calculate Indicators?
Biogeme	Python 3 (implemented in C++)	Yes	Yes, but unknown license	Yes, using Pandas package and internal methods	Yes	Yes, willingness to pay, value of time, market shares, revenues, and elasticities
PyLogit	Python 2 and Python 3	Yes	Yes, BSD-3-Clause license	Yes, using Pandas package. Datasets must be converted to long format.	Yes	No
ChoiceModels	Python 2 and Python 3	Yes	Yes, BSD-3-Clause license	Yes, using Pandas package	Yes (only with PyLogit equation format)	No
mlogit	R	Yes	Yes, GPLv2	Yes, datasets must be converted to long format.	No	No

Table 2 – Comparative of the discrete choice model packages

3. PYKERNELLOGIT PACKAGE

The PyLogit package provides a good set of characteristics, integrates a variety of discrete models and its source code are available with an open-source license, therefore, it has been decided to extend this package to incorporate KLR models, which has led to the creation of the PyKernelLogit Python package. Figure 1 summarizes the main functionalities and dataflow necessary to estimate MNL and KLR models on PyKernelLogit. All the necessary functionalities for the estimation of KLR models have been integrated over the previously existing functionalities of PyLogit for the estimation of MNL models. In the following lines, the functionalities involved in the specification and estimation of a KLR model are described.

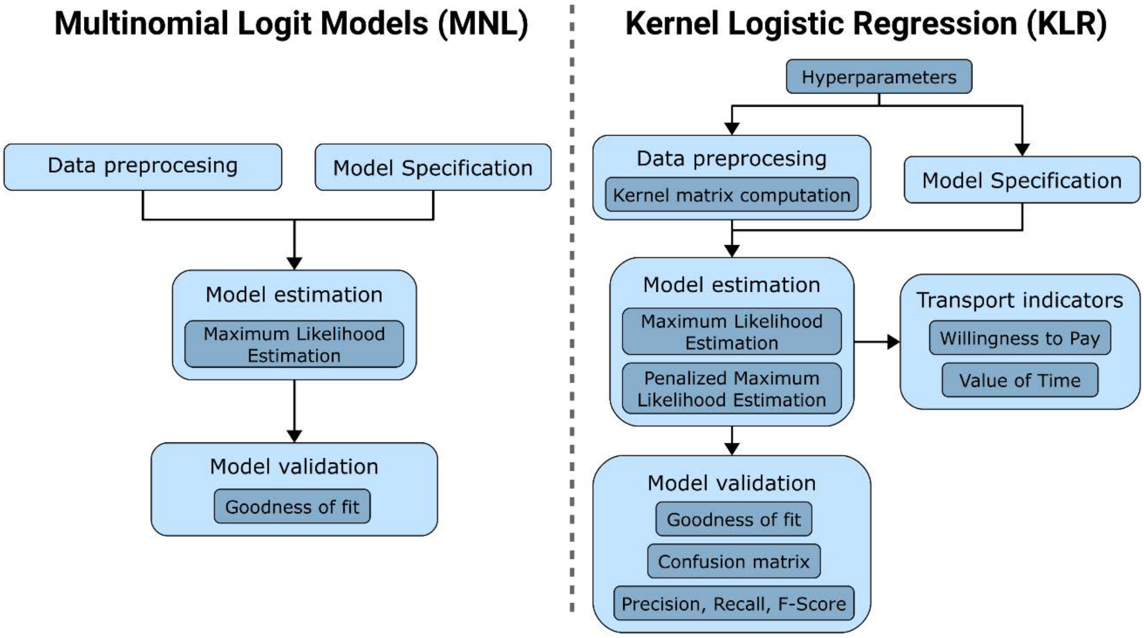

Fig. 1 – Comparison of MNL and KLR models on PyKernelLogit

3.1. Specification of the Kernel Logistic Regression Model

The KLR model builds some *latent functions*, $V_i(\mathbf{x})$ for all the alternatives i in the choice set C, which are equivalent to the systematic part of the utility functions in RUM, but in KLR they are considered as black box functions. The main problem is to find for each alternative i, its latent function $V_i : \boldsymbol{X} \mapsto \mathbf{R}$. KLR search for functions $V_i(\mathbf{x})$ within function spaces which are named *Reproducing Kernel Hilbert Spaces* (RKHS). The RKHS space is a vector space which is univocally generated by the so-called *kernel function* $k(\mathbf{x}, \mathbf{x}')$, and its associated RKHS space is denoted by $\mathcal{H}_k$. The family of functions $\{k(\mathbf{x}, \mathbf{x}')\}_{x' \in \mathcal{X}}$ constitutes a basis of the vector space. Any element from $\mathcal{H}_k$ can be represented as a linear combination of the basis elements, in particular, from $V_i(\mathbf{x}) \in \mathcal{H}_k$, the expression of the utilities is given by

$$V_i(\mathbf{x}, \alpha_i) = \sum_{n=1}^{N} \alpha_{in} k_i(\mathbf{x}_n, \mathbf{x}) \qquad (1)$$

KLR provides estimates of the class probabilities based on these utility functions $V_i(\mathbf{x})$

$$P(i|V, C) = \frac{\exp(V_i(x))}{1+\sum_{i=1}^{I-1} \exp(V_i(x))}. \qquad (2)$$

It should be noted in Eq. (1) that the non-parametric utilities defined by the KLR model are linear in their parameters. In the MNL models the deterministic part of the utility V_{in} can be defined using the linear function $V_i(x_{in}, \beta_i) = \beta_i^T x_{in}$. Therefore, the methods defined in PyLogit to estimate a MNL model can be also used to estimate the KLR model, but the vector $\mathbf{x}$ should be substituted by the kernel function $k(\mathbf{x}, \mathbf{x}')$.

Hence, instead of estimating the $\boldsymbol{\beta}$ vector of parameters, the program is going to estimate $\boldsymbol{\alpha}$. But first, it is necessary to pre-compute the Gram matrix (or kernel matrix) $\mathbf{K}^{(\mathrm{i})}$, which is defined as

$$\mathbf{K}^{(\mathrm{i})}_{\mathrm{n}',\mathrm{n}} = \mathrm{k_i}(\mathbf{x}_{\mathrm{in}'}, \mathbf{x}_{\mathrm{in}}). \tag{3}$$

Intuitively, the Kernel matrix represents how similar is the decision-maker n' with respect to the decision-maker n for the alternative i. PyKernelLogit allows to compute the kernel matrix for any input dataset. The software package allows to specify many different types of kernel functions, such as the Radial-basis function, the Rational Quadratic kernel, the Matern Kernel, etc. It also allows to specify compound kernels, which are kernel functions composed of a set of other kernels. Figure 2 shows a sample kernel matrix computed using a Radial-basis function for a dataset with 453 observations. PyKernelLogit provides the possibility to specify a reference dataset $\mathbf{Z}$ to be used when computing the kernel matrix. If no reference matrix is provided, then the kernel matrix would be a square matrix which contains the similarity between any two observations from the dataset. Nevertheless, as this approach is computationally heavy, sometimes it is required to use a resampling method to select a subset of the observations as the reference matrix $\mathbf{Z}$ or to generate this reference matrix artificially, for example using a grid over the domain of the data. If $\mathbf{Z}$ is specified, then Eq. (3) becomes

$$\mathbf{K}^{(\mathrm{i})}_{\mathrm{n}',\mathrm{n}} = \mathrm{k_i}(\mathbf{z}_{\mathrm{in}'}, \mathbf{x}_{\mathrm{in}}). \tag{4}$$

Fig. 2 – Kernel matrix $\mathbf{K}^{(\mathrm{i})}$

Once the kernel matrix has been created, PyKernelLogit allows to automatically define the kernel model specification, which was presented in Eq. (1), using the PyLogit syntax.

The user can select in the model specification if the same vector of parameters to estimate $\boldsymbol{\alpha}$ is going to be used for all the alternatives or, otherwise, if one vector of parameters $\boldsymbol{\alpha}_i$ is going to be used for each alternative i. Once the model has been specified, the choice model can be created an estimated.

3.2. Estimation of the Kernel Logistic Regression Model

PyKernelLogit extends the estimation capabilities of PyLogit by implementing a Penalised Maximum Likelihood Estimation (PMLE) procedure. In order to estimate the KLR model the following optimization problem must be solved

$$\underset{\boldsymbol{\alpha}}{\text{Minimize}} \sum_{n=1}^{N} \sum_{i=1}^{I} L\big(y_{in}, V_i(\mathbf{x}_{in}, \boldsymbol{\alpha}_i)\big) + \lambda \sum_{i=1}^{I} R_i(\boldsymbol{\alpha}_i) \quad (5)$$

where L(·) is a loss function that measures the discrepancies between the observed and the predicted classifications and λ is a regularization parameter in charge of controlling the trade-off between the goodness of fit and the complexity of the model. Finally, $R_i(\cdot)$ is the penalty function of the α_i parameters. PyKernelLogit integrates two of the most relevant penalty functions $R_i(\cdot)$ proposed in the literature, which are the LASSO and the Ridge regression (Castro, 2013).

The estimation of the KLR model is computationally heavy if the number of observations is high enough (Ouyed & Allili, 2018; Zhu & Hastie, 2005). The implementation of the PMLE procedure reduces significantly the estimation time. Nevertheless, PyKernelLogit allows to use different optimisation algorithms, so it has been tested the use of tree canonical methods for solving the PMLE problem defined in Eq. (5). The selected methods are:

- Newton-CG. This method, also known as the truncated Newton method, uses the nonlinear conjugate gradient algorithm by Polak and Ribiere to compute the search direction (Nocedal & Wright, 2006). This method is suitable for large-scale problems.
- BFGS. This method uses the quasi-Newton method of Broyden, Fletcher, Goldfarb, and Shanno (Nocedal & Wright, 2006). It uses the first derivatives only. BFGS has proven good performance even for non-smooth optimizations.
- L-BFGS-B. It is an optimization method based on quasi-Newton methods that approximates the Broyden, Fletcher, Goldfarb, and Shanno (BFGS) algorithms using a limited amount of computer memory (Byrd et al., 1995). It is a popular algorithm for parameter estimation in ML, because it is optimized for functions with a large number of parameters or with a high degree of complexity.

A KLR model has been estimated for all the combinations of penalty functions and optimisation algorithms previously described. The estimation was executed using a 5-Fold cross-validation procedure on a choice model problem.

Table 3 shows the mean value for the CPU time, the objective function (the log-likelihood) and the precision value obtained using the different combinations of penalty functions and optimization algorithms. The best recommendation based on the results obtained is to use the L-BFGS-B algorithm and the Ridge regression model. Nevertheless, if the number of variables to estimate is not considerably large, the BFGS algorithm can also be applied.

Estimation model	Algorithm	CPU time (seconds)	Objective function	Precision (%)
Maximum likelihood	Newton-CG	8.63	-265.5857	66.65
	BFGS	5.65	-265.9253	65.54
	L-BFGS-B	0.80	-273.1642	66.20
LASSO	Newton-CG	0.59	-342.8578	67.09
	BFGS	3.55	-307.6523	67.53
	L-BFGS-B	0.46	-312.3938	67.31
Ridge	Newton-CG	6.32	-291.4132	67.31
	BFGS	0.33	-291.4132	67.31
	L-BFGS-B	0.07	-291.4136	67.31

Table 3 – Comparison of different penalty functions and optimization algorithms

3.3. Model validation and assessment

PyKernelLogit allow to obtain several metrics for assessing whether a model is good enough for a specific application. One of them is the goodness of fit of the model (Train, 2003), which is a statistic that describes how well a model, with its estimated parameters, performs compared with a model in which all its parameters are zero (which is usually equivalent to having no model at all). Once the model is estimated, PyKernelLogit provides the likelihood ratio index (also called McFadden R square), which is defined as

$$\rho^2 = 1 - \frac{LL(\hat{\beta})}{LL(0)}. \qquad (6)$$

However, goodness of fit metrics cannot assess how the model predicts on new data points, for which it has not yet seen the true value of the dependent variable (the alternative chosen).

For this reason, PyKernelLogit integrates some other model validation techniques. One of these techniques is the confusion matrix (Géron, 2019). Once the model has been estimated using training data, the confusion matrix can be computed over the test data for which the true values are known. Each column of the confusion matrix represents the instances in a predicted class while each row represents the instances in an actual class. Using this matrix, it easy to identify if the model is confusing two classes.

The confusion matrix gives useful information, although sometimes it is preferred a more concise metric. Another interesting way of assessing the performance of a model is to look the accuracy of the positive predictions, which is called *precision*. This metric has an important drawback because if the model makes a single positive prediction and it is correct, then the precision will be 100%. For that reason, the precision metric is commonly used along with another metric called *recall*, or *sensitivity*. The recall is the ratio of positive instances that are correctly detected by the classifier. Finally, there is a third metric called *F-score*, which combines the precision and the recall results to compute the score. The *F-beta score* is the weighted harmonic mean of precision and recall, reaching its optimal value at 1 and its worst value at 0. The β parameter determines the weight of recall in the combined score. When $\beta < 1$, the F-score lends more weight to precision, while $\beta > 1$ favors recall. The evaluation of the precision, recall and F-Score metrics requires to compute for each class i the number of True Positives (TP), False Negatives (FN), True Negatives (TN) and False Positives (FP) instances.

The previous metrics are defined por binary classification problems, i.e. only two alternatives are considered. Nevertheless, when there are more than two alternatives in the model, the quality of the overall classification is usually assessed using two techniques (Sokolova & Lapalme, 2009):

- Marco-averaging. Each measure is the average of the individual measures calculated for all the alternatives.
- Micro-averaging. Each measure is obtained computing firstly the cumulative TP, FN, TN and FP for all the alternatives.

PyKernelLogit allows to obtain the precision, recall and F-score metrics for micro- and macro-average methods. Table 4 shows how the previous metrics have been implemented in the software package.

	Precision	Recall	F-Score
Micro-average (m)	$\frac{\sum_{i=1}^{I} TP_i}{\sum_{i=1}^{I}(TP_i+FP_i)}$	$\frac{\sum_{i=1}^{I} TP_i}{\sum_{i=1}^{I}(TP_i+FN_i)}$	$\frac{(\beta^2+1)\text{ Precision}_m \text{ Recall}_m}{\beta^2 \text{ Precision}_m+\text{Recall}_m}$
Macro-average (M)	$\frac{\sum_{i=1}^{I} \frac{TP_i}{TP_i+FP_i}}{I}$	$\frac{\sum_{i=1}^{I} \frac{TP_i}{TP_i+FN_i}}{I}$	$\frac{(\beta^2+1)\text{ Precision}_M \text{ Recall}_M}{\beta^2 \text{ Precision}_M+\text{Recall}_M}$

Table 4 – Precision, recall and F-score metrics for multi-class classification

3.4. Computation of economic indicators

Once a discrete choice model has been estimated using the PyKernelLogit package, it can be useful for the analyst to extract some indicators from this model. There are many indicators that are particularly relevant in the context of discrete choice models, such as, Willingness to Pay (WTP), Value of Time (VOT), elasticities, consumer surplus, market shares and revenues. Currently, PyKernelLogit allows the estimation of the WTP and VOT indicators.

The WTP allows to analyse the trade-off between any variable from the model and money. Let consider that c_{in} is the cost of the alternative i for a decision-maker n, and x_{in} is the value of another model variable. Now, let $V_{in}(c_{in}, x_{in})$ be the value of the utility function that is associated to an alternative i for a decision-maker n. Then, the WTP can be computed as

$$\text{WTP} = -\frac{\partial V_{in}/\partial x_{in}}{\partial V_{in}/\partial c_{in}}. \quad (7)$$

The VOT indicator is closely related with the previous one, as it reflects the price that a traveller is willing to pay to decrease the travel time in one unit. Therefore, VOT can be computed as

$$WTP = \frac{\partial V_{in}/\partial t_{in}}{\partial V_{in}/\partial c_{in}}. \quad (8)$$

The WTP and VOT indicators can be computed using a closed form expression for linear MNL models. Nonetheless, in KLR Eq. (7) and (8) does not have a closed form expression for some kernel functions and the partial derivatives must be approximated numerically. PyKernelLogit allows to calculate the WTP and VOT indicators for KLR models easily. It implements the Newton's difference quotient method to compute the partial derivatives of Eq. (7) and (8). One advantage of PyKernelLogit is the fact that it allows to compute the WTP an VOT indicators for certain values of the attributes.

3.5. PyKernelLogit package installation

PyKernelLogit source codes are available under an open-source license in a Github repository (https://github.com/JoseAngelMartinB/PyKernelLogit). In addition, a compiled version of PyKernelLogit is available for its installation on the Python Package Index (PIP) at https://pypi.org/project/pykernellogit/. The package can be installed on a computer with any operating system, provided that a Python distribution is available (preferably Python 3.7 or later), using the command:

```
$  pip install PyKernelLogit
```

Interested authors can find more detailed information on Martín-Baos, (2019).

4. CONCLUSIONS

In this work, an open source software package called PyKernelLogit has been developed for Python programming language. This software package allows to implement several discrete choice models, to apply several model validation techniques and to obtain a set of economic indicators. The package extends the capabilities of the original PyLogit package, which was able of estimating MNL models and its derivatives, and integrates the KLR models. The interest on aggregating the KLR model to the software package arises from two reasons. Firstly, KLR models are machine learning models which relieves the analyst from specifying a functional expression of the utilities beforehand through the use of the kernel functions. Moreover, KLR models have better predictive capabilities than the MNL models for non-lineal effects.

Our future work will be focus on extending the KLR model utility specifications to other discrete choice models such as Nested Logit models.

In addition, we will integrate into PyKernelLogit estimation procedure the Tikhonov regularization procedure. Finally, new features will be implemented to retrieve other economic indicators such consumer surplus, market shares, elasticities, revenues, etc.

ABSTRACT

The phenomenon of "smart cities" generalizes the use of Information and Communication Technologies. The generation and use of data to manage mobility is a challenge that many cities are betting on and investing in. Through the Internet of all things (IoT) and the use of sensors and mechanisms for capturing information, the number of data analysis tools such as Big Data, Artificial Intelligence (AI), and Augmented Reality (AR) has increased.

The tools that are used to interpret events are applied to the analysis of video and photographic images and comprise of a set of programs, mathematical algorithms and protocols. The implementation of procedures could enable the automatic interpretation of image information, from the most basic such as changes in the presence of objects or people, to the identification of complex shapes and relevant event detection. With the constant use of the assisted process learning (Machine Learning), it’s possible to improve event interpretation through the customization of learning protocols.

Repetitively trained software can identify relevant events and report changes in critical scenarios that can trigger a series of protocols. The use of artificial intelligence techniques makes it possible to automate monotonous processes and improve transport management.

This article analyzes different technologies used to generate transport information and data validation. It is intended to experiment with the use of technologies in the detection of relevant facts, changes of state, and identification of events. It also measures the reliability level when detecting events, and studies the implementation of possible solutions into the transport management system, in order to assist in decision making processes.

1. INTRODUCTION

There is an increasing interest in the potential of the Information and Communication Technologies to manage and police urban transport issues. Recent advances in urban monitoring and sensoring applications have broadened the landscape of managing transport operations and infrastructures. Monitoring of transport processes is a key issue in efficient mobility. Sensoring and monitoring not only reduces the need for expert operators, thereby lowering costs, but it also allows quicker incident detection and consequently its prompt risk management.

This article aims to show a series of experiments in the field of transportation management in which Big Data, Artificial Intelligence and Augmented Reality techniques are used with different levels of interaction and integration. The experiments carried out are intended to show in an empirical way potential uses of these technologies separately and with different degrees of integration in order to try to manage specific situations of parking places management in urban sections.

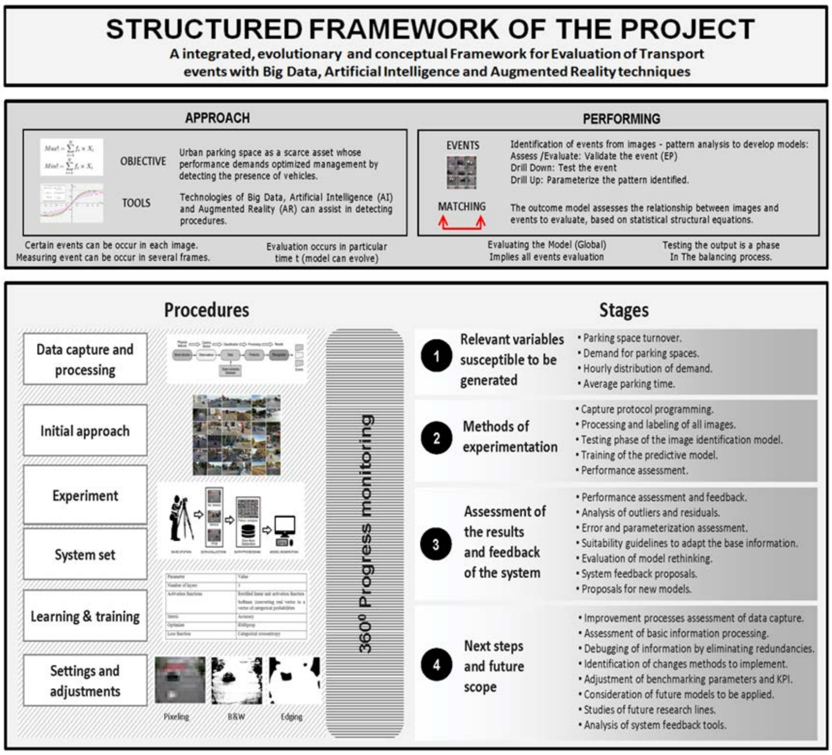

Figure 1. Structured framework of the project.

The purpose of the experiments carried out in this study is to provide better tools for managing parking spaces. Vehicles detection is considered as a challenging field in computer vision. The experiments are based on the recognition of traffic-related events, specifically the identification of changes in traffic and parking status. Artificial Intelligence protocols will be used for this purpose. Next, management and communication techniques of relevant information and assistance in decision making by the agents involved in mobility management will be used, evaluating in some cases the introduction of Augmented Reality methods. Finally, Big Data techniques have a transversal character as they are present in the implemented applications of Artificial Intelligence and Augmented Reality.

The article frames some applications in the domain of mobility, Smart Cities and urban space Management. In addition, several experiments were carried out to develop a vehicle detection system. Various smart technologies have been repurposed to inform appropriate response measures. It has been evaluated as the combination of AI and AR technologies yielded the best results.

2. AWARENESS OF THE PROBLEM

2.1. Urban parking space as a scarce asset that should to be optimized.

In urban environments, motorized vehicle trips require the reservation of space for circulation and parking, especially in areas with high demand and intensive land use. Traffic space is shared by private vehicles, but also by public transport, bicycles and pedestrians. For the authorities in charge of managing public space, it is a challenge to distribute uses for transit, private vehicles, pedestrian and parking mobility.

In urban central districts, public space is a scarce resource that is assigned to different uses. It can be considered, that much of the public areas are divided between the surface reserved for pedestrian traffic, mainly sidewalks and roads dedicated to traffic. The sidewalks are reserved for the priority transit of pedestrians, although in certain sections the circulation of bicycles and the parking of two-wheeled vehicles are allowed. In turn, there are areas of unique access to pedestrians (parks, gardens, beaches ...). The circulation routes are dedicated to the vehicles with reserved sections according to uses (bus-taxi lane, bike lane ...). A part of the road is reserved for parking vehicles on the surface with different types of regulations and different reservations.

The great demand for public space in dense urban environments pressures the specialization of land uses and its reserve for specific uses, both dedicated and by time slots. The management of such a scarce resource requires the application of different techniques and technologies that allow optimizing its use. In this sense, different technologies can contribute decisively in the management of mobility and optimization of public space uses.

The use of Big Data, AI, AR applications in the field of urban mobility can bring advances in the control of the mobility that can result in the improvement of safety conditions and the transports system efficiency.

The allocation of public space and its distribution among different users and modes of transport is one of the most important policy areas of territorial management in general and mobility in particular. The management of public space includes traffic management, integrating measures aimed at adjusting the supply of public space with the demand for mobility, taking into account the different modes of transport and their road space requirements.

The city of Barcelona has 1,362 kilometers of roads. The basic network comprises 27.5% of the streets of the city, which absorb 82.04% of circulation. The City Council has carried out, in recent years, pacification projects, especially in the central areas of the different neighborhoods. The measures implemented consist of reconverting areas for pedestrians, widening sidewalks, raising roadways and creating unique platforms, as well as reducing the accessibility of motor vehicles and speed of traffic to ensure the safety conditions.

From the data of the statistical yearbook of Barcelona, table 1 shows the evolution of the surface of sidewalks, road and the length of the streets. It can be observed how the extension of surface area for pedestrians has expanded in recent years, while that for cars has decreased (AJUNTAMENT de BARCELONA 2015; 2018).

Public Road	**2011**	**2012**	**2013**	**2014**	**2015**	**2016**	**2017**
Street KM	1361,8	1369	1369	1368	1368	1368	1368
Total Surface of Barcelona (km^2)	102,6	102,6	102,6	102,6	101	101,3	101,3
Surface intended for the vehicle (km^2)	10,9	11,4	11,4	11,4	11,4	11,4	11,4
Surface intended for the pedestrian (km^2)	15,32	15,81	15,81	16,18	16,83	17,52	17,52

Table 1. Evolution of the distribution of space in the city of Barcelona.

The municipal forecast is that all streets that are not part of the basic network have to become part of a pacified zone. These streets have to have a different character, depending on the hierarchy they occupy within the secondary network (segregated spaces, single platform, etc.) and they have to abide by the restrictions in the speed of the vehicles and priorities of step that regulate them. According to the municipal data, currently, about 56% of the city's road network gives priority to pedestrians or is pacified.

The road network has acquired a great specialization. It has gone from a wide basic road network, to a greater segregation of the road by uses, so that the local road network or non-basic network, is hierarchies in different categories. In urban dense areas such as the City of

Barcelona, mobility management implies acting on a great variety of modes of transport. The priorities are to reduce private vehicles mobility and promote public transport. Although it is desirable to discourage the use of private vehicles, it is also important that those private vehicles that circulate can do it smoothly, without congestion.

The challenges posed by the "smart cities" and their concretion in the "smart mobility" involve the implementation of technologies such as assisted and autonomous driving, sensitization, processing and massive use of data (Big Data), geolocation, systems navigation, Artificial Intelligence (AI) and other areas that make the knowledge of the current behavior of users of motorized two-wheelers have a great future potential and opens the way to a wide field of research (VIDAL TEJEDOR, N. 2015; VIVES, A 2018).

3. USE OF BIG DATA, ARTIFICIAL INTELIGENCE (AI) AND AUGMENTED REALITY (AR) IN URBAN TRANSPORT MANAGEMENT

The Big Data, the Artificial Intelligence (AI) and the Augmented Reality (AR) tools use will reshape the urban transport management, leading to fast adoption of more efficient transport integrated systems at an unprecedented rate. Traffic professionals continuously apply management strategies in order to maximize the productive use of the infrastructures. The use of those technologies could elevate and improve the transport management experience dramatically. This article focus on use of Big Data, Artificial Intelligence (AI), and Augmented Reality (AR) has increased to help solve problems of Transportation Analysis aiding human intelligence in functioning of machine and systems.

Big data implies an exponential availability of information and its accessibility, which enhances the capacity to assess data relevance. The significance of information is proportional to its meaningfulness. Its value lies in how we use it to guide our decisions and place it in a specific knowledge framework.

Some authors have highlighted the potential that Augmented Reality has, so that they consider that a breakthrough is not only machines that think, but machines that allow us to increase our perception and how the fact that officials will have improved cognition systems can transform power relations (Anderson, R. 2020.). Thanks to the development of the Artificial Intelligence (AI) new forms appear in the convergence of machine learning and deep learning. The union of Machine Learning algorithms with artificial neural networks and deep learning are being used in numerous and several fields. Artificial intelligence is already embedded into traffic control the ability to detect the presence of pedestrian and vehicles (BENGTSSON, P. 2018).
The developments that Big Data has brought about in the efficiency processing of huge quantities of data are closely related to Artificial Intelligence and Augmented Reality applications, making possible better learning algorithms (PASTOR, R. (2018).

On the basis of the number-crunching power is the improvements of digital computers. The exponential rise in crunch power lets ordinary-looking computers tackle tougher problems of Big Data and pattern recognition.

The optimal approach to getting machines to solve difficult real-world challenges is to set them up as statistical learning machines that can benefit the most from exposure to massive amounts of data. These technologies can come to learn to solve complicated tasks by detecting patterns, and patterns between and within patterns, hidden from the vast data streams to which they are exposed. Big Data technologies have made it possible to provide a capacity to manage enormous amounts of data with which to feed the algorithms that underlie Artificial Intelligence technologies. Data crunching is at the basis of the operation of deep learning algorithms that make it possible to profoundly examine data flows, yielding systems that work to provide solutions to solve problems, but whose knowledge structures are opaque to the technicians who created the system, so that the resulting algorithms can be used with levels of significance of the results, totally unaware of the reasons that make their significance levels possible. In this way is acceptable that current and future AIs solutions are forms of intelligence feeding off Big Data and crunching statistics in ways that render their operational engines opaque to human understanding.

Artificial Intelligence (AI) applied to the interpretation of video or photographic images comprises a set of programs, mathematical algorithms and protocols that make it possible from a process assisted learning (machine learning), the possibility of interpreting events from the computer processing of images. From the customization of learning protocols, in an automatic way it is possible to interpret events in images, from the most basic ones, such as the presence of objects or people, to the identification of complex shapes.

The use of Artificial Intelligence (AI) can be a valuable tool to assist in the detection, interpretation of events, state vision, and identification of relevant facts. In this sense it can be useful in assisting in case detection, alert triggering and helping in decision making to assist in dealing with situations that demand more or less immediate responses.

There are several areas in which these technologies are used in the management of traffic. One of the main fields is vehicle identification: AI in the area of traffic management can be used mainly in traffic jam recognition and management. These systems could perform the task of tracking and locating vehicles in real time and adapt traffic management according to current or predicted conditions to accommodate lanes or fast sections for emergency services. These technologies can also be used to detect infractions, which will help municipal and traffic authorities to identify them, develop effective prevention systems and apply the corresponding penalty (JIN, J. and DENG, Y. 2017).

However, the adaptation of these technologies to cities and roads must consider safety, so it is necessary to establish systems that prioritize avoiding traffic accidents; one of the additional facilities performed by these technologies are the identification of people at risk, in order to warn or prevent reckless actions of pedestrians, crossing streets inappropriately, identifying motorcyclists who did not wear helmets properly (CHIVERTON, J. 2012) and estimating the driver's workload (MANAWADU, U. E. et al. 2018).

BARLOW,H.(1989) was one of the first to appreciate the importance of unsupervised learning as opposed to reinforced learning, so that unsupervised learning applied to big data and artificial intelligence allows to identifies "statistical regularities", or patterns in its inputs in the form of possible discrepancies that allow it to identify and deal with potential underlying patterns. This information theory-based approach embodies many modern approaches to unsupervised learning in neural networks and Bayesian learning.

4. RELEVANT VARIABLES SUSCEPTIBLE TO BE GENERATED

The purpose of the experiments carried out in this study is to provide better tools for managing parking spaces in urban sections. Vehicles identification is considered as a challenging field in computer vision. We consider the vehicle detection problem as the basis for extracting relevant variables for parking space management in urban areas sections.

We study the case of the vehicle presence identification in parking line section. Our research goal is to test a method to identify vehicles and types of vehicles presence in a street section. Once an object has been detected, the next challenge is object localization in the section. Object detection deals with finding the objects that are present in an picture. The technologies for the recognition of elements in a road section are based on the interpretation of a set of digitized data captured by different means. Based on these data, different tools can create analogies and models that simulate the presence of defined objects on a road section. One of the most common applications of Big Data, AI and ER is the use of photography to identify events. In the case of urban traffic a primary event would be to recognize the presence or not of vehicles on a section road.

Once the presence of vehicles on a stretch has been detected, we can lay the foundations for building variables such as counting vehicles, estimating speeds, identifying vehicle types, calculating parking space turnover, detecting violations and many other different variables relevant to traffic and parking management. With the above technologies we can develop accurate techniques to identify the presence or not of vehicles in a stretch and we can have a basic tool to develop traffic management devices.

A basic stage would be to have a device, in this case that answers the bionomial question: Are there or not vehicles on a specific section, with a Boolean answer.

Knowing whether there are vehicles on a road or in a parking space is relevant information for traffic management. If the information can be obtained periodically, we are able to evaluate changes in status.

So it can be used to detect presence, and count vehicles in a section (measuring capacity) or to determine the rotation of parking spaces. In this way, the dynamic management of information and its analysis can be relevant in traffic management.

Relevant variables related to parking space management that can be expected to be generated in future phases of our experiments are:

- **Parking space turnover:** number of vehicles parking in a space over a period of time.
- **Demand for parking spaces:** Usage ratio, based on the number of vehicles driving on the section and the number of vehicles that end up parking.
- **Hourly distribution of demand:** Use of parking spaces throughout the day and therefore peak and off-peak periods.
- **Average parking time:** Length of time the vehicle is parked in the space.

In order to generate all of the above variables, the basic variable to work with is to detect the presence of vehicles on a section of road. So if it is not possible to detect the presence of vehicles, it is not possible to progress to the following phases. This is why the experiment focuses on identifying the presence of vehicles on a stretch of road. Once a high level of reliability is achieved in identifying the presence of vehicles on a stretch of road, it is possible to move on to more complex phases of information generation, such as identifying parking in a spot and, from there, estimating parking times.

5. METHODS OF EXPERIMENTATION AND PROCEDURES TO DETECT PRESENCE OF VEHICLES IN A STREET SECTION

5.1 Outline of the methodology applied.

The study is forward-looking in approach. The initial objective is to produce a large number of images that will allow the building of a database in which each image will be linked to certain attributes for fields. Starting from the basic information, the learning process is conducted, following which the levels of accuracy are evaluated. Then different techniques are applied to improve the reliability of the results. Finally, the results are presented and a proposal is made for uses and future developments.

The phases of the project are:

1. **Capture protocol programming.** In order to obtain images from the installed cameras, it will be necessary to develop a computer program to capture the images. For this purpose, software will be developed with code that will implement the following operations at each programmed interval: open the browser with the IP address, capture the images for each image, label the images and store them sequentially in a database.
2. **Processing and labeling of all images:** Generation of image database. A database will be designed with the identified attribute fields of the images. Then a specialist will analyze the images one by one and will fill the database with the selected attributes.
3. **Testing phase of the image identification model.** Based on the images and the associated database, it is possible to develop the testing phase for the identification of events in the images.
4. **Training of the predictive model.** The central phase of the application of Artificial Intelligence techniques goes through the training of the model, from different treatments of the images adapted pixel matrices and chromatic treatments.
5. **Test run. Once the model is trained, it is possible to identify the degree of reliability in the identification of events.** Once the program has been run with the images to be detected, reliability tests can be performed in different scenarios.
6. **Performance assessment.** Result study to improve predictability, elimination of false positives and robustness of the system. From the statistical reliability data of the systems, different techniques can be applied to debug the results and filter out false positives, thus increasing the degree of reliability of the system.

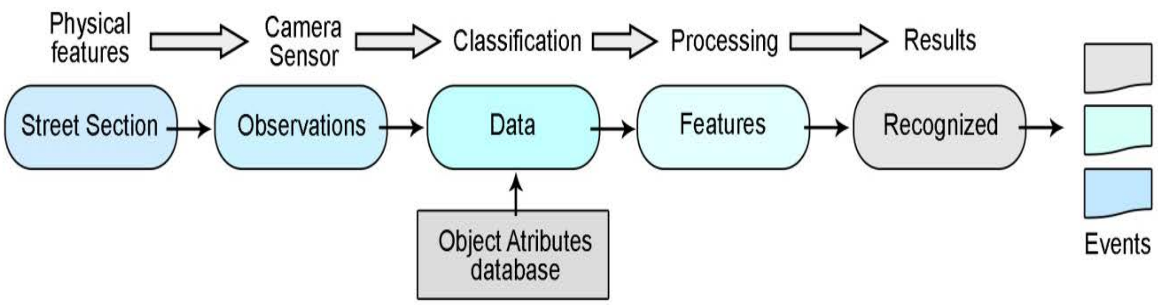

Figure 2. Process scheme of the built-in procedure from the data collection system to the handling of the data and the identifying stages.

5.2 Initial approach to vehicle presence identification.

A first exploratory experiment has been carried out, consisting of analyzing photographs from different sources related to stretches of roads. The purpose of the exercise was to assess the feasibility of assessing the presence of vehicles on different stretches of roads regardless of the origin of the information collected, so that if the experiment proved to be satisfactory, we should be able to have a generalist tool for assessing the detection of the presence of vehicles on stretches of traffic sections.

In this experiment the first level was carried out in the following way: Initially we proceeded to capture images of the Google Street View application with the intention of having a sufficiently large bank of images to start testing with the AI software. A total of 2,097 photos were captured, which were classified manually on the one hand, depending on whether vehicles were observed or not; and on the other hand, depending on whether they were in an urban or interurban environment.
The classification of the images was carried out to evaluate the degree of success of the application, being able to compare the results obtained from the analysis of the images by the analysis application with those observed by a person.

Figure 3. Sample of images used in the performance of the experiment to identify the presence of vehicles and the type of road section.

Two different experiments were carried out on two scopes of information contained in the pictures: One experiment tested whether or not vehicles were detected on the section and the second experiment tested whether the section was an urban street or an interurban road. The analysis was carried out by performing binomial tests in which two sections were performed: a first phase of model training and a second level of testing on the presence or absence of the event.

The results were found to be poor and unreliable. Therefore, it became obvious that the kind of images used did not lead to results that could be suitable as a basis for the development of any kind of application.

It was found that there are different factors causing the poor results, among others the different sizes, lighting, exposure, orientation, quality and accuracy of the images. These considerations lead to the conclusion that in order to conduct this type of experiments it is necessary to consider initially the use of images taken by the same camera, focus, ambient, exposure, orientation and zooming.

6. EXPERIMENT

6.1 Design of the experiment.

In this section, we described in detail the experiment carried out about how to detect vehicles on an urban street section from images and the usage of the technology.

The poor results of the initial approach using external images and explained in the previous section led us to the perspective that in order to have a better control of the experimentation it is relevant to generate one's own images. That is why we conducted this new experiment using raw images captured by our own devices and which are explained as follows.

The experiment consisted of selecting a section of urban section to initially analyze the phenomenon of the presence of vehicles on the stretch. Once a high reliability in the detection of the presence of vehicles is achieved, it is possible to advance in the generation of variables for monitoring the use of parking spaces by vehicles.

An ideal environment was sought in Barcelona that met the requirements: continuous presence of vehicles, among which: cars, taxis, motorcycles, bicycles, as well as the presence of pedestrians.

The photos had to be taken from a certain height in order to obtain a clear image of several lanes of traffic and thus control vehicle traffic. All these requirements were met, in the centre of the town of Barcelona, which supports a high rate of circulation compared to other parts of the city.

The place chosen was the Carrer de Provença, from a floor where the circulation of the vehicles was observed properly by the two existing lanes, as well as a two-way bike lane is observed and a pedestrian alley is available. It implies the continuous transit of pedestrians which cross the Carrer de Provença.

Figure 4 shows the elements of the set. Image capture was conducted with a Canon camera (model EOS 50D DS126211 and Canon zoom lens EF-S 17-85mm F 4-5.6 IS USM) and the storage of the images was downloaded into a DELL laptop. OpenCV, a computer-vision library was used for automatic image processing.

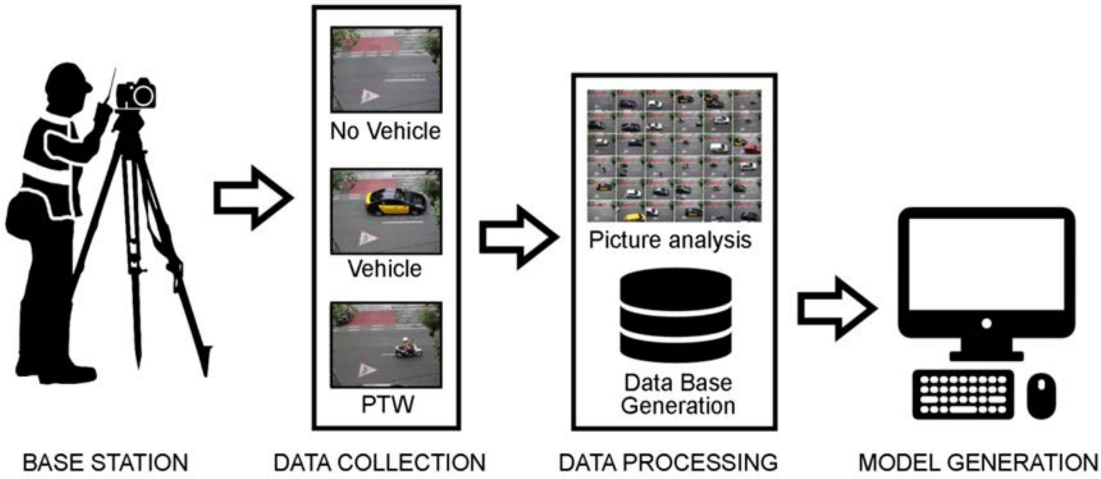

Figure 4. System Set. Design of the images capture system from a base station and data processing for the preliminary pretreatment of the data.

Once the location was chosen, several tests were taken to evaluate the chances to collect the images in the adequate environment conditions. The frame of action has been a stretch of road considering the width and the set of lanes that make up the section.

The location had adequate visibility conditions so that data collection could be performed in an automated manner without the continuous assistance of operators.

A camera was pointed at the road and pictures were taken over a period of time. The camera was connected via cable to the DELL laptop. The first realized were made from the time-lapse of the camera while was connected to the laptop, it was programmed so that every five seconds it took a picture. Once this step was done, they began to classify the photos.

For the management of the photographs, it was used as a photographic assistant the software of the Canon Reflex camera used to perform image capture. The computer used for data processing has an Intel I5-9400 processor running at 2.9 GHZ, with a RAM memory of 19 GB, and the graphics card used is a Radeon RX-580 graphics card.

Figure 5. Sample of different pictures taken for the performance of the experiment.

Each photo was analyzed by a specialist and a database was created in which the numeration of the photograph was collected and the following fields were filled in with binary data (0: negative; 1: positive): presence of vehicle, the vehicle is a car, the vehicle is a PTW, the vehicle is a heavy vehicle, the vehicle is a cab. (LIM, G.H. et al.).

Picture #	Vehicle presence	Car	PTW	heavy	Cab
#00001	0	0	0	0	0
#00002	0	0	0	0	0
#00003	1	1	0	0	0
#00004	1	0	1	0	0
#00005	0	1	0	0	0

Table 2. Fields of the dataset

The use of deep learning allows detecting an object with certain accuracy. Open source AI libraries and data flow graphs were used to develop the neural network. To create neural networks with different layers, TensorFlow and Keras (an end-to-end open source platform for machine learning by Google) as a R modules was used, which allows building a neural network based on the requirements of the model with Keras deep learning API.

Once pre-processing data was done, before training the sequential model, values for hyper parameters were chosen. Batch size (number of training examples present in a single batch), epoch's number (number of iterations passing the full dataset by the network) and learning rate (amount that the weights are updated during training) have to be fixed.

The used hyper parameters are shown in the following table:

Hyper parameter	Value
BATCH-SIZE	128
NUM_EPOCHS	100
LEARNING RATE	0.01

Table 3. List of the selected values for the hyper parameters selected for sequential training.

The API requires other general parameters to compile the Keras model that in this case are fixed as the following table summarizes:

Parameter	Value
Number of layers	3
Activation functions	Rectified linear unit activation function Softmax (converting real vector to a vector of categorical probabilities
Metric	Accuracy
Optimizer	RMSprop
Loss function	Categorical crossentropy

Table 4. Summary table of additional general parameters applied in the compilation procedure of Keras model.

About 2100 images were prepared to train. In our research, the primary target output is whether or not there was a vehicle on the section of road.

Two experiments were performed: the first one was to identify the presence of the vehicle on the stretch and the second one was to try to identify the type of vehicle.

The first experiment consisted in identifying or not the presence of a vehicle on the section. From the training phase images with and without vehicles on the section where used and then went on to a second phase to perform the testing of the training carried out previously. Once the algorithm is selected, we proceed to split the pre-processed data. A percentage of the data, typically 80% of the total, will be used as training data and the rest 20% to evaluate the model performance.

Once the model is fitted, the next step is the model evaluation phase. This will be done with the remaining data, that which was not used for the training phase, which will be referred to as model evaluation data. In other words, it will be the data to which will be applied the fitted model. On this data will be used to achieve the initial objective and evaluate it.

The metric for assessing the results of the experiments is accuracy (simply a ratio of correctly predicted observation to the total observations) and precision (ratio of correctly predicted positive observations to the total predicted positive observations), which are calculated as shown below:

	Predicted class		
Actual Class		Class = Yes	Class = No
	Class = Yes	True Positive	False Negative
	Class = No	False Positive	True Negative

Table 5. Relation of the parameters applied in the classification of the classes and results of the events.

$$Accuracy = \frac{TP+TN}{TP+FP+FN+TN} \quad (1)$$

$$Precision = \frac{TP}{TP+FP} \quad (2)$$

Where TP= correctly predicted positive values, TN= correctly predicted negative values, FP= incorrectly predicted positive values and FN= incorrectly predicted negative values.

The experiment of identification vehicles on the section was performed and a level of 64 % was matched.

The results have a level of significance that allows us to propose in the advance of performing calculations to count vehicles in a street section.

The second experiment that was carried out was to try to identify the type of vehicle. It must be taken into account that it is already part of a high determining factor and that is that the system has an accuracy level of 64% to detect or not vehicles in the section, so there is already a level of lack of precision to pass to the second experiment.

After the training phase (machine learning) and testing of the second experiment it was found that the results were not representative and therefore that the type of vehicle that circulated on the section could not be reliably identified.
Once the two initial experiments have been carried out, the conclusion is reached that for the

time being we discontinue advancing in an identification model of the typology of vehicles that are on a section of road and we focus on a model of identification of the presence/absence of vehicles in a section of urban road.

The next steps to be carried out in the following sections are the implementation of image processing adjustments and the use of augmented reality techniques, in order to improve the reliability of the model and the reduction of the volume of information to be managed.

Some adjustments were made to the images to reduce their size, decrease their resolution and switch them to black and white, so that more pictures could be taken in order to develop an experiment and obtain the most detailed results possible.

The following sections show different image debugging procedures and the application of data optimization methods to evaluate possible variations in the results obtained.

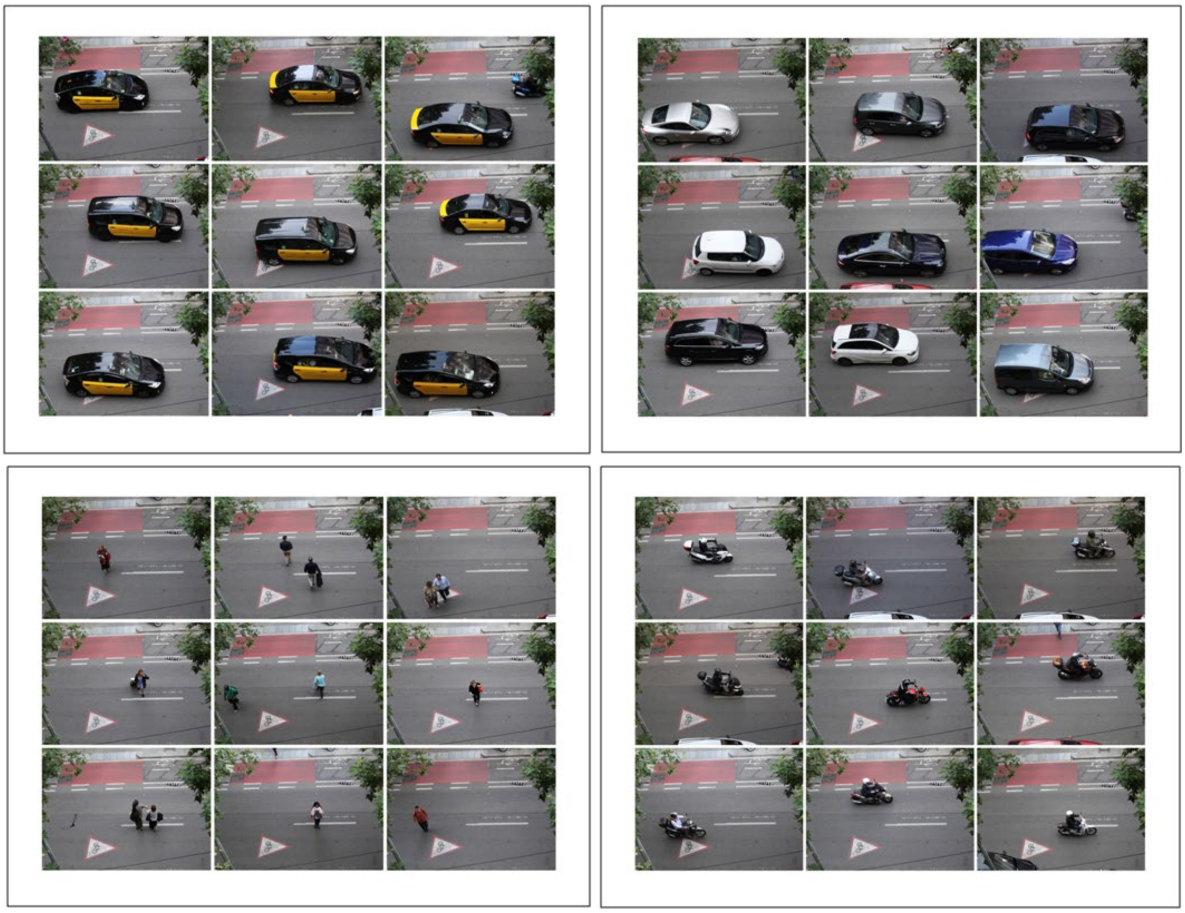

Figure 6. Different types of entities that can be identified in the information capture and analysis environment.

6.2 Reduction of image size by pixel processing.

One of the problems of working with photographs is that the more information they contain, the more accurate they are, but there is a significant increase in the size of the files, which makes them difficult to manipulate and process in the analysis and elaboration of results. (DEY, V., et al. 2010). Image pixelation allows the clustering of spectral information and enables the matrix comparison of a smaller quantity of data, which increases the processing rate of the information.

In this stage, we proceeded to apply techniques to reduce the size of the photographs by increasing the pixel size. The size of the photos has been reduced by enlarging the pixels. This is intended to manage the photos, improve the processing speed and even the data transfer if smaller photographs are available to keep the results high, the system experiences several improvements. First of all, a smaller volume of information is required, which increases the speed of data processing, analysis and transport.

It can be seen how by means of image pixelation techniques it is possible to significantly reduce the size of the images. The training phases (machine learning) and testing of the results are carried out and a reliability of 51% is found. Therefore, a significant reduction in the accuracy of the results is observed.

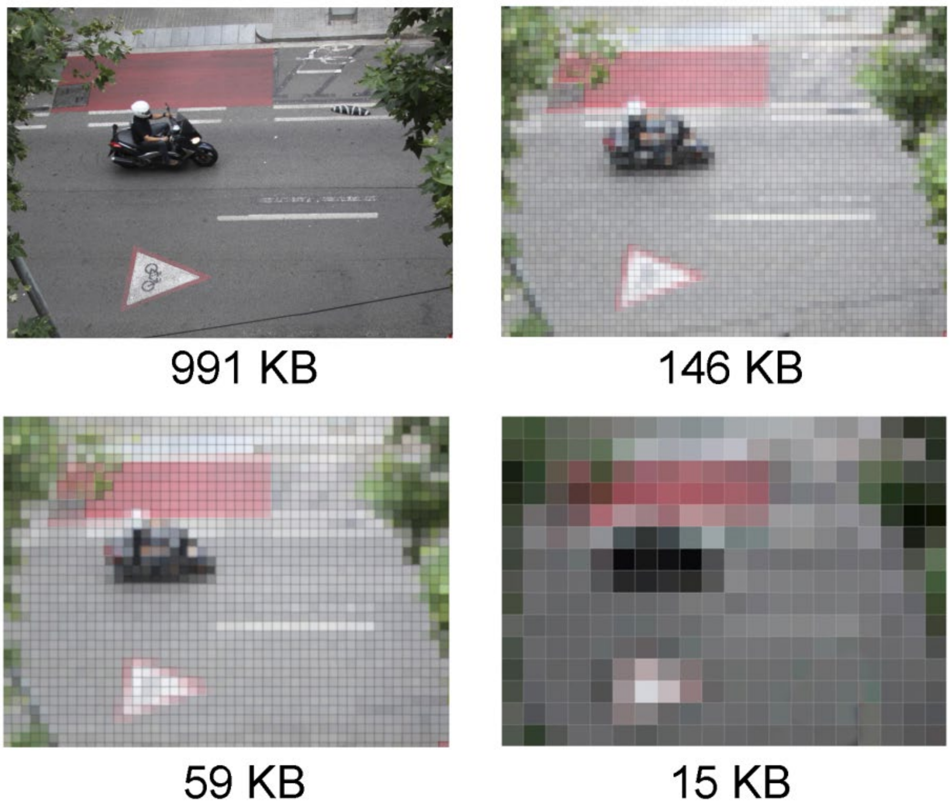

Figure 7. It can see the pixel processing with the output grid for size reduction in a ratio 65 times smaller.

6.3 Transformation of black and white photos.

We proceeded to process the images in black and white. Working with black and white images also helps to mitigate problems such as errors associated with shade and mitigates problems with bright light. The processing of the images goes through a phase of change to grayscale and then to black and white. It should be noted that the focus cannot cope with gradual illumination changes in the scene.

Vehicle detection is hampered by bright sunny conditions combined with shaded areas. Using black and white images can diminish the influence of excessive brightness and shadows "noise" in the frame. If the shadow contour is not clearly detached from the objects, the possibility of detecting moving targets is enhanced. Different algorithms for moving object detection work on detaching vehicles from their shadows to achieve better results (KILGER, M. 1992).

It is stated that the processing of the images to black and white allows reducing the size of the frames in the order of 7 times lighter in weight and thus simplifies data processing and transmission.

Once the images have been processed and rendered to black and white, the training process (machine learning) and testing of the results is carried out and a reliability of 48% is found. A significant reduction in the accuracy of the results is noticed.

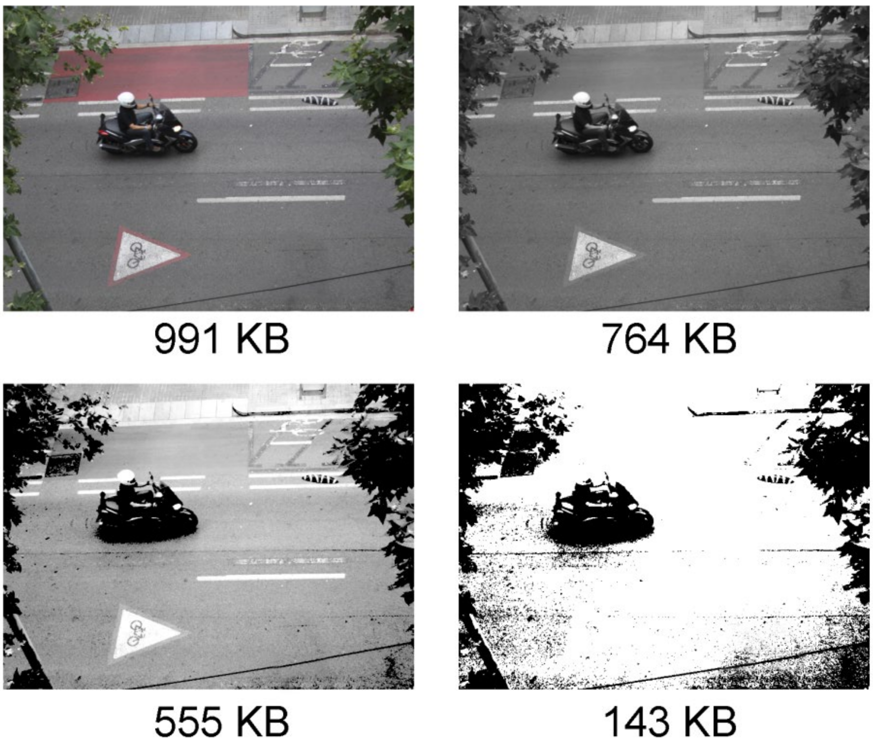

Figure 8. Sequence of frames of the processing of the color picture to grayscale, and subsequently to black and white with fading of the shadows and shines effect. It is evident a reduction in the size of the image of almost seven times the weight of the photograph.

6.4 Use of augmented reality techniques.

One technique that can be employed is to focus the analysis on the areas of the photograph where changes can occur. When working with a vehicle detection algorithm, one of the problems faced is that of redundant features not associated with the object to be detected. That is why in order to reduce the risk of presence of redundant elements it is useful to narrow down the plane of possible relevant events.

The subtraction or reduction of study areas involves analyzing a reference image shrinking the analysis area in each frame and scaring the result threshold. This is achieved by reducing the information and adjusting the binary segmentation of what is to be examined in the image, especially the detection of non-stationary objects. A photo processing technique can be applied in order to select attributes that can be mobile entities within the image and therefore, if their presence is detected in the picture, it means that there is a vehicle in the scene.

First of all, a reduction in the size of the images of more than 9 times the size was verified. After the training process (machine learning) and testing of the results, a reliability of 42% is checked. Therefore, a remarkable reduction in the accuracy of the results is registered.

The following is a sequence of images treated in order to identify features with volumetric attributes that could be related to a vehicle.

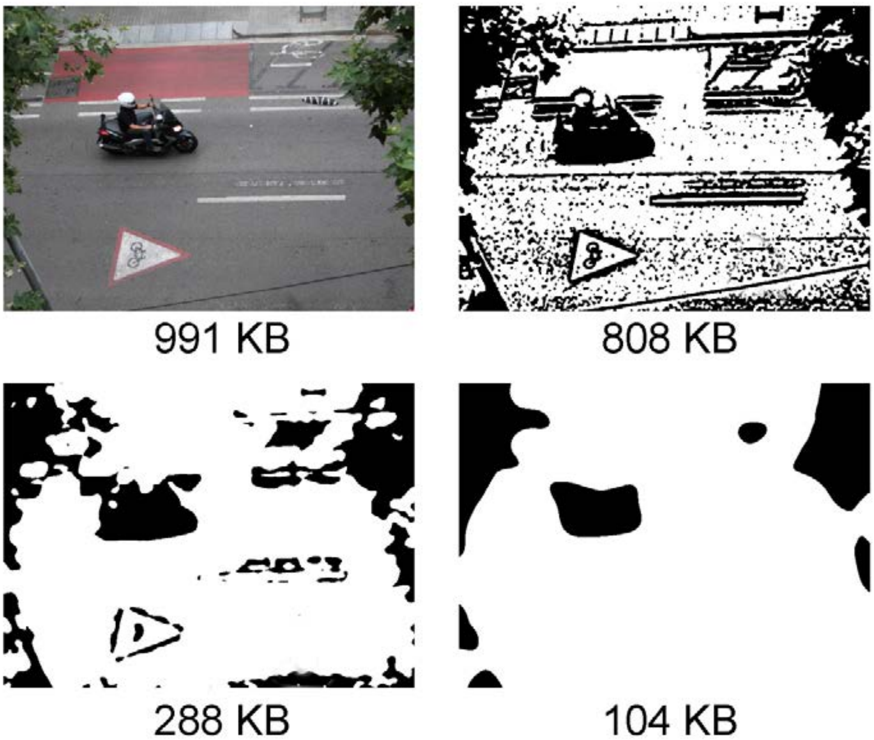

Figure 9. Transformation process of an image by reducing the information to volumes that could be identified as vehicles, and based on their presence or absence, test the detection model.

7. FUTURE SCOPE

7.1 Debugging of information by eliminating redundancies through the identification of changes.

SHANNON, C.E. (1951) emphasized how "redundancy" can be something like an opposite of information. BARLOW, H. (1961) developed an idea about redundancy reduction and pattern recognition, whose ramifications have influenced the debugging of Artificial Intelligence models, vindicating the need for interpreting the goals of the system to avoid heaps of irrelevant data that may result in crucial observations being overlooked. According to information theory, this can be achieved by eliminating redundancy through inhibition and adaptation. BARLOW, H. (1961) and ATTNEAVE, F. (1954) proposed the reduction of redundancies as a response through systems of transmission inhibition of non-relevant information. Barlow, H. suggested that at the level of the biological systems of sensory perception there are mechanisms adjusted to eliminate massive redundancy in order to avoid constantly informing about the state, so the relevant information to be reported to the system is changed in state, leaving the system to assume that everything not reported remains the same. In this way, the system reports information only when there is a change. This achieves a significantly reduction of the amount of information and it ensures that practically all the information that is managed is relevant, since by avoiding repetitions (redundancy).

If most of the data to be analyzed by the system come from events of possible changes, great savings in management and greater efficiency in interpretation are achieved. These methods have some problems and involve a training period with no objects in the plane under analysis. The movement of background objects after the training period and foreground objects without movement during the training period would be regarded as permanent foreground objects. (CHANGALASETTY, S. B. et al. 2014).

An intuitive method is to apply a Kalman filter to track changes in the background of each pixel in the image (KALMAN, R.E.1960). That tool attempts to assist in predicting future states of the system by taking the series of previous records. It’s an algorithm for identifying states of a dynamical system that relies on the known information of the previous states of the given system by comparing with the previous ones.

An additional starting stage can be performed using a customized version of the moving segregating objects. An adaptive filter-based Kalman model could implement in future steps, to analyze the changing background conditions. The foreground is refreshed at each frame using the following update equation:

$$B_{t+1} = B_t + (\alpha_1(1 - M_t) + \alpha_2 M_t)D_t \tag{3}$$

7.2 Assessment of use of logistic regression to improve machine learning and binomial event classification.

In order to work with a dichotomous outcome predictor variable, Logistic Regression algorithms allows assigning the probability between 0 and 1. In this way a binary classification is obtained, with only two possible outcomes. The regression algorithm is one of the most prevalent and common classification algorithms found valuable in machine learning. The binary options allows to plot the coordinates of the set of features with their values and then attempts the most accurate function possible that can predict the output values of the input features.

The logistic regression model has two dependent and independent variables, while the dependent variable with two values is represented by proxy variables shown in the following equation.

$$P(x) = \frac{e^{(\beta_0+\beta_1 x_1 \cdots\cdots \beta_n x_n)}}{e^{(\beta_0+\beta_1 x_1 \cdots\cdots \beta_n x_n)+1}} = \frac{1}{e^{-(\beta_0+\beta_1 x_1 \cdots\cdots \beta_n x_n)+1}} \in [0,1] \qquad (4)$$

7.3 Use of other software or analysis procedures.

In the field of study there is a continuous great amount of innovations and applications that can be implemented on the basis of images already available. In this case study it is relevant to have generated the images themselves, so that we can have our own base material. This material has been applied to carry out the present study, but as there are continuous innovations in the procedures, it is feasible to continue advancing in the improvement of the results already obtained from the use of other protocols and programs such as Wolfram, MatLab...

Advances are increasingly being made in computing power at a significantly higher level than ever before, benefiting from built-in computational intelligence based on a great depth of algorithms and knowledge that can substantially improve the results already obtained.

Futures line of research are the identification of possible innovations that may appear and the wide range of already available programs and methods that can test different domains of mathematical modeling, statistical applications, information management and data processing.

8. CONCLUSIONS

Several experiments have been carried out in order to develop tools to identify vehicles in urban areas using different technologies of Big Data, Artificial Intelligence (AI) and Augmented Reality (AR).

A first attempt has been made to identify vehicles in a stretch of road using images from different sources and it has been found that it was not an adequate approach. Subsequently It has been performed an experiment based on the shooting of our own images by locating an observation station and collecting pictures pointing to a specific segment of road.

After applying image training techniques, it was found that the most reliable results were obtained with the least treated frames, which retain the greatest amount of raw information. By applying artificial intelligence techniques on the unprocessed images, a result of 64% identification of the presence of vehicles on the section was achieved.

The subsequent experimentation carried out consisted of image processing refinements, the application of augmented reality techniques, in order to improve the reliability of the model and the reduction of the volume of data to be handled. To this end, the black and white photos were processed, the images were pixelated to reduce the information and size, and an attempt was made to identify the volumetry of moving objects. The summary of the results obtained is as follows:

Picture treatment	Recognition Accuracy
Raw	64
Pixel processing	51
Black & White	48
Edging	42

Table 6. Comparison table recognition accuracy (%).

It should be noted that there has been significant advances in the use of images own collected in a controlled environment, because it allows to work with data that are easier to be treated and adjusting the parameters to improve the result. The tests of different treatments of the images were carried out, obtaining mixed results. There were satisfactory results for the detection of the vehicle's presence, but in the application for the determination of the type of vehicle, the results were not reliable.

In global terms we must validate as adequate the concept of the experiment, the location and the methodology adopted. We can also consider the results as satisfactory and encouraging as a starting point for further progress in improving reliability.

Next challenges of using these technologies in the transportation sector will be to expand the fields of analysis to different areas such as pollution reduction, road safety, improved accessibility and seamless mobility.

Future lines of progress in the research could be considered such as the application of techniques for filtering the information by eliminating redundancies through the detection of modifications in the images; exploring the implementation of mathematical models to increase machine learning and binomial events, as well as examining the application of other software or analysis protocols.

ABSTRACT

Because of the fast expansion of the COVID-19 pandemic in 2020, many countries established lockdowns, implementing different restrictions on people's mobility. Analysing the effectiveness of these measures is crucial to better react to similar future scenarios. This research uses anonymous mobile phone data to study the impact of the Spanish lockdown on the daily dynamics of the Madrid metropolitan area. The analysis is focused on a reference week prior to the lockdown and on several weeks of the lockdown in which different restrictions were in place. For this timeframe, population distribution is compared during the day and at night and presence profiles are obtained throughout the day for each type of land use. In addition, a multiple regression analysis is carried out to determine the impact of the different land uses on the local population. The results in the reference week, pre-COVID-19, show how the population in activity areas increases in each time slot on a specific day and how in residential areas it decreases. However, during the lockdown, activity areas cease to attract population during the day and the residential areas therefore no longer show a decrease. Only basic essential commercial activities, or others that require the presence of workers maintain some activity during lockdown.

1. INTRODUCTION

The COVID-19 pandemic has abruptly changed the way in which citizens interact, move or make use of different urban activities. The change has been radical particularly in the initial phases of the pandemic, with the adoption of the most severe measures and the lockdown, which has led to the closure of most activities and changes in habits when carrying out the most basic activities. Without any warning, cities were forced to slow down, reduce and even stop much of their activity for months. Knowing how the pandemic has transformed urban dynamics and what the patterns of these dynamics are in the phases of lockdown and subsequent restrictions is essential for decision-making, establishing new measures or evaluating their effectiveness in preventing and controlling the spread of the pandemic and in understanding the city's resilience to these measures to contain severe outbreaks.

New geolocation technologies offer significant possibilities to study population mobility and the possible spread of contagious diseases are well known (Sirkeci and Yucesahin, 2020, Ferretti et al., 2020). Mobile phone data had only been rarely used in epidemiological research, but their enormous potential has been demonstrated during the COVID-19 pandemic to estimate the effectiveness of the control measures in many countries (Oliver et al., 2020b).

This research aims to study the impact of the pandemic on the dynamics of the city throughout the day and its spatial relationship with land uses, an aspect that the authors believe has not as yet been discussed in depth. The presence of the population in each area of the metropolitan area of Madrid (Spain) is calculated throughout the day using information from mobile phones. This daily distribution of the population is analysed for a typical week, and then compared with the daily distributions in the weeks of confinement decreed due to the state of emergency in Spain. During this lockdown period, we also analyse the effects of the different phases, where measures to restrict the mobility of the population and the opening of the different activities have been tightened or eased.

In order to analyse urban dynamics, mobile phone data were crossed with the distribution of land uses within each transport zone. Typical hourly activity profiles have been obtained for each land use and multiple regression models (OLS) have been calculated for four major moments in time (morning, afternoon, evening and night). The analyses carried out show the level of activity throughout the day that each type of land use has maintained according to the degree of restrictions imposed.

Madrid metropolitan area as a case study is also of special interest, given the high impact that the disease has had. Spain has been one of the countries most affected by the pandemic, with rates of confirmed cases and deaths among the highest in the world (Johns Hopkins University, 2020). Madrid, the most affected metropolitan area in Spain, was also one of the first affected areas in Europe to establish a lockdown and has also witnessed various phases in the application of the measures, which allows us to evaluate the impact of different types of measures and serves as a reference in the evaluation of the same.

2. CASE STUDY, DATA AND METHODOLOGY

2.1 Study Area and Phases

The study area consists of the municipalities included in the Morphological Urban Area (MUA) (ESPON, 2014) of Madrid that are located within the Region of Madrid. With an extension of 202,478.46 Ha, the study area enables us to analyse Madrid's behaviour on a metropolitan scale, and study in detail what happens in each of the 1,062 transport zones into which it is divided (Figures 1 and 2). Just over 5.7 million people reside in the metropolitan area of Madrid according to the 2019 census.

When it comes to the time frame, the research analyses the impact of the COVID-19 pandemic on the distribution of the population in the study area over 6 weeks (March 23 - May 10, except Easter). In these weeks, the Government of Spain had activated the State of Alarm prior to the adoption of the Transition Plan to the New Normal. They were the weeks of greatest restrictions, with various measures to regulate activities in the different phases. Additionally, the analysis extends to the week of February 14-20, 2020, taken as a reference (W0), representing the distribution of the population in a normal week, prior to the pandemic.

The weekly analysis allows us to study the impact of the different measures decreed by the government on mobility and the degree of confinement of the population.

To understand the results obtained, the phases of the lockdown decreed by the Government of Spain and the most important measures established in each of them (Table 2) must be defined. Table 1 shows the dates of the study weeks, relating them to the phases and measures indicated in Table 2.

Study weeks	Dates	Corresponding phase
W0	14-20 February	Reference week. Normal activity prior to COVID-19.
W1	23-29 March	Second week after the Declaration of the State of Alarm
W2	30 March - 5 April	First week of Extension of State of Alarm 1
W3	13-19 April	First week of Extension of State of Alarm 2
W4	20-26 April	Second week of Extension of State of Alarm 2
W5	27 April - 3 May	First week of Extension of State of Alarm 3
W6	4-10 May	Second week of Extension of State of Alarm 3 and first week of Transition Plan to New Normality: Phase 0

Table 1. Study weeks, dates and correspondence with the State of Alarm phases

Phase	Dates	Summary of measures
Declaration of a State of Alarm	14-28 March (2020)	● Suspension of face-to-face classes in all learning centers. ● Prohibition to circulate in the streets, except for: Buying food or medicine, going to health centers, going to or coming from the workplace, going to banks or insurance companies, taking care of the elderly or children. ● Recommendation of teleworking. ● Closure of most premises, shops and businesses. Exceptions: Food stores, pharmacies, medical centers, gas stations, and others. ● Closure of museums, libraries and leisure or sports centers. ● The public transport service is maintained.
Extension of State of Alarm 1	29 March - 12 April (2020)	This is the phase with the greatest restriction of activities. The measures adopted during the State of Alarm also include: ● Suspension of non-essential face-to-face work activity. Fundamentally, the following are considered essential activities: health, food and fuel distribution, public maintenance services, cleaning and waste collection, state security, postal services, funeral services and media.
Extension of State of Alarm 2	13 - 26 April (2020)	Measures relating to those defined in the previous phase: ● People are allowed to return to their workplaces for non-essential activities where teleworking measures cannot be implemented. ● Circulation of private vehicles is allowed to carry out the permitted activities.
Extension of State of Alarm 3	27 April - 10 May (2020)	Measures relating to those defined in the previous phase: ● Children under 14 years of age may go out with someone one hour a day but must not go further than one kilometer from home. ● From 2 May: Those defined by the Transition Plan to the New Normal.
Transition Plan to the New Normality: De-escalation - Phase 0	2 - 10 May (2020)	On April 28, a 4-phase Transition Plan to the New Normal was established. On May 2, Madrid enters Phase 0 of the plan, allowing: ● Departure for minors, individual non-contact sports activities and walks, once a day and at regulated hours. ● Opening of establishments by appointment for customer's service.

Table 2. Phases, dates and measures adopted by the Spanish Government

2.2 Data

This research is based on the datasets described below:

1. **Mobile phone records**. The data used for the extraction of mobility indicators consists of a set of anonymized mobile phone records corresponding to the defined weeks of study, obtained through a collaboration agreement with one of the three main Mobile Network Operators (MNOs) in Spain, with a market share of more than 20%. The records include Call Detail Records (CDRs), produced every time a mobile phone interacts with the network through a voice call, a text message or an Internet data connection, as well as passive events coming from network probes. Among other information, each record contains an anonymized identifier of the user, a timestamp and the position of the tower to which the device is connected at that particular moment. This provides an indication of the geographical position of the user at certain moments along the day. The temporal resolution of the records depends on the frequency of use of the mobile device; most users typically generate a register at least every 15-20 minutes.

2. **Land Use data**. Land use data provided by the Directorate General for Cadastre in Spain (Cadastre), by built entity of the study area. The databases define the surface area [m^2] of each type of land use. The data set used corresponds to the update of January 24, 2020. Figure 1 represents the transport zones of the study area according to a classification of predominant land uses.

3. **Population Data**. Census data for 2019 at the census section level, obtained from the National Institute of Statistics. The data has been aggregated at the transport zone level, and it has been used as the sampling frame for expanding the sample of the MNO customers. Figure 1 shows the population distribution in the study area.

4. **Territorial boundaries**. The demarcation of the Morphological Urban Area (MUA) of Madrid has been obtained from the ESPON DATABASE project. The transport zones defined in Madrid have been obtained from the Open Data Portal of the Consorcio de Transportes de la Comunidad de Madrid.

5. **Data on State of Alarm phases and measures**. They come from the Royal Decree of the Ministry of the Presidency of the Government of Spain published in the Official State Gazette.

To extract meaningful mobility indicators, the sample is expanded to the total population of the study area. The expansion factor is calculated as the ratio between the number of residents of the district according to the census information and the sample of users with their home location at the given district.

In the present study the mobile phone records were used to build OD matrices with origin and/or destination in the 1,062 zones of the study area. The matrices were segmented by day and start time of the trip, considering 24-time segments.

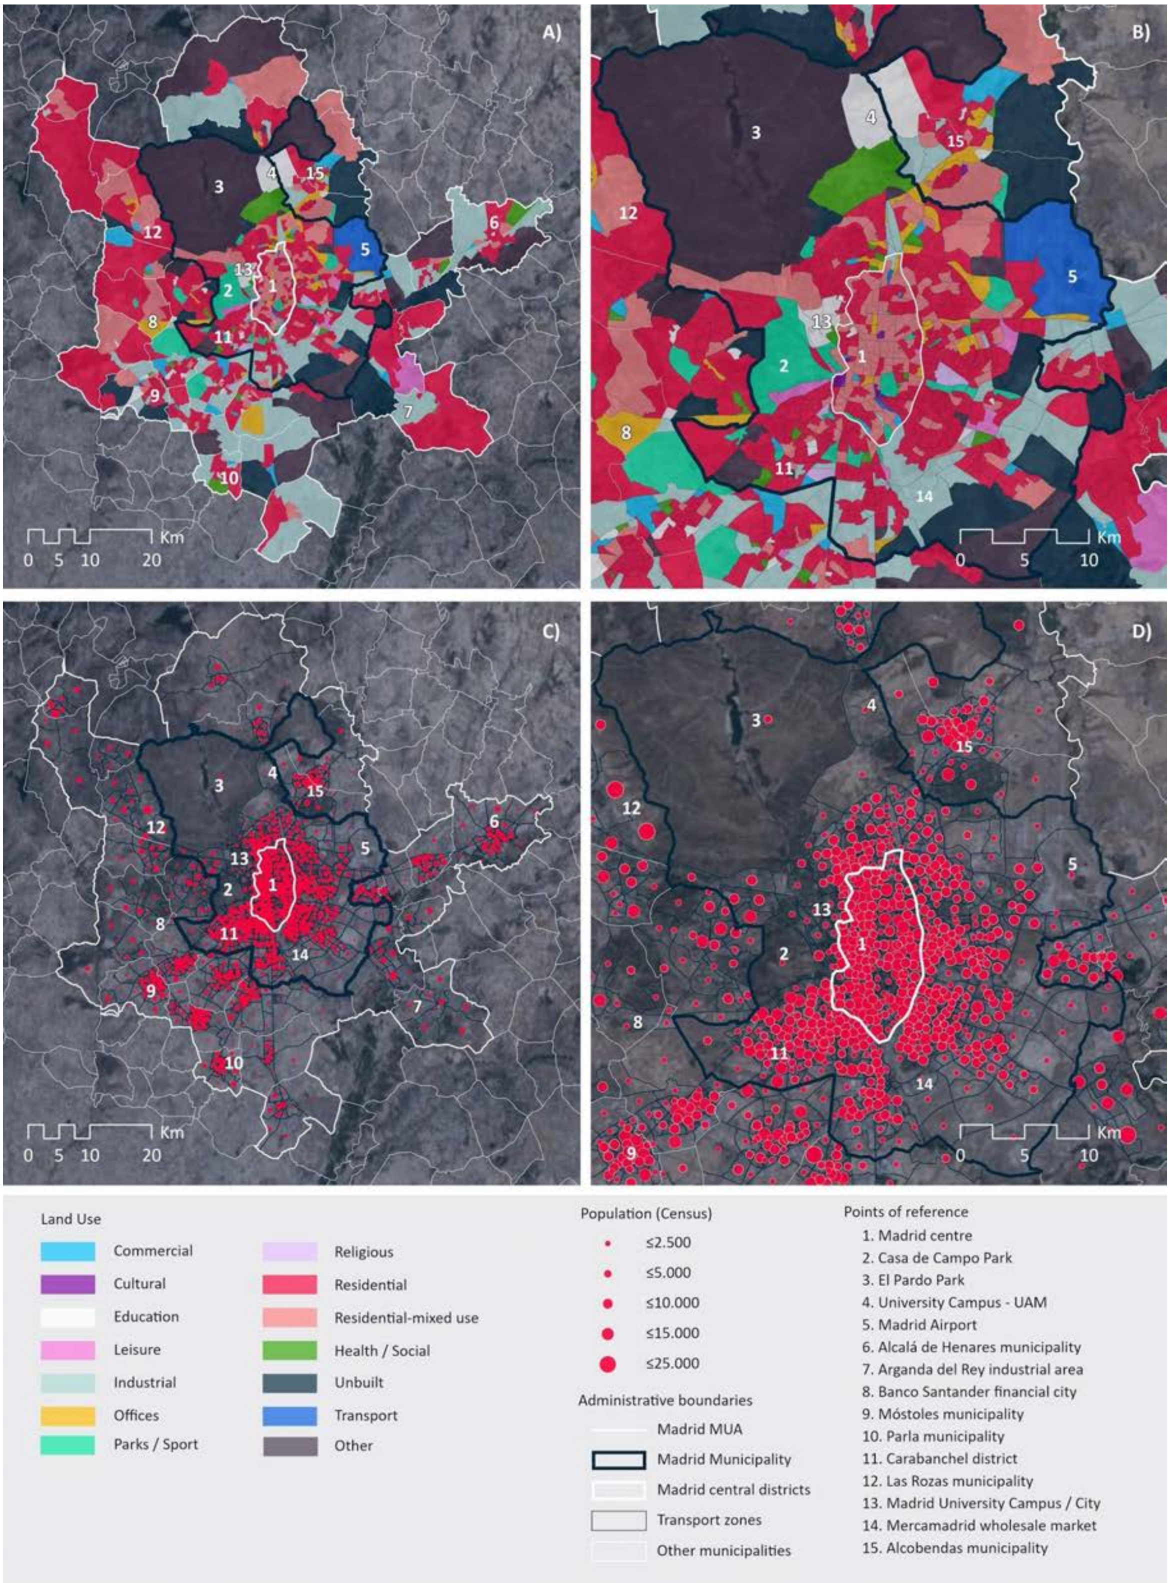

Figure 1: Land Use and Distribution of population (in the reference week at night) in the study area

2.3 Study of the spatial distribution of population according to time slot

Because of the different activities carried out, population distribution in the study area varies throughout the day. For analysis purposes, the number of people present in each transport zone for each hour and week was estimated from the O-D matrices. The following criteria were considered:

1. A single matrix of hourly trips per week was obtained, in which the average number of trips for each O-D pair is the average of the trips made between Monday and Thursday of that week.
2. It was considered that the number of people in the census corresponds to the number of people present in each transport zone at 02:00, when the lowest number of trips generated in W0 in the study area is observed.
3. The number of people present in each transport zone per hour was estimated as those indicated in the census (situation 02:00 hours) plus the sum of average weekly trips of people attracted to that transport zone, between 02:00 and the corresponding time, minus the sum of average trips for the week generated in that transport zone for the same time period.

Firstly, we explored the data through video-visualization, which represents the evolution of the population density [people/km^2] for each time slot in the reference week (W0) and the week of greatest restrictions (W2).

Secondly, bivariate Ordinary Least Squares (OLS) analyses were performed in order to compare the different population distributions according to time slots for each of the study weeks: Morning (08:00 to 14:00), Afternoon (14:00 to 19:00), Evening (19:00 to 22:00) and Night (22:00 to 00:00). The coefficient of determination indicates the degree of overlap between population distributions, while the regression residual maps show where differences (positive or negative) between time slot distributions emerge. This analysis was focused on differences between the reference time slot (night) and the rest of the time slots for each of the study weeks. These differences are expected to be especially high in the reference week W0 (people move within the city without restrictions) and particularly low during the week of strictest home confinement W2 (most people stay at home).

2.4 Analysis of temporal profiles according to predominant land use

Population presence according to predominant land use were calculated for each time slot and study week and represented through different temporal profiles. The total number of people present in a zone was assigned to the predominant land use in the zone, and then the total number of people according to land use was added up for each time slot in order to obtain the specific temporal profile of each land use in each study week.

With the aim of performing this temporal analysis, the percentage of built-up area pertaining to each land use in each transport zone was calculated based on cadastral data. Firstly, three main types of transport zones were distinguished: residential (when more than 66.6% of built-up area in the zone is residential), activity (when more than the 66.6% is non-residential, e.g. offices, industry, retail or education) and mixed residential (all other cases).

Secondly, activity (non-residential) areas were classified in 10 types: offices, industry, retail, health, education, culture, entertainment, large transport terminals, parks and others.

3.RESULTS

3.1 Spatial distribution of population according to time slot

The visual analysis of the spatial distribution of population according to time slope in weeks W0 and W2 shows a very clear picture of the impact of the measures restricting mobility and performance of activities established with the decree of the State of Alarm. During the lockdown week (W2), the population variations with respect to night-time distribution are minimal, which is also shown in the animated graph that represents the evolution of the population in each type of urban area according to the basic classification of predominant land use: residential, mixed residential and activity. However, a more detailed visual inspection reveals more significant changes in specific areas of the city, where activity registers a particularly sharp decline (for example in educational, financial or office areas) or where it remains at outstanding levels (some areas of logistics or health). Figure 2 shows a screenshot of the video-visualization, which is attached as supplementary material in this paper.

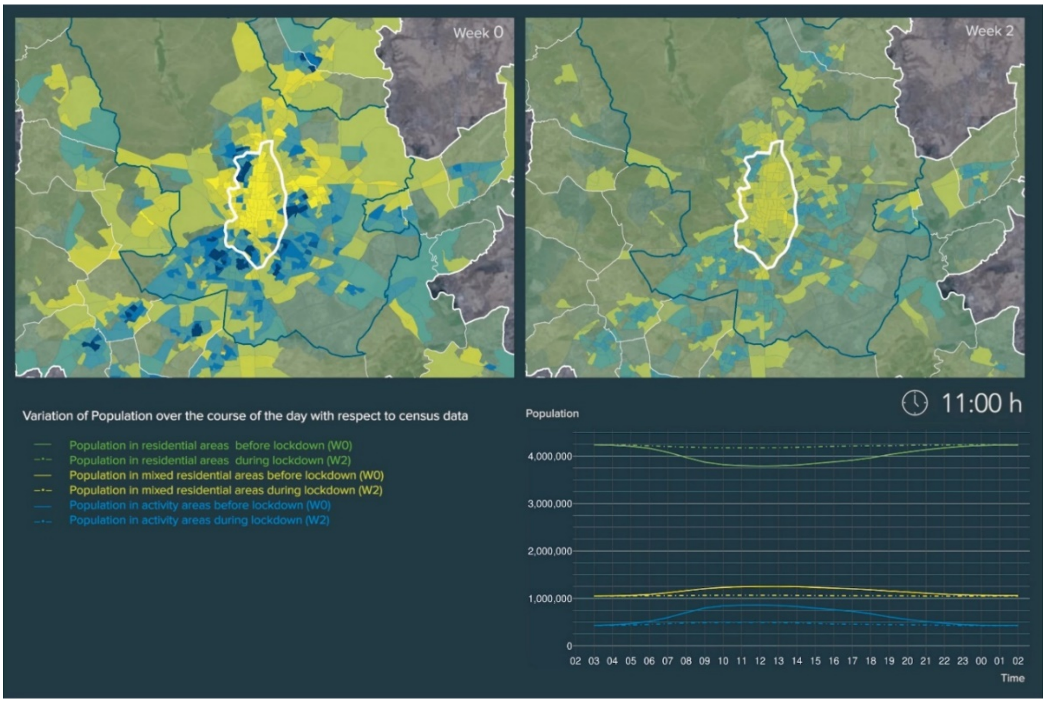

Figure 2: Layout of the video-visualization representing the variation of population density according to time slot for the reference week (W0) and the second week of the

lockdown (W2).

The first visual approximation is complemented by the weekly bivariate analysis between large time slots, allowing us to obtain a numerical indicator for comparing the different scenarios. Taking night-time as the base period, the differences in distributions of the population throughout the day can be analysed from bivariate correlations (Table 3). Madrid and its metropolitan area have a high mix of land uses, meaning that the coefficients of determination are high in all cases. The biggest differences are between night-time (residence) and morning (activities). On the contrary, between Night-time - Afternoon and, especially, between Night-time - Evening the correlations are very high, because many people have already returned to their areas of residence. The confinement situation makes the correlations between night-time and the rest of the time slots practically equal to 1.

Week	Morning 08:00 to 14:00	Afternoon 14:00 to 19:00	Evening 19:00 to 22:00	Night 22:00 to 00:00
W0 Night (22:00 to 24:00)	0.711***	0.814***	0.978***	1
W1 Night	0.987***	0.996***	0.999***	1
W2 Night	0.994***	0.998***	0.999***	1
W4 Night	0.984***	0.996***	0.999***	1
W6 Night	0.976***	0.993***	0.998***	1

*** P Value < 0.001

Table 3. Relationships in the distribution of population according to time slot (r^2)

A very different spatial behavior between night-time and morning in weeks W0 and W2 (Figure 3) is shown by the mapping of the correlation residuals. In a normal situation (W0), the morning activity spaces become highly active (positive residual in yellow), such as office areas (Points of interest 1 and 8) and mixed areas of the center, industrial areas (Points 4, 7 or 9), large facilities, university campuses (Point 2) or hospitals, as well as transport terminals, such as railway stations or the airport (Point 3). Whereas residential areas have high negative residues (blue color).

During the week of greatest restrictions (W2) the intensity of the residuals is very low. Some equipment areas are shut off (for example, Ciudad Universitaria - Point 2) and the intensity of activity is significantly reduced in the central office spaces (Points 1 and 8). On the other hand, some industrial spaces on the periphery now show the greatest deviations (Points 4, 7 and 9), together with strategic logistics facilities, such as Mercamadrid (Point 5).

Mercamadrid is the largest wholesale market in Spain, and presents an even greater deviation than in the reference week (W0), which is related to the fact that supermarkets increased sales during the first weeks of the state of alarm.

Finally, attention should be drawn to the activity detected in specific points of the city, such as the Feria de Madrid-IFEMA (6), which was converted into the largest emergency hospital in Madrid during the State of Alarm.

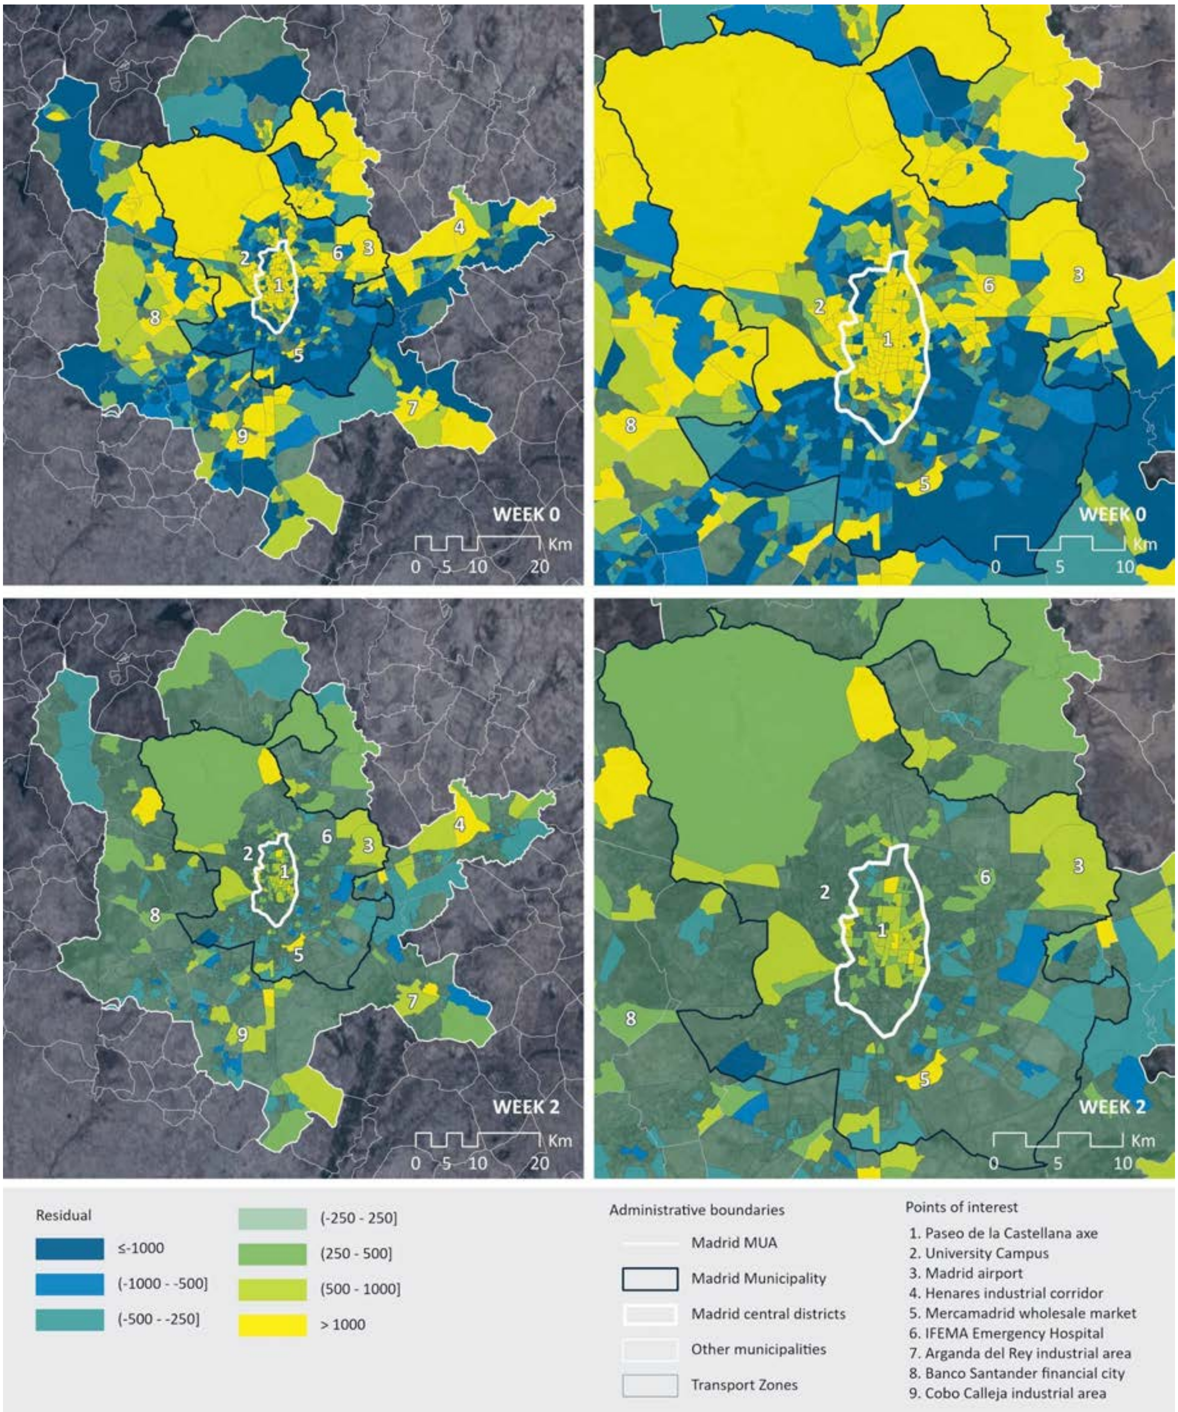

Figure 3: Residuals in the bivariate correlations of the distribution of population at night and in the morning

On the contrary, residential areas tend to lose a large part of their population during the hours of activity during the reference week (W0), while these losses have decreased substantially between night and morning in the week with the highest restrictions (W2).

3.2 Temporal profiles according to predominant land use

Population distribution according to land use and time slots for the reference week (W0) is shown in figure 4a. Most of the population can be found in residential areas during all time slots. Although residential use is dominant in these transport zones, other activities, mainly commercial, services and equipment can also be found. Many of these areas therefore maintain a high population presence also during working hours (morning and afternoon).

Temporal profiles according to large types of land use and their behavior during the weeks of the pandemic are very different from the reference week (Figures 4). In week W0, the departure of the population from residential areas does not compensate for arrivals. The areas of activity show an opposite profile, with very important gains in the morning and falling during the afternoon. The mixed areas have an intermediate situation. However, during the pandemic, the three curves have tended to flatten significantly. Data also show the evolution of the different phases.

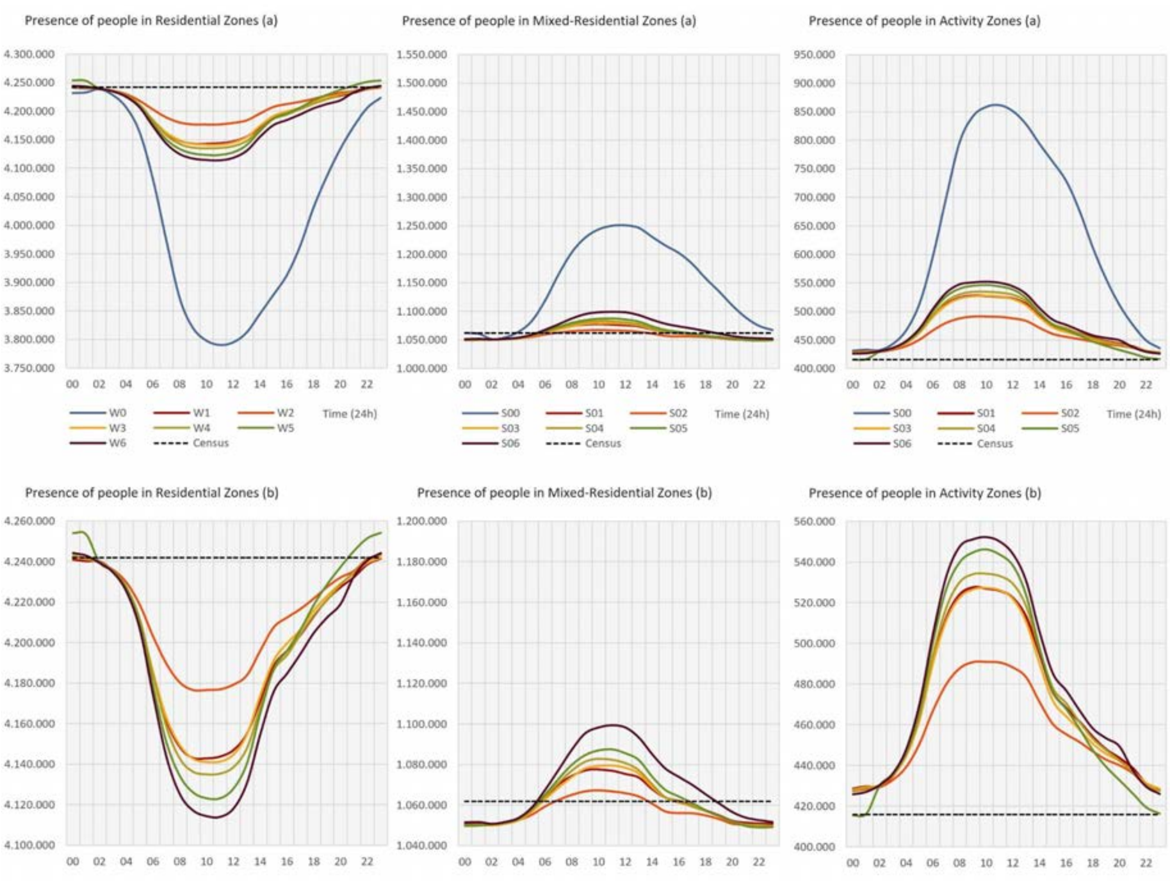

Figure 4: Population distribution profiles throughout the day during the study weeks (W1-W6), including the reference week W0 (a) and without it (b).

The temporal distribution of the population in the activity areas shows different profiles and different behaviors during the study weeks according to the characteristics of their activity (Figure 5). For instance, during the reference week (W0), the curves of office or industrial activities are very similar, however their behavior is different during the pandemic.

Office workers have been able to implement teleworking to a greater extent, so that the presence of the population in these spaces has been reduced very significantly, to the point of practically flattening the profiles.

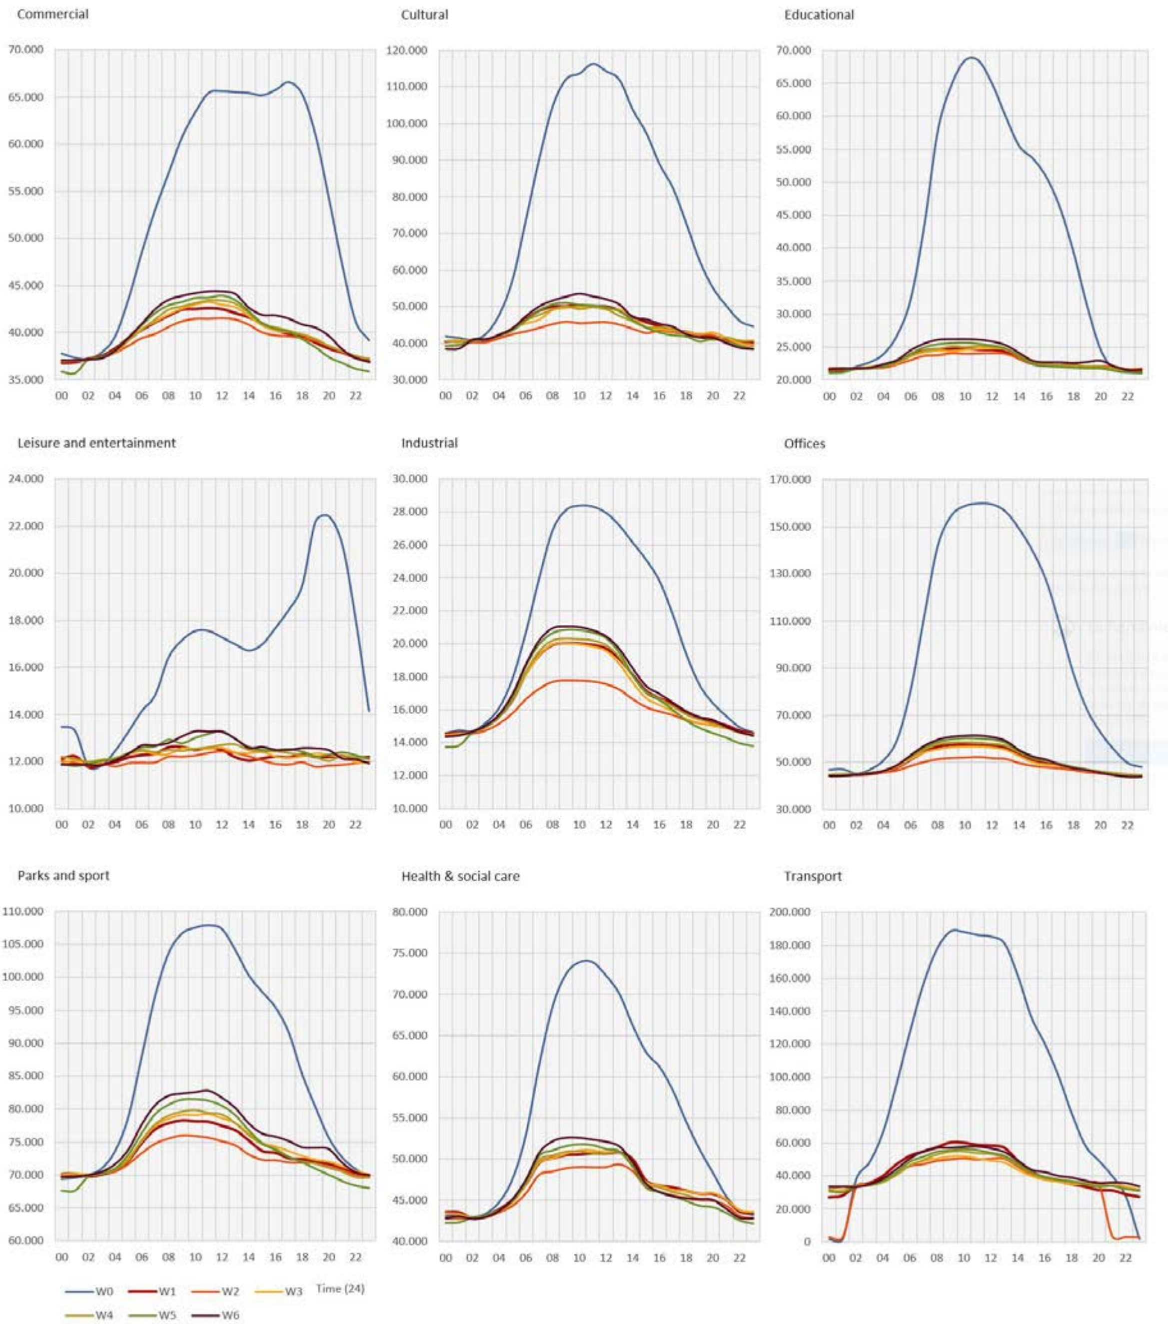

Figure 5: Population distribution throughout the day in the different activity areas during the study weeks (W0-W6).

4.CONCLUSIONS

The first visual analysis allowed us to explore the variation in population in the different urban areas throughout the day, comparing the reference week prior to the lockdown (W0) with that with the greatest restrictions on mobility (W2), showing very significant changes.

The second analysis, based on the study of bivariate correlations of population distributions between large time slots, allowed us to obtain a numerical indicator to globally compare the impact of the lockdown measures in the different study weeks. The city of Madrid presents a high mix of land use, so that even in a reference week (W0) the correlations between the strips are very high. However, while in week W0 the correlations between morning and night decreased, due to the differences between residential and activity spaces, correlations were practically 1 during the lockdown, showing a similar distribution of the population in all time bands at night. The mapping of the residuals of these correlations showed that the few active zones during the morning hours were mainly logistics and industrial areas (positive residues).

In addition, the hourly population distribution profiles for the dominant land use in each zone also showed a radical change with respect to the reference week (W0), especially in the weeks of greatest restrictions (W2). These profiles are simplified, since they consider only the dominant use, when in most areas there are several uses of the land. However, the results explicitly showed the drastic reduction in population in activity spaces in the morning and afternoon, while residential spaces conserve the population in those time bands. All profile curves tended to flatten significantly, but once again the activities related to industry, commerce or health maintained more active profiles, compared to very subdued educational, leisure or office areas.

The different analyses carried out provide helpful information for pandemic management and post-recovery planning. First, they enable us to improve our knowledge of urban dynamics during each of the confinement phases and the degree of restricted mobility of the population. Changes in population density according to mobility restrictions help to assess the level of follow-up of the measures. Second, they help us to determine in which spaces and activities a greater presence of the population is concentrated during the weeks with restrictions and those when the restrictions are lifted. This is of interest to identify the areas of the city, the activities and the population groups associated with them, which remain functional and, consequently, pose a greater risk of virus transmission. In addition, once the restrictions are lifted, these analyses will show the pace of the city's recovery and the different recovery speeds of each urban activity.

AKNOWLEDGEMENTS

This research was financed by the Spanish The Ministry of Science, Innovation and Universities through the project “DynMobility - Análisis dinámico de los patrones de movilidad a partir del Big Data” (code RTI2018-098402-B-I00), and also supported by the Madrid Region authority through the Research Network “INNJOBMAD-CM - Atracción de actividades económicas innovadoras y creadoras de trabajo en Madrid.”

ABSTRACT

This paper explores the user profile, spatial aspects, and mobility patterns affecting the adoption of teleworking and shopping online as a replacement for the working and shopping trip. The study is based on an EU-wide survey on mobility patterns and preferences with 26.500 respondents. The questionnaire combined socio-economic, mobility behaviour and the use of ICT in mobility-related issues, as well as teleworking and online shopping.

The methodology used combines classical statistical inferences and a classification Machine Learning (ML) algorithm to find the most important factors affecting the typology of the users adopting these tools.

The results suggest that while the new consumption patterns are high on average, the new working arrangements still have a margin to improve. Furthermore, there are significant differences among countries and between different socio-economic profiles. Online shopping was already prevalent, but teleworking was still limited (given that the survey was conducted in 2018, i.e., before the COVID-19 pandemic).
The findings of this work can be useful for the analysis of policies to encourage the uptake of new technologies in transport and mobility. Also, they can be a good reference point for future studies on the ex-post analysis of the impacts of the pandemic on mobility.

1. INTRODUCTION

Work and shopping constitute two of the main trip purposes for urban mobility and are responsible for the largest share of passenger transport activity (Eurostats, 2020).

Teleworking and e-commerce are two technology-enabled options that can modify individual daily mobility patterns and potentially reduce total transport demand and its associated impacts (energy consumption, CO2 and pollutant emissions, congestion, etc.).

The objectives of this paper are, on the one hand, exploring the main characteristics of individuals adopting teleworking and online shopping as a substitution of the trip to the workplace and to the traditional shop (socio-demographic, mobility-related characteristics, and the use of ICT). On the other hand, our target is to find the main election drivers by analysing the factors affecting the uptake of teleworking and online shopping.

2. METHODOLOGY

We used the second wave of the EU survey on issues related to transport and mobility, carried out in 2018, which applied a CAWI (Computer Aid Web Interview) methodology (Scarcella & Fiorello, 2017). The sample includes 26.500 questionnaires along with the 27 members of the European Union and the United Kingdom, with 1.000 respondents in each country, except Cyprus, Luxembourg, and Malta with 500 each. The sample was stratified by socio-economic characteristics based on age, gender employment status, level of education, and region of residence.

The questionnaire contains information on four categories: socio-demographics and car availability questions, information on the most frequent trip, details on medium and long-distance trips, and use of Information and Communication Technologies (ICT) related to transport, where trip substitution by teleworking and online shopping is included.

The analysis is based on a classification model, made by each of the studied variables, in which the outcome or **dependent variable** takes the value explained as follow.

On the one hand, it is defined a discrete dichotomous dummy variable **Telework (Y)** which takes the value 1 if the individual has ever replaced commuting by teleworking, once per month, 3-4 times per month, or more than 4 times per month. Likewise, the variable Y takes the value 0 if the respondent has substituted the trip to work only once or never.

On the other hand, and similarly to the previous one, the second analysis was made for the shopping trip substitution by e-commerce.

The variable **Online Shopping (Y)** takes the value 1 if the respondent has substituted the shopping trip by online commerce, rarely, sometimes, or often. Otherwise, the variable takes the value 0 if the individual has replaced the trip to the shop by buying online only once, or never.

The independent variables considered in the analysis, as explained before, include four categories (socio-economic and car availability, daily mobility, long trips and use of ICT).

3. SURVEY DESCRIPTION

In this section, we explore the impact of individual respondent characteristics on their choices, concerning telework and online shopping, by descriptive analysis, including frequency distributions and odds ratios. Later on, we use the machine learning algorithm XGBoost to obtain the relationship between the variables, highlighting the most important factors affecting individuals' choice and the overall impact on the outcome.

3.1. Trip substitution by teleworking

Males tend to telework at a higher proportion than female respondents. The odds ratio between the two genders is 1,4:1. The difference is probably due to a higher share of male respondents employed in jobs that are more suitable for teleworking. The relevance of the job type can be also induced from the correlation with education and income level. As a general trend, the ratio of teleworkers increases as the higher the education and the income level of the respondent is. Respondents with a university degree (or higher) are 2,4 times more likely to telework than respondents with just primary education. Similarly, the group of individuals with higher-middle or high-income levels are 3,8 and 6,1 times (respectively) more likely to telework than respondents with low-income level. Furthermore, looking at the income distribution by grouping teleworkers by age, we find the same pattern, so that, the higher the income, the more likelihood for teleworking. A teleworker profile that might be intuited based on the above is a male independent professional or manager with high education and high-income level.

Concerning age, the data shows an inverse association with teleworking, being the younger workers more likely to telework than advanced aged ones. This association may be related to younger's education in ICT and the lack of this type of skills in older people, but also because the group of students, normally young, might combine studies and telework.

The working day duration seems not to be an important factor for teleworking, neither seems to be for students who declare some type of telework. By contrast, people over 65 presents more probability to telework when part- or full-time work is declared, probably because they are linked to liberal and managerial professions.

Regarding the household place of residence, teleworkers present a higher likelihood of teleworking when they live in metropolitan areas or big cities rather than in small cities or rural areas. This might occur because teleworking is often linked with big companies usually placed in big cities.

Other factors affecting the probability of teleworking are car-related and mobility questions. Thus, people holding a driving license (motorcycle or car) presents a higher proportion of teleworkers. Taking this into account, owning a car presents also more teleworking probabilities despite this factor can be confounding and related to income level.

Nevertheless, individuals with a car subscription also tend to telework more than people without a car subscription, probably because this profile is associated with young professionals with low car availability and living in metropolitan areas where this kind of service is offered.

The most used mode of transport for the most frequent trip between teleworkers and not teleworkers is the car, followed by walking, private bicycle and bus services. However, using the car, the bus or going by foot are more used between non-teleworkers compared with teleworkers. Furthermore, the odds of teleworking are 5,5 times greater for bike-sharing relative to private car drivers, as do car-sharing users by 2,5 times.

In reference to the destination of the most frequent trip, the principal travel is made within the same urban area (49%) and to another urban area (34%), being this last movement more prevalent in the group of teleworkers. On the contrary, travelling outside an urban area is more prevalent in non-teleworkers. Once more, it could be due to the fact that teleworkers tend to live in metropolitan areas. Furthermore, the proportion of individuals commuting every day (or every working day) is higher in non-teleworkers compared with teleworkers.

On the contrary, people travelling two to four days per week is more prevalent in the group of teleworkers, travelling longer distances compared with non-teleworkers. This can be explained because of the size of the metropolitan city where teleworkers tend to live.

Another factor associated with teleworking is the number of long and medium distance trips, finding more trips for work business and study reason in the group of teleworkers, as well as for leisure and personal reasons. This behaviour may be associated with qualified jobs and the high-income level of the teleworker profile.

3.2. Trip substitution by online shopping

E-commerce is widely extended across Europe and is frequently used by male and female in the same proportion, being more prevalent in youngers compared with old-aged people.

Online shopping is also more used among people with high education level, for instance, graduates are 2,4 times more likely to shop online than individuals with primary education.

This could be due to higher ICT education but also because of the link with higher income level since above average income implies shopping online more frequently. For instance, people with high income are 2,3 times more likely to shop online than low-income individuals.

Similarly to the teleworking case, online shoppers tend to live in metropolitan areas and large cities, despite they have within easy reach a large product offer in the city. What is more, the bigger difference between online shoppers and traditional ones is presented in people living in the centre of a metropolitan area. At this point, this phenomenon can be explained because of gentrification of the city centre, the higher income level of the people living in central areas or the lack of car availability because of the vehicles ban in historical areas. This last assumption is reinforced with the fact that online and traditional shoppers holding a car driving license is similar. By contrast, the proportion of motorcycle license is bigger in the group of online shoppers, probably because they live in the city centre and this type of vehicles is more accessible within the downtown. Additionally, the proportion of people without a driving license is smaller in the group of online shoppers, hence not holding a driving license seems not to be a determinant for buying online.

The number of cars in the household, particularly two, presents a higher probability to buy online than households without a car. This could be explained because of the income level, nonetheless, households with more than two cars present the same proportion between online shoppers and traditional ones. This is not the case of car subscribers, where the relation is clearer, being 2,2 times more likely to buy online than non-subscribers.

The car remains to be the predominant mean of transport for the most frequent trip in both types of purchases. Concerning other means of transport, and in line with general mobility trends, walking, going by private bike and commuting by bus services are the most used means to reach the destination in the most frequent trip. This destination is usually located in the same urban area for almost half of the interviewed and more than one third are travelling to a different urban area, presenting a similar share between both types of shoppers. Given the fact that online shopping could avoid trips, we observe that people buying online tend to commute more frequently than traditional shoppers. For instance, the odds ratio of teleworkers travelling one day per week and daily commuters is 1:1,3. In addition, online shoppers spend more time and travel longer distances in the most frequent trip than traditional shoppers.

This could be due to the fact online shoppers living in metropolitan areas are more likely to commute more time and more distance to reach the frequent destination.

Lastly, online shoppers present a similar share of long-distance travels for work, business, or study purposes, but they are more likely to trip long distances for personal and leisure reasons. Furthermore, online shoppers do more medium distances trips for both purposes.

3.3. Methods

The initial data analysis suggests a strong correlation between teleworking or online shopping and certain respondent characteristics, but also suggest the existence of several confounding factors that can limit the possibility of interpreting the importance of each specific characteristic. Education level and income -for example- are to a certain degree correlated and a simple statistical analysis would not be sufficient to quantify their individual impact on the respondent's choice.

In order to solve that, we constructed a classification model that allows the generalization of the relationship between the variables taking into account the various collinearities. The model applied a tree-based approach using the well-known machine learning XGBoost algorithm. XGBoost has been tested and compared with Multinomial Logit Models in travel mode choices by Wang and Ross (2018) getting better performance. Other machine learning classifier in transport has been conducted in user choice modelling resulting in higher precision than conventional methods (Hagenauer & Helbich, 2017). Christidis and Focas (2019) analysed the uptake of electric and hybrid vehicles and car use (Focas & Christidis, 2017) within the EU using gradient boost decision trees and Random Forest respectively.

The model is set up in three parts randomly split. The first one is selected to perform the training model with 40% of the observations. The second one is the test set, with 40% of observations, which is used to evaluate the performance of the model trained before, using the previous model to predict the outcome. The third one is the validation set (20% of observations left), used to ensure the generalization of the model with unseen data.

Feature engineering is used to adapt the variables to the algorithm. We used One Hot Encoding (OHE) for the categorical variables.
XGBoost hyperparameters were selected based on the best AUC evaluation score, while the final variable election was carried out based on the outcome of the most important feature, from the predictor feature importance, and Shape Values.

The performance of the model has been evaluated with the AUC (Area Under the Curve) measure. The range of this evaluation goes from 0 to 1, being 0 when all predictions are wrong and 1 when all predictions are correct.

4. RESULTS

In this section, we describe the main results obtained from the analysis of the binary classification model regarding teleworking and online shopping.

We applied the XGBoost classification algorithm (tree-based Machine Learning model, non-linear model) to obtain the main factors affecting the uptake of teleworking and online shopping as a substitution of the trip for work and shop, respectively. For the teleworking model, the dependent variable takes the value 1 if the respondent has used this work system once per month or more, while takes the value 0 if has substituted the trip by teleworking once in his life or never.

Similarly, for the online shopping model, the outcome variable takes the value 1 if the shopping trip has been substituted rarely, sometimes, or often. If the respondent has used this service once or never, the variable takes the value 0.

In both cases, data pre-processing, feature selection, model training and evaluation has been performed. From all analysed variables, the most important features were selected in a second analysis to obtain a better performance. This selection was also based on how well these variables might explain the reasons why people perform telework and online shopping, thinking about causes and not effects.

The selected variables for the classification model were gender, age, education level, employment status, household members, income group, urbanization type, urban situation, driving license, number of vehicles per household, urban frequent destination, number of passengers in the last trip, country, population in 2018, vehicles per household member, car sharing subscription and urban-centre (combination of Urbanization type and Urban situation).

The number of observations after the data cleaning is 23.931.

4.1. Determinants of Teleworking

Once applied to the XGboost algorithm, the main factors affecting the trip substitution by teleworking are displayed in the next figure. The next graph represents the feature importance score for the most important variables ordered by how much they are helping in the prediction outcome. Thus, the more used to make the decision, the higher relative importance the variable will have.

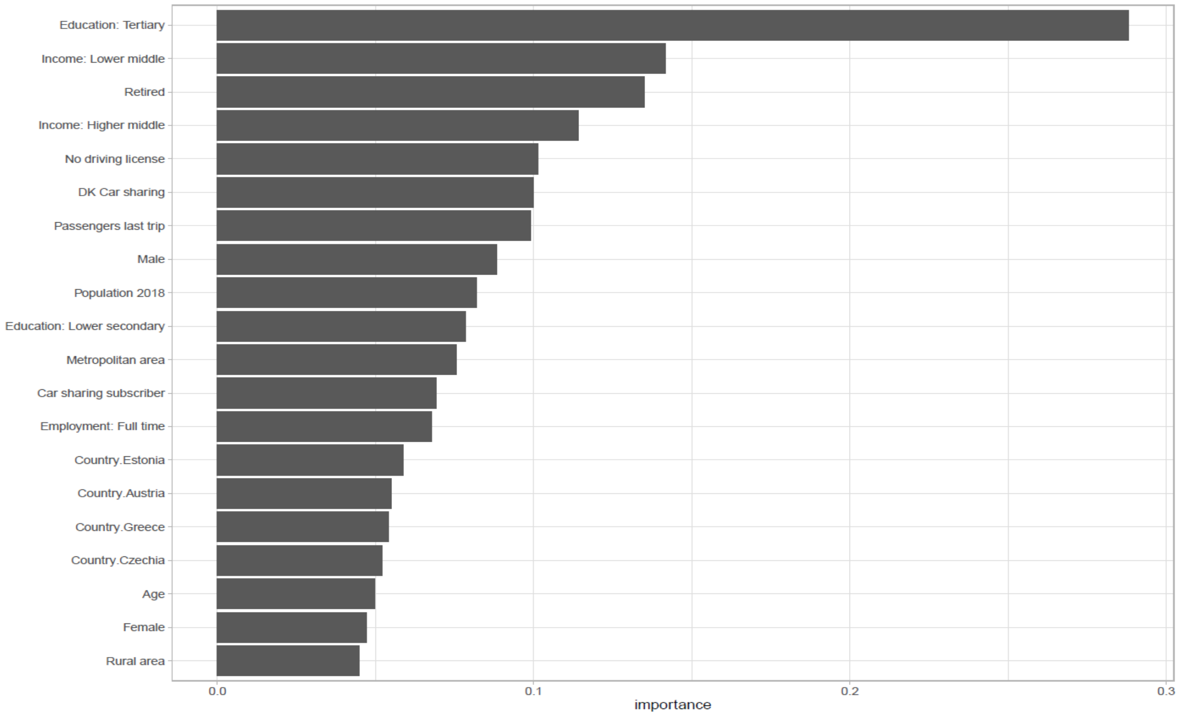

Fig. 1 – Predictor feature importance. Teleworking.

Prediction about using or not teleworking as a substitution of the working trip is influenced in the first positions by people with a high education level (tertiary or higher), with lower-middle and higher-middle income group, with employment status, with people without driving license, with gender (males), location of the household, country and age.

Figure 1 represents the main factors affecting the uptake of the trip substitution by teleworking, however, explainability is not the main feature of this kind of graphs. To resolve this, we use SHapley Additive exPlanation (SHAP), one of the most advanced methods to interpret results from tree-based models. SHAP values show the importance of each feature, the direction, and its contribution to the model outcome.

For the teleworking model, the contribution of each variable (impact on model output) is given through the shape value and the feature value as seen in figure 2. For instance, the first (and most important) variable found by the model to perform telework is having a tertiary education level, i.e., university degree or higher. The contribution to the model is given by the number on his side (0,288), which is the score. Following, we observe two dots, one yellow and one blue, meaning telework (value 1) and no telework (value 0). If the dot is on the right side, the contribution is positive, on the contrary, if the dot is on the left side will be negative. So that, having a tertiary level education will be positive for the model (feature value 1) and not having it will be negative (feature value 0)

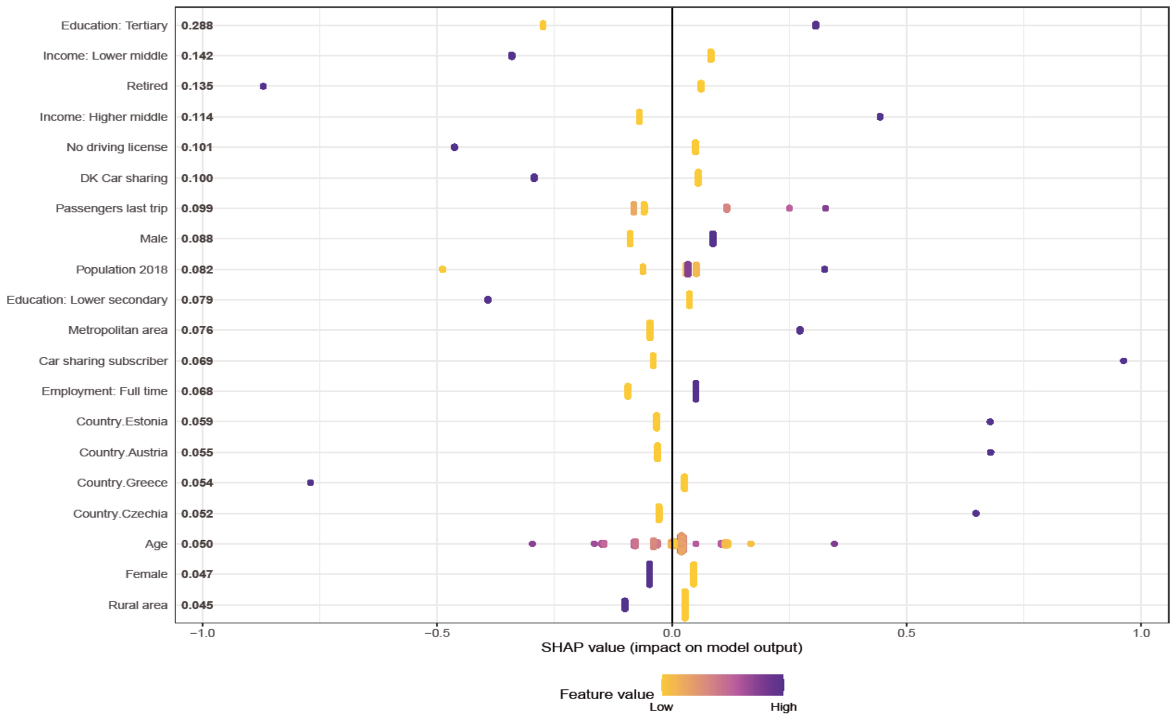

Fig. 2 – SHAP values. Teleworking.

The most important variable describing the likelihood for teleworking is to have a university degree (or higher) giving a positive value for the model, i.e., the model finds that people with high education level present more probabilities to telework. On the contrary, for individuals with a lower education level (lower secondary), the model finds a negative shape value, reducing in this case the teleworking likelihood.

Income level is normally linked with education level such as the model captures, so those individuals with lower-middle income present a negative shape value when replacing the working trip by teleworking and with higher-middle income present a positive shape value. In other words, people with higher-middle incomes tend to telework more frequently, while having a lower-middle income reduces the likelihood of telework. Gender appears to be also determinant. While male workers are more likely to telework, female professionals tend to work traditionally, probably because of the type of job developed typically by both genders.

Age presents a high variability as regards teleworking adoption, as seen in figure 2. While young people present a higher score (i.e., more prone to telework), the likelihood decreases until around 65 years old. According to the previous analysis, young professionals tend to telework more than seniors. However, when retirement age reaches, usually just liberal and managerial workers extend their professional career, precisely those with more probabilities to perform telework.

Regarding the employment status, we can identify respondents with full-time contract present a positive SHAP value (hence, full-time workers present more teleworking likelihood), in contrast to retired people, being negative, so that, retired people declaring having worked in the past are more likely to perform traditional work. This may be confounding with the previous paragraph, but it could be explained as far as retired declare to have teleworked in the past, while other people over 65 might remain working as an extension of his professional career.

Mobility patterns may also influence the teleworking choice. On the one hand, individuals without driving license are more prone to perform traditional work. On the other hand, car subscribers tend to telework more frequently, even though this profile normally is linked with high education level and living in metropolitan areas (where those services are present), which may be confounding for the model.

As for spatial factor, in accordance with the previous analysis, our model finds a positive relationship with metropolitan areas, meaning people living there present more chances to telework. By contrast, living in rural areas reduces the probability of teleworking. In addition, countries with a high population tend to telework more than countries with a low population, although work culture in every country is a determinant factor regarding remote work. For instance, individuals living in Estonia, Austria and Czechia got a positive shape value, resulting in more telework possibilities, while on the contrary, living in Greece gives a negative outcome, meaning fewer telework probabilities.

4.2. Determinants of Online Shopping

The following chart shows the main factors affecting the uptake of online shopping as a replacement of the traditional shopping trip.

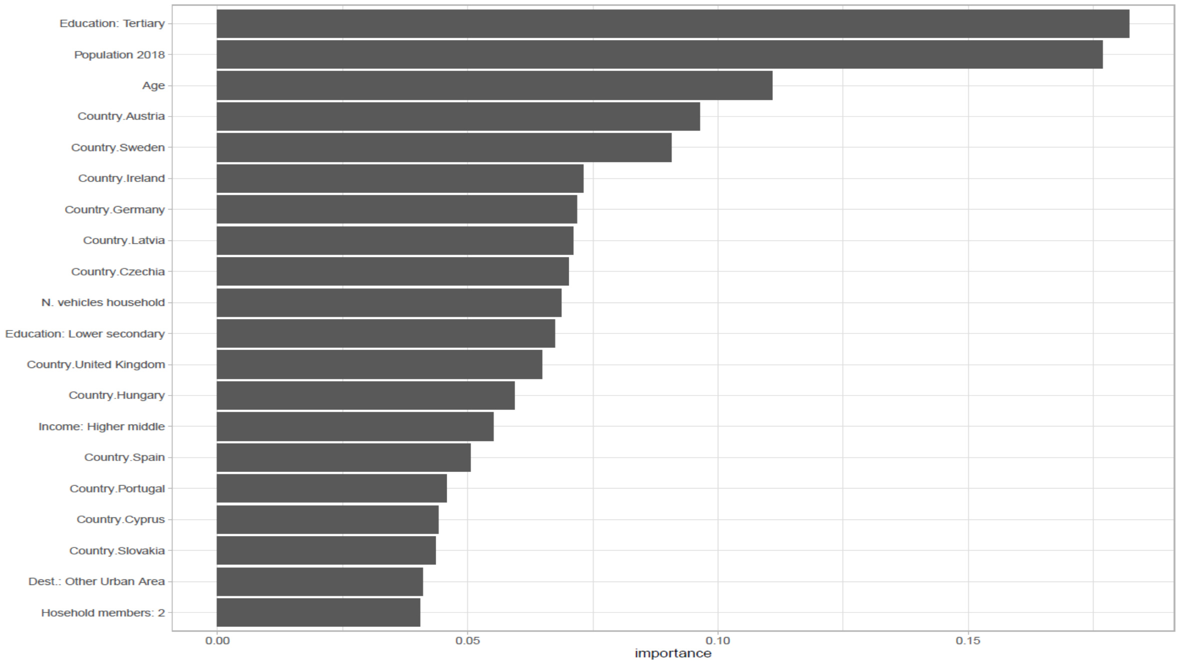

Fig. 3 – Predictor feature importance. Online shopping.

Predictions about using or not using e-commerce as a substitution of a traditional shopping trip are influenced in the first positions by people with high education level (tertiary or higher), with the level of population, age, and with people living in different countries like Austria, Sweden, Ireland, Germany, Latvia, or Czechia. It is also important the number of vehicles per household and the income level.

Next, we will explain with SHAP values the contribution of each feature affecting the prediction outcome found by the model.

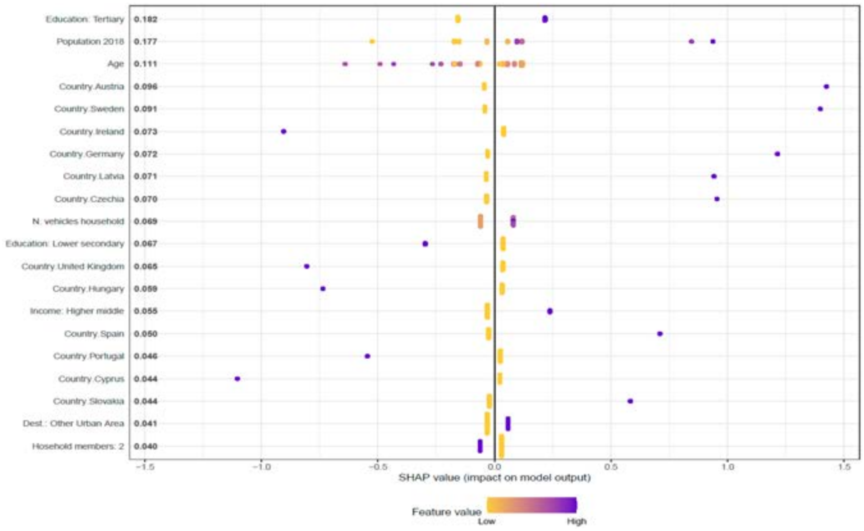

Fig. 4 – SHAP values. Online shopping.

In the same way as the teleworking case, having a high education level support the willingness to shop online as a substitution for the shopping trip, whereas people with lower secondary education tend to buy online less. Similarly, when income is higher-middle the predisposition to buy online increases. Furthermore, people between 19 and 46 years tend to shop online more frequently than younger and older individuals. In the first case probably because the acquisition power is lower, and in the second because of the lack of digital education.

Regarding individuals’ location, the model suggests high-populated countries tend to buy online more frequently than smaller countries. The country of residence appears to be a clear determinant factor affecting the online shopping choice. Countries like Austria, Sweden, Germany, Latvia, Czechia, Spain or Slovakia present a higher share of e-commerce than countries like Ireland, the United Kingdom, Hungary, Portugal or Cyprus. This result is difficult to explain given that there is not a clear pattern between both country groups, but differences in economic structure, culture and education factors, mobility schemes and accessibility or even supply chain may affect the uptake of online shopping.

4.3. Model performance

In this section, the analysis of the XGBoost classification model performance is presented. The most frequently used metric for classification problems is the Area Under the Curve (AUC) or Receiver Operating Characteristic curve (ROC). This aggregated measure of the model performance summarizes the True Positive rate (TP), versus False Positives rate (FP), by using different probability threshold.

In table 1 we present the results of the AUC-ROC test for teleworking and Online Shopping models for the test and validation datasets. The AUC range goes from 0 to 1, being 0 when all predictions are wrong and 1 when all predictions are correct.

Model	AUC Test	AUC Validation
Teleworking	0,712	0,710
Online Shopping	0,706	0,706

Table 1 – Summary of model performance.

Both models achieve a fair level of prediction, given the extensive number of variables included in the model.

5. CONCLUSIONS

This research explores the main determinant factors of teleworkers and online shoppers' profiles, replacing the trip with online procedures. The XGBoost algorithm used returns the most important factors and the impact on the model output, allowing us to determine the profile of individuals using this kind of services.

Firstly, our results confirm that the most important factors to substitute the working trip by teleworking are in general terms, having a high education level and a high-middle economic status. Gender remains determinant as far as men continue to be more likely to telework than women. As seen in the data analysis, living in low-populated countries perform fewer probabilities to telework than high-populated countries, being more likely in metropolitan areas with over one million inhabitants. However, living in certain countries favours the adoption of teleworking.

Secondly, our analysis also shows the profile of online shoppers replacing the shopping trip by e-commerce, being more likely to perform this activity by people with higher-middle education level, living in countries with high population, even though there is a high disparity between countries. The age continues to be determinant, but the range spreads from young people to the mid-age population.

The high dispersion between countries on the teleworking and online shopping adoption shows a high diversity among different regions and can be useful to bridge the gap for those who have less adoption for both ways of reducing trips through ICT.

Teleworking and online shopping can be two excellent tools to avoid trips and their negative effects (energy, congestion, pollution, transport externalities) but they must be monitored to address negative rebound effects. These rebound effects do not have to be necessarily negative. For instance, as far as more people can telework full time outside the default place of work, it can help rural or low-populated cities to attract new citizens looking for a bigger and cheaper house to live in, which eventually could change real estate market prices in big cities.

It has been mentioned high differences among European countries in the uptake of teleworking and online shopping to avoid trips. Likewise, the intensity of use shows a high variation.

On the one hand, Eastern Europe presents the lowest rate of teleworking, whereas most intensive teleworkers (declaring teleworking “often”) are placed in Finland, Austria, and the Netherlands. Besides, people declaring teleworking “sometimes” is more prevalent in Sweden, Iceland, the UK, the Netherlands, and Switzerland.

On the other hand, countries like Austria, Germany, Czech Republic, France, Sweden, and Spain present the most active (“Often” & “Sometimes”) share of online shoppers. On the contrary, countries like Cyprus, Ireland, Hungary, and Portugal present the lowest rate of e-commerce interaction (“Never” & “Once”).

As far as clean transport become more spread in the transport sector (higher share of rail mode, generalization of the electric vehicles, rising successful deliveries and optimization routes), the benefits of online shopping will be higher than now. However, congestion and most of the associated externalities will not improve with this change of technology, even though other technologies as automated cars could enhance this situation.

The scope of teleworking and online shopping remains uncertain and future work should be compared in upcoming years in order to see the evolution of these tools and the contribution to the GHG emissions mitigation. This upcoming work should answer questions about the real adoption of teleworking and online shopping habits in Europe in the post-pandemic era when both tools perform in a stable situation.

ACKNOWLEDGEMENTS

This research was carried out with the collaboration of the Joint Research Centre of the European Commission within the framework of the Doctoral Collaboration Agreement No. 35364.

ABSTRACT

Budgetary constraints are prompting many governments to encourage private financing of transportation infrastructure through Public-Private Partnerships (PPPs). Fiscal support measures have been often used to improve the financial feasibility of these projects, but also to rebalance the economics of the contracts to compensate for changes imposed by the government. This paper analyses the awarding of subordinated public participation loans (SPPLs) to ten brownfield shadow-toll motorway PPPs in Spain after additional works were imposed by the government. SPPLs are government loans, subordinated to the senior debt, that were intended to facilitate the PPP contractors the financing of the aforementioned works. This paper evaluates the financial and social impacts of the awarding of these loans to three of these projects. To that end, the SPPL repayment capacity of the PPPs and the social benefits derived from the improvement in road safety are estimated to evaluate whether the government's decision to support these projects was justified from a social perspective. The results show that, although the government's decision was reasonable, the design of the SPPL and its awarding conditions should be improved to guarantee the public interest.

1. INTRODUCTION

Over the last few decades, budgetary constraints have led many governments to implement new mechanisms to encourage private sector participation in the financing of infrastructure (OECD, 2008). In this respect, Public-Private Partnerships (PPPs) and concession approaches have acquired a special prominence, particularly regarding the construction and operation of transport facilities. Through these schemes, the private sector finances, builds, maintains, and operates the infrastructure in exchange for a fee linked to either demand or availability for a period of time contractually agreed in advance (Yescombe, 2007). Fiscal support measures have often been used to improve the financial feasibility of these projects (Vassallo and Sánchez-Soliño, 2007), but also to rebalance the economics of contracts to compensate for changes imposed by the government.

However, this form of government intervention may impose greater risk on the government and even threaten the financial sustainability of the public sector.

This paper evaluates the awarding of subordinated public participation loans (SPPLs) to ten brownfield motorway PPPs in Spain (known as first-generation motorways) as a means to rebalance their economics after the government imposed additional works not included in the original contracts. These government loans, subordinated to the senior debt, were intended to facilitate the PPP contractors the financing of the aforementioned works. On the one hand, the upgrading of these motorways, built in the 1980s, was deemed necessary by the government given the large increase in traffic volumes and accident rates. On the other hand, the conditions of these loans were very advantageous for the PPP contractors, to the point that could be considered insufficient to guarantee the interest of the State against that of the shareholders. The objective of this research is to evaluate whether the government's decision to support these projects was justified from a sustainability standpoint, taking into account the social benefits, the financial feasibility of the loan and the public interest. To that end, an *ex-post* evaluation of the financial and social impacts of the awarding of the SPPLs to three of the ten PPP contracts of the first-generation motorways is carried out.

The paper is organised as follows. After the Introduction, Section 2 focuses on the Spanish PPP context and describes how SPPLs are implemented to support infrastructure PPPs. Section 3 describes the case study, particularly regarding the context and conditions under which the SPPLs were awarded. Section 4 outlines the methodology adopted to evaluate the SPPLs performance from the sustainability point of view and the suitability of the government's decision to support the projects. Section 5 presents the results of our analysis. Section 6 discusses the results and sets out the most relevant implications arising from the case study analysed. Finally, Section 7 presents the main conclusions and highlights further research questions.

2. SPANISH SUPPORT TO PPP PROJECTS

Spain has extensive experience in promoting toll motorways through concession contracts. Since the late 1960s, 54 concessions totalling 3,307 km have been awarded, of which 2,759 km are State motorways (Ministerio de Fomento, 2018). Since the late 1990s, the country has gained significant experience in shadow toll road projects. At the regional level, 26 shadow toll projects totalling around 1,200 km (Acerete et al., 2018) have been awarded so far. For its part, the Central government has tendered and awarded 10 projects based on a combination of shadow toll and availability payment approaches, and one project that relies entirely on availability payments, totalling 1,042 km altogether.

Although these schemes have allowed the construction and update of an extensive network of high-quality privately financing motorways, they have prevented neither overcapacity nor frequent recourse to contract renegotiation, with consequent changes in initial terms, prices, and recourse to public aid (Engel et al., 2015). In this respect, Spanish law obliges the government to restore the economic balance of the contract, to the benefit of the relevant party as it corresponds, in the following cases: (i) when the government modifies, for reasons of public interest, the contractual terms originally agreed; (ii) when circumstances of force majeure or actions undertaken by the government lead directly to the substantial disruption of the economics of the contract; and (iii) when the assumptions established in the contract itself for its revision occur. However, the Spanish Government has gone beyond these causes to avoid the bankruptcy of road concessions. This way of acting has been highly motivated by the effects of a legal provision (known as the State's Financial Liability) included in the public contracts law that regulates the compensation to the PPP contractor in case of early termination of the contract. This clause commits the government to compensate the private sponsors for the works that have been built and not yet depreciated in case that the early termination of the contract has not been caused by their negligence. It is worth noting that, until the amendment of the public contracts law in 2015 (Law 40/2015), bankruptcy caused by low traffic levels was not considered negligence by the private sector so it prompted this compensation. This situation encouraged the government not to let concessionaires go bankrupt and, consequently, to assist them when they experienced financial difficulties (Baeza and Vassallo, 2011).

As a result, a large number of concessions have had their economic balance restored so far (Acerete et al., 2018; Baeza and Vassallo, 2011) at the expense of the user, the taxpayer or both. Mechanisms often used to adjust the economic balance of contracts include contract term extensions, fare increases, *ex-post* introduction of revenue mitigation mechanisms, and the awarding of cash subsidies or SPPLs. These government loans are presently the most important public instrument for supporting PPP contracts in Spain since they allow to improve the financial feasibility of projects without increasing the national public deficit, but also establish a fairer means of sharing profits between the private sector and the government (Vassallo and Sánchez-Soliño, 2007).

2.1 SPPL's Regulation

SPPLs are currently regulated by Royal Decree-Law 7/1996, which defines them as a subordinated financial instrument whose main characteristic is that the lender would receive a variable interest depending on the evolution of the outcomes of the borrowing company's activity. The criteria to determine such evolution may be either profit, revenues, sales or any other variable demanded by the government or freely agreed by the contracting parties. The characteristics of these loans can be freely designed by the government as long as they comply with three rules (Vassallo and Sánchez-Soliño, 2007):

- SPPLs must always be subordinated to other senior debt. Therefore, SPPL holders (the government in this case), will be repaid only after the PPP contractor has met its obligations to the senior lenders.
- The expected return of SPPLs must be related to the economic performance of the PPP contract. The idea behind this approach is that the government partially shares the project's profits and losses with private sponsors.
- The expected yield of SPPLs should be market–based, otherwise the government could use SPPLs to provide hidden subsidies that should be accounted for in the public deficit.

Likewise, the PPP contractor may not amortise the borrowed capital in advance, unless the early amortization implies payment of the net present value of the expected future benefits according to the economic-financial plan approved by the competent government body at the time of the return of the capital.

Although this mechanism has important advantages compared to other means of fiscal support, it also has some issues (Vassallo and Sánchez-Soliño, 2007). One of the problems is that the government could misuse this mechanism as an implicit subsidy by providing loans that the PPP contractor will ultimately not be able to repay. Also, this mechanism turns the government into a borrower of the project. Therefore, if the project does not perform as expected, the annual interests incurred will significantly decrease while the risk that the loan is not repaid will increase. Finally, if the supported project cannot turn its financial position around and goes bankrupt, the contract must be liquidated with the consequent activation of the State's Financial Liability. In that case, the government —and ultimately the taxpayer— will bear both the costs associated with assuming responsibility for the infrastructure and the non-repayment of the SPPL and its interests until the end of the contract.

2.2 Practical implementation of SPPLs in motorway concessions and PPPs in Spain

SPPLs have been implemented by the Spanish government either as an *ex-ante* support mechanism or as an *ex-post* means to rebalance the economics of concession and PPP contracts. Regarding the first case, bidders have been offered the possibility of requesting SPPLs at an early stage of the procurement process to strengthen the economic feasibility of the project and, consequently, encourage private participation in the tender. This approach was used, for example, in 2004 in the procurement of the *Cartagena-Vera*, the *Madrid-Toledo*, and the *Ocaña-La Roda* motorways and the Alicante's ring road; and, two years later, in the procurement of the *Málaga-Alto de las Pedrizas* motorway (Vassallo and Sánchez-Soliño, 2007).

However, SPPLs have also been granted to already awarded PPPs to compensate the contractor for amendments to contracts or changes made by the government on the grounds of promoting the public interest; or to improve the viability of PPPs in the event of poor economic performance or even on the brink of bankruptcy. The suburban toll motorway concessions around Madrid (R-2, R-3, R-4 and R-5) represent a good example of the use of this instrument by the government in a failed attempt to avoid those concessions going bankrupt. The economic performance of these concessions was pretty damaged by traffic shortfalls caused by the economic recession (and an overly optimistic estimate of traffic demand), and large cost overruns in the expropriation process. In this context, the government granted SPPLs to help them pay the additional costs incurred when acquiring the right-of-way and to provide liquidity because of the revenue shortfall (Baeza and Vassallo, 2011; Vassallo et al., 2012). However, despite the regulatory and financial aid, estimated at around €600 million, all concessionaires eventually went bankrupted (Bel et al., 2017).

Another example of the use of SPPLs to rebalance the economics of the contract to compensate PPP contracts for a discretionary change in the initial contractual conditions by the government is the present case study. As will be later explained, PPP contractors of the first-generation motorways received SPPLs as compensation for the government's imposition of additional works not foreseen in the original projects.

3. CONTRACT ANALYSIS OF THE FIRST-GENERATION MOTORWAY PPPS

3.1 Main characteristics

In 2006, the Spanish Ministry of Transportation (MT) launched the First-Generation Motorways Plan (hereinafter the Plan). Its purpose was to improve the alignment standards, quality and safety levels of a set of important motorways in Spain that were built in the early 1980s with quality standards far below those of motorways designed and built years later, making these roads much less safe than the rest of the network. Given the government's budgetary constraints and the need to improve the roads as soon as possible, the government decided to procure them as PPPs. Thus, the MT tendered the upgrading, maintenance and operation of eleven brownfield sections, totalling 993 km, which were finally awarded during 2007.

The contracts included three types of works: (i) initial works to adjust the motorway design to the current technical and functional standards required; (ii) major repairs to guarantee a proper level of service; and (iii) routine maintenance activities throughout the life of the contract. The private sector was entrusted with the design, financing, construction and operation of the infrastructure for a period of 19 years.

The government decided to keep the motorways free of charge by using a combination of shadow toll and availability payment approaches, committing itself to pay a fee to the PPP contractor based on both traffic demand and a set of performance indicators during the life of the contract. The “demand fee” is calculated monthly according to (i) the type of vehicle (light or heavy); (ii) the number of vehicles-kilometres of each type circulating on the motorway; (iii) the fare applicable to each type of vehicle per kilometre travelled; (iv) until the completion of the initial works, the percentage of motorway section in service at the end of the previous year; and (v) the correction factor, upwards or downwards, depending on a set of performance indicators stated in the contract that measure the condition of the road and the quality of service provided.

3.2 Amendments to the contracts

The financial crisis, which began shortly after the contracts were awarded, had a great impact on the actual traffic volumes on the motorways. This situation was exacerbated by the government’s reluctance to approve the definitive designs provided by the PPP contractors, which caused important delays in the beginning of works. In these circumstances, the feasibility of the contracts was at risk, and with it the possibility of improving the motorways and, henceforth, their safety rates. For this reason, in 2010 the government prompted an overall change in the contract terms aimed at both including additional works and imposing stricter requirements considered indispensable to provide the right service.

According to Spanish law, the government has the right to change the terms of the contract to bring it closely into line with the public interest. If this change affects the economic balance of the contract, the initial conditions can be modified in favour of the private contractor or the government to compensate for this change (Vassallo et al., 2012). The main measures established for restoring the economic balance of the PPP contracts included: (i) the increase in the fares originally approved to compensate for additional works; and (ii) the possibility of granting SPPLs to PPP contractors to finance these additional works. The criterion established to calculate the new fare was to preserve the Internal Rate of Return (IRR) before taxes of the projects. The PPP contractors submitted new Economic-Financial Plans (EFPs) that included the additional investment and the new fares and, once approved by the government, became part of the contract documents. This rebalancing meant an increase in fares ranging from 21% to 67% over those initially approved, and an average increase in the price of the contracts for the government of around 37%. In addition, the value of the SPPLs granted to PPP contractors reached almost €400 million.

3.3 Granting of SPPLs

The PPP contractors were also granted SPPLs as compensation for the government's requirement of additional works not foreseen in the original contracts. The selection of this mechanism was motivated by two main reasons: (i) to facilitate the PPP contractors the financing of additional works at a time when the country was going through a deep financial crisis, and (ii) to avoid incurring a greater public deficit, since the Euro Pact required Spain to adopt strict control over national public accounts.

The conditions of the SPPLs were very advantageous for PPP contractors. First, the debt to the State was classified as subordinated debt, which allowed contractors to reduce pressure on equity, improve the risk profile of the senior debt and mitigate the liquidity risks of the project. Secondly, the repayment of the principal was set to take place six months before the end of the contract through a single payment. These repayment conditions allowed them to benefit from the entire loan during the whole contract period. Thirdly, a three-year grace period was established for the payment of the loan interests. The interests accrued in this period are to be capitalised together with the loan principal. This allowed the private sponsors not to pay interests during the most sensitive stage of the project, the construction phase. Finally, interest rates were, at least initially, below those of the market since the government would receive as remuneration from the loan the higher of the following amounts: (i) the amount resulting from applying a fixed interest rate of 175 basis points on the outstanding SPPL, or (ii) the amount resulting from applying equation (1).

$$R = 0.5 \times I \times \frac{RaDf}{MaDf} \times PL \qquad (1)$$

where R is the annual remuneration; I, the project IRR before taxes; RaDf, the actual annual demand fee; MaDf, the maximum annual demand fee; and PL, the outstanding amount of the participation loan.

4. METHODOLOGY USED IN THE CASE STUDY

This section undertakes an *ex-post* evaluation of the impacts of the SPPLs awarded by the government to the PPP contractors of the first-generation motorways. These projects have exceeded half of their contract period, which is a reasonable time to conduct the analysis proposed. Specifically, three of the ten sections are analysed: (i) *Autovía del Arlanzón* (A1-T2), the project with the best economic performance among the first-generation PPPs so far; (ii) *Autovía Medinaceli-Calatayud (Aumecsa)* (A2-T3), the worst economic-performing project within the sample; and (iii) *Autovía de los Llanos (Aullasa)* (A31-T1), which has shown an average economic performance compared to the rest of the first-generation motorways. The analysis is aimed at evaluating the positive and negative impacts of the government's decision to support these projects from the financial and social perspectives. The methodology used comprised 3 main steps that are summarised below.

4.1. Selection of a set of performance indicators

The first step consists of the selection of a set of indicators to assess the actual performance of the selected PPP projects from 2010 to 2015. Two different types of indicators are selected: financial and social. On the one hand, the evolution of the financial indicators will later be compared with that foreseen in the EFPs approved after the economic rebalancing of the contracts. This comparison will allow us to evaluate whether the projects are performing as expected from the financial standpoint and, consequently, if they will be able to face the payback of the SPPLs principal. On the other hand, the social indicators are intended to evaluate the benefits arising from the projects themselves to evaluate their social feasibility. The financial indicators selected are investment, income, and dividends; and the social indicators: accident rates and anticipation in the commissioning of the works.

4.2 Analysis of the financial sustainability for the government

The second step consists of analysing the financial impact of awarding the SPPLs for the government. To that end, the capacity of the PPP contractors to repay the principal of the loan together with the capitalization of the interests accrued during the three-year grace period is assessed. Since the reimbursement of the SPPL will take place six months before the end of the PPP contract, the last year's free cash flow (FCF) (2026) for each PPP is estimated. It is considered that, as there is no mandatory imposition of creating a reserve account, the SPPL repayment will be borne with last year FCF. This is a crucial variable to evaluate the capacity of the PPP sponsors to repay the SPPLs, given that other senior loans should have been previously repaid, as is usual in project finance.

For its calculation, the evolution of the main variables affecting the PPP cash flow in the period 2017-2026 is estimated by assuming the elasticities to socioeconomic variables calculated by previous research studies for the case of Spain (Gomez et al., 2015; Gomez and Vassallo, 2016). According to the aforementioned authors, there is a marked and stable correlation between the variation in GDP per capita and the evolution of light vehicle traffic; and between the variation of industrial GDP and the evolution of heavy vehicle traffic. In order to allow for uncertainty in the evolution of the economy, we have defined three potential scenarios based on the forecasts of Spanish GDP growth from different agencies: a base scenario, an optimistic scenario, and a pessimistic scenario. Then, the simplified FCF estimate is made for each project and scenario by calculating the difference between income and expenditure. Finally, we estimate whether the government is running a risk of not being repaid by contractors by comparing the expected FCF in 2026 with the SPPL commitments to be reimbursed by contractors that year.

4.3 *Ex-post* evaluation of the social impacts of the SPPLs

The last step of the methodology consists of assessing whether the government's decision to support these projects was justified from a social perspective. To that end, an estimate of the social gains of the projects in terms of improved road safety is used as a proxy of the social impact derived from the awarding of the loans. The estimation has been carried out following the methodology developed by Pérez de Villar (2015), whereby the annual social benefit derived from improving road safety on a certain motorway is calculated according to equation (2):

$$SB_{annual} = PIA\ x\ V_{PIA} = (PIA_{ex} - PIA_{\mathrm{r}})x\ V_{PIA} \tag{2}$$

Where: PIA is the number of accidents with victims avoided as a result of the execution of a certain measure, which is calculated as the number of accidents expected on the motorway according to the general trend (PIA_{ex}) minus the real number of accidents that occurred in the motorway (PIA_{r}). Since PIA_{ex} is a highly uncertain value, Pérez de Villar (2015) recommends using as an approximation of the average value corresponding to roads with similar characteristics. V_{PIA} is the average statistical value of avoiding a victim in a traffic accident on roads with characteristics similar to that analysed, which is calculated according to equation (3).

$$V_{PIA} = \frac{\sum_{sr} FAT x\ V_{FAT} + \sum_{sr} SEI x\ V_{SEI} + \sum_{sr} SLI x\ V_{SLI}}{\sum_{sr} PIA} \tag{3}$$

Where: $\sum_{sr} FAT$, $\sum_{sr} SEI$, $\sum_{sr} SLI$ are the total number of fatalities, seriously and slightly injured on roads with similar characteristics. V_{FAT}, V_{SEI} and V_{SLI} are the value of avoiding a fatality, a seriously injured and a slightly injured. $\sum_{sr} PIA$ is the total number of victims on roads with similar characteristics.

Finally, we compare the estimated social benefit produced by road safety improvements until the end of the PPP contracts (2026) with (i) the additional investment made with respect to a scenario 0 in which the government has not supported the projects and, therefore, the existing roads have not been upgraded, and (ii) the potential financial loss estimated for the government in the pessimistic scenario. These comparisons allow us to evaluate the social feasibility of the projects and the extent to which the risk borne by the government in providing SPPLs to the projects was offset by the social benefits. It is worth noting that the evaluation of social benefits is very conservative for two reasons. On the one hand, society will keep on benefiting from accident rates reduction beyond 2026. On the other hand, other social gains (such as travel time savings, comfort improvement, fuel savings or reduced air pollution emissions) are not taken into account in this estimate.

5. RESULTS

This section summarises the main findings of the three selected PPP projects of the Plan. First, it shows the actual performance of the projects compared to the new EFPs approved. Then, the SPPL repayment capacity of PPP contractors is calculated for different scenarios in order to estimate its potential impact on the public budget. Finally, social gains derived from the improvement in road safety are estimated to assess whether the government did it right when deciding to grant SPPLs to support the projects.

5.1 Financial performance and social benefits

5.1.1 Capital and O&M costs

Regarding the capital cost of the initial works, all PPPs managed to adjust very well to the estimates conducted in their EFPs. As can be seen in Table 1, two of the three projects analysed incurred lower costs than expected. In contrast, there has been significant under-investment in major repairs and rehabilitation actions compared to the original estimates.

In this regard, only A2-T3 and A31-T1 carried out rehabilitation works worth, in both cases, far less than expected. Finally, PPP contractors incurred higher O&M costs than originally planned. This was likely caused by the incentives provided by the contracts to achieve better maintenance and operational performance through service indicators.

Section	Construction costs	Rehabilitation costs*	O&M costs*
A1-T2	-2.69%	-100%	17.36%
A2-T3	-7.94%	-74.13%	4.27%
A31-T1	1.18%	-88.30%	54.52%

* In the period 2009-2015

Table 1 - Deviation of the main costs from EFP's estimation

5.1.2 Income

Table 2 shows the evolution of the deviation of current revenues —both from traffic and availability— from those foreseen by the EFPs, which considered no income from availability payments. It can be observed that all PPPs, especially A2-T3, obtained less income than originally expected, especially during the first years of operation. In the last years analysed, due to the improvement of the Spanish economy and the availability bonuses, the total revenue obtained almost coincides with the original estimates.

Section	2009	2010	2011	2012	2013	2014	2015	2016
A1-T2	-	-	-29,7%	-17,3%	-1,5%	7,2%	1,4%	-6,3%
A2-T3	-	-15,6%	-67,0%	-48,9%	-31,9%	-2,7%	-12,2%	-3,5%
A31-T1	-1,7%	-33,6%	-2,8%	-17,5%	-5,0%	-6,5%	10,4%	-4,1%

Table 2 - Income deviation from EFP's estimation in the period 2009-2016

The actual dividend distribution to project shareholders for two of the PPPs analysed has substantially differed from that envisaged in the EFPs. In the case of A1-T2, dividends began to be distributed in 2013, one year later than planned. However, the accumulated amount distributed till 2016 was 37% higher than initially envisaged, with an over-distribution of €3.03 million. In the case of A31-T1, dividends began to be paid in 2014, four years ahead of schedule, with €4.24 million being over-distributed. Finally, as of 2016, A2-T3 had not yet distributed dividends, following the schedule established in the EFP, with dividends to be distributed from 2018 on. This PPP has obtained lower economic results than expected so far and has been incurring losses despite the additional income from indicators, obtaining the worst economic performance of the PPPs under study.

5.1.3 Accident rates

Table 3 shows the evolution of the hazard (HI) and mortality (MI) indexes. An important decrease in their values can be observed comparing the situation before the projects were awarded (2006 and 2007) and after works were completed (2014 and 2015).

Quantitatively, the HI on the motorways analysed with respect to the starting situation has improved between 78 and 90%, while the MI has fallen by 29% on average. As can be observed in the same table, two of the three motorways are significantly safer than the rest of the State roads with similar characteristics in terms of traffic levels (AADT) and road type (urban or interurban).

Section	Before works				*Works in progress*	After works				Equivalent roads
	2006		2007		*2008-2013*	2014		2015		2015
	HI	MI	HI	MI		HI	MI	HI	MI	Average HI
A1 - T2	18.64	0.46	15.48	0.17		3.63	0.27	3.37	0.27	6.06
A2 -T3	19.25	0.94	27.89	1.75		6.26	0.45	4.22	0.21	3.97
A31 - T1	14.7	0.22	17.82	0.84		2.07	0.13	1.86	0.37	6.06

Table 3 - Evolution of hazard and mortality indexes of the PPPs analyzed before and after the completion of works and average hazard index of equivalent roads for 2015

5.1.4 Anticipation in the commissioning of the works

One of the main reasons why these projects were undertaken under the PPP approach was the urgency of the Plan and the insufficient resources to undertake these actions through conventional budgetary approaches within a reasonable period of time. In that respect, the Strategic Plan of Infrastructure and Transport (PEIT) estimated that it would take about eight years to meet all investment needs if they were to be built with budgetary resources (Ministerio de Fomento, 2005). This estimation was, however, based on an economic growth scenario that did not occur given the economic downturn that soon after affected the country and resulted in continued budget reductions for the road infrastructure program since 2009. The PPPs analysed were completed within 1.5 (A31-T1) to 3.5 years (A2-T3).

Therefore, the implementation of the actions was anticipated in a range between 6.5 and 4.5 years with respect to the option of undertaking the actions through the conventional procedure estimated by the MT. As a result, society has been reaping the benefits of the positive savings and externalities derived from the works in advance.

5.2 Estimates of the debt repayment capacity of the PPP contracts

In order to estimate the repayment capacity of the SPPL, according to the methodology previously defined, we have estimated the FCF in the last year of the contract (2026). To that end, we estimated: (i) traffic revenues; (ii) availability payments; (iii) O&M costs; (iv) capital costs in major repairs and rehabilitation projects, and (v) corporate taxes. The hypotheses and the procedure adopted for their calculation are summarised below.

- Annual traffic revenues are calculated as the product of the volume of traffic on the road section (in vehicles x km) each year and the fare (excluding VAT) applied in the same period, differentiating between traffic and fares for light and heavy vehicles. The evolution of light and heavy traffic over time has been obtained, for each scenario, by applying the elasticities estimated by Gomez et al. (2015) and Gomez and Vassallo (2016) to the socioeconomic variables of each scenario (GDP per capita and industrial GDP). For its part, the fare is updated yearly according to the variation of the national Consumer Price Index (CPI) by using the Spanish CPI forecasts for the period 2017-2026 from the International Monetary Fund (IMF).
- Annual availability revenues in the period 2017-2026 are assumed to be a constant percentage of total revenues consistent with previous years.
- Annual O&M costs in the period 2017-2026 have been calculated based on those of the previous years, assuming that the only increase they will experience in the future will be caused by inflation.
- Given the difficulty of estimating future investments in road rehabilitation, the values foreseen for this purpose in the EFPs delivered by the PPP contractors have been adopted in the analysis.

- The corporate tax is calculated as the legal rate (25%) times the Profit Before Taxes (PBT). The PBT has been annually calculated for each of the proposed scenarios as annual revenues minus O&M costs, depreciation of the assets, and financial expenses.

After obtaining the expected FCF in 2026, the last step of the analysis consisted of estimating whether they are enough to cover the repayment of the principal of the SPPL including the capitalization of interests accrued during the three-year grace period. Table 4 shows that the amount that PPP contractors have to return to the government the last year of the contract is, for all scenarios, higher than the expected FCF generated. Thus, according to the principles of project finance, whereby lenders should only rely on project cash flows for debt repayment, PPP contractors will not be able to repay the full amount of the loan in the last year of the contract.

Section	SPPL principal + 3-year interests	Scenarios	Last year FCF (M€)	Difference with respect to the scenario (M€)
A1-T2	49.56	Optimistic scenario	43.37	-6.19
		Base scenario	*40.98*	*-8.58*
		Pessimistic scenario	38.33	-11.23
A2-T3	51.30	Optimistic scenario	28.16	-23.14
		Base scenario	*26.66*	*-24.64*
		Pessimistic scenario	26.15	-25.15
A31-T1	20.58	Optimistic scenario	18.77	-1.81
		Base scenario	*17.51*	*-3.07*
		Pessimistic scenario	16.24	-4.34

Table 4. Amount to be returned by each PPP contractor to the government in the last year of the contract, estimated free cash flow (FCF) available that year for that purpose and estimated amount that would not be returned in each scenario

5.3 Estimate of the social benefits of the PPP projects

In order to obtain an approximation of the social gains derived from the projects, a conservative estimate of the social benefit derived from the improvement in road safety since the commissioning of the first section (A31-T1) until the end of the PPP contracts (2026) is made according to the methodology previously explained (Pérez de Villar, 2015).

To that end, it has been assumed that if these motorways had not been upgraded, the evolution of the accident rates —measured through the HI— of the first-generation motorways under study would have followed the same trend of the rest of the Spanish roads with similar characteristics.

The annual social benefit (SB_{annual}) is calculated following equation (2) as the product of the number of victims avoided on the motorway sections analysed with respect to the hypothetical scenario where no upgrading actions are undertaken, and the value of preventing a victim calculated according to equation (3) with the monetary values provided by the Handbook on External Costs of Transport (DG MOVE, 2014).

From the analysis conducted, we estimated that the social benefit derived from the reduction of accident and mortality rates on the three motorways in the 2011-2026 period totalled €363.82 million actualised to 2007 prices. On the other hand, the total investment related to the establishment and upgrading of the motorways, including additional works approved in 2010, updated to 2007 amounted to €360.91 million. This estimate shows that the social benefit derived from the reduction of the accident rate exceeds the total investment made for the establishment and upgrading of the three sections, which endorses the social feasibility of the projects. Finally, the potential financial loss estimated for the government in the pessimistic scenario, actualised to 2007 prices with the same discount rate used for the social benefit, amounts to €16.8 million, which is negligible compared to the social benefits of the motorways.

6. DISCUSSION OF THE RESULTS AND POLICY IMPLICATIONS

The *ex-post* evaluation enabled us to evaluate whether the government's decision to support the PPPs analysed was socially justified. The SPPLs, together with the rest of measures agreed when restoring the economic balance of the contracts, allowed the government to push ahead with the projects and undertake the works it deemed necessary to improve road safety on the motorways. The analysis shows that these projects have proven to be extremely successful in decreasing accidents rates, thereby producing high social benefits that greatly exceed the potential financial loss estimated for the government in the pessimistic scenario analysed. Moreover, both users and society have been enjoying these benefits well in advance thanks to the government's decision to support the PPP contracts. Finally, if the government had chosen not to do so, the contracts would have likely been early terminated, thereby entailing important costs for society (termination payments to contractors, additional cost to re-tender the contracts, etc.) and the benefits arising from the projects would have been delayed.

The case study analysed also provides future lessons for governments that need to make prompt decisions responding to sudden PPP problems. The first lesson is that a right *ex-ante* design of the contract substantially contributes to reducing problems once the contract is awarded. In the case shown in this paper, the government's reluctance to approve the final designs provided by PPP contractors, even though they met the minimum requirements, delayed the financial close of the projects and, subsequently, the beginning of the works.

This fact, along with traffic shortfalls caused by the economic recession, were the main causes that threatened the projects' viability.

Thus, if the government had included in the projects' tendering specifications the technical requirements and all the works deemed necessary, the problems would have been much limited.

The second lesson is that support mechanisms must be properly designed so that the government does not take a higher risk than the shareholders. In the present case study, the conditions under which the SPPLs were awarded did not set sufficient measures to guarantee the public interest against that of the shareholders. The results show that, if no action is taken in this regard, there is a significant risk that PPP contractors will not be able to repay the principal of the loans even though the PPP projects are performing well and, in two of the cases, distributing more dividends than expected. In this respect, some of the issues identified might have been avoided if the government had set some provisions to safeguard the SPPL seniority to the shareholders. For example, the government could allow for a more flexible amortization approach of the SPPL, or require PPP contractors to set up a SPPL service reserve account at the end of the grace period for its provision.

The third lesson is that the level of risk actually borne when providing support mechanisms to PPPs should be assessed and if possible quantified. SPPLs may involve contingent liabilities with a significant impact on the future public budget, but they were not assessed before being awarded. The fourth lesson from this paper is that an independent entity, rather than the MT, should be in charge of measuring the contingent liabilities arising from these loans. These contingent liabilities, once estimated for all the projects, should be accounted for within the national budget at the time the loan is granted. This way, governments will have the correct incentive to provide SPPLs at the right price, and only when they add value.

7. CONCLUSIONS

This paper is a good example of the complexity of managing PPPs due to the incompleteness inherent to these contracts. The case study sheds some light on key aspects to respond to government decisions about providing support to PPPs in trouble with potential high benefits for the society. It also shows how taking drastic decisions in that respect, such as forcing the termination of the contracts, may not be the best solution from the social point of view. This case study proves how governments often try to solve problems as quickly as possible without conducting the right analysis to measure the impact, both social and fiscal, in the medium and long term.

The main conclusions from the paper are two. The first one is that a good governance approach along with the right *ex-ante* design of the contract will mitigate the impact of future unexpected problems.

The second conclusion is that the best way to deal with problems over the life of the contract is to define the right procedure to address them. In this respect, a proper design of the support measure and assessing the consequent government exposure to risk is necessary to ensure the financial sustainability of the public sector when adjusting the contracts to unexpected events.

Future research should focus on using more quantitative approaches to find an optimal equilibrium between commitment and flexibility in PPPs to ensure that decisions are taken to maximise sustainability. This analysis should value the impact on different stakeholders.

ACKNOWLEDGEMENTS

The authors wish to thank the Spanish Ministry of Transportation and particularly to Pablo Pérez de Villar for providing us the data needed to carry out the analysis.

RESUMEN

Tras la publicación del Libro Blanco del Transporte (2011) surgen múltiples directivas europeas proponiendo reformas estructurales en el sector para fomentar su eficiencia. En materia de inversiones, buscan optimizar la labor de los administradores de infraestructura, tanto a nivel técnico como presupuestario y financiero. Estas directivas se han ido incorporando progresivamente al ordenamiento jurídico español, donde el Ministerio de Transportes, Movilidad y Agenda Urbana (MITMA) es el organismo que establece las directrices generales de planificación del transporte mediante la elaboración planes estratégicos. La planificación pormenorizada se detalla en planes directores, sectoriales o programas de actividad, en los que generalmente intervienen los gestores de infraestructura.

Actualmente, el desarrollo de estos instrumentos incide en la importancia de identificar las inversiones más urgentes y priorizar las actuaciones a desarrollar. En este sentido, el presente artículo describe una metodología para priorizar actuaciones en transporte con el fin de optimizar las inversiones en dicho sector.

La metodología consta de dos fases: una priorización inicial basada en un análisis multicriterio a tres niveles: a nivel estratégico (nivel 1), donde se planifican actuaciones globales, de carácter de red, y se tiende a priorizar corredores, nodos o ámbitos territoriales sin llegar a priorizar actuaciones concretas; y en planes directores o sectoriales, priorizando actuaciones que pueden ser muy dispares (nivel 2) o de la misma naturaleza (nivel 3). Por tanto, se trata de una metodología aplicable a diferentes instrumentos de planificación combinando niveles según las características propias de cada uno de ellos.

La segunda fase consiste en un contraste de los resultados obtenidos en el análisis multicriterio por un grupo de expertos que, con una visión crítica e integradora, apliquen criterios de priorización no contemplados en la fase previa y consideren posibles solapes en la planificación a distintos niveles y con otras planificaciones previas en el ámbito de estudio, permitiendo perfeccionar la priorización y facilitando la posterior estimación de recursos y plazos de implementación.

1. INTRODUCCIÓN

1.1 Origen y antecedentes

Con la publicación en 2011 del “Libro Blanco de Transporte, hoja de ruta hacia un espacio único europeo de transporte”, la Comisión Europea comienza a establecer las bases para la creación de un entorno común de transporte a nivel europeo. En el caso del transporte ferroviario, estas bases se han ido concretando en los denominados “Paquetes Ferroviarios" y, finalmente, en la Directiva 2012/34 RECAST que señala la necesidad de mejorar las condiciones de inversión en el sector como uno de sus objetivos fundamentales.

En España, la Ley 38/2015 del Sector Ferroviario, que resulta de la transposición de la Directiva RECAST, establece la necesidad de que los Estados miembros redacten una Estrategia Indicativa para el desarrollo de la red ferroviaria y que los administradores de infraestructuras aprueben un Programa de Actividad para un periodo no inferior a cinco años. En este sentido, actualmente se está trabajando en la elaboración del Programa de Actividad de Adif y Adif AV. Para el desarrollo de éste y de otros instrumentos de planificación ferroviaria, cada vez adquiere mayor importancia el poder identificar las inversiones más necesarias y priorizar el conjunto de actuaciones previstas en la red ferroviaria. Por este motivo, Adif solicitó a Ineco su colaboración para la elaboración de una metodología que permitiera priorizar, de forma práctica y objetiva, las inversiones correspondientes a las actuaciones ferroviarias contempladas en diferentes programas de necesidades de inversión. La metodología desarrollada y los criterios de priorización fueron definidos de manera conjunta y consensuada entre Ineco y Adif, aplicando dicha metodología con éxito a distintos planes directores y al conjunto de la red ferroviaria convencional.

A raíz de este trabajo, surge la necesidad de ampliar el alcance y el ámbito de aplicación de la metodología propuesta a otros territorios y a otros niveles de planificación, incluso para la priorización de actuaciones previstas en otros modos de transporte, no sólo en transporte ferroviario.

1.2 Marco general y objetivos

El objetivo del presente trabajo es desarrollar una propuesta metodológica que, de forma práctica y basada en una serie de criterios objetivos y medibles, permita la priorización de inversiones no sólo de carácter ferroviario, sino que sea igualmente aplicable para priorizar actuaciones que afectan a otros modos de transporte. La metodología desarrollada será especialmente útil en la elaboración de planes directores, planes sectoriales u otros instrumentos de planificación, siempre y cuando contemplen actuaciones específicas que lleven aparejadas partidas de inversión.

En España, el organismo que establece las directrices en materia de planificación de transporte es el Ministerio de Transportes, Movilidad y Agenda Urbana (MITMA) a través de la elaboración de los planes estratégicos de infraestructuras a nivel nacional. En este sentido, en julio de 2005 se aprobó el Plan Estratégico de Infraestructuras y Transporte (PEIT) para el periodo 2005-2020, donde se indicaban las prioridades para el desarrollo de las políticas sectoriales en materia de infraestructuras. Sin embargo, debido a la coyuntura socioeconómica de los años siguientes a la aprobación del PEIT, fue necesaria la reconfiguración de dicha planificación con la inclusión de nuevos objetivos, aprobando en 2015 el Plan de Infraestructuras, Transporte y Vivienda (PITVI), cuyo plazo de vigencia finaliza en 2024.

El PITVI contempla un conjunto de actuaciones concretas en los distintos modos de transporte, definidas como resultado de materializar las nuevas directrices de eficiencia y sostenibilidad y de mejora de la seguridad del sistema de transporte en su conjunto. La valoración económica de dichas actuaciones según la distribución de recursos prevista hasta 2024 entre los distintos programas de actuación definidos (Programa de Regulación, Supervisión y Control, Programa de Gestión y Prestación de Servicios, y Programa de Actuación Inversora) y por modo de transporte se muestra de forma resumida en la siguiente imagen.

Valoración económica de las actuaciones del PITVI [Millones de € constante de 2012]		
Carreteras	36.439	26%
Ferrocarriles	61.302	44%
Aeropuertos y navegación aérea	7.222	5%
Puertos	6.788	5%
Ayudas al transporte	15.899	11%
Inversión ajena puertos	6.575	5%
Inversión privada carreteras	4.030	3%
Total transportes	**138.255**	**100%**

Tabla 1 – Estimación económica de las actuaciones del PITVI en infraestructuras y transportes, 2012-2024, por modos y conceptos

Sin embargo, en el PITVI no se detalla la valoración económica ni el plazo de ejecución previsto para cada una de ellas, ni de forma individualizada ni por bloques o subprogramas de actuaciones. Por tanto, el Plan no muestra expresamente una priorización de las actuaciones que contempla, aunque sí establece entre sus directrices la necesidad de "*adoptar una evaluación sistemática de las actuaciones para una eficaz priorización y racionalización de las inversiones, incorporando mecanismos de análisis coste-beneficio y previsiones de rentabilidad económica, financiera y social*".

En España también se elaboran planes estratégicos sectoriales que desarrollan la planificación estratégica de infraestructuras y/o servicios de transporte, pero de un elemento concreto del sistema. Generalmente, los planes estratégicos sectoriales son documentos que establecen los objetivos y las directrices a seguir, pero que no recogen actuaciones de carácter muy concreto. A nivel nacional destacan, por ejemplo, la Estrategia Logística de España o la Estrategia Indicativa del desarrollo, mantenimiento y renovación de la infraestructura ferroviaria del MITMA, esta última en cumplimiento a lo establecido en la Ley 38/2015 del Sector Ferroviario y que actualmente se encuentra en proceso de redacción. De forma análoga, la nueva Ley de Carreteras 37/2015, que también persigue adaptar la ordenación del transporte por carretera a la normativa comunitaria siguiendo criterios de seguridad y eficiencia en la asignación de recursos, establece la necesidad de elaborar un Plan estratégico de las carreteras del Estado que, como instrumento técnico-jurídico de política sectorial de carreteras, recoja las previsiones y los objetivos a cumplir, así como las prioridades de actuación.

Un escalón por debajo en la planificación del transporte se encuentran los planes directores o sectoriales para un modo de transporte y/o un territorio concreto. En estos documentos ya intervienen los propios gestores de la infraestructura y contemplan actuaciones más concretas que generalmente llevan asociadas partidas de inversión. Los Planes Directores de los puertos de titularidad estatal, por ejemplo, son elaborados por las propias Autoridades Portuarias, quienes definen las necesidades de desarrollo del puerto durante un horizonte temporal determinado y su valoración económica, entre otros aspectos. En el sector ferroviario, Adif establece en sus Planes Directores las actuaciones e inversiones previstas en la red ferroviaria de un determinado territorio por anualidades o periodos concretos.

Finalmente, la planificación más pormenorizada, tanto a nivel nacional como regional, se desarrolla en programas de actuación o programas de actividad, en los que se detallan actuaciones, generalmente a corto plazo y muy concretas, que llevan aparejadas partidas de inversión. En estos casos, además del MITMA y los propios gestores de la infraestructura de transporte, pueden intervenir otras Administraciones Públicas autonómicas o locales y organismos asociados.

En cualquier caso, en todas las etapas e instrumentos de planificación comentados se incide cada vez más en la importancia de racionalizar la asignación de recursos y priorizar las acciones a desarrollar. Pero tanta variedad de planes, ámbitos y agentes que intervienen en estos procesos, sumado a la diversidad de modos y servicios de transporte, suponen en muchos casos un conjunto de actuaciones tan heterogéneo que dificulta en gran medida su priorización, haciendo que la toma de decisiones sea verdaderamente compleja.

Por todo lo anterior, el presente trabajo define una metodología para priorizar inversiones en el sector transporte que sea capaz de adaptarse a las diferentes casuísticas, de modo que pueda aplicarse en múltiples instrumentos de planificación y a diferentes sectores del sistema tan sólo realizando algunos ajustes.

2. METODOLOGÍA PARA LA PRIORIZACIÓN DE INVERSIONES

Tras analizar algunos antecedentes sobre procesos de priorización de actuaciones desarrollados en diferentes instrumentos de planificación con el objetivo de analizar las metodologías empleadas en dichos documentos e identificar todos los criterios utilizados, se ha propuesto una metodología para la priorización de las inversiones en transporte que consta de dos fases:

I. Priorización de actuaciones mediante un análisis multicriterio a tres niveles:
   - Nivel 1: Priorización entre corredores, nodos o ámbitos territoriales
   - Nivel 2: Priorización de actuaciones de distinta índole
   - Nivel 3: Priorización de actuaciones de la misma naturaleza

II. Contraste de los resultados del análisis multicriterio por un grupo de expertos

A continuación se describen cada una de las fases metodológicas.

2.1 Fase I - Priorización mediante análisis multicriterio a partir de indicadores

En una primera fase se realiza una priorización de las actuaciones contempladas en el Plan en base a un análisis multicriterio. La categorización de las actuaciones que se puede llevar a cabo a tres niveles distintos:

Nivel 1. Priorización de corredores, nodos o ámbitos territoriales.

Se trata de una priorización especialmente útil para infraestructuras lineales. Permite valorar la ejecución de un conjunto de actuaciones previstas sobre una determinada vía o línea ferroviaria, o bien la ejecución de una nueva infraestructura, priorizando unos corredores frente a otros. En este caso no se evalúan actuaciones específicas, como podría ser la electrificación de un determinado tramo ferroviario o el desdoblamiento de un tramo de carretera, sino que se estudia la conveniencia de actuar sobre una carretera o línea ferroviaria concreta con respecto a actuar en otras, categorizándola con mayor o menor prioridad. El resultado es un listado de corredores, carreteras o líneas ferroviarias, catalogados según el orden de prioridad para actuar sobre ellos atendiendo a una serie de criterios generales que evalúan la relevancia del corredor, tramo o trayecto en el conjunto de la red, independientemente del cúmulo y tipo de actuaciones que deban desarrollarse en cada caso (criterios de priorización de categoría 1).

El nivel 1 de priorización es aplicable tanto a corredores íntegros como a trayectos más concretos. A modo de ejemplo, en el “Programa de Necesidades de Inversión en las Líneas de Galicia y Asturias y sus conexiones” de Adif se realiza una priorización de grandes itinerarios ferroviarios conformados por subtrayectos. Más adelante se detallan las diferentes categorías de criterios de priorización empleados y los que aplican en cada caso. Este nivel de priorización también es válido en caso de querer valorar en qué nodos logísticos o de transporte (puertos, terminales intermodales, etc.) es prioritario actuar, o incluso entre distintos ámbitos territoriales, si bien conviene señalar que en estos casos no todos los criterios de priorización establecidos en el análisis multicriterio aplican, por lo que el resultado no es tan riguroso como en el caso de las infraestructuras lineales.

Nivel 2. Priorización de actuaciones de distinta índole.
Como se ha comentado anteriormente, existe una gran diversidad no sólo de instrumentos y agentes que intervienen en los procesos de planificación, sino también de tipologías de actuaciones a programar. No obstante, en el marco de un plan director o un plan sectorial se contempla generalmente todo tipo de actuaciones y en ocasiones resulta interesante poder catalogarlas según su orden de prioridad, independientemente de su tipología.

A modo de ejemplo, el PITVI cataloga las actuaciones previstas en el horizonte del Plan (año 2024) en 22 categorías, tal y como se muestra en la figura adjunta.

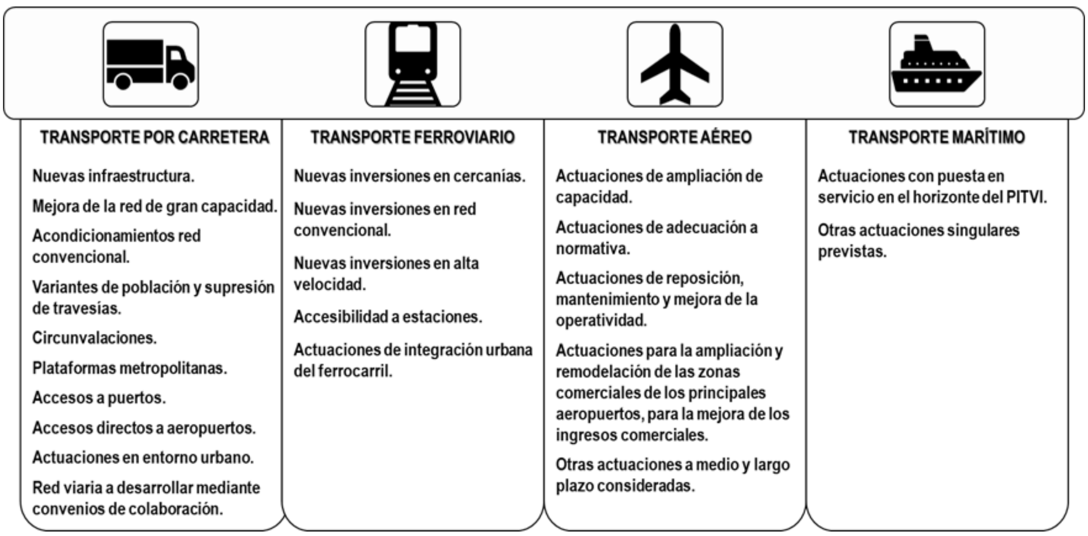

Fig. 1 – Clasificación de las actuaciones que contempla el PITVI (2012-2024)

Cada una de estas categorías es, a su vez, divisible en múltiples tipologías de actuaciones. Tan sólo en el modo ferroviario, las necesidades de inversión en la red pueden deberse a actuaciones de tipo infraestructural, duplicaciones de vía, renovaciones de catenaria, mejoras en los sistemas de señalización, etc.

Por tanto, en ocasiones se precisa estudiar si resulta más prioritario realizar, por ejemplo, la electrificación de una línea en un trayecto ferroviario determinado o la duplicación de vía en otro trayecto ferroviario. Incluso en un mismo trayecto, puede ser necesario analizar si resulta más conveniente la electrificación de la línea o la actualización del sistema de control y gestión del tráfico.

Para estos supuestos se diseñó un segundo nivel de priorización en la propuesta metodológica, en el que intervienen tres categorías de criterios de priorización. Por un lado, un conjunto de criterios generales (criterios de priorización de categoría 2) que catalogan los corredores, tramos o trayectos atendiendo a la complejidad y relevancia del conjunto de actuaciones que en ellos deben llevarse a cabo. Por otro lado, un conjunto de criterios específicos para llevar a cabo la priorización de actuaciones encaminadas a la mejora de prestaciones (criterios de priorización de categoría 3) o a la reposición y gestión de activos (criterios de priorización de categoría 4). Las diferentes categorías de criterios de priorización empleados se detallan en el apartado 3.2.

Nivel 3. Priorización de actuaciones de la misma naturaleza.
Con este tipo de priorización se evalúan y clasifican actuaciones de la misma tipología, resultando especialmente útil en el desarrollo de programas de actuaciones específicos, como programas para la reparación/conservación de carreteras.

En estos supuestos, el proceso de priorización funciona de manera muy similar al nivel 2. Por un lado, se clasifican los corredores por orden de prioridad atendiendo a un conjunto de criterios generales (criterios de priorización de categoría 2) que evalúan la complejidad y relevancia de las actuaciones a desarrollar. Por otro lado, dentro del conjunto de criterios para la mejora de prestaciones (criterios de priorización de categoría 3) o para la reposición y gestión de activos (criterios de priorización de categoría 4) se aplican aquéllos específicos para la tipología de actuaciones que se están evaluando.

Conviene señalar que no todos los documentos e instrumentos de planificación que priorizan actuaciones lo hacen siguiendo estrictamente uno de estos tres niveles. Por ejemplo, el "Programa de Necesidades de Inversión en las Líneas de Galicia y Asturias y sus conexiones" de Adif determina en una primera fase cuáles son los trayectos ferroviarios prioritarios, para después clasificar las actuaciones a realizar en cada trayecto según su tipología y priorizar sus inversiones en diferentes horizontes temporales.

En cambio, el documento "Seguridad en carreteras convencionales: un reto prioritario de cara al 2020" de la Asociación Española de la Carretera, también analizado en el estudio de antecedentes, prioriza aquellos tramos que soportan mayores niveles de tráfico y que tienen un índice de peligrosidad superior a la media con relación a determinados tipos de accidentes. Sin embargo, las actuaciones propuestas, cuya tipología responde a las causas que producen esos tipos de accidentes mayoritarios, no se priorizan unas sobre otras.

En la figura 2 se muestra una clasificación tipo de los instrumentos de planificación del transporte generalmente utilizados.

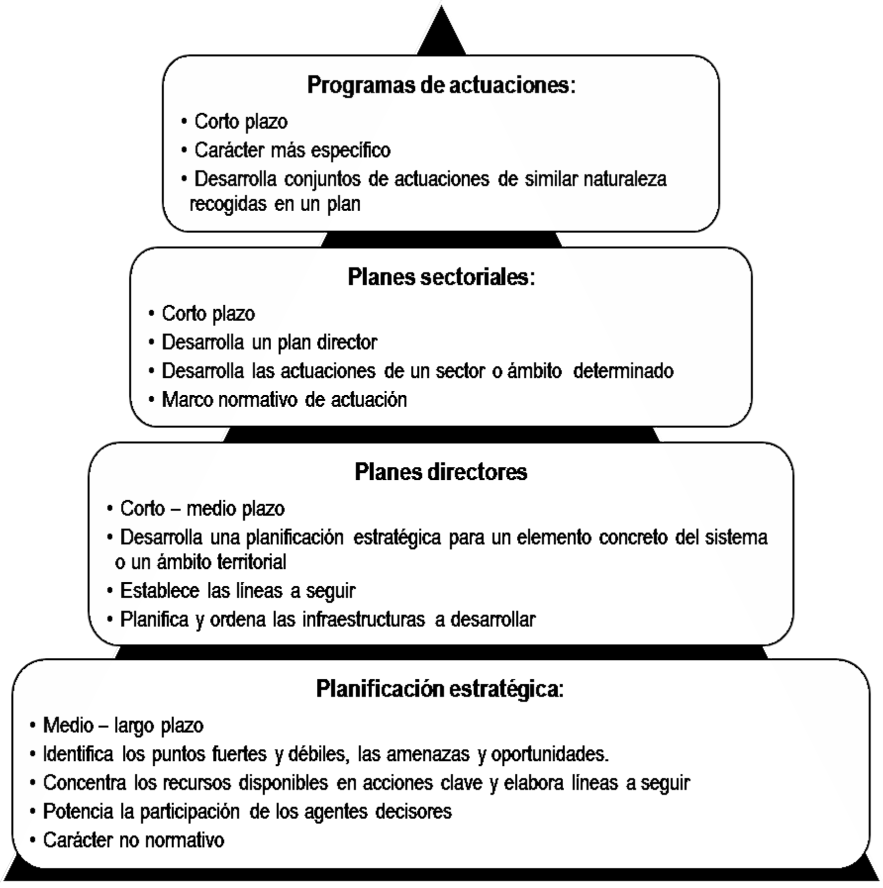

Fig. 2 – Instrumentos de planificación del transporte. Fuente: Planificación y explotación del transporte. Universidad Europea de Madrid.

Tal y como se ha comentado en la introducción, a nivel estratégico, donde se planifica actuaciones de carácter global de red, se tiende a priorizar tramos de carreteras o trayectos/líneas ferroviarias (nivel 1), sin llegar a priorizar actuaciones concretas.

En los planes directores o sectoriales, lo habitual es priorizar unas acciones sobre otras, dentro de un conjunto de actuaciones que pueden ser muy dispares (nivel 2) o todas de la misma naturaleza (nivel 3) porque previamente han sido debidamente clasificadas.

Mientras que en el caso de planes específicos o programas de actuaciones, se prioriza actuaciones que son todas ellas de la misma tipología y responden, por tanto, a criterios de priorización muy específicos (nivel 3). No obstante, tanto en los planes directores o sectoriales como en los planes específicos o programas de actuaciones, se considera de especial interés introducir una primera fase en el proceso en la que se realice una priorización también de trayectos o líneas ferroviarias.

Por tanto, en base a las características propias de cada instrumento de planificación, se propone seguir el siguiente esquema para la priorización de inversiones en transporte mediante análisis multicriterio por niveles:

	ANÁLISIS MULTICRITERIO POR NIVELES	
	Priorización por multicriterio (paso 1)	**Priorización por multicriterio (paso 2)**
Planificación estratégica	Nivel 1: Priorización de corredores, tramos o líneas	
Planes directores y/o sectoriales	Nivel 1: Priorización de corredores, tramos o líneas	Aplicar uno de los siguientes niveles de priorización: • Nivel 2: Priorización de actuaciones de distinta índole • Nivel 3: Priorización de actuaciones según su tipología
Programas de actuaciones	Nivel 1: Priorización de corredores, tramos o líneas	Nivel 3: Priorización de actuaciones de la misma tipología

Tabla 2 – Priorización de inversiones mediante análisis multicriterio por niveles

La fase I de la propuesta metodológica descrita ha sido trasladada a una hoja de cálculo para simplificar su aplicación práctica. La herramienta tiene múltiples funcionalidades que se irá detallando en posteriores apartados. No obstante, conviene señalar que para una mejor visualización de la priorización resultante y su posterior tratamiento resulta conveniente la representación gráfica del análisis multicriterio por niveles en mapas o esquemas mediante códigos de colores.

2.2 Fase II - Contraste de los resultados por un grupo de expertos

Tras la priorización mediante análisis multicriterio de la Fase I, se debe realizar un contraste de los resultados obtenidos por un grupo de expertos con amplia experiencia en planificación de transporte. Dicho contraste deberá llevarse a cabo cubriendo al menos los siguientes aspectos:

- Análisis crítico e integración de las priorizaciones anteriores (niveles 1, 2 y 3).
- Identificación de solapes con otras planificaciones existentes, descartando aquellas actuaciones incluidas en otros planes.
- Análisis de la urgencia de las actuaciones priorizadas.
- Análisis de resistencias y propuestas de soluciones.
- Categorización final de actuaciones por orden de prioridad:
    - Actuaciones estratégicas (prioridad alta)
    - Actuaciones relevantes (prioridad media-alta)
    - Actuaciones ordinarias (prioridad media-baja)
- Estimación de recursos y propuesta de plazos de implantación.

3. PRIORIZACIÓN MEDIANTE ANÁLISIS MULTICRITERIO

3.1 Lógica y etapas de la priorización mediante análisis multicriterio

En el ámbito del transporte, el análisis multicriterio se emplea generalmente para emitir un juicio comparativo entre distintos proyectos o medidas heterogéneas. Por tanto, puede contribuir a la evaluación de un programa o de una política concreta valorando los efectos que sus acciones ya ejecutadas han generado con relación a diferentes criterios. Sin embargo, en los procesos de planificación, las alternativas o actuaciones a evaluar todavía no se han ejecutado. En estos casos el análisis multicriterio permite evaluar otros aspectos, tales como la necesidad de actuación en determinados territorios/elementos del sistema, o la capacidad que las distintas acciones contempladas tienen para alcanzar unos determinados objetivos. En definitiva, facilita la toma de decisiones y contribuye a definir el contenido de los programas y las asignaciones de los recursos entre las distintas acciones contempladas durante el proceso de planificación.

En el caso que nos ocupa, en la primera fase del estudio se ha planteado una priorización de actuaciones basada en un análisis multicriterio de múltiples etapas:

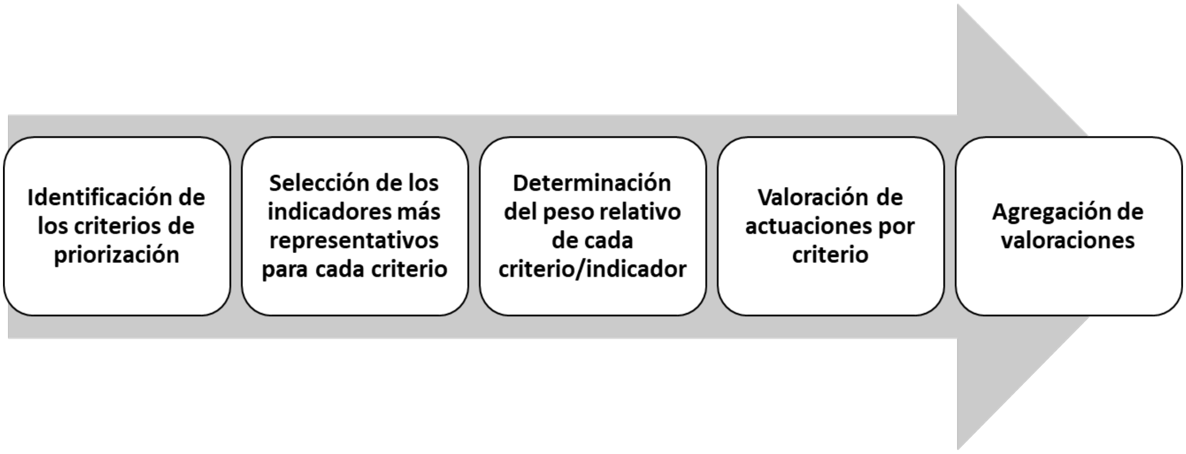

Fig. 3 – Etapas del análisis multicriterio para la priorización de actuaciones, fase I.

El análisis parte de la identificación de los criterios de priorización a considerar, los cuales deben definirse antes de realizar el análisis a partir de unas reglas consensuadas entre todos los agentes que intervienen en el proceso de planificación para contemplar todos los puntos de vista. Los criterios no deben resultar redundantes aunque es inevitable que exista cierta relación entre muchos de ellos. En cualquier caso, deben conformar uno o varios conjuntos coherentes que por sí solos conduzcan a resultados objetivos y admisibles. En el siguiente apartado se detallan las categorías en las que se clasifican los criterios empleados atendiendo al nivel de priorización donde se emplean y los objetivos que persiguen, así como los bloques en los que a su vez se desagregan.

La segunda etapa consiste en seleccionar, para cada uno de los criterios identificados en el punto anterior, uno o varios indicadores asociados que permitirán poder medir su progresión y realizar una valoración numérica del mismo. Estos indicadores han de ser evaluables y se consideran de tres tipos distintos: cuantitativos, cualitativos o dicotómicos.

Los indicadores cuantitativos se miden de acuerdo con sus parámetros de cálculo y se clasifican en base al rango en el que se encuentren. Algunos ejemplos son la intensidad media diaria (IMD) de una carretera, el número de circulaciones programadas en un tramo ferroviario o la demanda esperada con el desarrollo de una determinada actuación. Los indicadores cualitativos se miden según el grado de incidencia en cada actuación, como por ejemplo la definición de la facilidad de ejecución de una actuación (que podría ser baja, media o alta). Por su parte, los indicadores dicotómicos se miden de acuerdo con la existencia o no de un atributo en las distintas actuaciones y, por tanto, se clasifican en "sí" o "no".

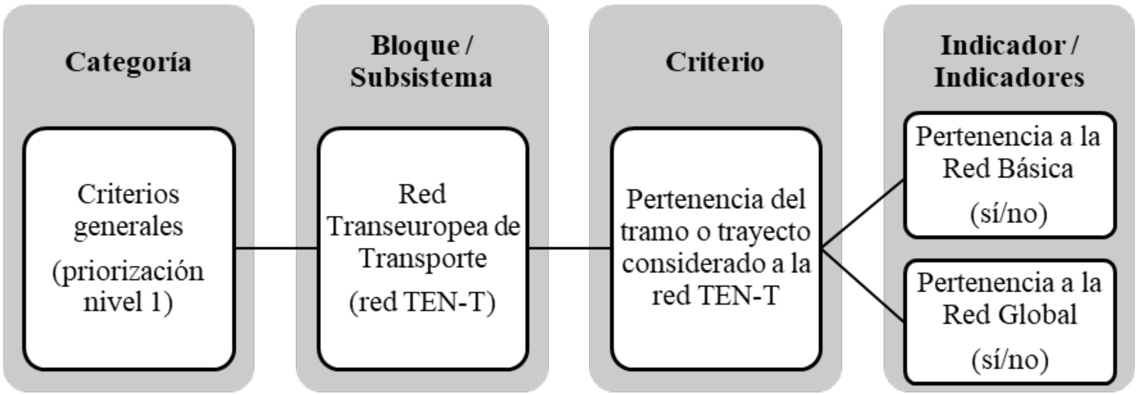

Fig. 4 – Ejemplo de categorización de criterios de priorización e indicadores asociados

La siguiente etapa consiste en determinar el peso relativo de cada indicador. Como la metodología desarrollada contempla cerca de una centena de indicadores, se ha optado por asignar un peso a cada una de las categorías de criterios y, dentro de cada categoría, se ha asignado un peso a cada bloques o subsistemas, para finalmente asignar un peso a cada uno de los indicadores que lo componen, de modo que el peso relativo de cada indicador se obtiene como resultado de todos los anteriores. En este punto conviene señalar que, al tratarse de una metodología adaptable a diferentes instrumentos de planificación, modos de transporte, etc., el número de criterios que aplica en cada caso puede variar sustancialmente.

No obstante, la herramienta está diseñada de modo que el cálculo del peso relativo de cada indicador se ajusta al número de criterios finalmente contemplados en el análisis.

En la cuarta etapa del análisis, para cada elemento analizado (corredor, tramo de carretera o trayecto, actuación, etc.) se da respuesta a cada uno de los indicadores que aplican, asignándoles valores numéricos independientemente del tipo de indicador de que se trate (cuantitativo, cualitativo o dicotómico), homogeneizando la puntuación en un intervalo de 1 a 10. De esta forma se consigue que todos los indicadores tengan una puntuación equivalente.

Para poder llevar a cabo este proceso ha sido necesario recurrir a distintas modalidades de calificación atendiendo a la naturaleza de cada parámetro. Concretamente, se han empleado 4 modalidades distintas, que son:

- **Calificación gradual positiva**: se aplica a indicadores cuantitativos en los que se priorizan aquellos trayectos que adquieren valores más altos, como por ejemplo en el caso del número de circulaciones existentes o de la demanda esperada.
  En estos casos se otorga la calificación más alta (10 puntos) al valor máximo de todos los obtenidos para el conjunto de elementos analizados y una calificación de 0 puntos al valor más bajo, distribuyendo la calificación del resto en función del valor de datos que se le haya otorgado. Para ello se ha empleado la siguiente expresión:

$$\text{Calificación} = \frac{(\text{Vi} - \text{Vmin}) \text{ x } 10}{(\text{Vmax} - \text{Vmin})} \qquad (1)$$

  Siendo Vi el valor otorgado a cada uno de los trayectos.
- **Calificación gradual negativa**: se aplica a parámetros cuantitativos en los que se priorizan aquellos trayectos en los que se adquieren valores más bajos, como por ejemplo los parámetros relacionados con la inversión requerida.
  En estos casos se otorga la calificación más alta (10 puntos) al valor mínimo, y una calificación de 0 puntos al valor más alto, distribuyendo la calificación del resto de tramos/trayectos en función de su valor asignado, en base a la siguiente expresión:

$$\text{Calificación} = \frac{(\text{Vmax} - \text{Vi}) \text{ x } 10}{(\text{Vmax} - \text{Vmin})} \qquad (2)$$

Siendo Vi el valor otorgado a cada uno de los trayectos.

- **Calificación dicotómica**, que se emplea en el caso de indicadores de tipo dicotómico formulados de tal manera que la respuesta es única y se corresponde con un "sí" o un "no". En estos casos se otorga la máxima calificación (10 puntos) a los trayectos cuya respuesta es "sí" y 0 puntos a aquellos cuya respuesta es "no". Para que esta modalidad de calificación sea efectiva hay que ser muy cuidadoso a la hora de definir los criterios dicotómicos, de modo que para todos ellos la respuesta "sí" corresponda a un mayor grado de prioridad.

- **Calificación específica:** se aplica a criterios cualitativos y también a aquellos criterios cuantitativos o dicotómicos cuyos valores posibles responden a distintas categorías o bien no se adaptan a las modalidades de calificación anteriormente comentadas. Por ejemplo, el nivel de saturación de un tramo ferroviario responde a cuatro categorías concretas (rojo, naranja, amarillo o verde) y cada una de ellas llevará asociada una calificación distinta. Lo mismo sucede con el nivel de servicio de las carreteras, escala cualitativa sobre las condiciones de circulación en relación a su capacidad, que abarca desde el nivel A (flujo libre) hasta el nivel F (congestión).

El objetivo de esta fase es llegar a otorgar a cada elemento analizado una puntuación por criterio. Gracias a estas calificaciones se pueden priorizar territorios, corredores, tramos de carreteras o líneas ferroviarias, además de poder comparar actuaciones entre sí.

En la última etapa del análisis debe comprobarse que las valoraciones se expresan de forma homogénea y sobre todo si diversas maneras de dirigir la operación conducen a resultados similares o, por el contrario, exageradamente dispares. Por ejemplo, que una acción ocupe el primer lugar en la priorización y el último en otra tan sólo modificando la escala de algunos parámetros. Finalmente, se procede a la agregación de las valoraciones. Existen distintos métodos (la suma ponderada, el producto ponderado, las relaciones de superación, etc.), aunque en la metodología propuesta se ha optado por el más sencillo, la suma ponderada, pero adaptando el cálculo al número de criterios finalmente contemplados en el análisis, como se ha comentado con anterioridad.

La herramienta desarrollada muestra los resultados en una o varias tablas de valoración (dependiendo de si la priorización se ha abordado a uno o varios niveles) que permiten sintetizar los resultados obtenidos por acción respecto de cada criterio y en su conjunto.

		Trayecto1	Trayecto2	Trayecto3	Trayecto4	Trayecto5
PRIORIZACIÓN NIVEL 1 (criterios Categoría 1)		3,9	2,2	3,0	6,6	5,5
PRIORIZACIÓN NIVEL 2		4,0	3,7	2,7	4,4	3,4
Valoración según criterios generales (criterios Categoría 2)		6,2	6,3	1,7	3,4	5,6
Valoración según criterios Upgrade (criterios Categoría 3)	Mejoras globales	0,7	0,7	1,0	0,8	0,5
	Infraestructura	0,5	0,6	0,8	0,6	0,4
	Vía	0,5	0,6	0,8	0,6	0,4
	Electrificación	0,5	0,6	0,8	0,6	0,4
	Control, gestión del tráfico y teleco.	0,5	0,6	0,8	0,6	0,4
	Estaciones viajeros	0,3	0,4	0,5	0,4	0,3
	Terminales mercancías	0,3	0,4	0,5	0,4	0,3
	Valoración según criterios Upgrade	3,4	3,7	5,1	3,9	2,7
Valoración según criterios de reposición y gestión de activos (criterios Categoría 4)	Infraestructura	0,6	0,3	0,3	1,4	0,5
	Vía	0,6	0,3	0,3	1,4	0,5
	Electrificación	0,6	0,3	0,3	1,4	0,5
	Control, gestión del tráfico y teleco.	0,6	0,3	0,3	1,4	0,5
	Valoración según criterios Reposición y gestión de activos	2,3	1,2	1,3	5,7	1,9

Tabla 1 – Ejemplo de tabla de resultados de priorización (niveles 1 y 2) para un plan director ferroviario que contempla múltiples trayectos.

3.2 Criterios de priorización

Tal y como se ha comentado con anterioridad, se han definido distintas categorías de criterios atendiendo al nivel de priorización planteado y a los objetivos que pretenden evaluar:

- Categoría 1 de criterios generales para la jerarquización por corredores, tramos de carretera o trayectos ferroviarios atendiendo a su relevancia. Son empleados exclusivamente para llevar a cabo la priorización de nivel 1.
- Categoría 2 de criterios generales para la jerarquización por corredores, tramos de carretera o trayectos ferroviarios, pero en este caso atendiendo al conjunto de actuaciones contempladas en cada caso. Se trata de la primera valoración que se obtiene en los niveles de priorización 2 y 3 cuando se comparan actuaciones a desarrollar en distintos corredores, tramos o trayectos.
- Categoría 3 de criterios específicos para llevar a cabo la priorización de actuaciones encaminadas a la mejora de prestaciones, bien de distinta índole (nivel de priorización 2) o de la misma naturaleza (nivel de priorización 3).
- Categoría 4 de criterios específicos para llevar a cabo la priorización de actuaciones encaminadas a la reposición y gestión de activos, bien de distinta índole (nivel de priorización 2) o de la misma naturaleza (nivel de priorización 3).

Estas categorías se componen de una serie de criterios que, a su vez, se agrupan en bloques o subsistemas que garantizan que todos los conceptos necesarios para evaluar correctamente las actuaciones han sido tenidos en cuenta.

Así, la **Categoría 1** (criterios generales para jerarquización por corredores atendiendo a la relevancia del corredor) se subdivide en cuatro bloques:

- ✓ Red europea: engloba criterios que valoran la pertenencia o no del nodo, tramo o trayecto a la Red Transeuropea (red TEN-T), distinguiendo entre red Básica perteneciente a algún corredor (Mediterráneo o Atlántico) o a sus propuestas de ampliación, Red básica, Red Global y otras y, en el caso de infraestructuras lineales, la existencia o no de tráficos transfronterizos en dicho tramo o trayecto.
- ✓ Conectividad: en infraestructuras lineales, conjunto de criterios que consideran si el tramo o trayecto conecta o no con la red TEN-T, con alguna carretera de alta capacidad, con algún eje ferroviario de Alta Velocidad o con nodos logísticos importantes.
- ✓ Demanda: se trata de un conjunto de criterios que valoran aspectos relacionados con la demanda. Comprende la demanda actual y potencial, distinguiendo entre viajeros y mercancías, el tráfico actual y el grado de saturación de la infraestructura.
- ✓ Seguridad: criterios principalmente relacionados con el número de accidentes e incidencias registrados en el tramo o trayecto considerado.

La **Categoría 2** (criterios generales para jerarquización por corredores atendiendo a la complejidad y relevancia de las actuaciones que en ellos deben desarrollarse) se divide en:

- ✓ Complejidad de ejecución: contempla criterios relacionados con la complejidad técnica de las actuaciones a desarrollar y con las afecciones que éstas podrían ocasionar al servicio prestado.
- ✓ Madurez: engloba criterios que miden la compleción de las actuaciones previstas en términos de inversión y de financiación comprometida con respecto a la inversión total prevista, bien por fondos europeos, por el Fondo Financiero de Accesibilidad Terrestre Portuaria o por convenios con CCAA y Ayuntamientos, entre otros.
- ✓ Funcionalidad: conjunto de criterios de distinta índole que buscan medir la funcionalidad de las actuaciones a desarrollar. Engloba la demanda esperada, tanto de viajeros como de mercancías, el ahorro en los tiempos de viaje que supondría actuar sobre ese tramo o trayecto y la mejora de conectividad, entendida como la mejora de la conexión con la red TEN-T, con carreteras de alta capacidad, con ejes ferroviarios de Alta Velocidad o con nodos logísticos importantes. Asimismo, incluye el criterio "efecto red", que trata de evaluar la repercusión que las actuaciones previstas podrían tener sobre el resto de la red. Por ejemplo, en el caso de la puesta en servicio de un nuevo tramo ferroviario, los efectos que tendría sobre la explotación

de la red ferroviaria asociada, como podrían ser la introducción de nuevos servicios o la descongestión de líneas ferroviarias paralelas.

- ✓ Sostenibilidad: engloba criterios de rentabilidad económica-financiera (inversión total, TIR, VAN y relación entre el VAN y la inversión realizada) y de sostenibilidad ambiental (emisiones y ruido).
- ✓ Territorio: valora aspectos relacionados con la cohesión y el reequilibrio territorial, como el incremento de población atendida o la conexión entre ciudades importantes.
- ✓

La **Categoría 3** se divide en:

- ✓ Mejoras globales: incluye criterios relacionados con mejoras de capacidad o mejoras de la velocidad de circulación.
- ✓ Infraestructura: engloba criterios para valorar la necesidad de desarrollar actuaciones de tipo infraestructural.
- ✓ Otros criterios específicos sectoriales: incluye criterios para medir la necesidad de desarrollar actuaciones relacionadas con aspectos más concretos del modo de transporte analizado: en transporte ferroviario, por ejemplo, criterios específicos de actuaciones de vía (duplicaciones o variantes de vía, adaptaciones de carga por eje para el transporte de mercancías, implantación de ancho UIC...), de electrificación, de instalaciones, etc.

Por último, la **Categoría 4** contempla criterios que miden el nivel de riesgo derivado del estado de los elementos que componen el sistema de transporte, así como otros criterios relacionados con la gestión de sus activos. Se divide en bloques atendiendo a cada uno de los subsistemas que lo conforman. Por ejemplo, en el modo ferroviario hay un bloque para infraestructura, otro para vía, otro para electrificación y otro para instalaciones de control de mando y señalización (CMS).

Como se ha comentado anteriormente, cada uno de estos bloques que forman las categorías engloba una serie de criterios que se desarrollan a través de uno o más indicadores. Éstos permiten priorizar la importancia de las diversas actuaciones a realizar, teniendo en cuenta tanto el marco general de implantación de las mismas como las afecciones que las nuevas acciones pueden generar.

4. CONCLUSIONES

En los actuales procesos de planificación, en línea con las directrices europeas que buscan el fomento de la eficiencia en materia de inversiones, está cobrando cada vez mayor importancia la labor de identificar las inversiones más urgentes y priorizar las actuaciones a desarrollar, en especial cuando se trata de inversiones en transporte.

En este sentido, el presente artículo describe una metodología para priorizar actuaciones en transporte en base a los resultados de un análisis multicriterio que puede llevarse a tres niveles: a nivel estratégico, priorizando, por ejemplo, unos corredores sobre otros, a nivel sectorial priorizando todo tipo de actuaciones, independientemente de su tipología, o a nivel específico, priorizando unas actuaciones sobre otras en el marco de un programa de actuaciones común.

La propuesta metodológica presentada es por tanto adaptable a diferentes instrumentos de planificación, e incluso a distintos modos de transporte. No obstante, del estudio realizado se concluye que en todos los casos es recomendable involucrar a todos los agentes implicados en el proceso de definición y selección de los criterios de priorización que serán utilizados en el análisis, de modo que puedan conformarse uno o varios conjuntos coherentes que por sí solos conduzcan a resultados objetivos y admisibles. Dichos criterios no deben resultar redundantes, aunque es inevitable que exista cierta relación entre muchos de ellos, en algunos casos incluso contradictorias, y deben ser mediable y evaluables mediante un conjunto asociado de indicadores que permitan estudiar su progresión.

El planteamiento inicial del presente trabajo, correspondiente a la Fase I de la metodología propuesta, buscaba tratar de objetivar la aplicación de estos criterios, desarrollando una metodología para priorizar inversiones en base a un análisis multicriterio que, como también sucede en otros procedimientos usados con el mismo fin, suele contar con cierto grado de subjetividad.

No obstante, los resultados de esta primera etapa deben considerarse con cierta prudencia, si va a servir de apoyo a la toma de decisiones en materia de planificación del transporte.

En un análisis multicriterio como el planteado no se pueden eliminar totalmente los factores subjetivos. Por ello, en la segunda fase se plantea la realización de un contraste de los resultados obtenidos por un grupo de expertos con amplia experiencia en planificación de transporte que realicen un análisis crítico de la priorización resultante, con el objetivo de identificar sinergias y solapes con otras planificaciones existentes, y considerar otros factores no incluidos en la fase de análisis multicriterio por ser difíciles de valorar, como la aceptación social de las actuaciones propuestas, los compromisos políticos preexistentes, o la elaboración de un análisis de urgencia.

THE EMERGENT LONG TAIL BUSINESS MODEL IN THE AIRLINE INDUSTRY. THE CASE OF VOLOTEA

José María Mateu Céspedes
Lecturer, Universitat Politècnica de València, Spain
Alba María García Torregrosa
Student, Universitat Politècnica de València, Spain

ABSTRACT

We analysed to what extent the business model of the Spanish airline Volotea can be understood as a distinct business model. We characterized this emergent business model, comparing it to other models applied in the short haul market. We conclude that this business model can be described as a long tail business model in the airline industry. We also point out that this emergent model can support a blue ocean strategy in some mature markets, although this strategy would require opening the business' black box to analyse it at the activity level.

1. INTRODUCTION

Business models are nowadays recognised as useful frameworks to understand how businesses work, and what their underlying economic logic is (Magretta, 2002). They are also used to describe how an interrelated set of decision variables are addressed to create sustainable competitive advantage in specific markets (Morris et al., 2005).

Business models have also been used in the airline industry to describe how airlines compete (Corbo, 2017; Klophaus et al., 2012; Lohmann & Koo, 2013), or to understand how their strategies evolve (Corbo, 2017; Daft & Albers, 2013; Jean & Lohmann, 2016; Mason & Morrison, 2008).

On the other hand, business model innovation, understood as "a process that deliberately changes the core elements of a firm and its business logic" (Bucherer et al., 2012, pg. 184), has the power to create new markets (Dew et al., 2011), reshape entire industries (Johnson et al., 2008) and create new ones (Teece, 2010). In the airline industry, the success of Southwest Airlines and what was its innovative business model at the time has been used as an example of a disruptive change capable of creating a huge blue ocean of new customers (Casadesus-Masanell & Enric Ricart, 2010; Kim & Mauborgne, 2005; Teece, 2010).

Academia has mainly used the concept as a descriptive tool. Going further and using it as a prescriptive tool could generate higher returns. We understand prescriptive to mean an earlier use of the tool, in order to generate new business models (Osterwalder & Pigneur, 2010), or at least to describe and understand the logic of new business models as soon as they emerge. This line of reasoning was used, for example, by Bachwich and Wittman (2017) in order to decide whether the business model introduced by Ultra Low-Cost Carriers (ULCC) can be understood as a distinct business model.

In this study, we shift our attention to what could currently be another emergent business model, i.e. the model implemented by the Spanish airline Volotea. The firm has implemented a differential business model, focusing on thin routes, with a unique definition of its target. This approach realigns the remaining components in its strategy, making it stand out from the other well-known business models.

Through a search of multifaceted literature, and using Volotea as a case study, we identify the features that differentiate this model from other similar ones in the airline industry, describing the logic behind it and cataloguing it as a long tail model (Anderson, 2006).

The article continues as follows. Section 2 reviews the literature that focuses on business models in the airline industry. Section 3 presents our case study. Section 4 presents our methodology. Section 5 presents and discuss the results, placing Volotea's business model in a wider context. Finally, Section 6 offers conclusions and opens up further opportunities for this line of research.

2. THE BUSINESS MODEL FRAMEWORK IN THE AIRLINE INDUSTRY

Most of the research carried out to date on applying the business model framework in air transport has focused on airlines, with few exceptions. One of these exceptions is the application of the framework to maintenance, repair and overhaul companies in the aviation industry conducted by Schneider et al. (2013).

In the airline industry, the business model framework has been applied almost from the emergence of the concept in management literature at the beginning of the century to explain the success of low-cost carriers, firstly in the USA and later in Europe (Casadesus-Masanell & Enric Ricart, 2010; Francis et al., 2006).

Most of the contributions have applied the framework at business level, although some authors have also transferred the framework to corporate level (Whyte & Lohmann, 2015). It could also be useful to apply the framework at a lower level (activity level) for some specific requirements (Schneider et al., 2013), as we will point out later, in Section 5.

An industry-specific parameterisation of business model components is required in order to use the framework. It is also important to distinguish the parameter values of the components that are subject to conscious managerial decisions from those that are outcomes or performance indicators of distinct business model practices such as load factor and profitability, which are not a constituent part of the business model itself (Daft & Albers, 2013).

The parameter values of business model components, which are managerial choices, also act as shift parameters, thus differentiating between and identifying alternative business models. This is the main use attributed to the framework in the literature. We now present a more detailed list of applications of the framework in the airline industry, organised by their main goal and adding some useful examples:

- Identifying and characterising different business models through their components (Pereira & Caetano, 2015).
- Capturing the emergence of a new business model: ultra low-cost carriers' business model in the case of Bachwich and Wittman (2017).
- Showing differences in the application of the same business model (hybrid model) between different carriers (Corbo, 2017).
- Comparing different options for the same business model: Mason and Morrison (2008) built a robust methodology for comparing the low-cost business model used by different airlines.
- Analysing the convergence of different business models: legacy or full-service carriers and low-cost carriers in the case of Jarach et al. (2009) and Daft and Albers (2013).
- Analysing the evolution of business models (Lohmann & Koo, 2013).

3. THE CASE OF VOLOTEA

Volotea began to operate in 2012. The firm was set up in Barcelona, Spain, by the same experienced team that created Vueling in 2004. Eight years later, in 2020, Volotea has carried over 25 million passengers, offering 346 short-haul routes that connect over 90 cities in 14 countries, with a fleet of 39 aircraft. In 2018, its revenue reached €396.1 million and its EBITDAR grew to €55.6 million. It carried 6.57 million passengers, up 36% over the previous year.

Volotea defines its strategy very simply: "…we connect small and medium-sized European cities with non-stop direct flights at very competitive prices" (taken from https://www.volotea.com/en/about-volotea/ in March 2020). Setting this risky managerial decision as the first element of its business model, Volotea then redefined the remaining components of the model, thus assuring their required coherence and accomplishing the most important conditions of a good business model. In order to describe this redefinition and to show the implications of this commitment, we tested Volotea's business model against the eight-indicator ex-ante assessment scale drown up by Mateu and March-Chorda (2016):

- *The value creation condition* is guaranteed by "a good service, sensible times, friendly airports and complicity with the local area and simple hospitality" (also taken from Volotea's website).
- *The complete value proposition condition* is accomplished because all the required resources and capabilities are available, including the knowledge gained by the team in past experiences, such as Vueling.
- *The sufficient size of the market condition* is achieved by expanding its operations to a huge part of the European geography (14 countries, at present). Here it is useful to remember that there are 38 cities in Europe with more than one million inhabitants, and 629 cities with between 100,000 and one million inhabitants. The number of possible routes between cities in the second group is ten times greater than the number of routes between cities in the first group and between the first and the second groups.
- Complying with *the access to the potential customer condition* is trivial because it is affordable to publicise the routes on offer in small and medium cities.
- *The predisposition to make efforts by potential customers' condition* is also obvious, given the competitive prices and the short travel times offered by direct flights.
- *The affordable cost condition* is accomplished by prompting mechanisms that can reduce unit costs when income increases. Given that it is difficult to achieve economies of scale in thin routes, density and scope economies must be mobilised by adding several routes and destinations (Caves et al., 1984).
- *The entry barriers existence condition* is granted by the small amount of traffic on these routes, which makes them natural monopolies (Fageda, 2006).
- Finally, *the superiority over competitors' condition* must be built, though this is easy in routes where there is no competition. This is also facilitated by the smaller size of the aircraft, as competitors may not be able to fill their larger planes.

The information presented here also frames Volotea's business model can be framed in a more general paradigm, *the long tail business model* (Anderson, 2006). We will come back to this in Section 6.

4. METHODOLOGY

Once ex-ante evidence of the robustness of Volotea’s business model had been demonstrated, we turned our focus towards analysing its main features, and examining how it differs from other short-haul business models. As our perspective was an exploratory one, we used an inductive and qualitative approach using case studies is useful (Yin, 1993).

We identified four different short-haul business models which were used for comparison. They dovetailed with the models implemented by low cost carriers, hybrid carriers, regional carriers and regional feeder carriers. This last case corresponded to carriers that feed the hubs of network carriers (also known as legacy or full-service carriers), usually through an agreement or operating for the network carrier as a subsidiary. On the other hand, although the ultra low-cost carrier business model has been suggested as a distinct business model (Bachwich & Wittman, 2017) we have not included it in this study because there are no airlines applying this business model in Europe.

Our methodology was based on the methods proposed in the literature in Section 2. We looked for specific indicators that showed significant variations between different business model components. When this specific literature did not provide these indicators, we looked for additional indicators in other fields (this is the case of the Degree Centrality indicator, for example). The final list is shown in the first column of **Table 1**. Although most of the indicators are related to several business model components, we included them under one component, in order to simplify the presentation of results in **Table 1**.

We include here the origin of the data, and the definition of some specific indicators. Most of the data for this work was obtained from the airlines’ websites, and was cross-checked with data provided by other specialised services. Specifically, routes and destinations were cross-checked using flightconnections.com, and fleets were crosschecked using airfleets.es and planespotters.net. We accessed these websites during January and February 2020. Flight frequencies were related to the middle week of February 2020, in order to avoid seasonal flights. The distance between airports was taken from dices.net.

Data related to the size of airports, in terms of number of passengers, was limited to Spanish airports, which were taken as a sample. This data referred to the whole of 2019, and was taken from aena.es. Routes departing from or arriving at Spanish airports represented a huge part of the total number of routes offered by Vueling (86.6%), Air Nostrum (100.0%) and Binter (100.0%). On the other hand, they only represented 26.3% of the total number of Volotea routes and 15.2% of Ryanair’s.

All in all, we considered this percentage a representative sample for our qualitative analysis.

Degree Centrality aims to define the extent to which a network is centralised around a certain node. To do so, we applied Freeman's work (1978) to the network of an airline. The *Degree of connectivity of a node* explains to what extent that node is connected to other nodes (see **Equation 1**).

$$\mathbf{c(k) = \sum_{i=1}^{n} f(i,k)} \qquad (1)$$

Where:

c(k) is the Degree of connectivity of node k

f(i,k) is a function that is equal to 1 if and only if the nodes i and k are connected by an edge (route) and 0 in any other case

n is the total number of nodes in the network

The *Degree Centrality* of the network is calculated using **Equation 2**.

$$\mathbf{DC = \frac{\sum_{i=1}^{n}(Max.c(k) - c(i))}{(n-1)(n-2)}} \qquad (2)$$

Where:

DC is the Degree Centrality of the network

Max.c(k) is the degree of connectivity of the node with the highest degree of connectivity of the n nodes in the network

c(i) is the degree of connectivity of node i

(n-1)(n-2) equals the maximum value that the numerator can reach and, once divided, normalises the result, making DC a number between 0 and 1

In order to complete the comparison, we chose a paradigmatic airline for each of the business models. The choice of these examples was based on two conditions. The first was that their affiliation to the business model was not controversial, at least to a reasonable extent. As Lohmann and Koo (2013) established, the passenger airline industry is a continuum of different business models. Nevertheless, Klophaus et al. (2012) developed a robust framework to measure the degree of hybridisation of low-cost carriers, with a scale that included 13 indicators. Ryanair was qualified by these authors in 2012 as a ‘pure low-cost carrier’. Although Ryanair has evolved since then to a certain degree of hybridisation, we found that it remains close to this original model.

The case of Vueling is quite different, dovetailing with only 8 of the 13 low-cost indicators established by Klophaus et al.' assessment. Today it is even farther from the pure low-cost model, and using the Klophaus et al. categorisation, it could be classed as a 'hybrid carrier with dominating full service airline characteristics'.

The choice of Air Nostrum as a regional feeder carrier (Fageda & Flores-Fillol, 2012) is similar, though much clearer in this case, because Air Nostrum does not sell tickets for its own flights. Air Nostrum's tickets are all marketed by Iberia, demonstrating the subsidiary role of Air Nostrum in Iberia's network. Binter's strategy is clearly regional, focused on the Canary Islands.

The second condition in the choice of airlines in this comparison was related to the availability of data. The specific situation of airport management in Spain, which is controlled by a semi-public organisation (AENA), facilitated access to data. We used data from Spanish airports as a sample for some indicators, in line with other authors (Fageda, 2013). This led us to choose airlines with a strong presence in the Spanish market.

5. RESULTS

Table 1 shows the results of our research. Further information about key indicators is shown in **Fig. 1** and **Fig. 2**.

As expected, the most distinctive features of the Volotea business model are related to frequencies, but also to its network structure and the aircraft models chosen for its fleet. Volotea's average weekly frequency is just over half of the next airline in this indicator (Ryanair), 2.69 vs. 4.16. Its frequency distribution is also distinctive, as shown in Fig. 2. Volotea's curve decreases sharply from a high figure in the first category (1 to 2 weekly flights). None of the other airlines have this type of pattern. In addition, the Degree Centrality of the Volotea network is also radically different from that of other airlines. Volotea's score in this indicator is 0.32, thus showing that its network is close to a theoretical point-to-point network. The closest Degree Centrality to that of Volotea was obtained by Ryanair, with 0.63. Finally, Volotea's fleet consists of small-size narrow-body aircraft. They are smaller than the planes used by Ryanair and Vueling, though larger than those of Air Nostrum and Binter.

In terms of airports served, **Fig. 1** shows Volotea's preference for medium-sized airports. 86% of Volotea's passengers fly to or from airports hosting between two and 30 million passengers. Its curve is similar to that of Binter, thus showing that Volotea avoids the largest airports, which only accounted for 7.1% of its flights in this indicator.

Conversely, Volotea serves an extensive geographical area, similar to that of Ryanair and closer to that of Vueling, as the distance between the furthest nodes reveals. Additionally, Volotea serves 14 countries, more than double regional airlines like Air Nostrum and Binter. Volotea does not come close to Ryanair and Vueling in this category, but this is probably due to it being a young airline.

Business model components • Indicator	VOLOTEA	RYANAIR	VUELING	AIR NOSTRUM	BINTER
Customer segments • Main target segments • Number of destinations • Airport size • Area served (furthest nodes) • Countries	All 83 (See Fig. 1) 4291 km. 14	Leisure & VFR, less attention to business 267 (See Fig. 1) 4932 km. 33	Leisure & VFR, more attention to business 151 (See Fig. 1) 6099 km. 25	All, mainly business 54 (See Fig. 1) 3237 km. 6	All 27 (See Fig. 1) 3563 km. 6
Value proposition • Number of routes • Average weekly frequency	319 2.69 (See Fig. 2)	1365 4.16 (See Fig. 2)	327 7.91 (See Fig. 2)	119 14.5 (See Fig. 2)	31 21.96 (See Fig. 2)
Key resources and activities • Fleet: o models o ranges (km.) o capacities (pax) • Network structure o Degree Centrality o Connecting flights	36 small-size narrow-body aircraft B717 / A319 3815-6950 125-156 0.32 No	273 medium-size narrow-body aircraft B737 5765 189 0.63 Sporadically	122 medium-size narrow-body aircraft A319 / A320 /A321 5600-6950 144-220 0.85 Yes	43 regional jets & turboprops ATR72 / CRJ200-1000 1665-3100 50-100 0.68 Yes	28 regional jets & turboprops ATR72/E195/CRJ1000 1665-4537 72-132 0.87 Yes

Table 1 - Business model components and indicators for the analysed airlines

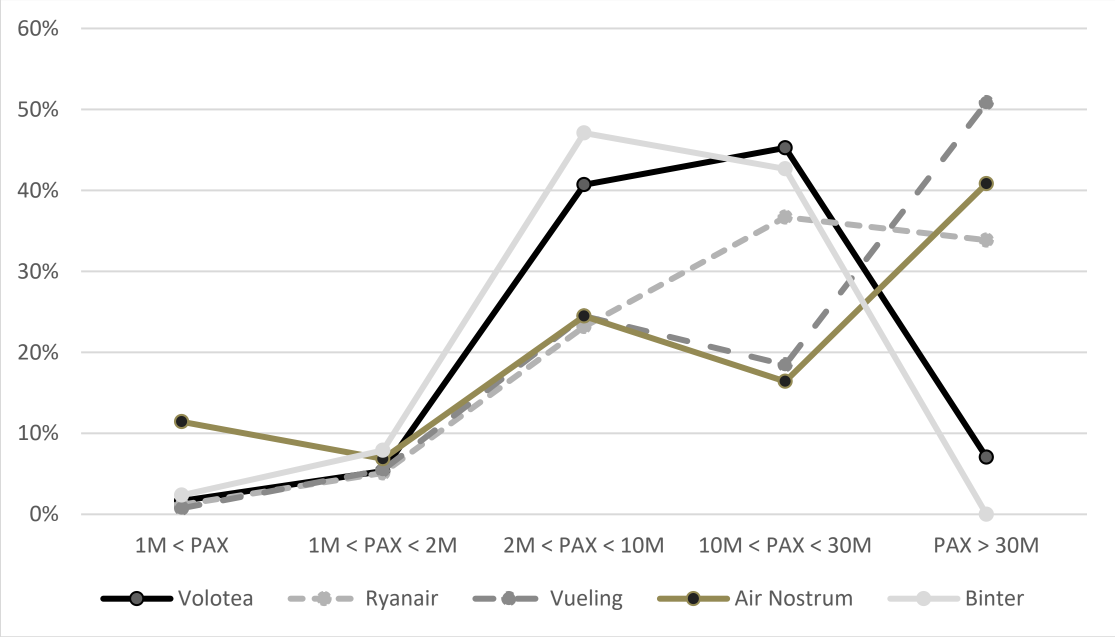

Fig. 1 - Distribution of passengers by airport size

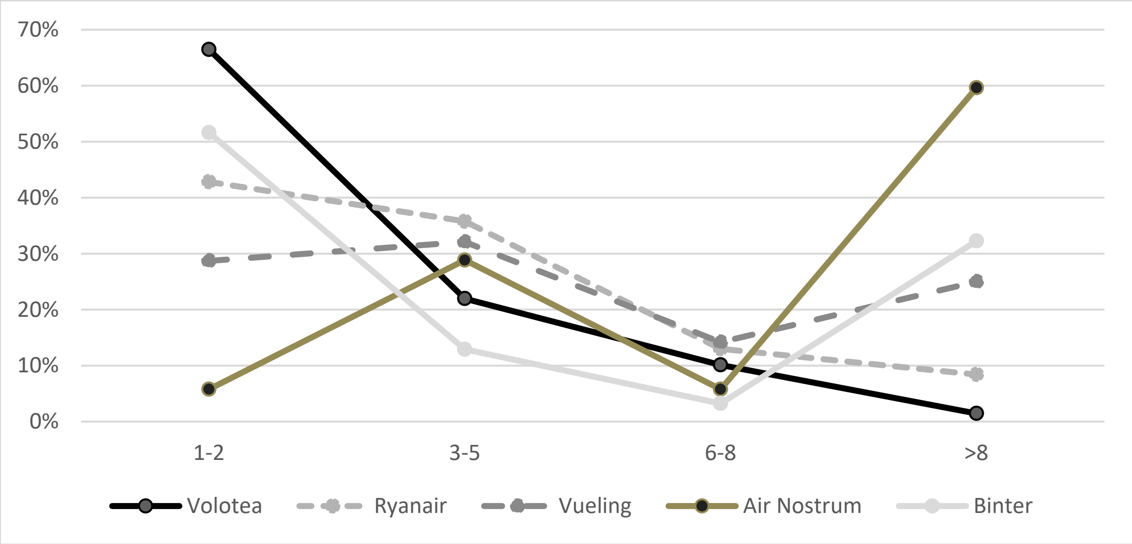

Fig. 2 - Weekly frequencies

We conducted a broader exploration of business model literature to search for a more generic business model that could dovetail with Volotea's model (Gassmann et al., 2014), and found that it could be framed as a *long tail business model* in the airline industry. The initial interest and subsequent definition and characterisation of the long tail business model was related to digital business. This is the kind of business which initially takes advantage of targeting a manifold of niche markets (Anderson, 2006). Well-known examples include the distribution of music, books and software.

The idea behind the long tail business model is that there are very few bestsellers, but a long list of items that only sell a few copies. Nevertheless, the store can sell a high number of units by joining all these less sold titles together. This a good business in this case for the distribution channel, probably not for the producers. This means that a business level analysis is not sufficient in this scenario and a useful analysis needs to be carried out at the activity level (Jarillo, 2003). In any case, the idea of serving a large number of low traffic routes conceptually matches the logic behind the long tail business model.

Economies of scale have been proposed as one of the key mechanisms of the low-cost business model. They bring significant cost reductions in key activities like buying aircraft, aircraft maintenance, handling, distribution and selling. Long-tail effects can bring this kind of cost reductions in a large part of the same activities (Sansonetti, 2010) although, in this case, we are talking about scope or density economies (Caves et al., 1984). Although these economies are less powerful, they can achieve sufficient savings to set attractive prices.

6. CONCLUSION

Volotea's business model brings together enough differential characteristics to be catalogued as a distinctive business model. It has distinguishing features from regional business carriers, and others that make it stand out from low-cost carriers and hybridised carriers. In addition, it has other characteristics that make it different from all other carriers.

The identification and characterisation of this business model reveals a large number of future developments that could be explored. An in-depth analysis could show the minimum threshold for thin routes to add value to the airline business, as well as other required conditions to make the effort rewarding. Our research also suggests the need to open the business' black box to analyse it at the activity level. Breaking down airline costs by activities would probably show how to increase the profitability of this business model, pointing to the activities that could act as leverage. Finally, a third line of research that we find promising and useful for practitioners would be to define and quantify the size of the market for this business model in Europe and other parts of the world.

TOLL HIGHWAYS IN FINANCIAL DISTRESS: THE WINDING ROAD TO TERMINATE THE CONTRACTS

ABSTRACT

Spain has extensive experience in the promotion of toll highways through contractual public private partnerships (PPPs) in the form of concession contracts. The Central Government has awarded thirty-two contracts since 1967, fourteen of them in the last two decades. Over time, Spain has been developing a broader legal framework to regulate these contracts. However, in 2013, nine out of the fourteen toll highways awarded between 1999 and 2006 filed for bankruptcy after years of financial distress. Most of these projects had been in operation for less than eight years and were severely affected by optimistic estimates of traffic demand and the economic crisis of 2007.

Given the imminent termination of the contracts, the government, the concessionaires and the financial institutions began to position themselves strategically, and adopted different measures to safeguard their own interests. Their decision-making has been highly motivated by a legal provision —known as State's Financial Liability— that guaranteed a termination payment to the PPP contractor in case bankruptcy was not attributable to the private sector.

This research shows the causes that motivated the bankruptcy of the contracts, and studies the strategical behavior of the different stakeholders involved according to their specific interests. From this case study, some lessons are provided on the correct way to design termination clauses in PPP contracts with the aim of safeguarding good service to the user while, at the same time, avoiding opportunistic behavior.

1. INTRODUCTION

Since the 1960s different Spanish governments have resorted to public-private partnerships (PPPs) as a means to construct and upgrade roads (Baeza, 2008). During 2018, the toll highway network in Spain consists of 2,957 km, of which 2,457 km are owned by the central government. Toll highways represent approximately 17% of the high-capacity road network, that is most of the high capacity network in Spain is free of charge (Ministerio de Fomento, 2019).

Toll highways in Spain have maintained most of their distinctive features over time. These are usually greenfield projects that were awarded through competitive tendering based on the open-procedure. They have been characterized by the allocation of most risks to the private sector, but also by the provision of an important termination guarantee by the government, the State´s Financial Liability (*Responsabilidad Patrimonial de la Administración o RPA)* (Ortega, Baeza and Vassallo, 2016).

This guarantee has been one of the most controversial issues of the concession regulation in Spain, since, in case of early termination of the contract, it commits the government to pay to the concessionaire the amount of capital costs (expropriation and construction costs) not yet depreciated at the time the contract expires. A new legislation passed in 2016 changed the concept by setting that, if the contract termination was not prompted by the government, the amount of the RPA will be the market value of the project. However, this new regulation does not apply retroactively.

The RPA and the government´s propensity to renegotiate contracts encouraged aggressive bidding behavior. Previous research has shown that Spanish bidders overestimated traffic forecasts and underestimated the capital investments in their bids as a strategic decision to win the tender at all costs (Baeza and Vassallo, 2010).

2. THE FINANCIAL PROBLEMS OF THE SPANISH TOLL HIGHWAYS

After twenty years, the central government recovered the toll concession approach to build new highways in 1996. The need to contain the country’s public deficit to comply with the European Union requirements to control government expenditure was one of the main reasons for returning to the concession approach.

Most of the toll highways included in this new program intended to supply greenfield alternatives to alleviate increasing congestion on sections of the existing toll-free highway network, especially those giving access to the city of Madrid.

However, in 2012 and 2013, nine of the fourteen toll highways awarded between 1999 and 2006 filed for bankruptcy after years of financial distress and negotiations between the government, concessionaires and lenders (see Table 1).

Currently, it can be claimed that the results of the latest toll-highway package have not been as expected. There are three main reasons for this situation: traffic underestimation, costs overruns during the expropriation and construction phases, and the economic crisis.

Highway	**Length (km)**	**Concessionaire**	**Year of award/ commissioning**	**Year of bankruptcy**
R-3 Madrid-Arganda	33.1	ACCESOS DE MADRID	1999 / 2004	2013
R-5 Madrid-Navalcarnero	29	ACCESOS DE MADRID	1999 / 2004	2013
Santiago-Alto de Santo Domingo	56.6	ACEGA	1999 / 2003	-
Ávila-Villacastín	23.1	CASTELLANA	1999 / 2002	-
Segovia-El Espinar	27.7	CASTELLANA	1999 / 2003	-
León-Astorga	38	AULESA	2000 / 2003	-
R-2 Madrid-Guadalajara	64.1	HENARSA	2000 / 2003	2013
R-4 Madrid-Ocaña	53	MADRID SUR	2000 / 2004	2013
M-12 EjeAeropuerto	8.8	EJE AEROPUERTO	2002 / 2005	2013
AP-36 Ocaña-La Roda	148	MADRID LEVANTE	2004 / 2006	2013
AP-41 Madrid-Toledo	60	MADRID TOLEDO	2004 / 2006	2012
AP-7 Cartagena-Vera	114	AUCOSTA	2004 / 2007	2013
AP-7 Circunvalación de Alicante	28.5	CIRALSA	2004 / 2007	2013
Málaga-Alto de las Pedrizas	24.5	GUADALCESA	2006 / 2011	-

Table 1 – Toll highway concessions awarded by the Central government from 1999 onwards

Firstly, the forecasts included in the economic-financial plans of the toll highway concessions were, in all cases, very optimistic. As a result, ever since the highways came into operation, actual traffic flows have been much lower than originally forecasted (Baeza & Vassallo, 2012).

Figure 1 summarizes the traffic deviations in the highways analyzed since their commissioning to the present. These deviations are measured as the percentage of actual traffic over that foreseen by concessionaires. Therefore, values below 100% show traffic overestimations.

The figure also differentiates those highways that ultimately went bankrupt (represented by dots) from those that stayed afloat (represented by triangles). The green line shows the average trend of traffic deviations for all the highways included in the sample.

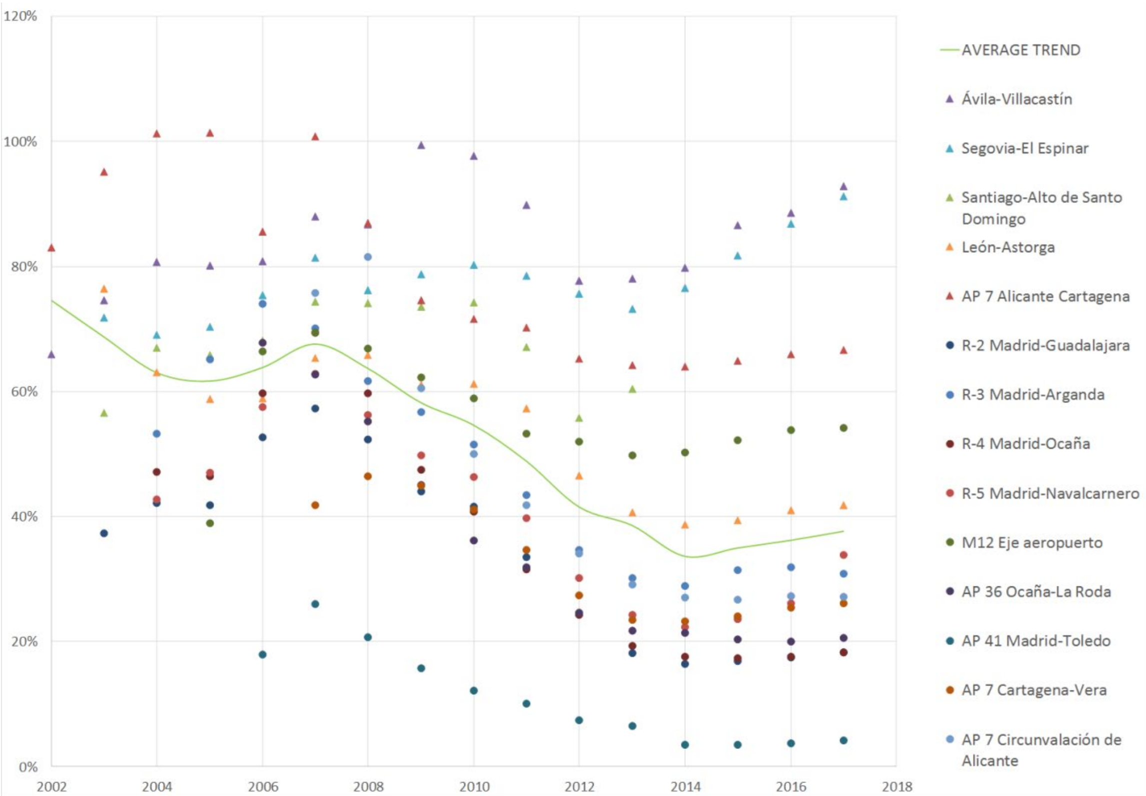

Figure 1 – Traffic deviations in the Spanish toll highway concessions since their commissioning

Secondly, the underestimation of construction costs conducted by the concessionaires in their bids was far from negligible (Vassallo et al., 2013). For example, the year in which the R-3 and R-5 highways came into operation, the cost overruns were 33.70%, and those of the Eje Aeropuerto exceeded 25%.

Moreover, the higher additional costs experienced by the highways were mainly due to expropriations. The cost of acquiring the right-of-way ultimately became much higher than expected as a result of a Supreme Court ruling stated in 2008 on how to quantify the price of land. The Supreme Court understood that highways are general road systems intended to create a city due to the existence of evident urban expectations (Baeza & Vassallo, 2011).

Finally, the impact of the economic crisis in Spain has been one of the greatest among the European countries. The country was in recession for seven quarters, which was reflected in negative GDP growths in both 2009 and 2010, and then it stabilized for a short period of time to fall back into recession for eleven quarters between 2011 and 2013.

Road demand on toll highways, which is very correlated with the evolution of the country's macroeconomic variables such as GDP per capita or industrial GDP (Gomez et al., 2015), was severely affected.

3. THE STRATEGIC BEHAVIOR OF THE STAKEHOLDERS

The strategic behavior followed by the main stakeholders involved in the process is studied in this section. The stakeholders considered are sorted into three different groups: the government, concessionaires and lenders.

3.1. Government

The general optimism in the country when the concessions were awarded led the government to conduct very optimistic feasibility studies assuming very high traffic growths and urban development expansions.

Between 2010 and 2012, the government approved a set of measures aimed at rebalancing the economics of the contracts to keep the concessions afloat. It began by granting subordinated public participation loans (SPPL) and compensation accounts.

On the one hand, SPPLs covered the expropriation costs exceeding 175% of the costs initially estimated by the PPP sponsors. The interest rates payable by the concessionaires over the life of the contracts would depend on the future revenues of the toll highways, with a minimum cap rate of 1.75%. On the other hand, the purpose of the compensation account was to provide liquidity to the concessionaire whose traffic and income were too low. Through the compensation accounts, the concessionaires would receive from the government the difference between 80% of the toll revenues originally expected and the actual revenue during a period of three years.

In 2012, a new conservative government took office in Spain. One of its priorities was to reduce the national public deficit and since highway traffic was not recovering, he opted to cancel the granting of additional SPPLs to the concessionaires, as well as the compensation accounts.

The subsequent declaration of bankruptcy of the nine aforementioned toll highways put the government in a complex situation. At that point, the maximum RPA related to the concessions bankrupted amounted to over €3.56 billion (Baeza & Vassallo, 2014), in a context where Spain was in the midst of a severe economic recession.

In addition, the Supreme Court ruled that the government was responsible for paying the additional costs of expropriation to landowners. To avoid paying twice, the government approved Royal Decree-Law 1/2014 that modifies the public procurement law on the valuation of state aid for land expropriation.
Under this provision, the government was allowed to reduce the RPA compensation to each concessionaire in the amount of money corresponding to the expropriation costs paid directly by the government when the SPV failed to meet its obligations to the owners.

3.2. Concessionaires

The optimism previous to the recession, the high competitiveness of the Spanish market, and the existence of the RPA guarantee encourage bidders to adopt aggressive strategies.

Between 2010 and 2011, the granted SPPLs represented a total of €532 million. With respect to compensation accounts, a total of €71.52 million were granted in these years. These measures eased the financial problems of the concessionaires for a few years. However, as traffic levels did not recover substantially, they ended up being useless in the long term for both the government and concessionaires.

After the government withdrew the state aid previously mentioned, private companies sued the government in court for withdrawing what had already been pledged, but the initiative was not successful.

Some sponsors negotiated with the lenders the restructuring of the debt to avoid insolvency. However, this option was finally not viable and triggered the start of a series of bankruptcies. Between 2012 and 2013, nine toll highway concessions were declared bankrupt. The reasons for synchronized bankruptcies are not clear. Sponsors might have thought that this situation could help them reach a better agreement in the negotiation phase given the fact that the government should avoid reimbursement of the RPA at all costs.

3.3. Lenders

The estimates conducted by the shareholders based on the feasibility studies produced by the government, along with the RPA and the seniority of their debt were sufficient for the lenders to join the project by providing large loans. The most common financial structure was a mini-perm (short-term loan) that had to be refinanced after few years of operation. However, the shortage of traffic and the excess of costs meant that the concessionaires could not refinance their mini permits (short-term loans), so long-term financing remain dependent of future government aid.

After the withdrawal of state aid, banks were no longer willing to accept a negotiated solution so sponsors ended up declaring bankruptcy. In this situation, financial institutions in Spain were required by law to create provisions for the total amount of credit granted to the bankrupt company. This measure had a great impact on the balance sheets and profit and loss accounts of the banks.

4. MEASURES TAKEN AFTER DECLARING BANKRUPTCY

The government proposed that an existing State-owned company called SEITTSA absorb bankruptcy toll roads without paying any compensation to the concessionaires. In return, creditors would have to waive around half of the senior debt outstanding at the time, which was around €2 billion. The remaining liabilities —around another €2 billion— would be entirely acquired by the main national banks in exchange for a 30-year treasury-backed bond. This bond would be issued by SEITTSA with a nominal value equal to the remaining liabilities, and a 4% guaranteed interest rate equivalent to the Treasury 30-year bond rate at that time. The most important banks of Spain (Santander, BBVA, Caixa, Bankia, Sabadell, Popular) would buy the liabilities of other banks with minor participation, most of them foreign ones. The main advantage of this solution for the government was that it avoided the payment of the RPA and its immediate consequences on the public deficit. However, some foreign banks, which financed few specific projects performing above the average, felt disadvantaged by a solution based on the average behavior of the portfolio.

In 2015, the Madrid Commercial Court initiated the liquidation process for the companies Autopista Madrid Levante, and Eje Aeropuerto, after no agreement was reached. The opening of the liquidation phase was an important date for the government because, once this phase was effective, the depreciation count for the final RPA calculation was stopped.

Some concessionaires managed to appeal to the courts to return to the negotiation phase, thus activating again the depreciation of the assets and reducing the value of the RPA. For this reason, between 2016 and 2017, lenders began selling their senior debt to hedge funds with the aim to recover at least part of their losses as soon as possible.

Cuts in these transactions ranged from 60% to 70% of the outstanding value of the loans. This clearly shows the little hope of lenders to achieve a good outcome in the liquidation process.

Hedge funds bought a large share of the senior debt from bankrupt concessions. Their strategy was to liquidate the firms as soon as possible to obtain the maximum value of the RPA.

Since the hedge funds had eliminated any possibility of restructuring the outstanding debt, the government decided that the nationalization of the toll highways with the subsequent payment of the RPA was the only solution to end the conflict.

In July 2017, the government decided that SEITTSA (a state-owned company) would take over both the toll roads that were already in the liquidation phase and those that would be liquidated in the future. In 2018, the liquidation plans of eight concessionaires were approved and SEITTSA gradually absorbed the toll roads.

At the date of this document, the government was carrying out the due diligence to estimate the final amount of the RPA liabilities to be paid, as well as the value of the new assets managed by SEITTSA.

5. CONCLUSIONS

The bankruptcy of highway concessions in Spain has had very negative reputational consequences since the credibility of the PPP model has been seriously damaged.

From the analysis performed, some lessons are pointed out. The first lesson is that the concession model requires risk allocation approaches resilient to economic cycles. If traffic flows are very sensitive to the evolution of the economy, it is advisable to apply other models, such as payment for availability, regardless of whether the government decides to charge users or not.

The second lesson is that guaranteeing a government termination payment in case of bankruptcy does not provide the right incentive for interested parties. On the one hand, this approach encourages the government to do everything possible to avoid termination of the contract, which can extend the litigation process without finding a good solution for the society. On the other hand, concessionaires take advantage of this guarantee to obtain cheap financing from lenders who do not pay much attention to assess the real viability of the project.

The third lesson is that legislation and contracts should be much better prepared to properly regulate the possible early termination of a concession. The lack of regulation seems to be the main cause that explains the long litigation processes and the difficulty in reaching a final solution to the problem.

Finally, one of the worst consequences of the process was the impact on the reputation that the negative experience has had on the concession model, the government and the legal system. This reputational aspect has been particularly sensitive for the general public and foreign institutions.

RESUMEN

La reducción de las emisiones derivadas del transporte es un asunto prioritario para la consecución de los Objetivos de Desarrollo Sostenible de la Agenda 2030. Por ello, incentivar el uso de medios de transporte sostenibles resulta fundamental y requiere de un análisis pormenorizado de las preferencias de los usuarios.

De ahí que en este trabajo se haya planteado el objetivo de analizar la predisposición que declaran los usuarios a realizar sus desplazamientos viajando como acompañante de un vehículo, como una de las medidas que puede reducir el uso individual del vehículo privado que es, además, uno de los principales problemas que caracteriza los patrones de movilidad en la isla de Tenerife. Específicamente, se analizará el caso de los estudiantes universitarios de la Universidad de La Laguna (ULL), en Tenerife. Para ello, se ha confeccionado una encuesta de preferencias reveladas, realizada en 2016, que permitió caracterizar la elección actual del modo de transporte y la predisposición que declaran los estudiantes a viajar como acompañantes en sus desplazamientos a los centros de estudio universitarios.

Entre los resultados obtenidos se encuentra que el número de vehículos disponibles en el hogar y el coste del viaje suponen un desincentivo para que los estudiantes conductores modifiquen sus patrones de movilidad actuales. Además, la estabilización de la jornada de estudio y la duración del viaje contribuyen positivamente a la probabilidad de que un estudiante opte por viajar como acompañante; mientras que los aspectos relacionados con la seguridad son los que hacen que los estudiantes estén menos predispuestos a compartir un vehículo. A la luz de los resultados obtenidos, se propone homogeneizar los horarios de clase del alumnado, reservar estacionamientos para vehículos de alta ocupación e impulsar la inversión en carriles BUS-VAO que permitan potenciar las ventajas más efectivas: las de índole personal.

1. INTRODUCCIÓN

La reducción de las emisiones derivadas del transporte es un asunto prioritario para la consecución de los Objetivos de Desarrollo Sostenible de la Agenda 2030, ya que influye en la consecución de los objetivos número 11 “Ciudades y comunidades sostenibles” y número 13 “Acción por el clima”. La Unión Europea se ha comprometido por ello a disminuir las que provienen del transporte un 60% por debajo de los niveles de 1990 para 2050. Siendo el vehículo privado el mayor contribuyente a las emisiones del transporte por carretera, incentivar el uso de medios de transporte sostenibles resulta fundamental y requiere de un análisis pormenorizado de las preferencias de los usuarios.

En este trabajo nos centraremos en la movilidad de los estudiantes universitarios de la ULL, en Tenerife. La isla de Tenerife (España), cuenta con una población de 928.604 habitantes, en la que el transporte terrestre se realiza fundamentalmente a través de la red de carreteras. Como única excepción cuenta en el área metropolitana de La Laguna-Santa Cruz con 16 km de metro ligero repartidos en 2 líneas. Éste, junto con el servicio de autobuses, forma la totalidad de la oferta de transporte público de la isla. La situación que ha caracterizado el transporte interno de la isla pone de manifiesto la necesidad de implementar medidas de gestión de movilidad que desincentiven el uso individual del coche, promueva el transporte público e introduzcan una intermodalidad en la que se impliquen modos de transporte sostenibles en las etapas iniciales y/o finales del viaje, como puede ser los desplazamientos a pie, viaje en bicicleta, etc.

Entre las diferentes medidas que se pueden aplicar, en este trabajo nos centraremos en la del uso compartido del coche. Así, tal y como señala el Parlamento Europeo (2019), los automóviles modernos pueden considerarse medios de transporte limpios si se comparten en lugar de utilizarse individualmente. Para fomentar esta modalidad de transporte, en muchas ciudades se han construido carriles exclusivos BUS-VAO. En España comienza con esta experiencia en 1994 con la construcción de dos carriles BUS-VAO en la CN-VI de Madrid. Basado en el uso de estos carriles, Pozueta et al. (1997) ponían de manifiesto, entre otros aspectos, la gran diferencia entre el número de personas que se declaran dispuestas a compartir, frente al número real de usuarios del sistema -que es mucho menor-.

Se puede encontrar en la literatura científica diversos estudios que tratan de averiguar cuáles son las principales razones que llevan a los usuarios a compartir el coche y, además, tratan de caracterizar el perfil de los usuarios de coche compartido. (Olsson, Maier, y Friman, 2019). Neoh, Chipulu y Marshall (2017) categorizaban en su metaanálisis las variables que influyen en la decisión de compartir en 3 subgrupos: Factores demográficos, situacionales (como la existencia de un carril Bus-VAO) y subjetivos.

Son los factores incluidos en esta última categoría, los que han adquirido un mayor foco de atención en los últimos años; ya que como señalan Homem de Almeida, de Abreu y Viegas (2013) la actitud juega un papel importante en la decisión de participar en un grupo de coche compartido.

Los factores psicológicos relevantes en la decisión varían entre los estudios, lo que puede ser debido a que la motivación de los usuarios cambia con el tiempo y las experiencias que hayan tenido. (Julagasigorn, Banomyong y Varadejsatitwong, 2018).

Dado que las universidades son tanto generadores como atractores de una porción importante de viajes en una región (Moreno, Sarmiento y González-Calderón, 2011) tienen un papel significativo como vectores para promover políticas sostenibles de transporte.

Además, la gestión del espacio de aparcamiento aparece como un problema habitual en entornos universitarios (Azzali y Sabour, 2018; Rotaris y Danielis, 2014; Ibeas, dell´Olio, dell'Olio y Barreda, 2010; entre otros). Ya sea con el objetivo de resolver los problemas de movilidad de la comunidad universitaria, o de fomentar en ellas sistemas de transporte sostenible; se ha estudiado en distintas universidades, cuál es el reparto modal de estudiantes y personal, así como el potencial y/o restricciones existentes al cambio de modo, con el objetivo de proponer o evaluar distintas medidas. (Balsas, 2003; Gurrutxaga, Iturrate, Oses y García, 2017; Papantoniou, Yannis, Vlahogianni, Attard, Regattieri, Piana y Pilati, 2020; Riggs, 2014) Así, por ejemplo, en la universidad de Western Australia (UWA) (Shannon, Giles-Corti, Pikora, Bulsara, Shilton y Bull, 2006) concluyeron que un 20-30% de los usuarios podría cambiar su comportamiento en el corto plazo. En la universidad de Barcelona (Miralles-Guasch y Domene, 2010) los usuarios que desean cambiar de modo suben hasta el 54%, si bien esta cifra se ve influenciada por efectos de demanda cautiva.

Aunque la opción del coche compartido no aparece en todos los casos de estudio, encontramos algunos donde se evalúa el uso de coche compartido en entornos universitarios (véase, entre otros, Tezcan 2016; Galatoulas, Koutra, Rycerski, Candanedo y Ioakeimidis, 2017; Gallo y Buonocore 2017). En general, se encuentre un resultado común que apunta a una actitud en favor del coche compartido.

Los antecedentes al actual estudio se encuentran en los trabajos previos realizados en la Universidad de La Laguna para captar los patrones de movilidad de los estudiantes en sus desplazamientos al centro de estudios, para evaluar diferentes políticas de transporte y derivar los valores del tiempo. Así, en el 2005 se obtuvieron las disposiciones a pagar de los estudiantes, por los ahorros de tiempo de viaje, teniendo en cuenta que las preferencias son heterogéneas (Amador, González, 2005). En el año 2007 se desarrolla una encuesta de preferencias reveladas y declaradas para captar el reparto modal y la predisposición a usar un tranvía que uniría los campus universitarios.

En el 2009 se realiza nuevamente una encuesta a los estudiantes de la ULL, en este caso solo de preferencias reveladas, para evaluar las declaraciones hechas por los alumnos dos años antes acerca de su predisposición a cambiar al tranvía.

Esta última encuesta permitió comprobar la fiabilidad de los modelos a la hora de predecir que el reparto modal una vez que el tranvía se implantara en la isla de Tenerife (González, Martínez y Esquivel, 2012; González, Lorente y Martínez, 2017), permitió evaluar el efectos sobre los valores del tiempo y las elasticidades de demanda cuando se utilizan datos de panel entorno a la implantación de un nuevo modo (González, Marrero y Marrero, 2016) y permitió captar la importancia del efecto inercia cuando se implantan políticas de ampliación de la oferta de transporte público (González, Marrero y Cherchi, 2017).

La Universidad de La Laguna forma parte del proyecto U-MOB (red de universidades por la movilidad sostenible) y ha implantado medidas como el circuito universitario de autobús, iniciativas para promover el uso de la bicicleta y puntos de recarga de vehículos eléctricos. Habiendo recibido el reconocimiento por su compromiso con la movilidad sostenible y segura, de la Dirección General de Tráfico y el proyecto europeo STARS. Sin embargo, cuando se analizan los patrones de movilidad se detecta como sigue teniendo un papel predominante el uso del coche sin acompañante y el transporte público tiene un elevado porcentaje de usuarios que son cautivos (lo eligen porque no tienen disponible otra alternativa). Todo ello pone de manifiesto la necesidad de seguir investigando de cara a aportar nuevas medidas que hagan que se dé un comportamiento más sostenible.

En este trabajo se plantea el objetivo de analizar la predisposición de los estudiantes de la Universidad de La Laguna a compartir el vehículo en sus desplazamientos, como una de las medidas que se podría proponer para mejorar los patrones de movilidad actuales de los universitarios de La Laguna. Concretamente se estudia la predisposición a cambiar del modo de transporte habitual y viajar como acompañante en un vehículo con otras personas. Se estiman diferentes especificaciones econométricas con el objeto de evaluar cuál produce un mejor resultado y se ajusta mejor a los datos utilizados. Específicamente, se ha trabajado con una encuesta realizada en 2016 a los estudiantes de la Universidad de La Laguna, con la intención de valorar la potencial demanda existente para un carril bus-VAO diseñado por el Cabildo de Tenerife en la TF-5. Dicha encuesta se estructuró en dos partes. La primera es una encuesta de preferencias reveladas que permitió caracterizar la elección actual del modo de transporte y la predisposición que declaran los alumnos a viajar como acompañante. La segunda parte es una encuesta de preferencias declaradas en la que se estudia cómo se podría modificar su comportamiento debido a la existencia del nuevo carril bus-VAO, donde se simula como serían las características de su viaje en cada uno de los modos que podría utilizar.

En la realización de este trabajo se han utilizado los resultados de la primera parte, es decir, de la encuesta de preferencias reveladas.

Los modelos que se utilizan este trabajo son modelos de elección discreta; específicamente se han utilizado las especificaciones de un logit binomial, un logit multinomial y dos logit ordinales; tal y como se comentó, el objetivo que se persigue es seleccionar el modelo que mejor se ajuste a la base de datos utilizada.

Una vez seleccionado el modelo, se pueden analizar los resultados y proponer opciones de políticas que permitan impulsar entre los alumnos el uso del coche compartido.

El resto del trabajo se organiza de la siguiente forma. En el apartado 2 se describen las principales características de la universidad, y se presenta un análisis descriptivo de los datos obtenidos en la encuesta de preferencias reveladas. En el apartado 3 se expone la metodología utilizada. A continuación, en el apartado 4 se comentan los resultados más destacados. Por último, se recogen algunas de las principales conclusiones que pueden extraerse del análisis realizado.

2. DATOS

2.1 Contexto del estudio: Universidad de La Laguna

La Universidad de La Laguna, situada en la isla de Tenerife (Islas Canarias, España) desde su fundación en 1792, es el centro de educación superior más antiguo de Canarias. La universidad se reparte entre 6 campus: Adeje, Anchieta, Central, Ofra, Santa Cruz y Adeje; estando la mayoría localizados en el área metropolitana de la isla, entre las ciudades de San Cristóbal de La Laguna y Santa Cruz de Tenerife. Con más de 25.000 personas entre personal y alumnado, es una entidad que genera una intensa actividad en la isla y atrae un importante número de viajes cada día.

2.2 Encuesta de preferencias reveladas y análisis de los datos

La información utilizada para estimar los modelos de elección discreta se obtiene de la encuesta de preferencias reveladas que se realizó a los alumnos de la Universidad de La Laguna en la primavera de 2016 en formato de cuestionario on-line. Esta encuesta obtuvo en el plazo de 2 meses una muestra de 3003 encuestados de entre los 18.343 alumnos matriculados en el curso 2015/2016.

Una vez filtrados los datos (se eliminan aquellos que no responden a preguntas clave en el análisis y a aquellos que entregan respuestas incompletas o incorrectas), se obtiene una muestra de 2695 respuestas, lo que supone un 14.7% del total de alumnos y es superior a los 2124 necesarios para un tamaño muestral para un margen de error del 2% y nivel de confianza del 95%.

En el cuestionario se pregunta a los alumnos acerca de:

- Las características socioeconómicas del encuestado y su unidad familiar (sexo, edad, tamaño de la unidad familiar, número de coches en la familia, ingresos…).
- El modo transporte habitual para desplazarse y las características del viaje (coste, tiempo).
- Los motivos principales por el que eligen este modo.
- La disponibilidad que tienen de utilizar otros modos de transporte.
- La predisposición a utilizar el coche compartido, y en el caso de los conductores de compartir su coche y las ventajas e inconvenientes de esta alternativa.

La Tabla 1 refleja las principales características socioeconómicas de la muestra, su modo de transporte habitual y su predisposición a compartir.

La mayoría de los alumnos acude a su centro de estudios 5 días por semana, sin embargo, menos de la mitad lo hace siguiendo un horario regular en el que acuden siempre a la misma hora. Esto puede ser relevante a la hora de valorar opciones de regularización de horarios del alumnado.

También se observa la predominancia del uso del vehículo privado e individual como modo de transporte, representando este un 39% de los encuestados, este ha sido un resultado habitual en los patrones de movilidad de los estudiantes estudiados previamente (González et al, 2016, 2017). De los 1165 alumnos que declaran que viajan en coche como conductor, el 72% lo hacen solos. Suponiendo vehículos de 5 plazas, esto supone que a diario se desplazan 3356 asientos vacíos. Por otro lado, vemos que un 39% de los alumnos, que viajan en transporte público, declara que elige su medio de transporte habitual debido a que no dispone de coche. Nos encontramos, por tanto, entre los usuarios del transporte público, con una demanda cautiva que aparentemente utilizaría el vehículo privado si dispusiera de esa opción.

El transporte público, en su conjunto, abarca otro 39% de la muestra, siendo el tranvía la opción de esta modalidad más utilizada, a pesar de que sólo está disponible en el área metropolitana de la isla. Esto se debe a que esta es también el área en la que residen de forma habitual la mayoría de los estudiantes y a la cercanía de la mayoría de los campus universitarios a las paradas del tranvía.

A pesar de que sólo el 27% de los conductores viajan acompañados y un 10% de los estudiantes declaran viajar en coche como acompañante, los estudiantes muestran una actitud a priori positiva ante la opción del uso del coche compartido, ya que un 68% afirman estar en gran medida o totalmente dispuestos a viajar en coche como acompañantes. Una vez que veamos qué factores son los que influyen en esta predisposición a compartir y que estimemos la importancia de cada uno de esos factores, a través del cálculo de los efectos marginales, podremos buscar opciones para fomentar que los alumnos den el paso y se decidan a utilizar este modo.

Cabe señalar, que a pesar de que el cuestionario original incluía información sobre el ingreso de la unidad familiar de los encuestados, no se ha podido utilizar durante el desarrollo de los modelos, debido a que la mitad de los encuestados escogieron no responder a esa pregunta.

Esto es una situación habitual en este tipo de encuestas, en los que la gente se muestra reacia a declarar su renta. Se opta, por tanto, aproximar esta variable económica de forma indirecta, atendiendo a la tasa de motorización en la unidad familiar de los alumnos, de la cual sí se tienen datos.

Tabla 1 – Características socioeconómicas de la muestra

En la Tabla 2 se recoge la información ofrecida por el Ministerio de Universidades acerca de los alumnos matriculados en la universidad de La Laguna en el curso 2015-2016. Comparando con la tabla 1 podemos ver que el reparto de nuestra muestra por género resulta muy similar al del total de la comunidad universitaria durante este curso, por lo que sabemos que la población está adecuadamente reflejada en la muestra. Lo mismo ocurre con el reparto por edades, en el que vemos que estamos ante una población joven, con un 93% menor de 30 años.

Total por género

Tabla 2 – Alumnado matriculado en la ULL durante el curso 2015-2016

Fuente: Sistema Integrado de Información Universitaria (SIIU). Secretaría General de Universidades.

Para poder obtener información acerca de la percepción subjetiva que tienen los alumnos sobre la opción de utilizar el coche compartido, se les preguntó acerca de las ventajas e inconvenientes que consideraban que tiene como alternativa. Los alumnos pudieron escoger uno o varios de los factores propuestos o señalar “Otro” y escribir los suyos propios.

Los factores recogidos pueden categorizarse como factores que les suponen ventajas o inconvenientes a diferentes niveles:

- Ventajas a nivel personal: Son factores que afectan al alumno de forma directa, como el ahorro económico, ganancias de tiempo o existencia de plazas de aparcamiento reservadas para vehículos con 2 o más ocupantes.
- Ventajas a nivel social: Factores que afectan al entorno social del alumno, como conocer gente.
- Ventajas a nivel externo: Son factores que resultan ventajosos para el conjunto de la sociedad como la reducción de la contaminación, la reducción de la congestión o el ahorro energético.
- Problemas de pérdida de libertad: Problemas relacionados con la pérdida de independencia a la hora de viajar con otras personas como someterse a un horario fijo, tener problemas a la hora de regresar a casa.
- Problemas de horarios: Retrasos, impuntualidad, dificultad para conciliar horarios.
- Problemas de seguridad: El miedo o inseguridad que les genera viajar en el mismo vehículo con desconocidos.

En la Tabla 3 vemos los resultados relativos a las ventajas e inconvenientes que declaran los estudiantes para viajar como acompañante.

Ventajas	
A nivel personal	83%
A nivel social	4%
A nivel externo	9%
No veo ninguna ventaja	4%
Inconvenientes	
Pérdida de libertad	35%
Problemas de horarios	55%
Problemas de seguridad	2%
No veo ningún problema	8%

Tabla 3 – Ventajas e inconvenientes de viajar en coche como acompañante

3. METODOLOGÍA

Dada la naturaleza de carácter discreto de las respuestas que entregan los estudiantes acerca de la predisposición a viajar como acompañante (véase Tabla 1), parece conveniente plantear el uso de modelos de elección discreta. Estos modelos permiten ejecutar regresiones para situaciones en las que la variable dependiente no es continua sino discreta, es decir, que solo toma valores concretos que se corresponden con las distintas categorías sobre las que el individuo realiza su elección.

Estos modelos se clasifican en distintos grupos, dependiendo de la naturaleza concreta de la variable discreta a modelizar, dependiendo de si esta es binaria o multinomial, ordenada o no, etc. La polivalencia y utilidad de estos modelos es tal que han sido aplicado a múltiples campos de investigación, como la demanda de transporte (González, Román y Marrero, 2018; Arbeláez, Sarmiento y Córdoba, 2020; Cherchi y Ortúzar, 2002, 2010) o la articulación de políticas públicas (Barroso, Abásolo y Cáceres, 2016; Pinilla, González, Barber y Santana, 2002), en otros campos (Rodríguez, Romero, Cano y Guirao, 2019).

En concreto, dada la naturaleza de carácter ordinal de las respuestas que entregan los estudiantes acerca de la predisposición a compartir el vehículo, los modelos más adecuados son los ordinales. Ello debido a que esta predisposición puede ser ordenada de menor a mayor predisposición. En particular, la especificación más usual en este escenario es la de un modelo logit ordinal que sigue la siguiente regresión de variable dependiente que, a su vez, es una variable latente o no observada (Y_i^*) que depende de un conjunto de variables explicativas que determinan la decisión del individuo.

$$Y_i^* = x_i'\beta + \varepsilon_i \tag{1}$$

De esta forma, la elección del individuo queda explicada por el componente sistemático de la regresión ($x_i'\beta$), el cual es observado directamente por el investigador, y por el componente aleatorio (ε_i), el cual representa los posibles errores de observación cometidos por el investigador, así como aquellos aspectos que no pueden ser observados como los gustos o las preferencias de los individuos investigados.

Así, la elección de cada individuo (i) entre las distintas alternativas ($0, \dots, J$) dependerá del valor de la variable latente (Y_i^*) y de los umbrales (μ_j) que separan los valores correspondientes a cada una de las categorías, de tal forma que

$$Y_i = \begin{cases} 0, \ si \ Y_i^* \leq \mu_0 \\ 1, \ si \ \mu_0 \leq Y_i^* \leq \mu_1 \\ 2, \ si \ \mu_1 \leq Y_i^* \leq \mu_2 \\ \vdots \\ J, \ si \ \mu_{J-1} \leq Y_i^* \end{cases} \tag{2}$$

A partir de este enfoque y considerando, como ya se adelantó, que la función de distribución del término aleatorio (ε_i) es logística (Λ), el modelo probabilístico que permite calcular la probabilidad de elección de cada alternativa queda definido como sigue:

$$P(Y_i = j) = P\left(\mu_{j-1} \leq Y_i^* \leq \mu_j\right) = P\left(\mu_{j-1} - x_i'\beta \leq \varepsilon_i \leq \mu_j - x_i'\beta\right) = \Lambda\left(\mu_j - x_i'\beta\right) - \Lambda\left(\mu_{j-1} - x_i'\beta\right),\ j = 0, \cdots, J \quad (3)$$

Tanto los umbrales ya mencionados como el vector de parámetros del modelo, que en especificaciones ordenadas es común a todas las alternativas, pueden ser estimados mediante el método de máxima verosimilitud.

A partir de la estimación, los resultados pueden ser interpretados mediante el uso de distintas herramientas como, por ejemplo, los efectos marginales que permiten conocer el efecto que, sobre la probabilidad de elección, tiene un cambio en las variables explicativas. Los efectos marginales se pueden obtener de la siguiente forma:

$$\frac{\partial P(Y_i=j)}{\partial x_{im}} = [f\left(\mu_{j-1} - \beta' x_i\right) - f\left(\mu_j - \beta' x_i\right)]\beta_m,\ j = 0, \cdots, J \quad (4)$$

Por la propia naturaleza de los efectos marginales en este tipo de modelos, se puede obtener una primera conclusión sobre las categorías extremo, y es que estas presentan signo opuesto. En este sentido, dado que es una relación que necesariamente se va a verificar, resulta conveniente examinar si la satisfacción de este supuesto resulta conveniente en el análisis de cada caso objeto de estudio (Rodríguez y Cáceres, 2007).

Por otra parte, los resultados también pueden ser interpretados a partir del cálculo de odds-ratios que, para un modelo logit ordinal, se definen como:

$$\Omega_j(x_i) = \frac{P(Y_i \leq j)}{P(Y_i > j)} = \frac{F(\mu_j - \beta' x_i)}{1 - F(\mu_j - \beta' x_i)} = e^{(\mu_j - \beta' x_i)},\ j = 0, \cdots, J-1 \quad (5)$$

Este cálculo permite comparar la probabilidad de estar en una categoría (menor o igual a j) frente a otra superior. Si se estiman a nivel individual, pueden ser interpretados como el patrón de sustitución entre dos categorías para un individuo con un vector de características concreto. De esta forma, el cociente de odds-ratios permite conocer el patrón de sustitución entre categorías cuando, además, se produce una variación unitaria en una de las variables explicativas.

Dado que uno de los objetivos de este trabajo es evaluar la adecuación de diferentes especificaciones econométricas para analizar la predisposición a compartir vehículo que declaran los estudiantes, se plantean además del logit ordinal otros modelos de elección discreta. Específicamente, las especificaciones de los logit multinomiales y binomiales.

Estas permiten suavizar algunos supuestos de la especificación ordenada y, sobre todo, permiten ver si las variables explicativas relevantes varían de acuerdo con la especificación planteada. A continuación, se presentan brevemente algunas de las características de los modelos mencionados.

El modelo logit multinomial no considera la existencia de un orden implícito en las alternativas entre las que elige el individuo, siendo esta la principal diferencia con la especificación ordinal además elimina ciertas restricciones como la exigencia de contar con signos distintos en los efectos marginales de las alternativas extremo. Estos modelos cuentan con el respaldo teórico de la Teoría de la Utilidad Aleatoria propuesta por Domencich y McFadden (1975).

Este enfoque se basa, principalmente, en cuatro pilares fundamentales: el individuo cuenta con toda la información y actúa racionalmente maximizando su utilidad, toma su elección de acuerdo con sus propias características y los atributos de las alternativas, cada alternativa reporta un nivel de utilidad determinado que depende de un componente sistemático u observable u de un componente aleatorio, y, una vez maximiza, elegirá aquella alternativa que le reporta mayor nivel de utilidad. A partir de estos fundamentos, la probabilidad de elección de cada alternativa viene definida así

$$P(Y_i = j) = \frac{e^{x_i'\beta_j}}{1+\sum_{k=1}^{J} e^{x_i'\beta_k}}, j = 0, \dots, J \tag{6}$$

Ahora bien, como ocurre con el modelo ordinal, para interpretar los resultados se deben emplear instrumentos como los efectos marginales

$$\frac{\partial P(Y_i=j)}{\partial x_{im}} = P(Y_i = j)\left[\beta_{jm} - \sum_{k=1}^{J} \beta_{km} P(Y_i = k)\right], j = 0, \dots, J \tag{7}$$

O los odds-ratios y cocientes de estos, los cuales permiten conocer el patrón de sustitución entre distintas alternativas, permitiendo así describir las preferencias de los individuos.

$$\Omega_{j/k} = \frac{P(Y_i=j)}{P(Y_i=k)} = \frac{e^{x_i'\beta_j}}{e^{x_i'\beta_k}} = e^{x_i'(\beta_j-\beta_k)}, j = 0, \dots, J, j \neq k \tag{8}$$

Por último, el modelo logit binomial parte del supuesto de que cada individuo debe elegir entre dos alternativas distintas, identificadas por los valores 0 y 1. Este modelo sigue, por tanto, la distribución logística y la probabilidad de elección de cada alternativa puede obtenerse a partir de la siguiente expresión:

$$P(Y = j) = \frac{e^{X\beta}}{1+e^{X\beta}} = \Lambda(X\beta) \tag{9}$$

En el caso del modelo binomial, el signo de sus parámetros sí que puede ser interpretado directamente, aunque, al igual que en el resto de los modelos, sus resultados pueden interpretarse a través del cálculo de efectos marginales u odds-ratios.

4. RESULTADOS

Tal y como se ha venido argumentando en el aparatado metodológico, la naturaleza de la variable dependiente de los modelos propuestos (predisposición del individuo a viajar como acompañante) y el objetivo de este trabajo justifican el uso de los modelos de elección discreta. Uno de los objetivos que se persiguen en este trabajo es evaluar cuál es la especificación econométrica que mejor se ajusta a los datos (ordenada, no ordenada, etc.) y ver si las variables explicativas cambian o no en función de la especificación utilizada.

El primer planteamiento que se hizo consistió en usar diferentes agrupaciones de las categorías de las respuestas a la predisposición a viajar como acompañante, ya que los individuos cuando responden no necesariamente considerar el agrupamiento que se les da y pueden estar considerando que varias categorías significan lo mismo. Así, inicialmente se consideraron las cuatro categorías entregadas, esto es: en absoluto, en poca medida, en gran medida y totalmente predispuesto. Posteriormente esas cuatro categorías se agrupan en tres y después en dos, dando lugar a diferentes modelos. Por esa razón, se presentan los resultados de tres especificaciones distintas, dependiendo del número de categorías que se consideren de la variable dependiente y de la propia naturaleza del modelo. En concreto, se plantean especificaciones de un modelo logit multinomial, un modelo logit ordinal y un modelo logit binomial.

Inicialmente se presentan, en la Tabla 4, las definiciones de las variables que han resultado significativas en uno o varios de los modelos, así como la agrupación que se ha hecho de las distintas categorías de la variable endógena (*Disposición a compartir vehículo)* y cuál de ellas actúa como referencia. Además, se recoge la variable dependiente que se utiliza en cada especificación y sus agrupaciones sucesivas.

Variable	***Valores***
Norte	1 = Reside en el norte 0= Reside en otro lugar
Tasa de motorización	Variable continua
Asistencia todos los días de la semana	1= Asiste 5 días a clase 0= Asiste 4 o menos días
Todas las asignaturas en horario de mañana	1 = Asignaturas concentradas en el turno de mañana 0 = Asignaturas concentradas en el turno de tarde o repartidas en ambos turnos

Variable	***Valores***
Disponibilidad de vehículo	1 = Dispone habitual u ocasionalmente de vehículo 0= Nunca dispone de vehículo
Tiempo de viaje	Variable continua
Coste del viaje	Variable continua
Elección del modo: no coche	1 = Elige el modo actual por no tener vehículo 0 = Otro motivo de elección del modo actual (p. ej.: tiempo)
Elección del modo: economía	1 = Elige el modo actual por razones económicas (p. ej.: más barato) 0 = Otro motivo de elección del modo actual (p. ej.: tiempo)
Ventaja: Fact. Personales	1 = Ventajas personales 0 = Resto de opciones
Ventaja: Fact. Sociales	1 = Ventajas sociales 0 = Resto de opciones
Ventaja: Fact. Externos	1 = Ventajas externas 0 = Resto de opciones
No encuentra ventaja	1 = No ve ventaja a compartir 0 = Resto de opciones
Problema: Libertad	1 = Problema asociado a la libertad 0 = Resto de opciones
Problema: Horarios	1 = Problema asociado al tiempo 0 = Resto de opciones
Problema: Seguridad	1 = Problema asociado a la seguridad 0 = Resto de opciones
No encuentra problema	1 = No ve problema a compartir 0 = Resto de opciones
Disposición a compartir vehículo modelo logit multinomial con cuatro categorías	0 = en absoluto 1 = en poca medida 2 = en gran medida 3 = totalmente predispuesto
Disposición a compartir vehículo modelo logit ordinal con tres y cuatro categorías	0 = en absoluto 1 = en poca medida 2 = en gran medida o totalmente pred.
Disposición a compartir vehículo modelo logit binomial	0 = en absoluto o en poca medida 2 = en gran medida o totalmente pred.

Tabla 4 – Descripción de las variables empleadas en los modelos

En primer lugar, se presenta el análisis del modelo logit multinomial en el que las alternativas son las cuatro opciones que se dan en el cuestionario a la pregunta relativa a la disposición a compartir vehículo en su viaje. Esta especificación, de acuerdo con el diseño inicial de la encuesta, modela la probabilidad de elección entre las siguientes cuatro alternativas: en absoluto, en poca medida, en gran medida y totalmente dispuesto. Los resultados de la estimación de este modelo, así como los efectos marginales para cada categoría, se presentan en la Tabla 5.

A pesar de que parece que el modelo se ajusta bien a los datos, si se toma como referencia aspectos como la significación individual y conjunta del modelo, sí que se observa que el porcentaje de observaciones que es capaz de predecir adecuadamente es inferior al 50%. Por esta razón, se optó por hacer distintas agrupaciones de las categorías de elección de la variable endógena que permitieran conocer qué aspectos podrían contribuir a la mejora predictiva del mismo. Finalmente, resultó que, tras unir las dos últimas categorías (predispuesto en gran medida y totalmente predispuesto) en una única, el modelo ganaba capacidad de predicción, por lo que se opta por realizar esta y las siguientes dos estimaciones con tres categorías de elección: en absoluta, en poca medida y en gran medida, esta última considerando la agrupación planteada.

	Estimación de parámetros			***Efecto marginal sobre la prob.***

$N = 2695 \quad R^2_{MCF} = 0.0712 \quad \chi^2(21) = 481.89\ (0.0000) \quad LnL = -3141.7279$

Niveles de significación: *** p < 0.01; * p < 0.05; * p < 0.10

Predicciones correctamente predichas: 44.2%

Tabla 5 – Estimación del modelo logit multinomial con cuatro categorías

A la luz de los resultados obtenidos cuando se hacen diferentes agrupamientos de la variable endógena, se observa que las estimaciones mejoran en su capacidad predictiva. Ello permite concluir que, para los individuos encuestados, la elección entre las dos categorías superiores

-aquellas que indican un mayor nivel de predisposición a compartir vehículo- no está del todo clara. Es decir, consideran ambas categorías como similares y por ello los modelos que las agrupan representan mejor el comportamiento revelado por los estudiantes acerca de la predisposición a compartir coche.

En relación con la especificación multinomial de tres categorías, esto es, sin considerar el orden que inicialmente se daba a las alternativas, se obtienen los resultados que se presentan en la Tabla 6. En cuanto a la adecuación del modelo, se observa que todas las variables resultan significativas individualmente, aunque a niveles distintos de significación del 1% y el 10%. A nivel conjunto, se rechaza la hipótesis planteada en el contraste, resultando así también adecuadas. Además, otros indicadores como el pseudo R-cuadrado (McFadden, 1974) y el porcentaje de predicciones correctas mejoran sustancialmente respecto al modelo anterior.

Tabla 6 – Estimación del modelo logit multinomial con tres categorías

Analizando las variables explicativas que resultan relevantes, se observa que las distintas ventajas y problemas declarados por los estudiantes son significativas. Además, como es de esperar, el signo del efecto marginal de estas variables es consecuente con su naturaleza, pues las ventajas contribuyen a un mayor nivel de predisposición a compartir, mientras los problemas reducen esta probabilidad.

Sin embargo, el valor de los efectos marginales sí que permite obtener una conclusión más relevante de cara al diseño de medidas que motiven el uso compartido del coche.

Así, en relación con las ventajas, se encuentra que son las asociadas a factores personales (ahorro económico o ganancias de tiempo) las que generan un mayor incremento (0.73

puntos porcentuales) en la probabilidad de compartir vehículo, siendo los factores externos (reducción de la congestión o de la contaminación) las que generan un menor impacto (0.52 puntos porcentuales). Por su parte, los problemas asociados con compartir el vehículo también arrojan resultados interesantes en el estudio de la magnitud de los efectos marginales relacionados con la última categoría considerada. En este caso, los problemas de seguridad son los que suponen un mayor desincentivo a compartir vehículo, con una caída de hasta un 66% en la probabilidad de viajar compartiendo. Sin embargo, los inconvenientes derivados de las esperas o los retrasos que podría llevar aparejado esta forma de movilidad cuentan con una disminución menor, aunque no deja de ser elevada -casi alcanza los 50 puntos porcentuales-.

En relación con los motivos de elección del modo de transporte actual, el único que resultó ser significativo fue la no disposición de vehículo, es decir, solo se encuentran diferencias significativas entre aquellos individuos que declaran no disponer de vehículo como razón principal para la elección del modo de transporte habitual frente al resto de modos. Además, la no disposición del coche supone un incentivo a abandonar el modo habitual y optar por viajar compartiendo el vehículo de otra persona. Este es un resultado interesante, si se tiene en cuenta que son los usuarios actuales del transporte público los que declaran en gran medida que el motivo principal de elegir ese modo de transporte es que no disponen de coche (se trata en cierta medida de una demanda cautiva del transporte público). Por último, el tiempo de viaje también resulta ser estadísticamente significativo cuando se toma la decisión planteada y, aunque la cuantía de las variaciones no sea elevada, ante incrementos en la duración, la probabilidad de no querer compartir vehículo se ve reducida.

La especificación de un modelo logit ordinal, por su parte, permite realizar el análisis de la probabilidad de elección de cada una de las alternativas de acuerdo con el esquema ordenado que inicialmente se diseñó para la encuesta. Por ello, la especificación ordenada podría ser considerada como la más adecuada dada la naturaleza del experimento, si bien se han especificado otros modelos, como ya se comentó, para ver las posibles discrepancias entre variables explicativas significativas, dependiendo del modelo estimado.

Los resultados derivados de la estimación del modelo ordinal (Tabla 7) con tres categorías permiten extraer las siguientes conclusiones. En cuanto a la significación individual de los parámetros, se concluye que todos resultan significativos al 99% de confianza, salvo dos de ellos que lo son al 95%. De igual manera, resultan ser significativos a nivel conjunto.

Este modelo, como el anterior, incluye variables referidas a ventajas y problemas que los individuos encuentran a la hora de viajar compartiendo vehículo y, al igual que en la especificación multinomial, las ventajas personales y los problemas asociados con la percepción de seguridad resultan los más importantes, si se considera la magnitud de sus efectos marginales como criterio de importancia. Esto llevo a pensar que, en cierta medida, las políticas que se lleven a cabo para potenciar el uso del vehículo compartido deben pasar por aspectos personales como el ahorro económico que le supone al individuo, además de incentivos como la reserva de plazas de aparcamiento para aquellos que se acojan a esta modalidad de movilidad.

Por otra parte, esta estimación incluye dos variables de sumo interés: asistencia a clase todos los días de la semana y contar con un mismo horario de entrada y salida todos los días.

Ambas variables indican, a luz de los valores de sus efectos marginales, que aquellos estudiantes que asisten a clase todos los días están más predispuestos a compartir vehículo y, a su vez, que aquellos que cuentan con un mismo horario durante la semana lectiva también muestran una actitud positiva ante la idea de compartir.

En conclusión, estas dos variables apuntan a que la frecuencia y regularidad horaria en sus estudios contribuye a aceptar nuevos modos de transporte como el propuesto en este trabajo.

Tabla 7 – Estimación del modelo logit ordinal con tres categorías

El tercer modelo considerado es el modelo logit binomial (Tabla 8). En este caso, la estimación se ejecuta considerando únicamente dos categorías de elección y, en consecuencia, realizando una nueva agrupación. Mientras se mantiene la unión de las categorías superiores, aquellas que expresan mayor predisposición, también se unen las dos categorías inferiores de la variable (en absoluto y en poca medida), obteniendo una única variable que indican la no predisposición a viajar compartiendo vehículo.

De esta forma, aún a pesar de la simplificación que pudiera darse en el análisis, se obtiene un modelo que, en términos generales, podría ser más sencillo de aplicar en algunos escenarios por su naturaleza dicotómica, lo que permite identificar, a priori, comportamientos más diferenciados: predispuesto o no predispuesto. Todos los parámetros incluidos en este modelo resultan ser significativos, también en términos conjuntos, y cuenta con un porcentaje de acierto del 70.6%.

La tasa de motorización, calculada como cociente entre el número de coches y el número de miembros del núcleo de convivencia del individuo, resulta ser significativa, como ya ocurría en el modelo ordinal y con la misma interpretación, esto es, los incrementos en la tasa suponen una disminución en la probabilidad de acudir al centro de estudios compartiendo un vehículo conducido por otra persona. En concreto, si se toma esta variable como variable proxy de la renta, esta viene a indicar la existencia de una correlación negativa entre renta y predisposición a compartir vehículo, pues aquellos individuos con una menor renta muestran mayor incentivo a emplear esta forma de movilidad.

	Coeficiente	***Efecto marginal***	***Odds-ratios***

Tabla 8 – Estimación del modelo logit binomial

No obstante, este resultado no parece estar afectado por el coste que cada individuo paga por acudir al centro de estudio en el modo de transporte que emplea en la actualidad. Si se observa la contribución de la variable coste a la probabilidad, se concluye que esta es negativa, es decir, a mayor coste, el individuo tendría menos incentivos a compartir.

Este resultado es muy posible que venga derivado de que en su mayoría son los conductores habituales los que declaran un mayor coste por trayecto, al mismo tiempo que son los que muestran mayor reticencia a cambiar de modo, de ahí que el efecto del coste resulta ser desincentivador a la hora de optar por viajar como acompañante.

Además, en esta especificación son relevantes variables de tipo académico como las ya mencionadas en el modelo ordinal, con la salvedad de una nueva variable: tener todas las asignaturas concentradas en un mismo turno y, en concreto, en el turno de mañana.

Estos individuos muestran mayor probabilidad a compartir vehículo que aquellos que cuentan con asignaturas repartidas en turnos o concentradas en la tarde.

Por tanto, la concentración de las materias en un turno también influye en la decisión. Además, en este caso concreto, debe señalarse que en el entorno de los campus universitarios suele concentrarse un importante volumen de vehículos sobre todo en horario de mañana, lo que podría venir a explicar esta diferenciación entre la concentración por turnos dado que la mayor congestión en la entrada y salida de la ciudad se da durante la mañana.

5. CONCLUSIONES

En este trabajo se utilizan los datos de una encuesta de preferencias reveladas realizada en 2016 a una muestra de estudiantes de la ULL, en la que se incluían cuestiones acerca de la predisposición a viajar como acompañante. El propósito que se persigue es analizar cuáles son los principales factores que influyen en la predisposición a compartir de cara a fomentar el uso del vehículo compartido entre los universitarios.

Esta medida de política de transporte resulta de gran importancia para corregir los patrones de movilidad actuales, que se caracterizan por el uso predominante del coche en los desplazamientos a los centros de estudio. Además, se observa que la mayoría de los que se desplazan en coche lo hacen solos, lo que pone de manifiesto una gran cantidad de plazas ociosas en los vehículos que conlleva un uso ineficiente del parque automovilístico y, en consecuencia, un mayor impacto medioambiental per cápita. En consecuencia, fomentar políticas tendentes al uso del vehículo compartido por parte de los estudiantes no solo lleva aparejado un uso más racional de la capacidad del vehículo, sino una importante minoración de las emisiones derivadas del transporte por carretera en la isla

En este trabajo se ha planteado una batería de modelos de elección discreta, con el propósito de analizar la predisposición a viajar como acompañante de los estudiantes universitarios en sus viajes al centro de estudios, considerando diferentes aproximaciones al problema objeto de estudio. A partir de los resultados obtenidos se plantea una primera conclusión relacionada con la elección de la tipología del modelo. A pesar de que los diferentes modelos considerados comparten un grupo de variables, sí que, dependiendo del modelo empleado, se añaden unos u otros regresores significativos. Por tanto, parece que la tipología del modelo puede determinar distintas relaciones causales estadísticamente significativas.

Así pues, para el desarrollo de medidas de política orientadas a la movilidad, resulta conveniente chequear diferentes aproximaciones metodológicas más allá de la del modelo ordinal, que pudiera parecer la más adecuada a priori.

Asimismo, se ha observado como la capacidad predictiva y analítica del modelo varía según se considere un número u otro de alternativas sobre las que el individuo debe elegir. Por tanto, se recomienda comprobar, en base a un proceso iterativo, si las categorías inicialmente consideradas en el cuestionario se corresponden con las que los individuos identifican a la hora de tomar su decisión. Ello puede llevar, como en este caso, a que la agregación de determinadas categorías suponga una mejora de los modelos, permitiendo concluir que las categorías que consideran los individuos cuando hacen su elección no tienen por qué coincidir con las que fueron previamente establecidas por el investigador.

De entre las ventajas que los individuos declaran, sobresale la importancia que estos dan a aquellas relacionadas con factores meramente personales, esto es, su propio ahorro económico o de tiempo, o la reserva de plazas de aparcamiento para aquellos que acudan al centro bajo esta modalidad.

Este hecho permite establecer una nueva recomendación que vaya en la línea de incentivar aspectos personales frente a otro tipo de ventajas, pues su impacto en la conducta del individuo es mayor. No obstante, esto también permite valorar otra conclusión y es que las ventajas relacionadas con el medio ambiente (reducción de la contaminación y de la congestión, etc.) son las que producen un menor impacto en la predisposición a compartir vehículo y, por tanto, a pesar de los esfuerzos actuales que en esta materia se realizan, parece que la conciencia social sobre este asunto no es tal.

Ello, pone de manifiesto la necesidad de hacer una revisión en los mecanismos de comunicación de las políticas dirigidas a la concienciación medioambiental entre los jóvenes.

Otra medida que podría contribuir a la utilización del vehículo compartido es la reducción de la sensación de inseguridad a la que aluden como principal problema los individuos encuestados.

Esta sensación podría ser mitigada con la implantación de redes comunicativas, por ejemplo, mediante el uso de una app, que permita a los estudiantes contar su experiencia como usuarios de vehículo compartido e incluso que puedan valorar cuál ha sido su experiencia durante el viaje, etc.

En definitiva, visibilizar la seguridad que, en general, presenta el uso de este modo, en contra de la inseguridad percibida a priori.

Por último, otro aspecto relevante que permite recomendar acciones para potenciar el uso del coche compartido es la política académica.

En los modelos planteados, variables como la asistencia regular al centro de estudios (todos los días frente a días aislados) y la concentración de la docencia en un único turno (frente al reparto en turnos distintos) muestran importantes contribuciones a la probabilidad de optar por viajar en vehículo compartido, por ello, los centros universitarios, a través de la construcción de horarios más estables, pueden aportar notablemente a la generalización de una movilidad más sostenible entre los estudiantes.

RESUMEN

La zona centro de la ciudad de Barranquilla, Colombia es un lugar predilecto por su comunidad debido a la gran variedad y accesibilidad económica de bienes y servicios, además de la concentración de los principales centros de comercio, almacenes mayoristas y diferentes grupos de interés como entes públicos y privados generando como consecuencia el incremento de altos niveles de contaminación ambiental, congestión vehicular, inseguridad y ocupación del espacio público que deterioran la calidad de vida de los residentes, transportistas, comerciantes, productores y consumidores.

El presente artículo es el resultado del trabajo de campo llevado a cabo en la zona centro con los principales actores con el propósito de realizar un análisis sobre la aceptación de diferentes políticas internacionales de transporte de carga. Los sectores analizados son calzado, parqueaderos, restaurantes, electrodomésticos, variedades.

Los resultados de la investigación arrojaron las tres políticas con mayor aceptación por parte de todos los actores, sin embargo, no existe unanimidad para elegir una política global, por lo tanto, se identifican los resultados de acuerdo con cada actor y sector.

1. INFORMACIÓN GENERAL

1.1 Introducción

Este trabajo está orientado a proponer soluciones a diversas problemáticas que son el resultado del transporte de carga urbana en el centro histórico de Barranquilla, esta área tiene una alta densidad de establecimientos que mueven mercancía para el funcionamiento diario del comercio de la ciudad.

En Colombia aún está muy insipiente la aplicación de nuevas políticas del transporte urbano de mercancías que se adapten a las necesidades de las zonas comerciales, por lo que surgen diversos problemas que dificultan el buen desempeño de estos procesos económicos como el incremento de contaminación ambiental, congestión vehicular, inseguridad y ocupación del espacio público que deterioran la calidad de vida de los residentes, transportistas, comerciantes, productores y consumidores.

La presente investigación tiene como propósito conocer cuál es la opinión de los diferentes actores acerca de las políticas planteadas con el fin de analizar viabilidad dichas políticas y concluir cuál se debería implementar.

1.2 Justificación

En la zona centro de Barranquilla las externalidades como congestión, contaminación, ruido están aumentando. Como resultado obtenemos el incremento de costos, tanto a los productos de consumo como a los transportistas. Cada vez que estas externalidades se incrementen representan un problema para la sociedad de manera que podría llegar a tornarse un escenario de colapso en esta zona, lo cual incide directamente en la economía al tratarse de un centro de comercio. Por lo tanto, utilizar políticas públicas para el transporte de carga urbano que han sido exitosas en el extranjero, se considera un buen ejercicio tanto académico como técnico, pero tal ejercicio no se puede sugerir e implementar sin analizar la operatividad y viabilidad de la política, por lo que es necesario hacer un análisis con los directamente afectados para conocer sus percepciones a partir de soluciones existentes.

En este sentido, se realizará la investigación y análisis mediante la información suministrada por los actores que intervienen en el comercio de la zona identificando así las posibles causas que ocasionan los problemas y un ranking de políticas potencialmente viables a implementar en la ciudad. De esta manera se busca cual sería la política de transporte más eficiente que disminuya las externalidades en esta zona, siendo de gran aporte para el desarrollo de la logística a nivel local.

1.3 Objetivo

1.3.1 Objetivo General

Analizar las diferentes perspectivas sobre la viabilidad de políticas para el transporte de carga urbano en el centro de Barranquilla.

1.3.2 Objetivos específicos

- Identificar los actores y sectores que hacen parte de la zona centro que resultan representativos para la investigación.
- Diseñar e implementar un instrumento que permita analizar la percepción de los actores ante las problemáticas de la logística urbana.
- Realizar un análisis comparativo con los actores y sectores de la zona centro sobre la aceptación de políticas.

1.4 Metodología

La metodología presentada en este artículo es de tipo cualitativa y cuantitativa. Para la ejecución y conclusión del proyecto de investigación se desarrollaron una serie de etapas:

1) Se realizó un inventario de cada uno de los negocios o lugares de la zona centro de Barranquilla y se caracterizaron, con el fin de identificar los principales sectores económicos de la zona. Ver Tabla 1.

2) Se usó como base la selección de políticas públicas del proyecto “Stakeholders perceptions to sustainable urban freight policies in emerging markets” que previamente desarrollaron (Amaya, Arellana, & Delgado-Lindeman, 2020).

    1. Crear bahías (estacionamientos junto al andén) para mejorar la carga y descarga de mercancía de camiones y reserva web de éstos.
    2. Crear estacionamientos para camiones y tracto mulas como centros de distribución para guardar y repartir mercancía.
    3. Crear un sistema de información con un único operador logístico que centraliza los pedidos y envíos.
    4. Peajes electrónicos para ingresar al centro de Barranquilla con exoneración a los propietarios, comerciantes, residentes, vehículos no contaminantes y con bajo nivel de ruido
    5. Prohibir el acceso a vehículos en ciertas zonas y peatonalización de zonas altamente comerciales (sólo se permite el paso de personas).
    6. Reubicar conjunto de almacenes de Ja misma actividad económica a un sector fuera de la zona centro.
    7. Micro-plataformas logísticas urbanas usando vehículos amigables con el medio ambiente (eléctricos o híbridos) como centro de distribución móvil (vehículos no convencionales: Uso de bicicletas, motos, etc.)
    8. Colaboración entre los transportistas o comerciantes para envío y recepción de carga colaborativa.
    9. Distribución nocturna de mercancía

3) Para la evaluación de las políticas se utilizaron técnicas como la recolección de información por medio de encuestas aplicadas a los principales actores y establecimientos de la zona centro de Barranquilla. El tamaño de muestra escogido se tomó según el número de negocios y establecimientos ubicados en dicha zona para el presente año; tratándose de una población finita y para lograr el tamaño ideal se hace uso de la siguiente fórmula propuesta por (Larry, 2017)

$$n = \frac{z^2\sigma^2 N}{e^2(N-1)+z^2\sigma^2} \tag{1}$$

$$n = \frac{(1{,}96)^2(0{,}5)^2(1163)}{(0{,}5)^2(1163-1)+(1{,}96)^2(0{,}5)^2} \tag{2}$$

$$n = 383 \tag{3}$$

Para el cálculo de la fórmula:

- n = es el tamaño de la muestra poblacional a obtener.
- N = es el tamaño de la población total, en este caso 1163 negocios y establecimientos en la zona centro.
- S = Representa la desviación estándar de la población. En caso de desconocer este dato es común utilizar un valor constate que equivale a 0.5.
- Z = es el valor obtenido mediante niveles de confianza. Su valor es una constante, por lo general se tienen dos valores dependiendo el grado de confianza que se desee siendo 99% el valor más alto (este valor equivale a 2.58) y 95% (1.96) el valor mínimo aceptado para considerar la investigación como confiable.
- e = representa el límite aceptable de error muestral, generalmente va del 1% (0.01) al 9% (0.09), siendo 5% (0.5) el valor estándar usado en las investigaciones, como lo demuestra (Larry, 2017)

4) Una vez obtenido el tamaño de muestra correspondiente al universo finito determinado, se procedió con la aplicación de las encuestas en la zona, para un total de 383 encuestas.
5) Por último, con la información obtenida en la investigación, se procedió a tabular, analizar e interpretar los resultados, con el fin de conocer la aceptación y viabilidad de cada una de las políticas por actor y sector.

2. RESULTADOS

Como resultado de la metodología aplicada, para establecer la clasificación y la cantidad de locales en la zona centro, en donde se agruparon los negocios que ofrecían productos o servicios de las mismas características, se elaboró el siguiente análisis.

Tipos de negocio	N° de locales	Porcentaje
Productos de almacén	187	16,08%
Partes de auto	156	13,41%
Textiles y confección	152	13,07%
Casas, lotes y locales vacíos	147	12,64%
Alimentos preparados	109	9,37%
Hotel/motel	57	4,90%
Productos electrónicos	48	4,13%
Bancos y giros	43	3,70%
Colegios, edificios e iglesias	41	3,53%
Ocio y entretenimiento	39	3,35%
Droguerías	30	2,58%
Mantenimiento y lubricante de vehículos	27	2,32%
Cuero y calzado	20	1,72%
Metales preciosos y casas de empeño	20	1,72%
Bodegas y almacenes	15	1,29%
Salón de belleza y estética	13	1,12%

Total general	1163	1

Tabla 1 Caracterización de los negocios de la zona centro de Barranquilla. Fuente: Elaboración propia.

En la tabla anterior se puede apreciar la participación de cada sector en el mercado. Con base en este resultado se hizo la priorización para realizar las encuestas a los tipos de locales con mayor porcentaje de participación en el mercado y a los diferentes actores que participan en su funcionamiento.

2.1 Políticas públicas

Del trabajo de campo realizado en la zona centro con la encuesta diseñada para que los actores formularan el ranking de las mejores políticas de acuerdo con la conveniencia de sus sectores (Calzado, parqueadero, restaurante, electrodomésticos, variedades) se analizaron los resultados generales y específicos de cada sector y actor.

Los resultados de la estimación se muestran en la figura 1. Para esto se utilizó un modelo de encuestas de las nueve políticas de logística urbana escogidas por los mismos actores y se empleó un procedimiento de integración numérica simultánea, mostrando la aceptación general de los diferentes actores (comerciantes, transportistas, productores y expertos) en los sectores analizados.

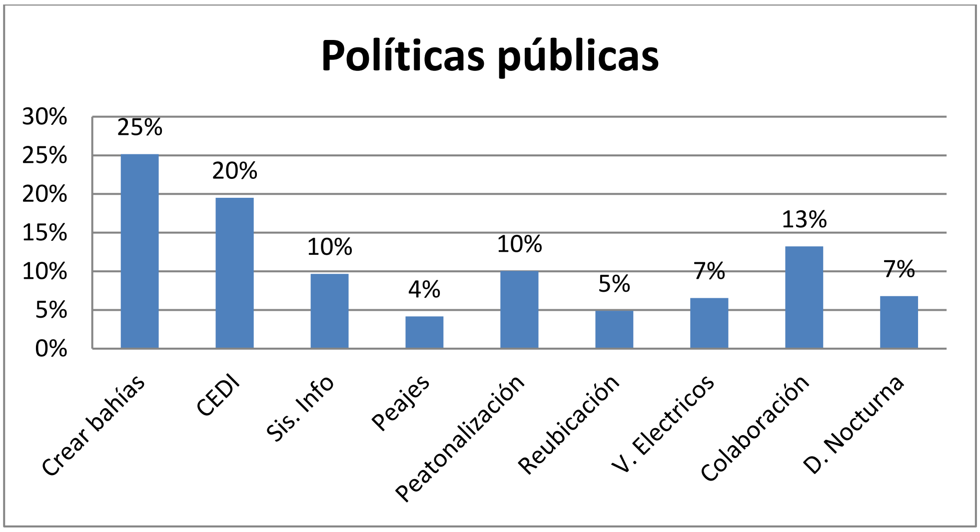

Fig. 1 – Ranking general de la aceptación de las políticas.
Fuente: Elaboración propia.

La figura 1 evidencia la aceptación de los diferentes actores sobre la viabilidad de las políticas de transporte de carga urbana, los resultados de la encuesta muestran que la política 1 fue escogida en los sectores analizados como la más viable a implementar en la zona centro con un porcentaje de aceptación del 25%, esta política consiste en crear bahías de estacionamientos junto al andén para mejorar la carga y descarga de mercancía de camiones y reserva web de estos espacios, con parquímetros o zonas azules.

Los resultados también muestran que segundo lugar los actores calificaron a la de creación de estacionamientos para camiones y tracto mulas como centros de distribución para guardar y repartir mercancía, con un porcentaje de aceptación del 20% y un 13% en tercer lugar del ranking para la política de colaboración.

2.2 Sector Calzado

Los almacenes de calzados dieron sus diferentes perspectivas sobre la viabilidad de las políticas de logística urbana que se encontraban en estudio.

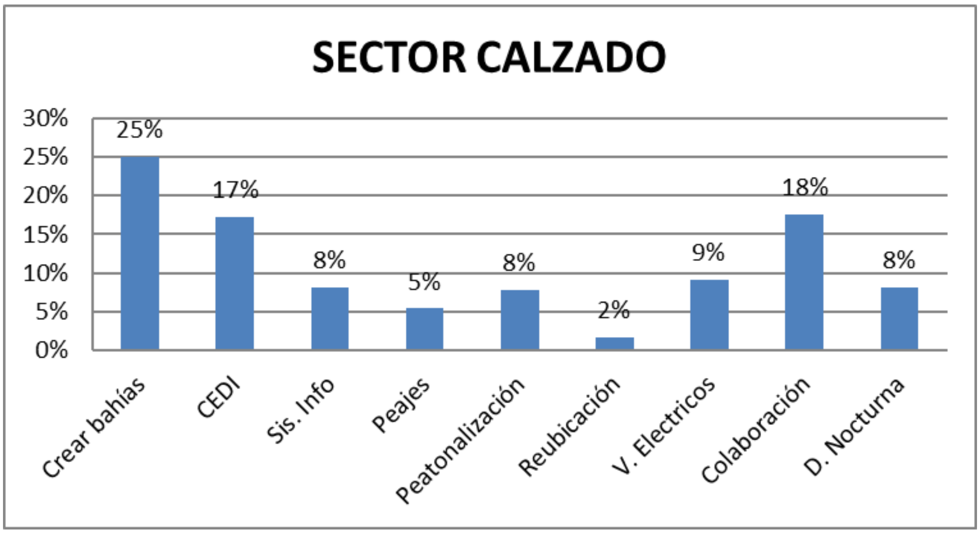

Fig. 2 – Ranking de la aceptación de las políticas, sector calzado.
Fuente: Elaboración propia.

Se evidencia el porcentaje de aceptación del Ranking de las políticas escogidas por su viabilidad según el sector de almacenes de calzado, la más aceptada es la creación de bahías.

2.3 Sector Parqueaderos

De los sectores analizados se encuentra los parqueaderos, los cuales dieron sus diferentes perspectivas sobre la viabilidad de las políticas de logística urbana que se encontraban en estudio.

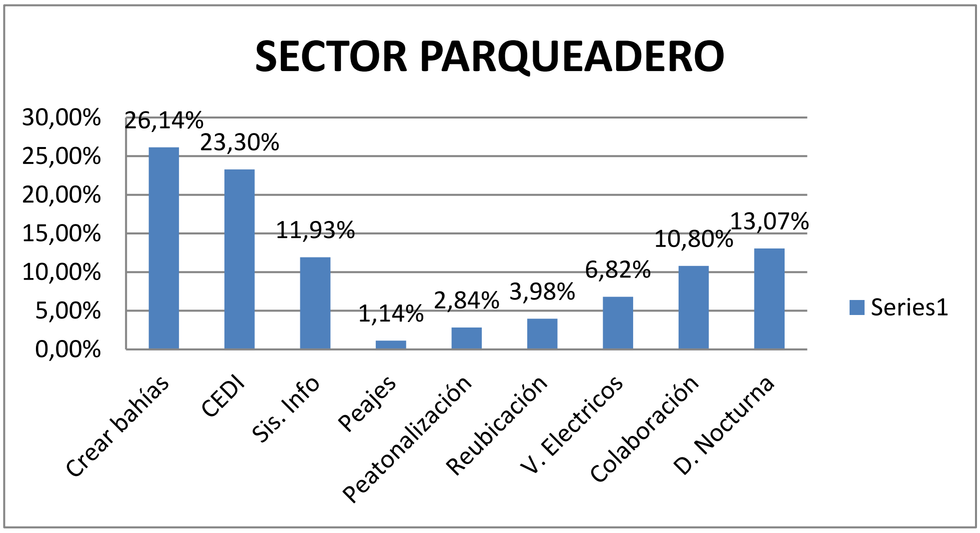

Fig. 3 – Ranking de la aceptación de las políticas, sector parqueaderos.
Fuente: Elaboración propia.

La figura 3 muestra los porcentajes de aceptación para cada política escogida, se concluye que para este sector tienen una mayor viabilidad la creación de bahías para mejorar la carga y descarga de mercancía con un porcentaje de aceptación del 26,14%; la creación de estacionamientos para camiones y tracto mulas como centros de distribución con un porcentaje de aceptación del 23,30% quedando en el ranking como segundo.

2.4 Sector Electrodomésticos

Los actores del sector de electrodomésticos mostraron sus diferentes perspectivas sobre cada una de las políticas de logística urbana propuestas, y categorizaron las que tenían mayor aceptación de acuerdo con las problemáticas presentadas en la zona en donde se encuentran localizados.

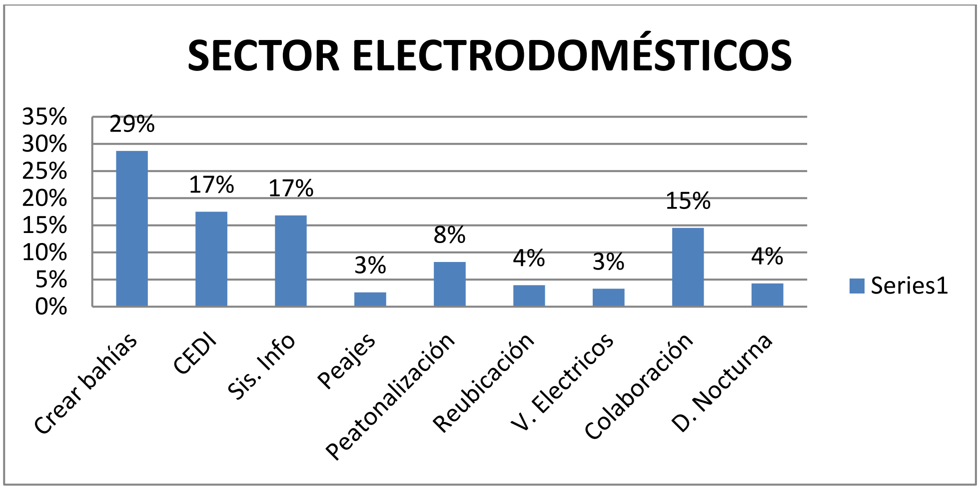

Fig. 4 – Ranking de la aceptación de las políticas, sector electrodoméstico. Fuente: Elaboración propia.

Teniendo en cuenta que por la ubicación en la que se encuentra el pequeño clúster de negocios de electrodomésticos, se presenta un alto flujo tanto vehicular como peatonal por lo que los espacios disponibles para un adecuado estacionamiento de camiones para la carga y descarga de mercancía es reducido. Es por esto por lo que la política que plantea la creación de bahías es considerada la mejor política por este sector con un porcentaje de aceptación del 29 %.

2.5 Sector Variedades

En este sector dedicado al comercio de variedades, dieron sus diferentes perspectivas sobre la viabilidad de las políticas que se encontraban en estudio.

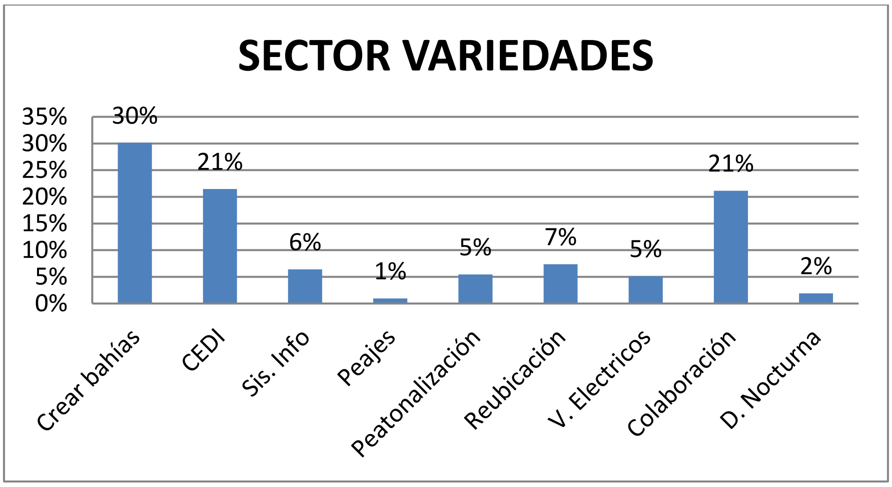

Fig. 5 – Ranking de la aceptación de las políticas, sector electrodoméstico.
Fuente: Elaboración propia.

Este sector mostró un nivel de aceptación elevado para la política "Crear bahías". Debido a que cuentan con una gran cantidad de artículos ofrecidos donde se hace necesaria la carga y descarga constante de mercancía, por lo cual asegurar un lugar de estacionamiento fijo, en los tiempos requeridos, optimizaría la operación.

2.6 Sector Restaurantes

El sector restaurante se diferenció de los otros sectores en cuanto a sus perspectivas sobre la política más viable.

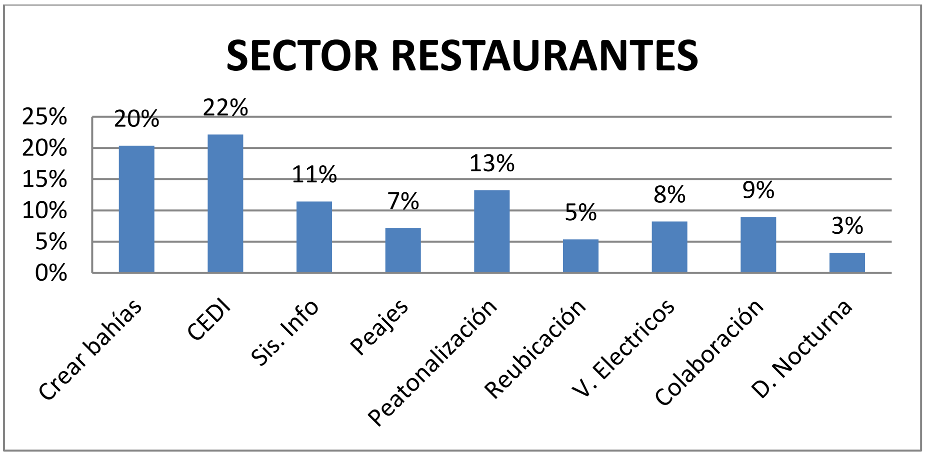

Fig. 6 – Ranking de la aceptación de las políticas, sector restaurantes.
Fuente: Elaboración propia.

En la figura 6 se observa que el primer lugar se encuentra la política 2, la cual propone crear centros de distribución permitiendo que un solo vehículo sea el encargado del despacho de mercancía en una misma zona.

En el segundo lugar se encuentra la política 1. Los actores la categorizaron como viable, debido a que disminuiría la congestión vehicular de su zona, dándole prioridad a los peatones, ya que, en muchas ocasiones, camiones de carga toman el espacio de la vía para parquear y obstruyen el ingreso a sus negocios o no los hace visible ante los peatones.

Fueron las políticas escogidas en general, ya que eran la solución a algunas problemáticas que sufren estos sectores, debido a que muchos de los clientes no tienen donde parquear cuando quieren adquirir o descargar mercancía, la mayoría de estos locales están ubicados en vías principales o secundarias y si no existen bahías de estacionamiento se les hace difícil el comercio, trayendo como resultado la congestión de las vías de la zona centro.

3. CONCLUSIONES

Para los sectores analizados, hay políticas con un buen nivel de aceptación para mitigar las problemáticas actuales, la viabilidad de éstas varía según las problemáticas y preferencias de cada sector. Esto se ve reflejado en el sector calzado, donde determinan como más viable la política de “Colaboración entre los transportistas o comerciantes” debido a que sus negocios están localizados en las vías donde se presenta más congestión vehicular, y la implementación de esta política les brindaría una disminución de camiones de carga a los diferentes negocios que se encuentran en la zona. Por otro lado, los sectores de parqueaderos, restaurantes, electrodomésticos y variedades prefieren la creación de bahías y los centros de distribución, manifestando que no solo supondría una disminución de congestión vehicular, sino que también aumentaría el flujo de clientes.

Es así como se puede concluir que las políticas de transporte de carga urbana con mayor viabilidad en los sectores analizados son la creación de bahías y creación de centros de distribución. Por tal razón se recomienda a los gremios que integran el sector público tener en cuenta estas políticas que cuales tuvieron gran aceptación en los participantes de la investigación para el mejoramiento del transporte de mercancía en cuanto a logística y movilidad se refiere.

AGRADECIMIENTOS

Agradecimiento especial a los integrantes del semillero de Logística Urbana Sostenible Eduar Javid Aponte Parejo, Daniela Sofía Vibanco González, Laura Vanesa Narváez Cantillo, Fabián José Correa Ordoñez, Ramiro Meléndez Uribe, Javier Enrique Pérez García & Hernando Fabio Morrón Polo.

THE STRATEGIC VARIANCE ANALYSIS OF LAN AND TAM AIRLINES MERGER IN THE EARLY 2010's

Luiz Augusto da Silva Alves
University of Brasília
Carlos Henrique Rocha
University of Brasília

ABSTRACT

LAN and TAM used to be the flag carriers of Chile and Brazil, respectively until late 2000's in the airline industry. The merger of both into LATAM Airlines was part of the strategy to construct a major regional power of air transportation, an evolution from national companies to a Latin America brand. This research analyzes the merger of LAN and TAM, which in the second decade of 21st Century formed one of the largest passenger air transportation groups. The concept of Strategic Variance Analysis (SVA) is used in some academic environments to evaluate a company's operational revenue in two time periods, in this specific case, 2010-2013. The concept is easy to understand and relates the financial statements with businesses strategies approaches.

Previous studies in the American airline industry have been conducted with SVA method. This paper compares the financial situation of former TAM before the merger (2010), and LATAM (2013), after the merger. The financial, operational, and fuel data are gathered from the National Civil Aviation Agency of Brazil, reclassified, and applied to calculate SVA. Then, as the final conclusion, SVA demonstrates that this merger was good, however it was insufficient to cover the rise in fuel prices during those years.

1. INTRODUCTION

After the September 11, 2001 terrorist attacks, civil aviation faced hard financial moments around the world after. The demand for air transport dropped significantly in the following months due to the fear and uncertainties that surrounded flight security. That triggered a reputation crisis in air transportation market due to aviation security. While new measures were taken by the civil aviation authorities worldwide, aerial activity gradually regrew from the panic.

Even so, traditional airlines that had been in the market for many years, saw their (already harassed) profit margins reducing a lot, while new players arose at that time proposing new business models. Between 2000 and 2020, several of those traditional airlines, in pursuit of survival, merged to form stronger companies, such as Air France and KLM in 2004; Continental and United Airlines in 2010; British Airways and Iberia in 2011; Gol and Webjet in 2011; American Airlines and US Airways in 2013; and Alaska Airlines and Virgin America in 2016 (Table 1).

The low-cost/low-fare airlines model popularization, with an aggressive proposal of low operational costs and offering reduced fare air services, forced not only competition with the traditional companies but also with other means of transportation. The the market itself put pressure on older Airlines to operate in an even more efficient way, and to offer more competitive fares to face the new age, otherwise their market share would tend to decrease due to the low-cost competition.

Fluctuations of oil price directly influence airlines' operating results. In Brazil alone, *ABEAR* (the Brazilian Airlines Association) estimated that in 2012, 37.8% of national companies' operating costs were related to fuel, which was at its highest historically registered value (ABEAR, 2019). That demonstrates the weight this input represents for their balance sheets. The scenario for Brazilian airlines, most of whose revenue is in Brazilian Reals (BRL) whereas the costs are in United States Dollars (USD), is even worse; it means that the exchange rate component implies higher costs and lower profit margins for airlines.

The year 2020 has established a new era in aviation worldwide. The COVID-19 Pandemic, also known as Coronavirus Pandemic, has triggered the worst possible unforeseen scenario for aviation; even worse than the September 11, 2001 attacks. The air transportation market worldwide has been affected by COVID-19. Among the options to survive this hard moment are mergers and acquisitions. In the first semester of 2020, market rumors said that coming examples may be Azul and LATAM, Air Canada and Air Transat, Air Asia and Malaysia Air. Others have filed for Chapter 11 (United States), *Recuperação Judicial* (Legal Recovery – Brazil), Insolvency Law (United Kingdom), or Voluntary Administration (Australia), or the least undesirable option: bankruptcy. Some 2020 airlines with financial issues are LATAM, LATAM Argentina, Avianca, South Africa Airways, Flybe and Virgin Australia.

Merger	Year	Location	Description
Air China, China Eastern, China Southern	early 2000's	China	Ten state-owned Chinese airlines were merged into only three big groups.
Air France–KLM	2004	France and the Netherlands	Two flag carriers consolidated into Air France–KLM Group, keeping both brands.
Lufthansa–Swiss	2005	Germany and Swiss	Lufthansa purchased Swiss.
Cathay Pacific–Dragonair	2006	Hong Kong	Cathay Pacific, a major airline in the Asian market, purchased its competitor Dragonair.
TACA–Avianca	2009	Colombia and El Salvador	Avianca, the flag carrier of Colombia merged with TACA, one of the main airlines of Central America.
Delta–Northwest	2010	United States	Delta purchased Northwest.
United Airlines–Continental Airlines	2010	United States	Two major US airlines merged into a single company, preserving United Airlines name and Continental Airlines logo.
Gol–Webjet	2011	Brazil	Two low-costs airlines, Gol purchased Webjet, keeping only the Gol brand.
British Airways–Iberia	2011	United Kingdom and Spain	Two flag carriers consolidated into International Airlines Group (IAG), keeping both British Airways and Iberia brands.
LAN–TAM	2012	Brazil and Chile	Two major flag carriers merged into LATAM.
Azul–TRIP	2012	Brazil	Azul, a young airline at the time, purchased regional airline TRIP, keeping only the Azul brand.
American Airlines–US Airways	2013	United States	American Airlines merged with US Airways keeping only the American Airlines identity.
Alaska Airlines–Virgin America	2016	United States	Alaska Airlines acquired Virgin America, keeping only the Alaska Airlines identity.

Table 1 – Major airline mergers since 2000.

1.1 Problems and Objective

The main problem of this research is to respond to the following question: how to identify, in an objective way, the causes of LAN (Chile) and TAM (Brazil) merger's synergy (or lack of). Thus, the investigation is into whether this merger was financially successful, and what the causes of success or failure were.

The main objective is to evaluate the merger between LAN and TAM in 2010 using the Strategic Variance Analysis (SVA) method, developed by Horngren et al. (2000) and extended by Sopariwala (2003). The paper is focused on TAM's financial data provided by Brazil National Aviation Agency. LAN data are not used in this study.

Section 1 introduces the scenario of mergers and acquisitions in the airline market, in which LAN and TAM were major South American players at that time. Section 2 is a short story of LAN and TAM merger, focused on financial aspects. Section 3 is a theoretical framework and presents a literature review and goes into greater detail as to how SVA works. Section 4 gathers the necessary data to apply SVA to the LAN-TAM merger according to the concepts learned from the previous section. Section 5 is the final analysis of the operational results of the merger, and what those financial numbers can reveal about what happened during those 3 years. Section 6 is the conclusion and final remarks of the research. Some suggestions are made to apply the same study to other scenarios of recent aviation moments.

2. LAN AND TAM MERGER HISTORY

Both LAN and TAM used to have their differences, due to history, cultural organization, corporate strategies, and target markets. The focus of this study is on the merger period, however Table 2 is a summary of LAN and TAM individual characteristics before the merger.

In 2010, there were six Airlines in Brazil's passenger air transportation market: TAM, Gol, Webjet, Azul, Avianca and TRIP (ANAC, 2010). In August of the same year, the companies TAM and LAN made a public announcement of the merger, integrating both Brazilian and Chilean operations the following year. According to LAN's Vice-President, Enrique Cueto in an interview to a Santiago newspaper, *"in current values (2010), without the synergies, the combined value of both companies is around 11.5 billion dollars"* (Soto, 2010).

Larroulet & Ardiles (2018) summarize the idea behind this phase: *"One brand name, one continent, one network. There is no other airline in the world named after a continent (LATAM), and this makes it easier for passengers to fly across the region. LATAM is very attractive as a partner in Joint Business Agreements (JBAs), and therefore British Airways, American Airlines, or Qatar Airways, for example, are willing to form global alliances with LATAM"*.

Figure 1 shows a panorama of the South and Central American industry before (2010) and after the merger (2013).

In March 2011, Brazil's ANAC approved the merger agreement of both companies; also at that moment, the binding agreement between the Amaro Family (controller of TAM) and the Cueto Family (controller of LAN) was signed to combine both businesses (LATAM, 2019). The competition regulators of both countries approved the merger, although with some restrictions: in September, the *Tribunal de Defensa de la Libre Conpetencia – TDLC* (Court of Free Competition Defense) of Chile, and in December, the *Conselho Administrativo de Defesa Econômica – CADE* (Administrative Council for Economic Defense), of Brazil.

	TAM	**LAN**

Hubs	São Paulo Brasília Rio de Janeiro	Santiago Lima

Table 2 – Summary of TAM and LAN historical analysis.

In November 2011, LAN and TAM signed up in the Securities and Exchange Commission – SEC in the United States, to negotiate shares on the New York Stock Exchange. In January 2012, TAM's shareholders agreed to a shares swap at the rate of 0.9 LANs share for each TAM share (Fernández, 2012). In May of the same year, the *Comissão de Valores Mobiliários – CVM*, Brazil's stock market regulator (equivalent to United States SEC), authorized the swap of shares between the companies.

Finally, on June 22, 2012, the merger was concluded, and **LATAM Airlines Group S.A**. was born, the largest airline of Latin America. Fernández (2012) goes deeper into the chronological order of the happenings of that operation.

The main idea behind that merger can be summarized as:

- Establish a global airline, with a regional identification under the LATAM brand (meaning Latin American Airlines) and international partnerships (American Airlines, IAG and Qatar Airways);
- Increase competitiveness in Latin America against other major groups: Gol, Avianca and Copa Airlines;
- Cost reduction, focusing on fleet standardization and high profit markets (including North America and Europe);
- Invest in Latin American long-term economic growth;
- LAN needed a way to enter the highly regulated Brazilian market, then shared basically between Gol and TAM (Azul and Avianca Brasil were not that big yet).

Nonetheless, the benefits of the merger also brought with them some challenges. Successive economic crisis in South America, instable politics and high rates of poverty must be considered when planning long-term demand. Larroulet & Ardiles (2018) remind us not only of the high boarding fees in the region, and the fact that each country has a different regulatory framework which increases costs, but also that in South America in 2018, the ultra-low-cost model was almost non-existent.

Figure 1 – Major airlines in the South and Central American industry in 2010 (left) and in 2013 (right).

3. THEORETICAL FRAMEWORK

Firstly,n the specific LAN–TAM analysis of Nóbrega et.al (2016) and Melo & Borges (2017), there are only financial outcomes based on stock values, without going deeper into the reasons why the companies came up with those numbers. It would be more relevant to ask, for instance, what the factors that contribute to such numbers are. Did the merger meet its expected objectives?

Schosser & Wittmer (2015) go deeper and state that "LAN followed a multimarket strategy with regional hubs whereas TAM mainly operated the Brazilian market with a traditional hub-and-spoke business model. Hence, LAN generated more than half of its revenues with international flights whereas TAM relied heavily on the domestic market." This sentence demonstrates that different corporate strategies and/or cultural organization may have a quota of influence along the whole merger transaction. Their conclusions are very interesting because they compare the mergers in North America, Europe and Latin America, considering the possible influence of geographic aspects.
Some mergers and acquisitions studies have not been capable of accurately pointing out the reasons for the differences on financial results between pairs of years (for example).

Thus, SVA – Strategic Variance Analysis – can suggest the corporate strategy to be adopted by a company. The examples of Caster & Scheraga (2011, 2013), Mudde & Sopariwala (2008; 2010; 2014), and Rocha (2020) must be part of the theoretical framework that supports the sutdy.

3.1 Strategic Variance Analysis – SVA

This study adopts the Strategic Variance Analysis (SVA) as the technique to evaluate the difference of a company's financial results between two periods of time (usually years). To reinforce understanding, "variance analysis is the term applied to the process of specifying the reasons why actual profits in any given period differ from the expected or planned level of profits" (Shank et. al., 1977). It is important to highlight that the concept of SVA discussed here, has nothing to do with the traditional concept of variance applied to statistical analyses.

According to Horngren et al. (2000), the SVA considers the details of some strategic components: growth component, price-recovery component, and productivity component. Furthermore, Sopariwala (2003) extends the analysis and includes a fourth component, namely, capacity underutilization.

One of the ideas originating from SVA is to relate what the financial-operational numbers say about a company and its market strategies used in competition. Porter (2008) posited three major strategies to get competitive advantage: a) cost leadership, when a company pursues operational efficiency to lower its costs; b) product/service differentiation, a strategy focused on providing a product or service with qualities that somehow differ from those of the other competitors; and c) niche-seeking, where a small part of consumers, willing to pay higher prices, are seeking specific premium products/services, but are not served by producers/suppliers (this strategy is characterized by low sales volume and high profit margins.

Searches in traditional journal bases and scientific paper indexing services such as Scopus, Web of Science and Google Scholar about SVA return only a few results on the United States air transportation market. Some examples of research that applied SVA: studies produced by Caster & Scheraga. (2011 and 2013), who analyzed the environment of American aviation at that time, when seven major airlines were competing; the same authors also made an analysis of Alaska Airlines strategic transformation in 2010; Mudde & Sopariwala (2008; 2010; 2014) investigated the strategic execution of Southwest Airlines in 2005; they also developed a paper about the American Airlines case; and published a journal article about the US Airways and America West merger. Rocha (2020) applied SVA to the Brazilian airlines merger between Gol and Webjet.

Basically, SVA is a technical evaluation of the operational situation in a certain year in comparison with a previous year (not necessarily the immediately previous year), inspecting the financial-operational numbers of a company. Although Horngren et al. (2000) have developed this SVA concept for the manufacturing industry, Mudde & Sopariwala (2008; 2010; 2014) adapted the framework for the specific issues of the airline industry.

3.2 SVA Components

In the next set of equations, the subscript word *"actual"* refers to the least recent year analyzed, 2010, while the subscript *"expected"* refers to the most recent year, 2013. The word *"expected"* is used instead of the word planned, because the calculated values are not officially provided by the airline, but it is an expectation based on the previous year's numbers.

As mentioned previously, Mudde *et. al.* (2008) explain that the SVA must be done by breaking it down into four specific components. The **growth component** measures the change of operating revenue caused by variations in Revenue Passenger Kilometers (RPK), keeping sales price, input costs and input-output relationships constant). The variance of this component is caused by changes in market share or in market size. This component is calculated by equations from (1) to (4), from year i to year :

a. Revenue effect of the Growth Component:

$$variance_1 = (revenue_i / RPK_i) \times \left(RPK_j - RPK_i\right) \tag{1}$$

b. Fuel cost effect of the Growth Component:

$$variance_2 = (fuel\ cost/liter_i) \times (used\ fuel\ liters/ASK_i) \times (ASK_{i\ (actual)} - ASK_{j(expected)}) \tag{2}$$

c. Flight-related cost effect of the Growth Component:

$$variance_3 = (flight\ related\ cost/ASK_i) \times (passenger\ load\ factor_i) \times \left(ASK_{i\ (actual)} - ASK_{j(expected)}\right) \tag{3}$$

d. Passenger-related cost effect of the Growth Component:

$$variance_4 = (passenger\ related\ cost/passenger\ emplanements_i) \times \left(passenger\ enplanements_{i(actual)} - passenger\ enplanements_{j(expected)}\right) \tag{4}$$

The **price recovery component** evaluates the variance in the operating revenue due to variations in unit input costs and sales price, holding sales unit and input-output relationships constant. Horngren et al. (2000) suggest that this component indicates a product differentiation strategy: a positive value in the component of price-recovery means that the differentiation strategy produced enough power pricing to the company, so that the passengers were induced to pay a higher amount than the increased costs the company had.

This component is calculated by equations from (5) to (6), from year i to year j:

e. Revenue effect of the Price-Recovery Component:

$$variance_5 = (RPK_j) \times (revenue_j/RPK_j - revenue_i/RPK_i) \quad (5)$$

f. Fuel cost effect of the Price-Recovery Component:

$$variance_6 = (ASK_{j\ (expected)}) \times (used\ fuel\ liters/ASK_i) \times (fuel\ cost/liters_i - fuel\ cost/liters_j) \quad (6)$$

g. Flight-related cost effect of the Price-Recovery Component:

$$variance_7 = (passenger\ load\ factor_j) \times (ASK_{j\ (actual)}) \times (flight\ related\ cost/ASK_i - flight\ related\ cost/ASK_j) \quad (7)$$

h. Passenger-related cost effect of the Price-Recovery Component:

$$variance_8 = (passenger\ enplanements_{j\ (expected)}) \times (passenger\ related\ cost/passenger_i - passenger\ related\ cost/passenger_j) \quad (8)$$

The **productivity component** is the difference in operating revenue produced by variations in the input-output relationships, making sales price and input costs constant. Horngren *et. al.* (2000) indicate that this component may show a tendency of the company to choose a low-cost strategy. Thus, a positive value in productivity component indicates that the company gets its operating revenue from the increase in productivity. This component is calculated by equations (9) to (11), from year i to year j:

i. Fuel cost effect of the Productivity Component:

$$variance_9 = (fuel\ cost/liter)_j \times (ASK_{j(expected)}) \times ((used\ fuel\ liters/ASK)_i - (used\ fuel\ liters/ASK)_j) \quad (9)$$

j. Fuel (ASK) cost effect of the Productivity Component:

$$variance_{10} = (fuel\ cost/liter)_j \times (used\ fuel\ liters/ASK)_j \times (ASK_{j(expected)} - ASK_{i(actual)}) \quad (10)$$

k. Passenger-related cost effect of the Productivity Component:

$$variance_{11} = (cost/passengers\ enplanements)_j \times \left(passenger\ enplanements_{j(expected)} - passenger\ enplanements_{j(real)}\right) \quad (11)$$

Finally, the **capacity underutilization component** measures the difference in respect to the operating income caused by variations of costs of unused capacity between time periods. Sopariwala (2003) proposes that this component shows whether a company achieves success managing its used/unused relationship capacity. This component is calculated by equations (12) to (14), from year i to year j:

l. Variations in flight-related costs relating to unused capacities:

$$variance_{12} = \left(ASK_{j\ (actual)} - RPK_{j(actual)}\right) \times \left((cost/ASK)_i - (cost/ASK)_j\right) \quad (12)$$

m. Variations in flight-related costs of available capacities:

$$variance_{13} = (cost/ASK)_i \times \left(ASK_{i(actual)} - ASK_{j(actual)}\right) \quad (13)$$

n. Variations in flight-related costs of used capacities:

$$variance_{14} = (cost_i/ASK) \times \left(RPK_j - RPK_i\right) \quad (14)$$

If more than one airline is to be compared, it is recommended that the calculated values from (1) to (14) be normalized, dividing the variances by the Revenue Passenger Kilometers (RPK).

4. METHOD AND DATA

In alignment with the studies Caster *et. al.* (2011) conducted, the following information was gathered: **financial data** (revenue and expenses, depreciation, amortization, profit, etc.), **operational data** (revenue enplaned passengers, revenue passenger kilometers (RPK) and available seat kilometers), **fuel data** (total used liters, total fuel cost and average fuel cost per liter). These data are considered sufficient to conduct the analysis.

In order to situate the context in time, a 4 year time frame (2010-2013) was defined for this study: embracing the exact moment of the merger announcement, disclosed in 2010; and the period following the moment when the merger was concluded in 2012. The justification for this period is that the changes triggered by the merger needed a certain time to cause financial and operational impacts in the new company. The SVA is a study of situations at distinct moments (usually years) thus an analysis of the intermediate years was unnecessary.

The primary data sources are the ANAC Air Transportation Annuals (2010, 2013) and ANAC Statistical Data (2010, 2013), both available on the agency's website (only in Portuguese). The date used in this research had to be better organized in several tables, to make it easier to understand the calculation.

Table 3 shows the operational data of the former TAM (2010) and of the current LATAM (2013), while the fuel data for the two years are listed in Table 4. The concept "Enplaned Passengers' considers those who effectively boarded the aircraft and paid for the air ticket. The fuel data used could have been retrieved from the ANP – Agência Nacional do Petróleo (*National Oil Agency*) official website, but the Operational Statement (*DRO – Demonstrativos de Resultado Operacional*) provided the amount of used fuel (in liters) and the total cost spent with fuel. Dividing the first by the second was the way used to come up with the average fuel cost.

	2010	**2013**
Enplaned Passengers	31,515,633	35,902,761
Revenue Passengers Kilometers (RPK)	50,467,259,599.00	59,261,578,110.00
Available Seats Kilometers (ASK)	70,046,837,151.00	74,355,999,311.00

Table 3 – Operational Data, ANAC (2010, 2013).

	2010	**2013**
Used Fuel Liters	2,398,143,381	2,486,504,931
Total Fuel Costs (R$)	**3,374,858,840.00**	**5,278,656,660.00**
Average Fuel Cost (R$/l)	1.40	2.12

Source: *ANAC (2010, 2013)*

Table 4 – Fuel Data, ANAC (2010, 2013).

The financial data obtained from official ANAC Annuals were organized and reclassified in Table 5 according to two major groups: flight related costs (excluding fuel) and passenger related costs. This table is quite similar to the one used by Caster and Scheraga (2011).

	2010	2013
Crew	1,384,702,200.00	1,546,284,400.00
Maintenance	850,197,630.00	1,384,601,190.00
Airport and Air Navigation Fees	593,698,570.00	873,618,640.00

Table 5 – Gathered and Reclassified Financial Data (R$), ANAC (2010, 2013).

The expenses were separated into two groups. The first, Flight Related Costs (excluding fuel), includes factors that directly influence the flight costs such as maintenance and ground organization. Although fuel is obviously related to the flight, following Caster and Scheraga’s (2010) proposal, this component was considered separately due to the traditionally high proportion of the expenses it represents. The second group, Passenger Related Costs, is limited to onboard services and passenger traffic organization, indirectly related to the flight, but directly related to passengers.

Then, some additional necessary data to run SVA were calculated based on Tables 3, 4 and 5, and displayed in Table 6: average revenue per RPK, passenger load factor, expected available seat kilometers (ASK), average RPK per passenger, expected enplaned passengers, average used liters per ASK, average related costs per ASK, average cost per enplaned passenger, idle or unused capacity (ASK) and expected idle or unused capacity (ASK).

	2010	2013
Operating Revenue	10,288,871,650.00	13,265,776,270.00
Revenue Passenger Kilometer (RPK)	50,467,259,599.00	59,261,578,110.00
Average revenue per RPK	0.204	0.224
Revenue Passenger Kilometer (RPK)	50,467,259,599.00	59,261,578,110.00
Available Seats Kilometer (ASK)	70,046,837,151.00	74,355,999,311.00
Passenger Load Factor (%)	72.05%	79.70%
Expected Available Seats Kilometers (ASK)		82,250,628,900.00
Revenue Passenger Kilometer (RPK)	50,467,259,599.00	59,261,578,110,00
Enplaned Passengers	31,515,633	35,902,761
Average RPK per Passenger	1601.34	1650.61
Expected Enplaned Passengers		37,007,493
Used Fuel Liters (l)	2,398,143,381	2,486,504,931
Available Seats Kilometer (ASK)	70,046,837,151.00	74,355,999,311,00
Average Used Liters per ASK	0.0342336	0.0334405
Flight Related Costs	5,332,591,680.00	7,225,631,523.00
Available Seats Kilometers (ASK)	70,046,837,151.00	74,355,999,311.00
Average Flight Related Costs per ASK	0.0761	0.0972
Passenger Related Costs	2,051,335,790.00	2,108,510,260.00
Enplaned Passengers	31,515,633	35,902,761
Average Cost per Enplaned Passenger	65.09	58.73
Revenue Passenger Kilometer (RPK)	50,467,259,599.00	59,261,578,110.00
Available Seats Kilometers (ASK)	70,046,837,151.00	74,355,999,311.00
Idle or Unused Capacity (ASK)	19,579,577,552.00	15,094,421,201.00
Expected Idle or Unused Capacity (ASK)		22,989,050,790.00

Table 6 – Processed Data used in SVA

The variance equations (1) to (14), were used to compile Table 6, based on data from Tables 3 to 6. For each SVA component, the values were summed to get the total of the component. In the end, the numbers of Table 7 indicate what the new company, LATAM, did strategically over the years along the merger process, and the factors that led them to profit or loss, according to further analysis in Section 6.

5. RESULTS

Table 7 displays the compiled results of SVA. Firstly, it is important to note that the airline increased its productivity between the year it announced the merger, and the year immediately after its conclusion. That is, after all, one of the objectives of a merger process. The productivity component generated more than R$ 1 billion of operating profit for the company, supported mainly by reduction of average cost per enplaned passenger (from R$ 65.09 to R$ 58.73); and by the increase of passenger load factors (occupancy rate) in the aircrafts (from 72.05% to 79.70). As a factor affecting productivity increase, it is worth mentioning that in the early 2010s, TAM phased out the four-engine Airbus A340 for long haul flights (Europe), and started operations with two-engine Boeing 777 (greater fuel efficiency).

Growth Component	
Revenue effect of the Growth Component	1,794,040,980
Fuel cost effect of the Growth Component	-584,891,615
Flight-related cost effect of the Growth Component	-669,134,512
Passenger-related cost effect of the Growth Component	-357,465,167
TOTAL	**182,549,686**

Price Recovery Component	
Revenue effect of the Price-Recovery Component	1,185,231,560
Fuel cost effect of the Price-Recovery Component	-2,027,329,290
Flight-related cost effect of the Price-Recovery Component	-1,250,422,530
Passenger-related cost effect of the Price-Recovery Component	235,367,655
TOTAL	**-1,857,152,605**

Productivity Component	
Fuel cost effect of the Productivity Component	138,293,904
Fuel (ASK) cost effect of the Productivity Component	865,173,904
Passenger-related cost effect of the Productivity Component	64,880,910,40
TOTAL	**1,068,348,720**

Capacity Underutilization Component	
Variations in flight-related costs relating to unused capacities	-318,492,287
Variations in flight-related costs of available capacities	-327,927,240
Variations in flight-related costs of used capacities	669,247,639
TOTAL	**22,828,112**

Table 7 – Strategic Variance Analysis TAM/LATAM (2010-2013) (R$)

The price recovery component of the TAM/LATAM merger stands out due to the huge negative value, a loss of R$ 2 billion. This component measures the capacity of an airline to increase fares, according to its increase in operational costs, holding all the rest constant.

It means that the fares charged to passengers could not cover the operational costs, coinciding with the rise of fuel prices throughout this period (from R$ 1,40 in 2010 to R$ 2,12 in 2013, an increase of more than 51%). Figure 2 shows a comparison of the component shares of the expenses. The fuel share increased by almost 5% in four years.

Another significant issue for a bad price recovery component was the increase of flight-related costs (from R$ 0.0761/ASK to R$ 0.0972/ASK, a variation of more than 27%). Table 5 demonstrates that aircraft leasing and insurance costs more than doubled. The handling, cargo and ground organization decreased by more than 4%. This result is interesting because until the year 2018 LATAM was the only airline in Brazil to self-provide the handling services; all the others used third-party companies. That seems to have been an advantage during those years.

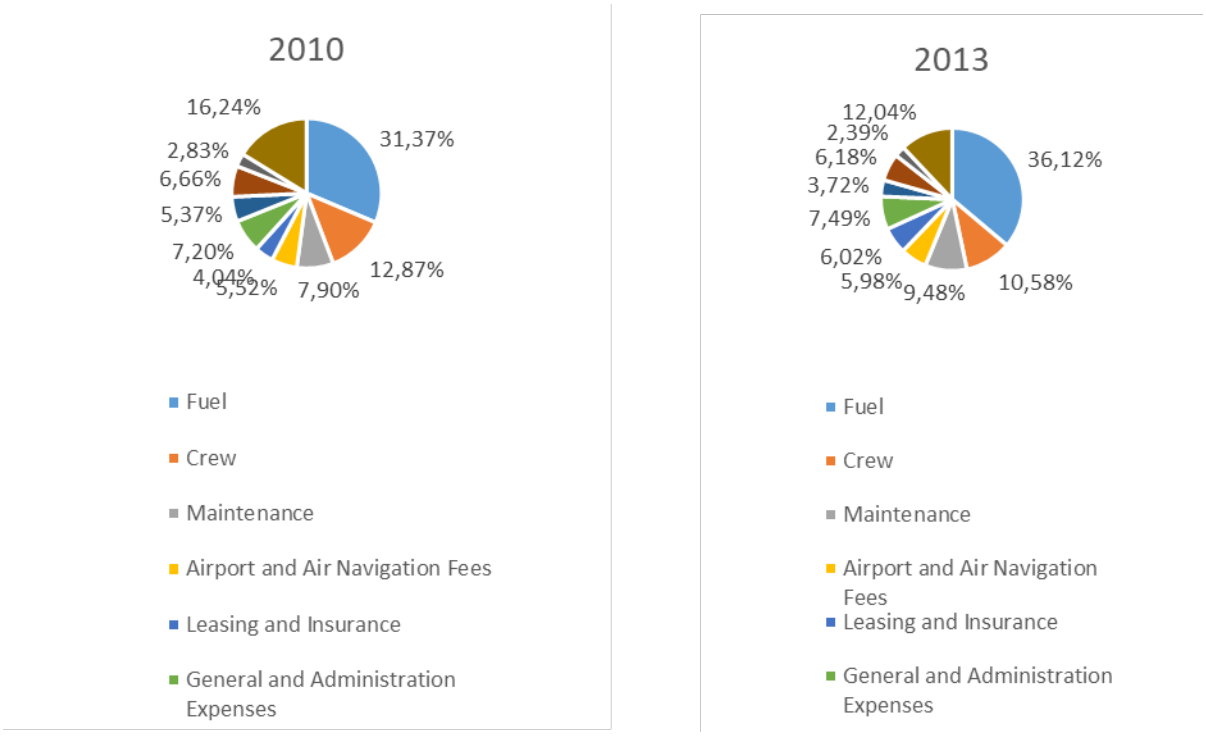

Figura 2 Pizza charts of each expense's share based on Table 5.

The growth component brought a little more than R$ 180 million of operating profit for LATAM, a reasonable value. The main ingredient which may explain this result is the increase of RPK in almost 9 billion flown-passengers-kilometers, influencing the increase of operating revenue in almost R$ 3 billion.

The capacity underutilization component showed a R$ 22 million increase for the company, which denotes that they were capable of reducing the underutilized capacity from more than 19.5 billion available-seats-kilometers to a little more than 15 billion. This ASK reduction implies that the airline succeeded in reducing its cost per unused ASK.

This study is a snapshot of TAM/LATAM’s situation before and after the merger, based on official reports published by the Brazilian regulatory agency of the air transportation market. This means that the financial data provided by ANAC are the only source taken into account.

Another issue is that the research would have been more effective if the data from LAN could have been retrieved from the Chile DGAC online platforms. The data provided for the period had fewer details than the data provided by the Brazilian ANAC, and fundamental information such as the amount of fuel consumed or the cost with maintenance was not available.

It may lack other market considerations such as the expansion of TAM’s main competitor, Gol, to South America and the Caribbean, the premium service offered by Avianca Brasil, or the expansion of Azul, applying effectively the hub-and-spoke model in Campinas Viracopos Airport.

Finally, ideally, the SVA should be applied to other airlines in order to give a broader dimension of the difference between 2010 and 2013 situations.

6. CONCLUSIONS

This research explored the numbers behind the LAN-TAM merger, applying the SVA method, which enabled identification, in the financial/operational balance sheets, of the causes of failure discussed in Section 5 – Results Analysis. As mentioned previously, Horngren *et al.* (2000) suggests that SVA is, *de facto*, more efficient if the data of all players of the industry are cross-referenced. Nevertheless, the SVA numbers, limited to the period between 2010 (merger announcement) and 2013 (the year after the consolidation of the new company), still managed to identify how, throughout the transition years, the expected benefits of the merger had already been overcame by high losses, although these data alone are not sufficient to affirm that the merger failed.

Among exogenous factors (increase of fuel price) and endogenous factors (increase in aircraft leasing and insurance costs, for example), the good productivity component performance emphasizes that a cost leadership strategy was adopted, which is quite reasonable because, naturally, it is one of the main objectives of an airlines merger. Thus, one conclusion that can be drawn is that the success of the productivity component was the fact that enabled LATAM to reduce its passenger-related costs.

On the other hand, a high magnitude price recovery component, but with negative value, indicates that product/service differentiation, was not LATAM’s strategy. It means that a slight increase in fares prices did not cover the operating costs, a recurrent problem in Brazil. In a historically low competition market such as Brazil’s airline industry, one is unlikely to come across a product/service differentiation strategy.

However, LATAM's evolution from a national airline to a transnational one took place with a huge operating loss. Immediately, it was identified with the increase of fuel costs in that time interval. In the early 2010s, the world faced a historical rise in oil prices that led to an increase in fuel costs; Brazil suffered more than other developing countries.

According to ANAC (2017), based on ANP, the average price of jet fuel (QAV) rose from R$ 1.13 per liter in August 2010 to R$ 2.06 per liter in March 2014. In an SVA perspective, this is *de facto* the main evidence of LATAM's huge operating loss, even though that on its own is not sufficient to justify the negative result.

By the end of the 2010 decade, the long-term geopolitical strategy of LATAM's merger, which started almost ten years before, finally seemed to have made its consolidation as the main "Latin American Airline" successful. Figures 3 and 4 display the top 20 airlines by RPK and absolute carried passengers in 2019 (IATA, 2020). It is important to highlight four major clusters with high level competition: United States, Europe, Middle East and China. LATAM is the only Latin American airline in the rankings (Figures 3 and 4).

The local competition in Latin America is quite intense with Azul, Gol, Avianca, Aeromexico and Copa Airlines. However, compared to them, as a global player, in 2019 LATAM was the only one to fly from Sydney to Johannesburg, from Los Angeles to Tel Aviv, from Ushuaia to Toronto, consolidating São Paulo, Santiago and Lima as major hubs.

Figure 3 – Top 20 airlines by Revenue Passenger-Kilometers (RPK) in 2019 according to IATA (2020).

Figure 4 – Top 20 airlines by absolute Carried Passengers in 2019 according to IATA (2020).

In future research, the SVA method can be expanded to other airlines at that time (Gol, Webjet, Azul, Trip and Avianca), comparing all the competitors in the market to provide a better understanding of the scenario.

Also, as this research applied SVA in a time interval that covered a relevant fact to TAM (its merger with LAN), it would be interesting to choose other periods associated to other important facts for Brazil's aviation: the concession and expansion of Guarulhos International Airport in 2013 (LATAM's main hub); the FIFA World Cup 2014; the checked baggage and the onboard food sale deregulation in mid-2017; Avianca Brasil's bankruptcy in 2019 and the COVID-19 Crisis in 2020.

RESUMEN

Los modelos de distribución de ayuda humanitaria ayudan a asignar recursos escasos en contexto de desastre. Estos deben considerar, además de los costos logísticos, los costos de privación como una medida del sufrimiento humano para así evitar una asignación desigual de los suministros.

Las funciones de costo de privación (DCF) comúnmente se estiman utilizando métodos de elección discreta, suponiendo que los afectados buscan maximizar su bienestar tomando decisiones racionalmente. Sin embargo, después de los desastres, las personas están bajo estrés, presión y trauma, y pueden adoptar comportamientos que no sean compensatorios ni basados en utilidad. Este artículo cuestiona el uso de la maximización de la utilidad para estimar las DCF comparando sus resultados con un enfoque de minimización aleatoria del arrepentimiento y un método que combina reglas de decisión basadas en el arrepentimiento y la utilidad para representar los mecanismos de elección.

Se estimaron las DCF para diversos suministros críticos utilizando datos de preferencias declaradas de dos casos de estudio: Colombia y Ecuador. Los resultados sugieren que los costos de privación tienen valoraciones significativamente diferentes dependiendo del mecanismo de decisión utilizado; las DCF estimadas usando maximización de utilidad aleatoria arrojaron costos más altos.

Esto sugiere que, al menos durante la ventana de tiempo analizada, las personas aspiran a maximizar su bienestar. Además, los resultados muestran que los costos de privación dependen del contexto y no deben transferirse directamente. Finalmente, se muestra que las funciones de costos de privación para múltiples productos se pueden agregar por separado en la misma función objetivo al planificar las operaciones. Esta investigación es el primer intento de considerar diferentes heurísticas de elección para estimar DCFs, y es la primera en comparar datos de diferentes ubicaciones. Las implicaciones de estos hallazgos brindan a los administradores y planificadores de desastres nuevos desafíos y direcciones de investigación.

1.INTRODUCCIÓN

En medio de los desastres, los sobrevivientes a menudo enfrentan escasez de alimentos, agua y otros bienes esenciales durante períodos prolongados. Por ello, existe una mayor demanda de suministros esenciales y un aumento en el sufrimiento de las personas afectadas, debido a la falta de acceso a suministros críticos como alimentos o agua. Con estas necesidades en mente, en la literatura sobre gestión de operaciones e investigación de operaciones se han propuesto modelos de distribución de socorro para establecer la mejor manera de asignar recursos limitados en el contexto de desastres. Los desafíos asociados a los modelos existentes son la determinación de una función objetivo apropiada y la comprensión de las compensaciones entre los objetivos múltiples y conflictivos de la entrega de ayuda: eficiencia, eficacia y equidad.

Equilibrar estos objetivos y comprender cómo cada uno contribuye al alivio del sufrimiento es difícil, al igual que la modelación dichos objetivos cuantitativamente para que se puedan utilizar modelos de optimización (Gralla et al., 2014).

La mayoría de las metodologías disponibles utilizan funciones objetivo de logística comercial como base para la toma de decisiones, lo cual es inadecuado para fines humanitarios (Macea, et al., 2018). En este contexto, la mejor forma de asignar los escasos recursos es minimizando los costos sociales que, además de los tradicionales costos operativos, consideran los costos de privación de la población impactada por el desastre (Holguín-Veras et al., 2016). Los costos de privación son una valoración económica del sufrimiento que experimentan las personas que no tienen acceso a suministros críticos; encontrar un método apropiado para cuantificarlos es fundamental para los tomadores de decisiones (Shao et al., 2020).

Investigaciones recientes han propuesto experimentos de elección discreta y valoración contingente como métodos para estimar las funciones de costo de privación. En estos enfoques, se asume que los individuos afectados son racionales y tratarán de maximizar su bienestar a la hora de tomar decisiones.

Sin embargo, las personas afectadas por desastres toman decisiones en condiciones de estrés, presión y trauma, y se pueden esperar comportamientos que no son sistemáticos y racionales. Dado que el uso de supuestos de comportamiento poco realistas podría producir estimaciones de costos de privación sesgadas, esta investigación cuestiona las premisas de comportamiento racional, compensatorio y maximizador de la utilidad utilizadas para estimar las funciones de costos de privación en las metodologías actuales.

En este artículo, evaluamos diferentes heurísticas de elección, distintas a la maximización de la utilidad aleatoria para estimar las funciones de costo de privación de agua, alimentos y un kit que contiene ambos. Estimamos las funciones utilizando enfoques de minimización de arrepentimiento aleatorio (RRM por sus siglas en inglés) (Chorus et al., 2008), utilidad modificada aleatoria (RMU por sus siglas en inglés) (Chorus et al., 2013) y maximización de utilidad aleatoria (RUM por sus siglas en inglés) (Mcfadden, 1981) con datos recopilados en áreas afectadas por desastres previos para determinar el efecto de los supuestos de comportamiento en las funciones de costos de privación. El objetivo es comparar las funciones resultantes e identificar si tales supuestos se cumplen en el contexto de desastres.

El resto del artículo está organizado de la siguiente manera. La sección 2 incluye una descripción general de la literatura relevante; La Sección 3 presenta la metodología utilizada en este estudio; La sección 4 analiza el proceso de recopilación de datos junto con un análisis descriptivo de la muestra; La sección 5 describe las especificaciones y los resultados del modelo; y la Sección 6 analiza las implicaciones derivadas de los resultados. El artículo concluye en la Sección 7.

2. ESTADO DEL ARTE

Las operaciones humanitarias requieren interpretaciones innovadoras de la equidad en términos de asignación de recursos, brindando una respuesta eficaz y eficiente que apoye a la población impactada. La priorización efectiva de la entrega es crucial en este tipo de operaciones, incluso cuando es inevitable que algunas necesidades se satisfagan antes que otras (Balcik & Smilowitz, 2020). Sin embargo, como mencionan Gupta et al. (2016), la equidad no parece estar suficientemente cubierta en el campo de la toma de decisiones.

Últimamente, lograr la equidad ha sido una consideración fundamental en muchos estudios relacionados con la logística humanitaria (Balcik & Smilowitz, 2020). A pesar de tales esfuerzos, las funciones objetivo comúnmente formuladas en las investigaciones existentes sobre logística humanitaria descuidan los efectos del sufrimiento humano o los consideran únicamente mediante el uso de medidas indirectas y penalidades. Estos enfoques son limitados, ya que no pueden dar cuenta correctamente de los complejos efectos no lineales asociados con el sufrimiento humano experimentado por los beneficiarios de la ayuda a lo largo del tiempo (Holguín-Veras et al., 2012).

El concepto de costos de privación surgió en las operaciones de distribución de socorro para incluir el sufrimiento humano.
Si los costos reales de privación que enfrentan los individuos son significativos, las medidas aproximadas no pueden representar correctamente la complejidad y las características (por ejemplo, demandas no aditivas y naturaleza no lineal) de la privación.

Holguín-Veras et al. (2016) fueron los primeros en estimar funciones de costo de privación (DCF por sus siglas en ingles) para el agua potable utilizando el método de valoración contingente y proporcionaron una mejor manera de evaluar los impactos de la logística de entrega de ayuda.

Utilizando el mismo contexto, Macea et al. (2018) estimaron un DCF para agua potable a través de modelos de elección discreta. Estimaron modelos multinomiales de tipo logit y concluyeron que ignorar los efectos de la privación, o estimar incorrectamente su valor económico, resulta en una asignación inadecuada de recursos. Cantillo et al. (2018) estimó los costos de privación de un kit de alimentos básico, incluida el agua. Propusieron modelos RUM que incluían heterogeneidad de los gustos sistemática y aleatoria, y utilizaron modelos logit mixtos para reflejar cómo varía el impacto de las decisiones logísticas en función de las características socioeconómicas de los individuos. Macea et al. (2018) estimaron los DCF para un kit de alimentos básico utilizando modelos Logit mixtos y modelos híbridos con variables latentes que consideran la percepción del riesgo, la cultura de seguridad y la confianza en los sistemas de respuesta a emergencias. Finalmente, Delgado-Lindeman et al., (2019) estimaron la disposición individual a pagar para evitar el sufrimiento que experimentan los pacientes que no reciben asistencia inmediata durante una emergencia médica; utilizaron preferencias declaradas y modelos logit mixtos. A excepción de Holguín-Veras et al. (2016), todos los estudios de investigación mencionados anteriormente emplearon un método de elección declarada con modelos de elección discreta formulados utilizando un paradigma de maximización de la utilidad aleatoria para estimar los DCF, utilizando desastres en el contexto colombiano como caso de estudio.

Usando un enfoque diferente, Wang et al. (2017) propuso un nuevo método para cuantificar el sufrimiento humano, utilizando una escala de calificación numérica. Las funciones estimadas con los datos de la escala de calificación numérica se definen como funciones de nivel de privación y brindan información sobre el grado (en lugar del valor económico) del sufrimiento humano causado por la falta de acceso a un bien o servicio. No obstante, los niveles de privación no se pueden utilizar directamente con los costos logísticos en la misma función objetivo, y son más difíciles de calcular y analizar que los costos de privación (Shao et al., 2020).

Aunque la inclusión de una medida de sufrimiento es ideal, cuantificarlo sigue siendo complicado. No es posible desarrollar modelos precisos para representar sistemas que no se comprenden bien.

Una vez que comienzan las operaciones humanitarias, las personas afectadas suelen decidir entre esperar hasta que llegue la ayuda y trasladarse a otro lugar en busca de suministros esenciales para sobrevivir. El supuesto más común en este proceso está asociado con individuos que intentan maximizar su bienestar mientras están sujetos a ciertas restricciones socioeconómicas. En otras palabras, la situación se trata como un problema de maximización de la utilidad en el que los individuos siguen comportamientos racionales.

La literatura relevante no aborda adecuadamente la ansiedad psicológica, el estrés, la presión y sus efectos en la recuperación de desastres (Hu & Sheu, 2013). Se han realizado estudios para esclarecer los procesos de reacción al estrés traumático, aprendizaje y memoria, duelo, ansiedad y miedo (Cohen, 2008). Ante el peligro, los sistemas cognitivo y afectivo responden y las funciones de identificación / evaluación se centran en la supervivencia. Dado que las reacciones de estrés afectan el comportamiento según el tipo de evento traumático, es importante analizar si las especificaciones actuales de DCF podrían ser poco realistas desde una perspectiva conductual y, por lo tanto, arrojar estimaciones sesgadas. También es importante considerar el efecto que el contexto podría tener en las estimaciones de DCF y determinar si los resultados son transferibles entre contextos.

3. METODOLOGÍA

3.1 Enfoque econométrico

La pérdida de bienestar debido al impacto de un desastre se puede medir utilizando las funciones de costo de privación (DCF), que dependen del tiempo que las personas han pasado sin acceso a un bien o servicio (tiempo de privación). Los métodos de valoración económica tienen como objetivo estimar la disposición a pagar (WTP por sus siglas en inglés) de un individuo por un bien o servicio. Estas técnicas suelen recurrir a datos de preferencias reveladas (PR) o preferencias declaradas (PD).

Los experimentos de valoración contingente (CV) y de PD son las técnicas más utilizadas para estimar los DCF. Los costos de privación se pueden aproximar mediante modelos econométricos que estiman el cambio de utilidad (o arrepentimiento, como se detalla a continuación) producido por un aumento en el tiempo de privación. Dado un modelo de elección discreta estimado a partir de experimentos de PD, una vez estimados los parámetros que explican la elección de los individuos, es posible calcular los valores de la WTP utilizando la tasa marginal de sustitución o el cambio en el excedente del consumidor.

La tasa marginal de sustitución, que representa, en este caso, el valor subjetivo del tiempo de privación, se puede estimar mediante la Ecuación (1) (Ben-Akiva & Lerman, 1985; Rizzi & Ortúzar, 2003):

$$SVDT_n = \frac{\partial V_n / \partial DT_n}{\partial V_n / \partial I_n} \qquad (1)$$

donde Vn representa la utilidad sistemática (o arrepentimiento, como se detallará a continuación) del individuo n, DTn representa el tiempo de privación e In representa el ingreso.

El resultado es una medida de cuán dispuesto está el individuo a pagar por ahorrar tiempo de privación si la utilidad permanece constante.

El cambio total del bienestar (ΔW) producido por la privación podría calcularse como el producto de la SVDT y la variación del tiempo de privación. Como los costos de privación no son lineales y el SVDT no es constante en el tiempo, es necesario calcular ΔW para cada unidad de tiempo integrando entre los límites del tiempo de privación inicial (DT0) y el tiempo de privación final (DT1). También se puede estimar discretizando el atributo de tiempo y agregando cada unidad como se expresa en la Ecuación (2):

$$\Delta(W)_n = \sum_{DT_0}^{DT_1} WTP_n(DT) \qquad (2)$$

Las DCF deben ser monótonamente crecientes, no lineales y convexas con respecto al tiempo de privación (Holguín-Veras et al., 2013). Para estimar los DCF, es necesario especificar una transformación funcional (G) en el atributo de tiempo de privación; se implementó el tipo Box-Cox (Gaudry & Wills, 1978). La transformación de Box-Cox de una variable positiva x es continua para todos los valores del parámetro de potencia τ y se puede definir como (3):

$$x^{(\tau)} = \begin{cases} \frac{(x^{\tau}-1)}{\tau}, & si\ \tau \neq 0 \\ \log\ (x), & si\ \tau = 0 \end{cases} \qquad (3)$$

3.2 Enfoque de modelación

En este articulo estimamos los DCF siguiendo las tres heurísticas que se describen a continuación para identificar la que mejor se adapte al proceso de toma de decisiones de las personas en el contexto de desastres.

3.2.1 Maximización de la utilidad aleatoria (RUM).

Este paradigma asume que los individuos pertenecen a una población homogénea, actúan racionalmente y poseen información perfecta sobre las alternativas disponibles, eligiendo siempre la opción que maximiza su utilidad. La utilidad U_{ni} (Ver Ecuación 4) percibida por un individuo n al elegir la alternativa i, es una medida que se utiliza para agregar todas las características de la alternativa en una sola figura de mérito (Mcfadden, 1981).

$$U_{ni} = V_{ni} + \varepsilon_{ni} = \sum_k \beta_k x_{ik} + \varepsilon_{ni} \quad (4)$$

donde Vni representa la parte observada de la utilidad capturada por una combinación lineal de coeficientes βk asociados con k atributos x_k. εni se refiere al término de error que representa la parte no observada de la utilidad que se supone que es independiente e idénticamente distribuida (iid) siguiendo una distribución de valor extremo. Corresponde a la formulación más utilizada, denominada modelo Multinomial Logit (MNL) (McFadden, 1973). Dada la distribución supuesta del término de error, la probabilidad de elección de MNL para un modelo RUM se calcula utilizando la Ecuación (5).

$$P_{ni} = \frac{\exp(V_{ni})}{\sum_j \exp(V_{nj})} \quad (5)$$

3.2.2 Minimización del arrepentimiento aleatorio - RRM (Chorus et al., 2008)

El modelo basado en RRM postula que, al elegir entre alternativas, los tomadores de decisiones apuntan a minimizar el arrepentimiento aleatorio de forma anticipada. Esta hipótesis tiene sus raíces en la teoría del arrepentimiento (Bell, 1982; Loomes & Sugden, 1982), en la que el mecanismo de elección equivale a elegir la alternativa que se asocia con el arrepentimiento menos esperado.

El nivel de arrepentimiento aleatorio anticipado está asociado con la alternativa considerada i y está compuesto por un arrepentimiento sistemático Ri y un término de error aleatorio. El término de error representa una heterogeneidad no observada en el arrepentimiento. Ri se define como la suma de todos los arrepentimientos binarios asociados con la comparación de la alternativa considerada con cada una de las otras alternativas en el conjunto de opciones. (Chorus, 2010) propuso una aproximación suavizada del modelo de arrepentimiento como en la Ecuación (6):

$$RR_{in} = \sum_{j \neq i} \sum_m \ln\left(1 + \exp\left(\beta_m * \left[x_{jmm} - x_{imm}\right]\right)\right) + \varepsilon_{in} \quad (6)$$

Inspirado por el RUM, en el modelo RRM clásico, el negativo del término de error ε se asume iid tipo I Valor extremo distribuido, lo que resulta en la fórmula logit de forma cerrada para las probabilidades de elección (Ver Ecuación 7):

$$P_{in} = \frac{e^{-R_{in}}}{\sum_J e^{-R_{jn}}} \qquad (7)$$

La investigación ha encontrado que la minimización del arrepentimiento es un determinante particularmente importante del proceso de toma de decisiones cuando el tomador de decisiones percibe las opciones como complicadas y relevantes para su bienestar (Pieters & Zeelenberg, 2007).

3.2.3 Utilidad modificada aleatoria (RMU)

Chorus et al. (2013) propuso un marco integrado que establece que, si bien algunos atributos pueden procesarse utilizando la maximización de la utilidad, otros pueden procesarse utilizando otra regla como la minimización del arrepentimiento. Suponiendo que los primeros q atributos se procesan usando RUM, mientras que los atributos M - q restantes se procesan en términos de una regla RRM, la forma RMU para la alternativa i (donde el error aleatorio es idd valor extremo tipo I-distribuido) puede expresarse como en la Ecuación (8):

$$RMU_i = MU_i + \varepsilon_i = \sum_{m=1\ldots,q} \beta_m x_{im} - \sum_{m=q+1,\ldots,M} \sum_{j\neq i} ln\{1 + exp[\beta_m(x_{jm} - x_{im})]\} + \varepsilon_i \qquad (8)$$

Las probabilidades de elección que consideran la maximización de esta función de utilidad modificada a través de alternativas se pueden estimar usando la Ecuación (9):

$$P_i = \frac{exp(RMU_i)}{\sum_{j=1,\ldots,J} exp(RMU_j)} \qquad (9)$$

4.CASOS DE STUDIO

Diseñamos dos encuestas basadas en la revisión de la literatura y las condiciones que pueden afectar la preparación, los planes de respuesta y las privaciones después de los desastres. Las encuestas recopilaron características socioeconómicas de los encuestados, junto con sus elecciones en un conjunto de escenarios de preferencia declarados. Los escenarios contextualizaron a las personas en una situación de desastre en la que su hogar y los suministros disponibles han sido destruidos, lo que los ha llevado a enfrentar la privación de alimentos y agua. Cada individuo respondió nueve escenarios de elección.

Tuvieron que decidir si comprar alguno de los bienes esenciales disponibles (es decir, solo agua, solo alimentos o ambos si era posible), o esperar un poco más hasta que se les proporcionara ayuda de socorro gratuita.

La última opción haría que el individuo ahorrara dinero para otras necesidades, teniendo en cuenta que tenía limitaciones presupuestarias y ya ha experimentado algún tiempo de privación.

El único dinero disponible para los supervivientes era el dinero que llevaban en el bolsillo.

Las encuestas se refieren a dos casos de estudio diferentes. El primer caso fue en Colombia, en el contexto de inundaciones y deslizamientos de tierra. El segundo caso se refiere a un terremoto en Ecuador. Las encuestas se aplicaron en el otoño de 2019. La Tabla 1 muestra los niveles de atributos utilizados en el diseño.

Atributo	**Niveles de los atributos (Colombia)**	**Niveles de los atributos (Ecuador)**
Privación actual de agua y comida (hr)	4, 8, 16, 24	4, 8, 16, 24
Espera adicional por ayuda gratis (hr)	4, 8, 12	4, 8, 12
Presupuesto disponible	50000, 60000, 80000, 100000 (COP*)	20, 24, 32, 40 (USD)
Precio del agua	10000, 20000, 30000, 40000 (COP*)	4, 8, 12, 16 (USD)
Precio de la comida	20000, 30000, 40000, 50000 (COP*)	8, 12, 16, 20 (USD)

***1 USD = 3,395 COP**

Tabla 1 – Niveles de los atributos de la encuesta

Se recolectaron 3.474 observaciones en el caso colombiano, pero fueron eliminadas 567 porque estaban incompletas. La encuesta se aplicó en noviembre de 2019 en 5 municipios diferentes de la región caribeña del país: Barranquilla (34%), Cartagena (29%), Manatí (14%), Santa Lucía (13%) y Campo de la Cruz (11%). Esta región se considera propensa a desastres, ya que se ha visto afectada continuamente por desastres de este tipo durante el invierno y la temporada de lluvias del país.

En Ecuador se recolectaron 3.537 observaciones. Se eliminaron 1,227 debido a respuestas incompletas de la encuesta. La encuesta se aplicó en agosto de 2019 en 6 municipios diferentes: Jama (21%), Jipijapa (20%), Pedernales (18%), Esmeraldas (15%), Portoviejo (14%) y Guayaquil (12%). Esta región también se considera propensa a desastres, ya que anteriormente ha sido afectada por terremotos.

Los datos recopilados representan una amplia gama de características socioeconómicas de las poblaciones; el resumen se puede encontrar en la tabla 2.

Tabla 2- Estadísticos de la muestra

5. RESULTADOS DE MODELACIÓN

Con los parámetros resultantes de cada formulación, estimamos las WTP para agua, alimentos y un kit de agua / alimentos. También estimamos los DCF correspondientes. A continuación, presentamos los resultados para cada heurística de elección y estudio de caso. Consulte el Apéndice para encontrar el diccionario de variables y las especificaciones del modelo para cada bien y heurística de elección.

5.1 Modelos de elección discreta

La Tabla 3 muestra los resultados de la estimación para el conjunto de datos de Colombia y cada tipo de modelo de elección. Los resultados indican que el costo asociado a los bienes ofrecidos, el presupuesto disponible y el tiempo que las personas están privadas de agua y alimentos son atributos importantes en la decisión de compra.

Además de esperar que los parámetros RUM tengan el mismo signo que los del RRM, es importante notar que los parámetros RUM tienen diferentes interpretaciones en comparación con la formulación RRM. En un modelo RRM, el parámetro resultante representa el cambio en el arrepentimiento causado por un aumento de una unidad en el valor del atributo de una alternativa no elegida en comparación con el valor del atributo de la opción elegida (Masiero et al., 2019).

En el modelo RMU, la interpretación depende de si el atributo se formula como basado en la utilidad o basado en el arrepentimiento.

La Tabla 4 muestra los resultados de la estimación para el caso de Ecuador. Al igual que en el contexto colombiano, el costo asociado a la compra de los bienes, el presupuesto disponible y el tiempo de privación resultaron ser atributos importantes en la decisión de compra.

En ambos contextos los signos del costo, los tiempos de espera tanto para el agua como para los alimentos y los parámetros presupuestarios fueron consistentes y esperados. También se encontró que los parámetros λ de la transformación box-cox asociados con el agua y los alimentos en ambos contextos eran significativos, lo que refuerza la naturaleza no lineal de los costos de privación.

Tabla 4 – Parámetros estimados (Ecuador) Nota: nivel de confianza *95%

Después de comparar los resultados de las tres formulaciones del modelo y ambas muestras, podemos ver que las log-verosimilitudes finales, los indicadores Rho y AIC son prácticamente iguales entre las formulaciones. La literatura respalda que las diferencias en el ajuste del modelo y el rendimiento predictivo entre los modelos RUM, RMU y RRM suelen ser pequeñas (Chorus et al., 2014), lo que también se confirma con nuestros hallazgos. Además, no existe consenso en la literatura sobre qué formulación de modelo proporciona el mejor ajuste, ya que los resultados son diversos. Sin embargo, las implicaciones derivadas de los modelos, como los pronósticos de participación de mercado y las estimaciones de la disposición a pagar, pueden variar sustancialmente (Chorus et al., 2014), como se mostrará a continuación.

5.2 Funciones de costo de privación (DCFs)

Se calcularon los costos de privación generados cada hora para una ventana de tiempo de 36 horas de privación (tiempo sin comer, beber o ambas). Luego, se acumularon los valores para graficar las DCF para cada bien y para cada formulación del modelo. Para calcular los costos de privación se usaron los parámetros resultantes en la sección 5.1 y las especificaciones de cada heurística de elección (ver Apéndice).

La Figura 1 muestra las curvas de costo de privación por privación de agua para ambos contextos estudiados. En general, las curvas RUM arrojan mayores costos de privación en ambos casos para la ventana de tiempo completo analizada, seguida de la estimación de

RRM y finalmente de las estimaciones de RMU. En las primeras horas de privación, los costos asociados tienden a ser similares entre las tres especificaciones, pero se vuelven más diferenciados a medida que aumenta el tiempo de privación. A medida que pasa el tiempo, es más conservador usar RUM dado que arroja estimaciones más altas, lo que sugiere que si las personas maximizan su bienestar, reconocen un valor más alto de su privación. Como se señaló en la sección anterior, se confirma la no linealidad de las DFC (esperada por definición), dados los parámetros de transformación box-cox resultantes (λ). En cada una de las tres heurísticas de elección, los costos de privación estimados resultaron ser más altos en el caso de Ecuador. Este resultado podría explicarse por las diferencias en contextos socioeconómicos, por el tipo de desastre enfrentado, indicadores de percepción, entre otros aspectos, todos los cuales deben ser analizados en profundidad en futuras investigaciones.

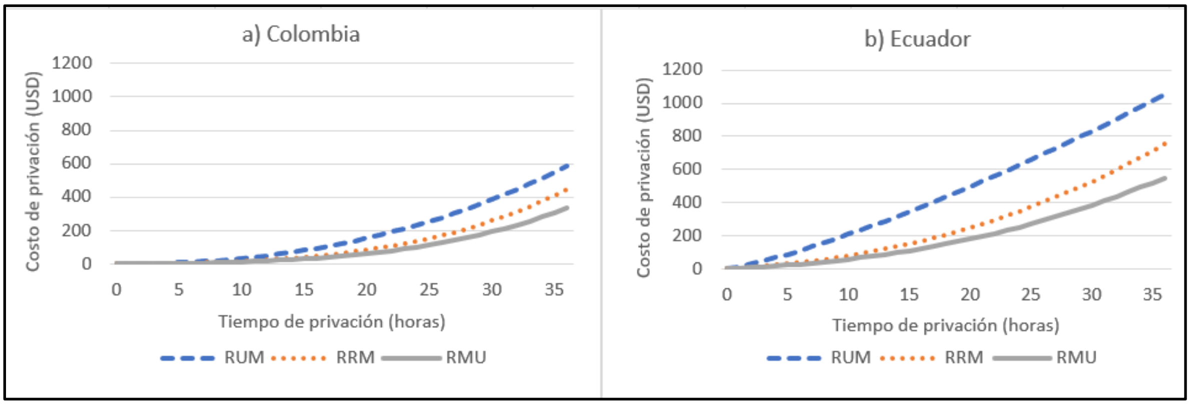

Figura 1 – DCF del agua

La Figura 2 muestra las curvas de costo de privación asociadas con la privación de alimentos para ambos casos de estudio. Aquí, la forma de los DCF es más similar entre los dos contextos y, como se encontró antes, la estimación de RUM siempre arroja costos de privación más altos, seguidos por las estimaciones de RRM y RMU, respectivamente.

Al contrario de lo que sucedió con las estimaciones de agua, los costos de privación son significativamente más altos para la muestra colombiana. Los resultados anteriores sugieren que los colombianos consideran que los alimentos son más críticos que el agua, dada la magnitud de los costos de privación asociados con cada bien analizado. Lo contrario ocurre cuando se analizan las decisiones que toman las personas en Ecuador. Este resultado sugiere que se debe analizar el efecto del tipo de producto, junto con el contexto en el que ocurre el desastre.

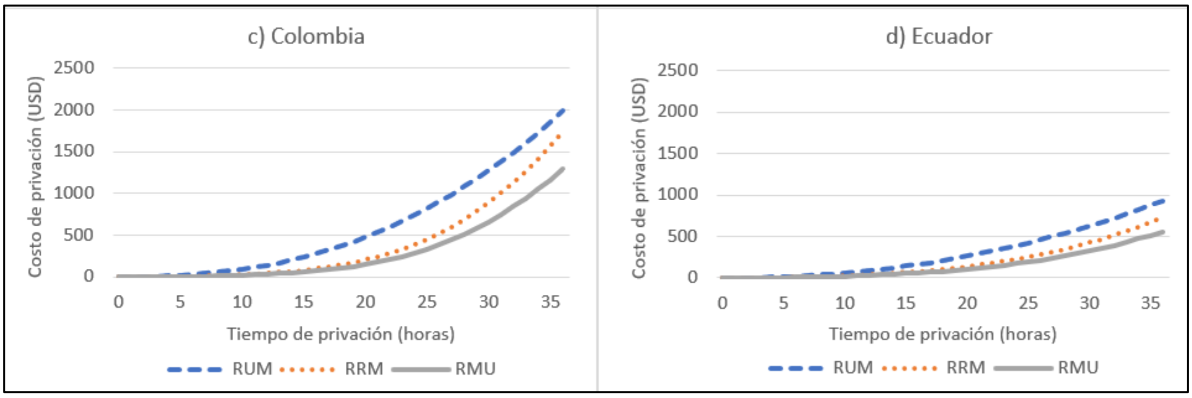

Figura 2- DCF de comida

La Figura 3 muestra las curvas de costo de privación asociadas con la privación de agua y alimentos simultáneamente (como un kit). Considerando que en el presente análisis el efecto de la privación de agua se consideró independiente del efecto de la privación de alimentos, la estimación conjunta del costo de privación de agua y kit de alimentos resultó ser la suma de los costos de privación de agua y comida. En general, las funciones estimadas para el estudio de caso colombiano son un poco más convexas y arrojan valores más altos, lo que confirma que el contexto local juega un papel en la estimación de las funciones de costos de privación. Por lo tanto, no se aconseja la transferibilidad directa de la estimación del DCF, incluso si las áreas en estudio pertenecen a la misma región geográfica (De Vries & Van Wassenhove, 2020), incluso entre países con características socioeconómicas similares.

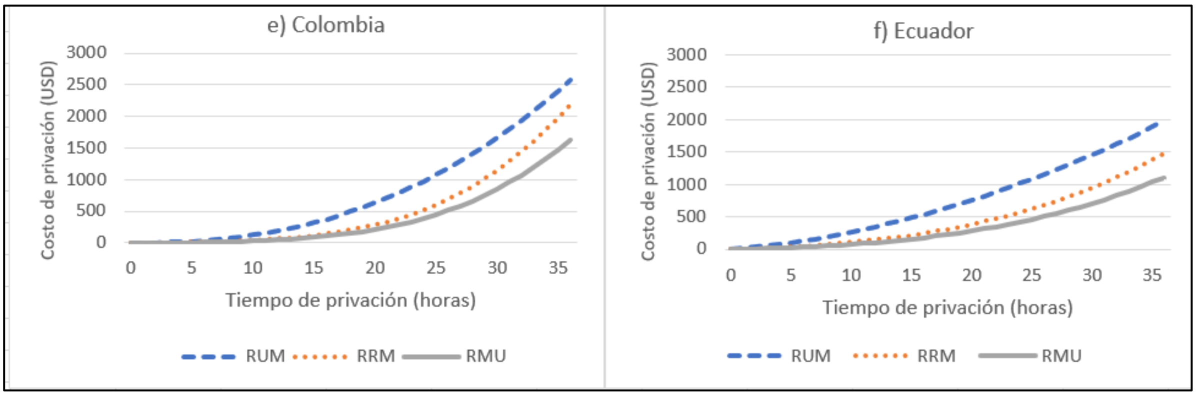

Figura 3- DCF de kit (agua y comida)

6. IMPLICACIONES DE LOS RESULTADOS

Este es el primer estudio que estima DCF para bienes esenciales fuera del contexto colombiano, y el primero en evaluar el efecto que la heurística de elección utilizada puede tener sobre las estimaciones resultantes.

En todos los casos considerados, la estimación basada en la heurística de elección RUM siempre arrojó valores de costo de privación más altos, lo que sugiere que, al menos para la ventana de tiempo analizada y para las condiciones propuestas en este estudio, el uso de esta heurística de elección sigue siendo la opción más recomendada. Como muestran Holguín-Veras et al. (2013), cuando las funciones de costos de privación sobrestiman los costos del sufrimiento humano, los patrones de entrega de las ayudas están determinados por los valores de los costos de privación, lo que garantiza que todas las personas de la comunidad afectada reciban ayuda.

Al final, una sobreestimación de los costos de privación no cambiará el orden en que se atenderán los puntos de distribución (POD), donde se ubica la población afectada. Sin embargo, dado que los parámetros de los modelos y el ajuste entre las formulaciones eran casi iguales, no hay suficiente evidencia para sugerir qué heurística de elección describe mejor el comportamiento de elección de los individuos. Cabe destacar que los resultados no desacreditan las estimaciones actuales de las funciones de costos de privación, ni sugieren que no sean válidas.

Resultados adicionales de este estudio muestran diferencias significativas en las estimaciones del costo de las privaciones entre los estudios de caso de Colombia y Ecuador, lo que respalda la conclusión de De Vries & Van Wassenhove (2020) de que la rentabilidad de las operaciones de logística humanitaria es muy específica del contexto. Por lo tanto, este estudio confirma empíricamente que la generalización de los resultados es crucial y no se recomienda la transferibilidad directa de la estimación de DCF. Esto plantea grandes desafíos para las organizaciones de socorro, ya que no deben utilizar un DCF para desarrollar planes de distribución de socorro en un país o ubicación geográfica que sea diferente del lugar donde se recopilaron los datos para las estimaciones. Esto agrega una nueva tarea a las organizaciones de ayuda. Si se quieren desarrollar planes equitativos, se necesitan DCFs y, con ello, se deben recopilar y analizar datos para estimarlos.

Además, los resultados sugieren que incluso la percepción de qué bien es más crítico después de los desastres depende del contexto. En el estudio colombiano, la falta de alimentos produce mayores costos de privación que la falta de agua, contrario al estudio ecuatoriano, en el que el agua parecía ser más crítica para los individuos en el contexto analizado.

Finalmente, las funciones de costo de privación estimadas para un kit de alimentos + agua resultaron ser la suma de las funciones de costo de privación para agua y alimentos por separado. Esto confirma empíricamente que, y las funciones se pueden incluir una por una en la misma función objetivo para optimizar el diseño de los planes de distribución de la ayuda.

7. CONCLUSIONES

En este artículo, se utilizaron modelos de elección discreta como método de valoración económica para estimar las funciones de costo de privación de bienes críticos (es decir, agua, alimentos y un equipo que contenga ambos) en el contexto de un desastre. Se diseñó e implementó una encuesta en dos casos de estudio diferentes. Presentamos un conjunto de escenarios de preferencia declaradas que fueron respondidos por personas de Colombia en el contexto de inundaciones y deslizamientos de tierra, y de Ecuador, en el contexto de un terremoto. En cada escenario de elección, las personas tenían que elegir entre comprar agua, comprar alimentos, comprar ambos artículos (si era posible con el presupuesto) o esperar más tiempo para que llegara la ayuda gratuita, dadas algunas limitaciones presupuestarias.

Los modelos de elección se formularon evaluando tres heurísticas de elección: maximización de utilidad aleatoria (RUM), minimización del arrepentimiento aleatorio (RRM) y utilidad modificada aleatoria (RMU). El objetivo fue comparar resultados y analizar cuál refleja mejor el comportamiento de las personas en situaciones de desastre y las diferencias en los costos de privación estimados.

En términos del ajuste de los modelos, los resultados fueron muy similares entre las heurísticas de elección, por lo que no se pueden sacar conclusiones sobre qué mecanismo de elección explica mejor el comportamiento de elección de los individuos. Las diferencias significativas en las estimaciones entre los dos estudios de caso sugieren que las funciones de costos de privación dependen del contexto.

Además, varían en función del bien / oferta analizada. En este estudio, la disposición a pagar por el agua y los alimentos después de un desastre fue bastante diferente en los dos países. En Ecuador, la privación de agua parece ser más crítica que en Colombia. Si bien el resultado anterior podría explicarse en parte porque el experimento colombiano consideró escenarios de inundaciones, al final sugiere que el contexto del desastre podría jugar un papel relevante en el proceso de toma de decisiones.

Los alimentos, por el contrario, fueron valorados casi el doble en el contexto colombiano en comparación con los valores obtenidos para Ecuador.

Además, las diferencias no son solo una cuestión de contexto. Dependiendo del desastre, los costos de privación por producto básico pueden variar ampliamente. Por lo tanto, la investigación adicional debe centrarse en estimar las funciones de costos de privación para diferentes artículos y al mismo tiempo considerar diversos escenarios de desastres.

Los hallazgos también sugieren que, para los contextos estudiados, RUM sigue siendo la opción heurística más recomendada para estimar los DCF. Como se muestra en la literatura anterior (Holguín-Veras et al., 2013), usar este enfoque arroja valores económicos más altos, y usar una función que sobreestima los costos reales de privación no cambiará el orden en que los puntos de distribución (POD). Por lo tanto, se podrían desarrollar planes de distribución de socorro.

Finalmente, como se muestra en el kit que contiene agua y alimentos, las funciones de costos de privación para múltiples productos no requieren estimaciones complejas. El DCF de cada bien podría incluirse por separado en la misma función objetivo al diseñar planes de distribución de socorro.

Despite the rigor of the research, this study has some limitations. Given this is the first study that proposes DCFs estimations using alternative choice heuristics, the results are not conclusive, and require further research. More research focused on different choice heuristics, critical supplies, and with data collected in various disaster contexts is needed to gather more evidence. Nonetheless, the findings discussed here provide key insights into the choice behavior of individuals after disasters. We empirically confirm that DCFs should not be transferable, as it was found that an individual's willingness to pay varies with the type of supply and the context in which the decision is being made. Studies collecting data in multiple countries and disaster types are recommended for future research to help identify the geographical and socio-economic effects of deprivation cost functions.

A pesar del rigor de la investigación, este estudio tiene algunas limitaciones. Dado que este es el primer estudio que propone estimaciones de DCF utilizando heurísticas de elección alternativas, los resultados no son concluyentes y requieren más investigación. Se necesita más investigación centrada en diferentes heurísticas de elección, suministros críticos y con datos recopilados en varios contextos de desastres para recopilar más evidencia. No obstante, los hallazgos discutidos aquí brindan información clave sobre el comportamiento de elección de las personas después de los desastres. Confirmamos empíricamente que los DCF no deberían ser transferibles, ya que se encontró que la disposición a pagar de un individuo varía con el tipo de suministro y el contexto en el que se toma la decisión. Se recomiendan estudios que recopilen datos en varios países y tipos de desastres para futuras investigaciones a fin de ayudar a identificar los efectos geográficos y socioeconómicos de las funciones de costos de privación.

ANEXO

Definición de las variables y notación

Variable	Descripción	Variable	Descripción
ASC_a	Constante específica del agua	β_p	Parámetro del presupuesto
ASC_c	Constante específica de la comida	$Pres_a$	Presupuesto disponible luego de comprar agua
$ASC_{a\&c}$	Constante específica del kit (agua y comida)	$Pres_c$	Presupuesto disponible luego de comprar comida
ASC_n	Constante especifica de no comprar	$Pres_{a\&c}$	Presupuesto disponible luego de comprar agua y comida
β_c	Parámetro del costo	$Pres_n$	Presupuesto disponible luego de no comprar. Igual al presupuesto total
$Cost_a$	Costo del agua	β_{ea}	Parámetro de la espera por agua
$Cost_c$	Costo de la comida	β_{ec}	Parámetro de la espera por comida
$Cost_{a\&c}$	Costo del kit de agua y comida	Esp_{actual}	Tiempo de privación actual: tiempo que llevan sin comer ni beber
$Cost_n$	Costo de no comprar. Definido como cero	Esp_{adi}	Tiempo adicional de privación que deben esperar para recibir ayuda gratuita
λ_a	Parámetro box cox para el tiempo de privación del agua	λ_c	Parámetro box cox para el tiempo de privación de la comida

Formulación de los modelos

RUM	Agua (a)	$V_a = ASC_a + \beta_c * Cost_a + \beta_p * Pres_a + \beta_{ea} * \frac{Esp_{actual}{}^{\lambda_a} - 1}{\lambda_a} + \beta_{ec} * \frac{Esp_{adi}{}^{\lambda_c} - 1}{\lambda_c}$
	Comida (c)	$V_c = ASC_c + \beta_c * Cost_c + \beta_p * Pres_c + \beta_{ec} * \frac{Esp_{actual}{}^{\lambda_c} - 1}{\lambda_c} + \beta_{ea} * \frac{Esp_{adi}{}^{\lambda_a} - 1}{\lambda_a}$
	Agua y Comida (a&c)	$V_{\text{a\&c}} = ASC_{\text{a\&c}} + \beta_c * Cost_{\text{a\&c}} + \beta_p * Pres_{\text{a\&c}} + \beta_{ec} * \frac{Esp_{actual}{}^{\lambda_c} - 1}{\lambda_c} + \beta_{ea} * \frac{Esp_{actual}{}^{\lambda_a} - 1}{\lambda_a}$
	Ninguno (n)	$V_n = ASC_n + \beta_{ec} * \frac{Esp_{adi}{}^{\lambda_c} - 1}{\lambda_c} + \beta_{ea} * \frac{Esp_{adi}{}^{\lambda_a} - 1}{\lambda_a}$

RRM	Agua (a)	$V_a = ASC_a + \log(1 + exp(\beta_c * (Cost_c - Cost_a))) + \log(1 + exp(\beta_c * (Cost_{a\&c} - Cost_a))) + \log(1 + exp(\beta_c * (Cost_a - Cost_a))) + \log\left(1 + exp\left(\beta_p * (Pres_c - Pres_a)\right)\right) + \log\left(1 + exp\left(\beta_p * (Pres_{a\&c} - Pres_a)\right)\right) + \log\left(1 + exp\left(\beta_p * (Pres_a - Pres_a)\right)\right) + \log\left(1 + exp\left(\beta_{ea} * \left(\frac{{Esp_{adi}}^{\lambda_a} - 1}{\lambda_a} - \frac{{Esp_{act}}^{\lambda_a} - 1}{\lambda_a}\right)\right)\right) + \log\left(1 + exp\left(\beta_{ea} * \left(\frac{{Esp_{act}}^{\lambda_a} - 1}{\lambda_a} - \frac{{Esp_{act}}^{\lambda_a} - 1}{\lambda_a}\right)\right)\right) + \log\left(1 + exp\left(\beta_{ea} * \left(\frac{{Esp_{adi}}^{\lambda_a} - 1}{\lambda_a} - \frac{{Esp_{act}}^{\lambda_a} - 1}{\lambda_a}\right)\right)\right) + \log\left(1 + exp\left(\beta_{ec} * (\frac{{Esp_{act}}^{\lambda_c} - 1}{\lambda_c} - \frac{{Esp_{adi}}^{\lambda_c} - 1}{\lambda_c})\right)\right) + \log\left(1 + exp\left(\beta_{ec} * \frac{{Esp_{act}}^{\lambda_c} - 1}{\lambda_c} - \frac{{Esp_{adi}}^{\lambda_c} - 1}{\lambda_c}\right)\right) + \log\left(1 + exp\left(\beta_{ec} * (\frac{{Esp_{adi}}^{\lambda_c} - 1}{\lambda_c} - \frac{{Esp_{adi}}^{\lambda_c} - 1}{\lambda_c})\right)\right)$
	Comida (c)	$V_c = ASC_c + \log(1 + exp(\beta_c * (Cost_a - Cost_c))) + \log(1 + exp(\beta_c * (Cost_{a\&c} - Cost_c))) + \log(1 + exp(\beta_c * (Cost_a - Cost_c))) + \log\left(1 + exp\left(\beta_p * (Pres_a - Pres_c)\right)\right) + \log\left(1 + exp\left(\beta_p * (Pres_{a\&c} - Pres_c)\right)\right) + \log\left(1 + exp\left(\beta_p * (Pres_a - Pres_c)\right)\right) + \log\left(1 + exp\left(\beta_{ea} * \left(\frac{{Esp_{act}}^{\lambda_a} - 1}{\lambda_a} - \frac{{Esp_{adi}}^{\lambda_a} - 1}{\lambda_a}\right)\right)\right) + \log\left(1 + exp\left(\beta_{ea} * \left(\frac{{Esp_{act}}^{\lambda_a} - 1}{\lambda_a} - \frac{{Esp_{adi}}^{\lambda_a} - 1}{\lambda_a}\right)\right)\right) + \log\left(1 + exp\left(\beta_{ea} * \left(\frac{{Esp_{adi}}^{\lambda_a} - 1}{\lambda_a} - \frac{{Esp_{adi}}^{\lambda_a} - 1}{\lambda_a}\right)\right)\right) + \log\left(1 + exp\left(\beta_{ec} * \left(\frac{{Esp_{adi}}^{\lambda_c} - 1}{\lambda_c} - \frac{{Esp_{act}}^{\lambda_c} - 1}{\lambda_c}\right)\right)\right) + \log\left(1 + exp\left(\beta_{ec} * \frac{{Esp_{act}}^{\lambda_c} - 1}{\lambda_c} - \frac{{Esp_{act}}^{\lambda_c} - 1}{\lambda_c}\right)\right) + \log\left(1 + exp\left(\beta_{ec} * (\frac{{Esp_{adi}}^{\lambda_c} - 1}{\lambda_c} - \frac{{Esp_{act}}^{\lambda_c} - 1}{\lambda_c})\right)\right)$

RESUMEN

La construcción de líneas ferroviarias en España a lo largo de la segunda mitad del siglo XIX sigue, en general, una configuración radial, uniendo Madrid con los principales puertos y centros urbanos de la costa española. Al objeto de satisfacer las demandas de movilidad en ejes transversales, pronto se planteó la necesidad de realizar una serie de tramos paralelos a la costa.

En este contexto, los antecedentes de la línea de vía métrica Ferrol – Gijón, de 321 km de longitud, se remontan al *Plan General de Ferrocarriles* (1864), aunque habría que esperar al *Plan de Ferrocarriles Estratégicos del Estado* (1883) para que se formalizase. Las obras se iniciaron en 1921, casi 20 años después de la redacción de su primer estudio. El último tramo fue inaugurado en 1972, medio siglo después de iniciadas las obras.

El trazado de esta línea, prácticamente paralelo a la costa, discurre salvando las estribaciones de la Cordillera Cantábrica y el Macizo Galaico, que descienden hacia el mar, mediante 34 túneles y 30 puentes realizados a lo largo de los 154 km de línea que discurre en Galicia. La línea Ferrol – Ribadeo tiene 52 estaciones y apeaderos

La extinción de la entidad pública empresarial *Ferrocarriles Españoles de Vía Estrecha* (*FEVE*), como consecuencia del Real Decreto-ley 22/2012, pareció definir el inicio de un paulatino proceso de deterioro de la oferta de los servicios prestados sobre la red de vía métrica del Norte de España y, en particular, los que se ofrecen sobre esta línea que, aunque actualmente están amparados bajo una obligación de servicio público (OSP), parecen tener un futuro incierto.

En la presente ponencia se analizan, entre otras, cuestiones relacionadas con su trazado, la situación de las paradas, el diseño de los servicios o la oferta en competencia, que permitirían explicar algunos aspectos de la actual situación y que dificultan hacer más competitivos los servicios prestados.

La construcción de líneas de ferrocarril de vía ancha en España se va desarrollando a lo largo de la segunda mitad del siglo XIX siguiendo una configuración básicamente radial, es decir, uniendo Madrid con los principales puertos y centros urbanos de la costa española. A esta pauta no fueron ajenos los principales puertos de la costa cantábrica y atlántica, a donde llegan las líneas ferroviarias que los comunican con Madrid: Bilbao (1863), Santander (1866), Gijón (1874), A Coruña (1875), Vigo (1878), Avilés (1890) o Ferrol (1913) (García Raya 2006).

Pronto se planteó la necesidad de construir líneas que permitieran satisfacer las demandas de movilidad en ejes transversales, más difíciles de atender por una red radial.

Ya en el Plan General de Ferrocarriles, redactado en cumplimiento de la ley de 13 de abril de 1864, se contempló entre los anteproyectos de la Junta Consultiva de Caminos, Canales y Puertos una conexión entre Santander y Zumárraga (Guipúzcoa) por Bilbao, en la red de Norte (A. D. 1864), y otra de Ribadeo a Oviedo por la costa, Lugo a Ribadeo y Santiago a Ferrol por A Coruña, en la red del Noroeste (Ministerio de Fomento 1905). Se trata de tramos que formarían parte de un corredor ferroviario costero que debía enlazar Galicia con el golfo de Vizcaya.

El primer tren de la Compañía del Ferrocarril de Santander a Bilbao que unió Santander con Zoroza circuló el 3 de julio de 1896. La prolongación desde Zoroza a Bilbao entró en servicio el 30 de julio de 1898. Dicho ramal finalizaba en el centro de la villa, con la estación modernista de Bilbao-Concordia.

A partir de 1905 comienza la explotación del tramo de Santander – Llanes (Compañía del Ferrocarril Cantábrico), cuyos servicios se prolongan hasta Oviedo a través de la Compañía de los Ferrocarriles Económicos de Asturias.

La construcción y progresiva entrada en servicio de estas líneas, junto con los favorables resultados económicos de las compañías ferroviarias que las explotaban, animó a completar el corredor ferroviario costero a lo largo de la cornisa cantábrica hasta Galicia. Este tramo ya se había planteado en 1883, en el Plan de Ferrocarriles Estratégicos del Estado (Ley de 27 de julio de 1883), para comunicar las zonas de productoras de carbón y las factorías armamentísticas asturianas (Trubia y Oviedo) con el arsenal de Ferrol. Por esta razón, el proyecto de Ferrocarril Ferrol – Gijón es igualmente conocido como “el Estratégico”.

Esta línea también se había incluido en el Plan de Ferrocarriles Secundarios de 1888 (apareciendo como Ferrocarril de Somorrostro a Ferrol), en el de 1893 y en el de 1905. En este último, la línea Ferrol – Gijón aparece descompuesta en los siguientes tramos, con sus longitudes estimadas (Ministerio de Fomento 1905) (Se consideraban ferrocarriles estratégicos los que, con independencia del servicio que prestaban a otros intereses generales, atendían directamente necesidades o conveniencias de la defensa nacional).

- Ferrol, por Santa Marta de Ortigueira, al Barquero (70 km).
- Barquero, por Viveiro, a Ribadeo (74 km).
- Ribadeo a Pravia (106 km).
- Pravia a Gijón (40 km).

Cabe señalar que la definición del trazado no estuvo exenta de dificultades, debido a las discusiones promovidas por los ayuntamientos que quedaban fuera de su trazado. Las variantes del Eo y de Pravia fueron motivo de vehementes debates, llegando las discusiones al Parlamento, como una cuestión de interés nacional.

Los estudios del que también se conoció como Ferrocarril de la Costa fueron llevados a cabo por la Sociedad Iberia Concesionaria, creada en 1902 en Bilbao, con el objetivo de desarrollar esta línea. Dicha Sociedad recibió la autorización para llevar a cabo estas tareas mediante la Real Orden de 17 de marzo de 1902. El anteproyecto fue realizado por los ingenieros José Borés y Romero y Luis Vasconi y Cano, y se presentó el 20 de abril de 1906. En él, entre otras cuestiones, se comentaban las ventajas que esta línea tendría para Galicia y Asturias (se estimaba que beneficiaría a más de un millón de habitantes en su área de afección) al objeto de que fuera declarado ferrocarril de servicio general (Heredia Flores 2017).

Con motivo de la presentación del anteproyecto, la Real Orden de Guerra de 17 de noviembre de 1906 consideraba que, dada la importancia estratégica de la línea, especialmente entre Pravia y Ferrol, sería conveniente que una comisión mixta de ingenieros civiles y militares estudiase las modificaciones precisas para proteger la línea contra posibles ataques de una escuadra o tropas de desembarco, y dotase a las obras de fábrica de mecanismos o dispositivos que permitieran su inutilización en caso de necesidad. Especialmente interesante fue la recomendación de que la línea se proyectase de manera que, a pesar de estar diseñada para vía métrica, pudiese, por sus características de planta y perfil, igualar la capacidad y velocidad que ofrecería una línea de vía ancha (Gómez Martínez 1999).(Como ferrocarriles secundarios se consideraban aquellos destinados al servicio público, con motor mecánico de cualquier clase, que no estuvieran comprendidos en la red de servicio general, tal como se había definido y establecido en la Ley de 1877).

Tras la incorporación de la línea al *Plan de Ferrocarriles Secundarios* de 1907, en 1908 (mediante Real Orden de 14 de mayo) se abrió el concurso que fijaba los requisitos que debía reunir el proyecto, entre los cuales cabe señalar:

- Vía métrica.
- Trazado por Ortigueira, Viveiro, Ribadeo, Pravia y Avilés.
- Pendiente máxima: 20 milésimas.
- Radio de curva mínimo: 120 m.
- Velocidad comercial de los trenes: 25 km/h.

La única empresa que presentó un proyecto fue la *Sociedad Iberia Concesionaria*, que lo hizo el 30 de enero de 1909. El presupuesto de construcción de la línea se estimó en cerca de 75 millones de pesetas. Tras las modificaciones precisas, el proyecto se aprobó, mediante Real Orden, el 10 de enero de 1914. La *Sociedad Iberia Concesionaria* fue la adjudicataria de la concesión.

Las obras se sacaron a concurso en tres ocasiones (12 de noviembre de 1915, 7 de noviembre de 1919 y 15 de junio de 1920), quedando en todas ellas desierto el concurso. Puesto que la concesionaria no pudo reunir el dinero suficiente para ejecutarlas, el Gobierno tomó la decisión de, a través de los presupuestos generales de 1920-1921, subastar la construcción de las secciones de mayor interés para los viajeros. La línea fue dividida en las siguientes secciones:

- Ferrol – Mera
- Mera – Ortigueira
- Ortigueira – Foz
- Foz – Ribadeo
- Ribadeo – Los Cabos (entre Pravia y Soto del Barco)
- Los Cabos – Gijón

Se decidió subastar la construcción de los tramos extremos, es decir, Ferrol – Mera y Los Cabos – Gijón (Gómez Martínez 1999).

La subasta para la construcción de las obras de explanación y fábrica del primer tramo de la sección de Ferrol a Mera se adjudicó el 25 de septiembre de 1921. Las obras se iniciaron ese mismo año.

En 1928 la línea fue incluida en el *Plan Preferente de Ferrocarriles de Urgente Construcción* (también conocido como *Plan Guadalhorce*, llamado así en honor del ministro de Fomento, Rafael Benjumea y Burín, conde de Guadalhorce). A pesar de ello, tendrían que transcurrir 44 años para que se inaugurase el último tramo puesto en servicio. Gómez Martínez (Gómez Martínez 2005) atribuye a las siguientes causas este dilatado periodo de construcción:

- El Estado se encargó de la construcción de la línea Ferrol – Gijón, cosa que no ocurrió con la mayoría de las líneas ferroviarias construidas hasta la fecha, en las que la construcción y explotación las llevó a cabo una empresa con capital privado. La intervención del Estado hace que los procesos burocráticos (reformados y modificaciones parciales de proyectos, desfase de los presupuestos, rescisiones de contratos, licitación y adjudicación de nuevos, etc.) se eternicen.

- La Guerra Civil, que interrumpió las obras hasta principios de los años cuarenta. Terminada la contienda, y aunque desde el Gobierno había interés en concluir las obras por ser Ferrol la ciudad natal del jefe del Estado, la necesidad de liquidar obras antiguas, redactar presupuestos adicionales o reformar los ya realizados, junto con la carestía de materiales y la escasez de fondos públicos, dilataron una vez más la ejecución de las obras.

En la tabla 1 se muestran las fechas de inauguración de los diferentes tramos en que se dividió la construcción de la línea Ferrol – Gijón.

Longitud [km]	**Tramo**	**Inauguración**
7,0	Aboño - Gijón	1 octubre 1950
24,3	Pravia - Avilés	11 septiembre 1956
45,9	Ferrol - Mera	29 enero 1962
57,8	Luarca - Pravia	13 septiembre 1962
6,66	Mera - Ortigueira	7 septiembre 1964
33,3	Ortigueira - Viveiro	24 junio 1966
67,0	Viveiro - Vegadeo	21 junio 1968
58,4	Vegadeo - Luarca	6 septiembre 1972

Tabla 1. Cronología de las inauguraciones de los tramos de la línea Ferrol – Gijón. (Gómez Martínez 2005).

El general Franco inauguró la totalidad de la línea, el 6 de septiembre de 1972. El coste final de la misma ascendió a 4.250 millones de pesetas de 1972, lo que supone un coste por kilómetro de 13,2 millones de pesetas. La línea, con una longitud de 321 km, tiene 121 túneles, numerosos viaductos, puentes y obras de paso, 27 estaciones y gran cantidad de apeaderos. Habían transcurrido más de 50 años para que finalizara su construcción, quedando unidas las ciudades de Ferrol y Gijón por ferrocarril de vía métrica.

A partir de 1972 se llevan a cabo diferentes actuaciones de mejora de la infraestructura ferroviaria (sobre puentes, túneles, instalaciones fijas, etc.), electrificación (el tramo Pravia – Avilés en 1986, y el Cudillero – Pravia en 1994), renovación de la vía (entre Avilés y Soto del Barco en 1996; entre Soto del Barco y Pravia, y entre Ribadeo y Vegadeo en 1997), señalización y enclavamientos.

2. SITUACIÓN ACTUAL DE LA LÍNEA FERROL – RIBADEO

2.1 Infraestructura

El tramo que se desarrolla en Galicia de la línea Ferrol – Gijón (321 km), tiene una longitud de 154 km, siendo sus estaciones extremas las de Ferrol y Ribadeo (figura 1). El trazado de esta línea, prácticamente paralelo a la costa, se caracteriza por la presencia de numerosos viaductos para salvar los valles que se forman como consecuencia de las estribaciones de la Cordillera Cantábrica y el Macizo Galaico que descienden hacia el mar. Por lo general, se trata de obras de fábrica con dos tipologías diferenciadas: viaductos formados por arcos ojivales, en el lado gallego, y de arcos de medio punto, en el sector asturiano.

Desde su inauguración, esta línea fue explotada por la entidad pública empresarial *Ferrocarriles Españoles de Vía Estrecha* (*FEVE*). De acuerdo con el Real Decreto-ley 22/2012, de 20 de julio, por el que se adoptan medidas en materia de infraestructuras y servicios ferroviarios, *FEVE* se extinguió el 31 de diciembre de 2012, momento en el que fundamentalmente *Adif* y *Renfe Operadora* asumieron sus derechos y obligaciones, así como la titularidad de sus bienes. El material móvil y la explotación de los servicios de transporte pasaron a ser gestionados por *Renfe Operadora*, mientras que la gestión de la infraestructura se encomendó a *Adif*.

Está integrada en la *Red Ferroviaria de Interés General* (*RFIG*), de acuerdo con la Orden FOM/710/2015, de 30 de enero, por la que se aprueba el Catálogo de líneas y tramos de la Red Ferroviaria de Interés General (BOE nº 97, de 23 de abril de 2015). Por ello, su gestión y mantenimiento corresponden al *Administrador de Infraestructuras Ferroviarias* (*Adif*), de acuerdo con la disposición adicional primera de la Ley 38/2015, de 29 de septiembre de 2015, del Sector Ferroviario (BOE nº 234, de 30 de septiembre de 2015). Entre Ferrol y Pravia el código de identificación de la línea es el 740.

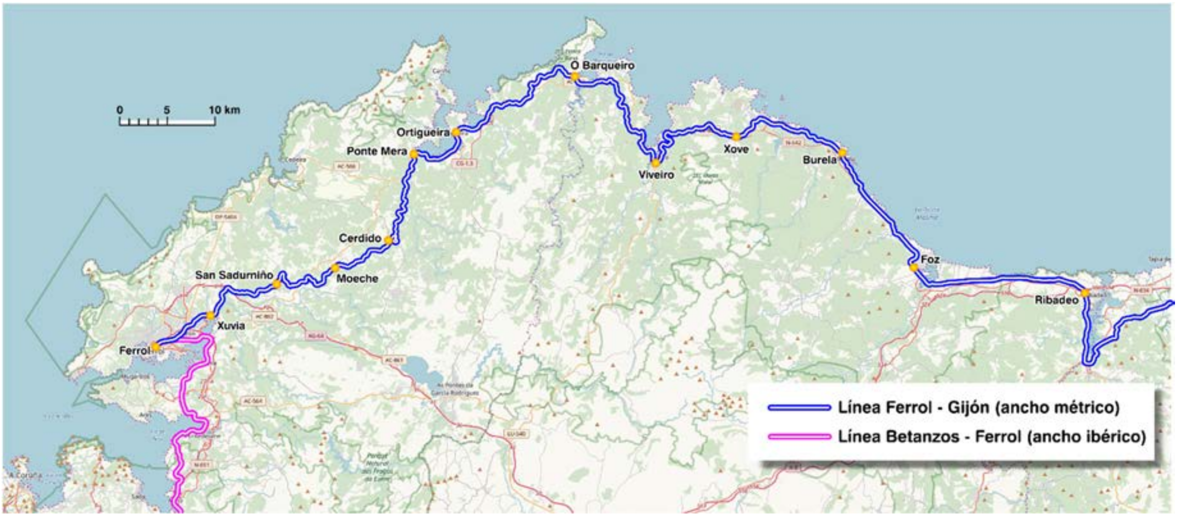

Figura 1. Trazado general de la línea Ferrol – Ribadeo, con sus estaciones principales.

2.1.1 Tipo de línea y ancho de vía

La infraestructura ferroviaria de la línea Ferrol - Gijón en la sección Ferrol - Ribadeo puede caracterizarse esquemáticamente por los siguientes aspectos:

- Vía única, sin electrificar.
- Ancho de vía métrico (1.000 mm).
- La superestructura está constituida, en general, por carril de 45 kg/m sobre traviesas de hormigón monobloque y balasto silíceo.
- En el tramo Ferrol – Ribadeo existen 34 túneles, numerados correlativamente. Totalizan 7.041 m de longitud, siendo el mayor de ellos de 813 m.
- Existen 30 puentes en el tramo Ferrol - Vegadeo, con una longitud total de 1.844,6 m. El más largo es el que salva el río Sor cerca de O Barqueiro (A Coruña), con una longitud de 241 m.
- Por lo que se refiere a pasos inferiores, existen 114, de los cuales 24 son mayores de 6 metros de luz.

2.1.2 Cargas máximas

De acuerdo con la *«Declaración sobre la Red 2021»* de *Adif* (Administrador de Infraestructuras Ferroviarias 2021), la carga máxima por eje es de 15,0 t y por metro lineal de 8,0 t.

2.1.3 Rampas características

De acuerdo con la *«Declaración sobre la Red 2021»* de *Adif*, los valores de las rampas características existentes en la línea Ferrol – Ribadeo se muestran en la tabla 2.

Tramo	**Rampa característica** [mm/m]
Ferrol → Cerdido	20
Ferrol ← Cerdido	20
Cerdido → Ortigueira	16
Cerdido ← Ortigueira	20
Ortigueira → Xove	15
Ortigueira ← Xove	17
Xove → Ribadeo	15
Xove ← Ribadeo	15

Tabla 2. Valores de las rampas características en la línea Ferrol – Ribadeo. (Administrador de Infraestructuras Ferroviarias 2021).

En la figura 2 se muestra el perfil longitudinal de la línea a partir de las cotas de sus diferentes estaciones y apeaderos.

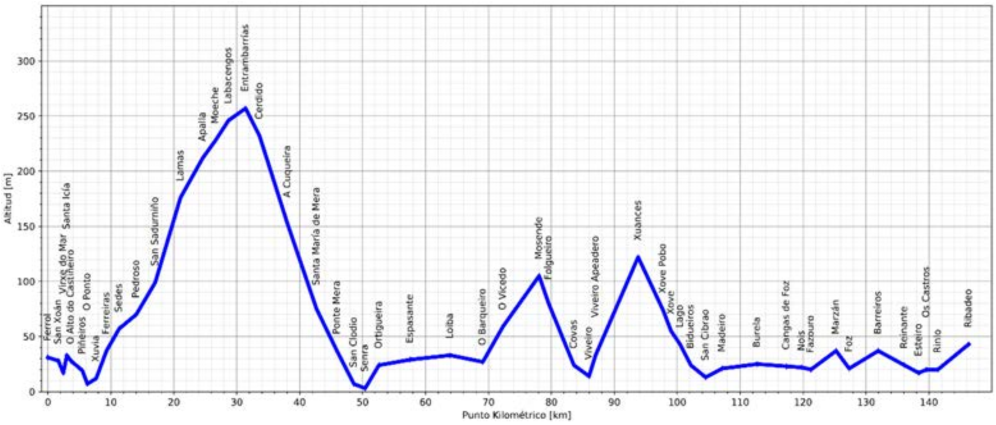

Figura 2. Perfil transversal aproximado de la línea Ferrol – Ribadeo.

Como puede apreciarse en la citada figura, el perfil se quiebra en los pasos de ría a ría, que lo hacen más difícil desde el punto de vista de la tracción:

- **Paso de la ría de Ferrol a la de Ortigueira.** En el ascenso desde Xuvia, la línea se pliega a la falda de los montes do Castro, la Pereiruga, Pedroso, O Pico, Moimentos, As Fervenzas, A Chousa, A Croa, Rapadoiro, Pousadoiro y Outeiro, hasta alcanzar el apeadero de Entrambarrías. Desde dicho punto, comienza el descenso hacia la ensenada de Mera, en la ría de Ortigueira, con un lazo inicial sobre el rego do Loureiro, y siguiendo a media ladera, paralelo al cauce del río Mera. Es la zona donde la línea tiene las mayores rampas características (20 milésimas), tanto en la zona Ferrol – Entrambarrías, como cuando se asciende desde Ortigueira hacia dicho apeadero.

- **Paso de la ría de O Barqueiro a la de Viveiro**, a través de O Vicedo, Mosende y Folgueiro.

- **Paso de la ría de Viveiro a la de Lieiro (San Cibrao)**, pasando por Xuances, Xove, Lago y Bidueiros.

En el primer caso, el trazado sigue una hipotética línea recta entre Ferrol y Ortigueira. Se trata de una zona de orografía irregular, caracterizado por las estribaciones montañosas de la sierra de la Faladoira. Con respecto a los dos últimos casos se deben a que el trazado sigue la línea de costa. En su desarrollo, encuentra las estribaciones de la cordillera Cantábrica, que llega con sus crestas a la costa, formando entre ellas valles que al entrar en el mar forman rías. La línea debe superar estas crestas para llegar a los puertos que albergan las rías.

Este trazado, tan ajustado a la orografía de terreno, obliga al empleo de curvas de radio reducido, que limitan la velocidad de circulación como se verá en el siguiente epígrafe.

2.1.4 Velocidades máximas

En la figura 3 se indican los valores de las velocidades máximas de circulación que se pueden alcanzar en esta línea.

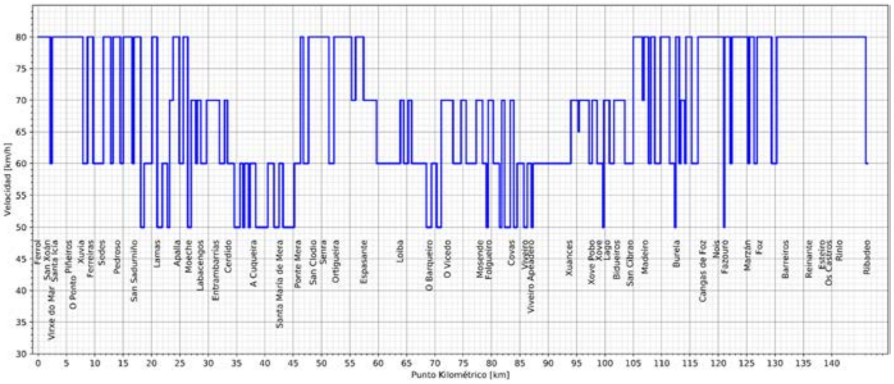

Figura 3. Velocidades máximas en la línea Ferrol - Ribadeo para trenes tipo N ($a_{csc} \leq$ 0,65 m/s^2).

Se puede apreciar cómo en cada tramo, aunque tenga un valor de la velocidad máxima común (por ejemplo, 80 km/h), existen múltiples zonas en las que es preciso reducir dicha velocidad (a 60 o 50 km/h). No es infrecuente que, aunque dichas zonas tengan una longitud relativamente reducida, la marcha de los trenes se vea afectada por dichas limitaciones.

2.1.5 Longitud máxima de los trenes

En la tabla 3 se presentan las longitudes máximas de los trenes, tanto de viajeros como de mercancías, admitidas en esta línea, de acuerdo con lo que indica la *«Declaración sobre la Red 2021»* de *Adif*. En ambos casos, se incluye la longitud máxima especial, para cuya utilización es necesario solicitar autorización expresa a la *Dirección de Gestión de Capacidad de la Dirección General de Circulación y Gestión de Capacidad* para los trenes Regulares u Ocasionales y a la *Dirección de Tráfico (H24)* para los trenes inmediatos.

Tipo de tren	Tramo	Parámetro	Valor [m]
Viajeros	Ferrol – Ribadeo	Longitud máxima básica	36
		Longitud máxima especial	250
Mercancías	Ferrol – San Sadurniño	Longitud máxima básica	160
		Longitud máxima Especial	290
	San Sadurniño – Ribadeo	Longitud máxima básica	200
		Longitud máxima especial	380

Tabla 3. Longitud máxima de los trenes en el tramo Ferrol – Ribadeo. (Administrador de Infraestructuras Ferroviarias 2021).

Al respecto de estos datos, cabe destacar dos ideas:

- Como puede comprobarse en la tabla 3, las longitudes básica y especial de los trenes de mercancías es ligeramente inferior en la sección Ferrol – San Sadurniño que en la comprendida entre San Sadurniño y Ribadeo. Parece razonable que la longitud máxima de los trenes fuera la misma en ambas secciones, al objeto de no limitar la capacidad de transporte de los trenes en la primera (por ejemplo, procedentes del puerto de Ferrol).

- La longitud máxima básica y especial de los trenes de mercancías en la sección Ribadeo – Pravia es, respectivamente, de 250 y 360 m. También en este caso parece que sería deseable que dichas longitudes fueran las mismas a lo largo de toda la línea Ferrol – Gijón, aunque habría que analizar con un detalle que excede el alcance de este documento, entre otras cuestiones, las capacidades de tracción de *Renfe Operadora* en dicha línea y la demanda de tráfico de mercancías existente y futura.

2.1.6 Sistemas de seguridad

De acuerdo con el documento *«Declaración sobre la Red 2021»* de *Adif*, el bloqueo de los trenes desde Ferrol a Cudillero se realiza mediante bloqueo telefónico (BT).

Desde el año 1997, la línea Ferrol – Gijón tiene operativo el sistema ASFA (Anuncio de Señales y Frenado Automático) analógico.

El Real Decreto 1513/2018, de 28 de diciembre, por el que se modifica la disposición transitoria única del Real Decreto 664/2015, de 17 de julio, por el que se aprueba el Reglamento de Circulación Ferroviaria, establece que:

> *«A partir del 1 de enero de 2019 en las líneas de ancho ibérico y estándar europeo y del 1 de julio de 2021 en la red de ancho métrico no se admitirá la circulación de trenes con el sistema ASFA analógico, debiendo sustituirse los equipos embarcados con dicho sistema por otros con el sistema ASFA digital».*

2.1.7 Estaciones y apeaderos

En la tabla 4 se muestran las estaciones y apeaderos que se sitúan a lo largo de la línea Ferrol – Gijón, en la parte de Galicia.

Denominación		Tipo	Situación [PK]
A Coruña	Ferrol	Estación	0,00
	San Xoán	Apeadero	1,65
	Virxe do Mar	Apeadero	2,44
	Santa Icía	Apeadero	3,00

	O Alto do Castiñeiro	Apeadero	3,65
	Piñeiros	Apeadero	5,47
	O Ponto	Apeadero	6,26
	Xuvia	Estación	7,66
	Ferreiras	Apeadero	9,30
	Sedes	Apeadero	11,30
	Pedroso de Narón	Apeadero	14,03
	San Sadurniño	Estación	17,04
	Lamas	Apeadero	21,06
	Apalla	Apeadero	24,60
	Moeche	Apeadero	26,63
	Labacengos	Apeadero	28,69
	Entrambarrías	Apeadero	31,40
	Cerdido	Estación	33,62
	A Cuqueira	Apeadero	38,08
	Santa María de Mera	Apeadero	42,68
	Ponte Mera	Apeadero	45,92
	San Clodio	Apeadero	48,62
	Senra	Apeadero	50,40
	Ortigueira	Estación	52,59
	Espasante	Apeadero	57,56
	Loiba	Apeadero	63,91
	O Barqueiro	Apeadero	69,10
Lugo	O Vicedo	Apeadero	72,30
	Mosende	Apeadero	78,05
	Folgueiro	Apeadero	79,56
	Covas	Apeadero	83,58
	Viveiro	Estación	85,98
	Viveiro Apeadero	Apeadero	87,02
	Xuances	Apeadero	93,78
	Xove Pobo	Apeadero	97,74
	Xove	Estación	99,02
	Lago	Apeadero	100,44
	Bidueiros	Apeadero	102,16
	San Cibrao	Apeadero	104,51
	Madeiro	Apeadero	107,15
	Burela	Estación	112,71
	Cangas de Foz	Apeadero	117,35
	Nois	Apeadero	119,77
	Fazouro	Apeadero	121,24
	Marzán	Apeadero	125,24

	Foz	Apeadero	127,32
	Barreiros	Apeadero	131,94
	Reinante	Apeadero	136,09
	Esteiro	Apeadero	138,38
	Os Castros	Apeadero	139,60
	Rinlo	Apeadero	141,43
	Ribadeo	Estación	146,31

Tabla 4. Estaciones y apeaderos de la línea Ferrol – Ribadeo.

Puede parecer que este elevado número de paradas conlleve una notable accesibilidad de los servicios ferroviarios sobre el territorio. Sin embargo, con frecuencia estas instalaciones se encuentran relativamente alejadas del núcleo principal de población, hecho que en ocasiones se agrava como consecuencia del estado de los accesos a las mismas.

3. SERVICIOS OFERTADO

3.1 Viajeros

En la actualidad, sobre la línea Ferrol – Ribadeo – Gijón circulan servicios de la entidad pública empresarial *Renfe Operadora*, tras la desaparición de *Feve* en aplicación del Real Decreto-Ley 22/2012, de 20 de julio, por el que se adoptan medidas en materia de infraestructuras y servicios ferroviarios.

Estos servicios, como otros prestados en la red de ancho métrico, fueron declarados obligaciones de servicio público (OSP) mediante Acuerdo de Consejo de Ministros de 28 de diciembre de 2012, por el que se declararon las obligaciones de servicio público del transporte ferroviario de viajeros de *“Media distancia”*. Esta declaración se realizó en cumplimiento del Real Decreto Ley 22/2012 antes citado, de tal forma que *Renfe Operadora* continuaba prestando, entre otros, los servicios ferroviarios de transporte de viajeros sobre la red de ancho métrico que en ese momento se venían prestando.

Es preciso destacar que en la línea Ferrol – Gijón se prestan los únicos servicios ferroviarios de cercanías que se ofrecen actualmente en Galicia. Se trata de los servicios Ferrol – Ortigueira, identificados como la línea C-1f.

La tabla 5 resume la oferta de trenes de viajeros establecida entre Ferrol, Ribadeo y Oviedo (se presenta la situación de la oferta en 2019, antes de la afección a la misma por la pandemia de la COVID-19).

Serv./día	Día	Origen	Destino	Horario	Observaciones
17 (8)	L-V (S-D)	Ferrol	Xuvia	7.25 --- 21.20 (8.20 --- 21.20)	13 (4) Serv. Cercanías L-V (S-D)
17 (8)	L-V (S-D)	Xuvia	Ferrol	7.39 --- 22.01 (8.20 --- 21.20)	13 (4) Serv. Cercanías L-V (S-D)
8 (5)	L-V (S-D)	Ferrol	Ortigueira	8.20 --- 20.05 (8.20 --- 19.05)	4 (1) Serv. Cercanías L-V (S-D)
8 (5)	L-V (S-D)	Ortigueira	Ferrol	6.35 --- 20.28 (8.43 --- 20.28)	4 (1) Serv. Cercanías L-V (S-D)
4	L - D	Ferrol	Ribadeo	8.20, 10.45, 15.30, 19.05	
4	L - D	Ribadeo	Ferrol	6.55, 11.34, 15.00, 18.40	
2	L - D	Ferrol	Oviedo	8.20, 15.30	
2	L - D	Oviedo	Ferrol	7.30, 14.30	

Tabla 5. Servicios ofrecidos en la línea Ferrol – Ribadeo (Oviedo), en 2019.

Los elementos básicos que configuran la oferta de servicios ferroviarios en la línea, desde un punto de desplazamiento regional e interregional, se presentan en la tabla 6. Además, en la tabla 7 se compara la oferta de transporte público que se realiza por ferrocarril y carretera en relaciones de ámbito provincial o regional.

Tipo servicio	Tiempo	$V_{comercial}$	Precio
Cercanías Ferrol – Xuvia	12 min	39 km/h	1,65 €
Cercanías Ferrol – Ortigueira	1 h 16 min	42 km/h	3,15 €
Ferrol – Ribadeo	3 h 5 min	47 km/h	11,15 €
Ferrol – Oviedo	7 h 11 min	43 km/h	24,10 €

Tabla 6. Características de los servicios ferroviarios que se prestan en la línea Ferrol – Ribadeo (Oviedo). Tiempos correspondientes al mejor servicio en cada tipo. Precios billete sencillo (2019).

Modo	Ser./día	Longitud	Paradas	Tiempo	$V_{comercial}$	Precio
Ferrol → Ortigueira						
Ferrocarril	8 (5)	52,6 km	23 (0)	1 h 16 min	42 km/h	3,15 €
Autobús	3 (1)	55,1 km		58 min	57 km/h	5,20 €
Automóvil		55,1 km		1 h 2 min	53 km/h	
Viveiro → Ribadeo						
Ferrocarril	4 (4)	60,3 km	21 (9)	1 h 7 min	54 km/h	4,75 €
Autobús	8 (2)	59,6 km	19	1 h 38 min	36 km/h	4,65 €
Automóvil		59,6 km		1 h	60 km/h	
Ferrol → Ribadeo						
Ferrocarril	4	146,3 km	51 (13)	3 h 5 min	47 km/h	11,15 €
Autobús*	3	149 km		3 h 30 min	43 km/h	13,45 €
Auto por autovía		131 km		1 h 23 min	94 km/h	
Auto por carretera		149 km		2 h 36 min	57 km/h	
Ferrol → Oviedo						
Ferrocarril	2	310,3 km	90 (35)	7 h 11 min	43 km/h	24,10 €
Autobús**	1	355 km	12	5 h 45 min	62 km/h	33,60 €
Auto por autovía		262 km		2 h 36 min	101 km/h	
Auto por carretera		283 km		5 h 5 min	56 km/h	

Tabla 7. Comparación de la oferta de transporte público por ferrocarril y carretera en el corredor Ferrol – Ribadeo (Oviedo), en 2019.

Tiempos correspondientes al mejor servicio. Precios tarifa general. Servicios diarios en día laborable. En FC, Se indican paradas totales (de ellas, el número de discrecionales entre paréntesis). En autobús, los servicios con estación – estación.

* Autobús con transbordo en Viveiro: Ferrol → Viveiro → Ribadeo

**Autobús con transbordo en A Coruña: Ferrol → A Coruña → Vilalba → Ribadeo → Oviedo.

Resultados automóvil procedentes de Google Maps.

Con los datos expuestos en las citadas tablas, cabe realizar las siguientes observaciones:

a) **Servicios de cercanías:** Entre Ferrol y Ortigueira se realiza una oferta de servicios ferroviarios con mayor número de expediciones y a un precio más reducido que la que se efectúa mediante autobús. En un recorrido de algo más de 50 km, los servicios ferroviarios realizan 23 paradas, lo que favorece su accesibilidad, aunque sea a costa de dilatar los tiempos de viaje.

   A pesar de la potencial accesibilidad de estos servicios debido a sus múltiples paradas, debe destacarse el hecho ya mencionado de que la ubicación de numerosos apeaderos, alejados de los núcleos principales de población, y/o su acceso, no facilitan el uso del ferrocarril. Este comentario es extensivo a otras secciones de la línea.

b) **Servicios de ámbito comarcal o provincial:** Entre Viveiro y Ribadeo la oferta que se efectúa a través del ferrocarril presenta características muy similares a la que se realiza con autobús. En esta relación concreta, la tarifa general es 10 céntimos más cara en tren, es decir, un 2%; o el número de paradas por ferrocarril (21, de las cuales 9 son discrecionales) es parecido al que realizan los servicios de autobús (19). Los servicios ferroviarios tienen un tiempo de viaje más reducido. No obstante, en días laborables se ofrecen en autobús el doble de expediciones que por ferrocarril, ocurriendo justamente al contrario en días no laborables.

c) **Servicios regionales:** Si se considera, por ejemplo, el servicio Ferrol – Ribadeo, la oferta realizada por ferrocarril presenta la notable ventaja de ser única, ya que este recorrido no es posible llevarlo a cabo en autobús si no es realizando transbordo con los servicios de otra empresa en Viveiro. Este hecho, aparte de la desfavorable percepción que tiene por parte de los potenciales usuarios, también origina un tiempo de viaje mayor en autobús, al tener que considerar el tiempo de espera entre un servicio y el siguiente en la estación de autobuses. Desde un punto de vista de servicio ferroviario regional típico, tienen un número mayor de paradas (en este servicio concreto, 51, de las cuales 13 son discrecionales). Ello se traduce en una mayor accesibilidad territorial de los servicios ferroviarios, si bien a costa de un notable incremento de los tiempos de viaje.

d) **Servicios interregionales:** Tal vez el más característico que se desarrolla sobre esta línea sea el que une Ferrol y Oviedo. Sorprenden las numerosísimas paradas que realiza (90, de las cuales 35 son discrecionales), muy por encima de las esperables en este tipo de servicios. A título de ejemplo, Pyrgidis indica que en servicios interurbanos convencionales normalmente se produce una parada del orden de cada 75 km (Pyrgidis 2016). Este hecho perjudica los tiempos de viaje, en este caso, si cabe, de forma más acentuada. De hecho, parece que el tren desarrolla un servicio de proximidad extendido a lo largo de la línea Ferrol – Oviedo.

3.2 Mercancías

En la tabla 8 se detallan los trenes de mercancías que habitualmente circulaban por la línea Ferrol – Gijón en 2019.

Mercancía	Operador	Origen	Destino	Última circulación
Aluminio	Renfe Operadora	Xove	Ariz	En servicio
Madera	Renfe Operadora	Xove	Ariz	En servicio
Madera	Renfe Operadora	Xove	Ariz [→ Lasarte-Empalme]	2019
Contenedores	Renfe Operadora	Ferrol	Ariz	Desconocida
Madera	Renfe Operadora	Cerdido	Aranguren	Desconocida
Madera	Renfe Operadora	Cerdido	Barreda	Desconocida
Madera	Renfe Operadora	Cerdido	Lasarte-Empalme	Desconocida
Madera	Renfe Operadora	Xuvia	Navia	Desconocida
Varilla	Renfe Operadora	Xove	Burtzeña (Lutxana)	Desconocida

Tabla 8. Trenes de mercancías en la línea Ferrol - Ribadeo.

Con respecto a los servicios de mercancías de *FEVE*, cabe apuntar que no constituyendo un gran número de expediciones, sin embargo se trata de servicios rentables, al tratarse del transporte de grandes masas (aluminio, madera, acero en diferentes formas, etc.) a distancias relativamente grandes (por ejemplo, entre Galicia y el País Vasco).

3.3 Utilización de los servicios ferroviarios de viajeros

Resulta muy difícil hallar información publicada sobre la evolución de los viajeros que han utilizado los servicios ferroviarios ofrecidos hasta 2012 por *FEVE* y, especialmente, a partir de dicho año, por *Renfe Operadora*. Por esta razón, para algunos años no ha sido posible conseguir el número de viajeros que utilizan determinados servicios ferroviarios de ancho métrico.

Esta dificultad se ha incrementado en los últimos años, toda vez que con la desaparición de *FEVE* también desaparece su Informe Anual, un documento en el que podía seguirse la evolución de numerosas variables de la Empresa (entre ellas, los viajeros transportados). Los informes económicos y de actividad de *Renfe Operadora* no contemplan el suficiente nivel de desagregación de la información para poder obtener los datos antes citados.

Por otra parte, la reducción del personal de intervención en los trenes y la ausencia de cerramiento en las estaciones, al objeto de llevar a cabo la cancelación de los billetes mediante máquinas automáticas, ha originado en estos últimos años (según las denuncias de sindicatos, colectivos de usuarios, etc.), un incremento del número de viajeros que utilizan estos servicios de transporte sin billete y que, por lo tanto, no aparecen reflejados en los resultados de explotación.

En la figura 4 se muestra la evolución del número de viajeros que utilizan los servicios de cercanías entre Ferrol y Ortigueira, junto con su tendencia (calculada mediante el ajuste de los datos con que se cuenta mediante regresión lineal. El área sombreada representa el intervalo de confianza al 95%).

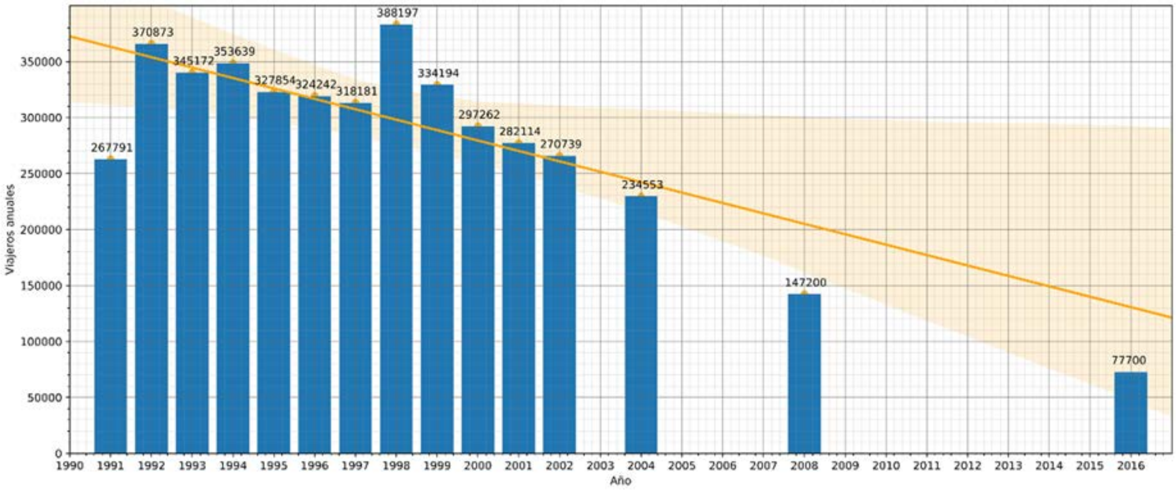

Figura 4. Evolución del número de viajeros anuales de Feve / Renfe Operadora, en servicios de cercanías entre Ferrol y Ortigueira.

En la figura 5 se presenta la evolución del número de viajeros que utilizan los servicios regionales en el corredor Ferrol – Ribadeo.

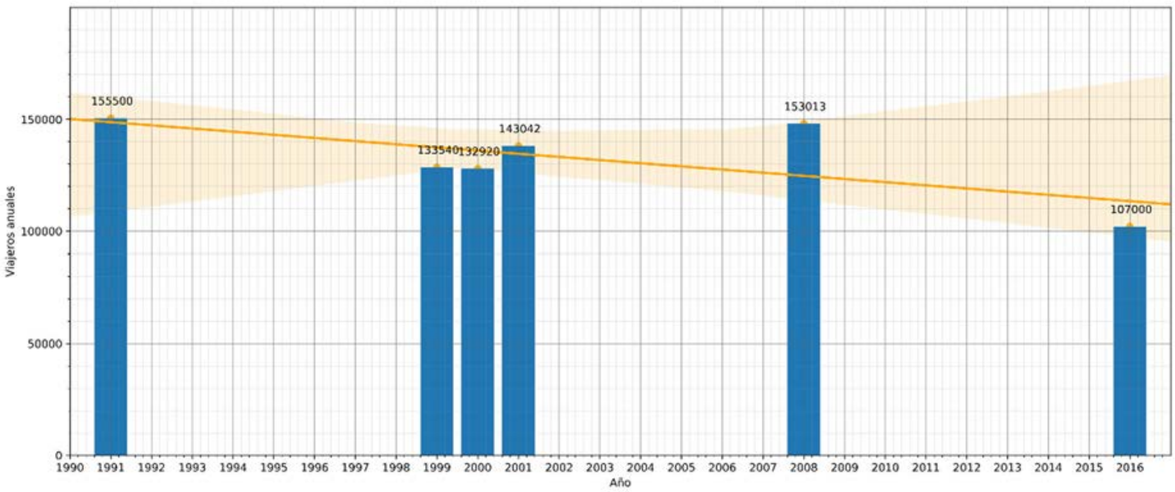

Figura 5. Evolución del número de viajeros anuales de Feve/Renfe Operadora, en servicios regionales entre Ferrol y Ribadeo.

Finalmente, en la tabla 9 se muestra el movimiento de viajeros en las estaciones del tramo Ferrol - Ortigueira en los años 2000 y 2001. Aunque se trata de datos que no se corresponden, en cuanto a su volumen, con la realidad actual, parece interesante reflejarlos en este documento para comprobar que del orden del 70% de los usuarios de los servicios de vía métrica en Galicia utilizaban la relación Ferrol – Ortigueira. En dicha relación, aproximadamente el 85% de los viajeros se movían entre las estaciones del tramo Ferrol – Xuvia.

Estación	Salidas		Llegadas		Total movimiento		
	2000	2001	2000	2001	2000	2001	% variación
Ferrol	131.104	125.792	141.607	135.246	272.711	261.038	-4,28

4. LA MODERNIZACIÓN DE LA LÍNEA

Como ha podido verse en los párrafos anteriores, las características de la línea Ferrol – Ribadeo impiden ofrecer servicios ferroviarios competitivos. Por esta razón, parece lógico plantear una modernización de la línea.

A pesar de la lógica de este planteamiento, debe señalarse que las líneas de *FEVE* quedaron fuera del *Plan de Transporte Ferroviario* (1987). En el *Plan Director de Infraestructuras* (1993) las actuaciones a desarrollar se centraron en mejorar la oferta de cercanías. Será precisamente la mejora de los servicios de cercanías (que, como se ha visto, representaban en Galicia la mayor parte de los viajeros transportados), lo que justificó la introducción de la propuesta de duplicación de la vía entre Ferrol y Xubia dentro de las actuaciones del *Plan de Infraestructuras* (2000), duplicación que finalmente no se llevó a cabo.

Con el *Plan Galicia* (2003), se planteó la construcción de una línea de Alta Velocidad del Cantábrico, que se mantuvo tanto en el *Plan Estratégico de infraestructuras y Transporte* (2005) como en el *Plan de Infraestructuras, Transporte y Vivienda* (2012).

Las dificultades de llevar a cabo tal proyecto, condujeron a que *Feve* explorase en el 2009 la posibilidad de adaptar el trazado de la línea Ferrol – Gijón – Santander para velocidades máximas de 160 km/h, con material móvil de cajas inclinables. El coste estimado de las actuaciones a desarrollar fue lo suficientemente elevado como para que no se tomase en consideración esta alternativa por el momento.

5. ELEMENTOS PARA UN DIAGNÓSTICO

De acuerdo con un informe realizado en 2009, en el marco del *National Transport Master Plan 2050* de la República de Sudáfrica (Rail Working Group 2009), el 16,6% de la longitud de las líneas ferroviarias que existen en el mundo son de vía estrecha (anchos de vía entre 914 y 1.067 mm), mientras que el ancho estándar (1.435 mm) está implantado en el 60,2% de la red ferroviaria mundial. Los anchos mayores (de 1.520 a 1.676 mm) están implantados en el 23,2%.

España cuenta con la red de vía estrecha más extensa de Europa, superando las de Suiza o Italia. Esta red no es homogénea. Frente a las subredes que, por ejemplo, se extienden por Cataluña, la Comunidad Valenciana o el País Vasco, las líneas que se desarrollan en la España septentrional (la línea Ferrol – Bilbao y la que une La Robla/León con Valmaseda) conectan municipios con baja densidad de población. Excepto las capitales de provincia y sus cercanías (Santander y Asturias), cuya densidad de población supera los 500 hab/km^2, los municipios conectados por ambas líneas tienen entre 10 y 100 hab/km^2 (Morillas-Torné 2014).

Esta baja densidad de población hace muy difícil justificar una explotación ferroviaria orientada al transporte de viajeros. De hecho, la línea La Robla/León – Valmaseda se construyó con la finalidad de transportar el carbón de las minas de León a las industrias de Vizcaya. Sin embargo, en el caso de la línea Ferrol – Gijón no existía tal justificación, como se ha visto. Esta insuficiente demanda potencial ya se puso de manifiesto antes de que se concluyeran las obras, tal y como señala un informe de la empresa *SOFRERAIL* (*Société*

Francaise d'Etudes et de Réalisations Ferroviaries) encargado en 1963 por la Comisaría del Plan de Desarrollo Español (Gómez Martínez 2005):

> *"Los resultados muy desfavorables obtenidos para las perspectivas de explotación de la línea Ferrol-Gijón inducen a recomendar el abandono inmediato y definitivo de las obras en la sección central Ortigueira - Luarca en donde no se han comenzado aún ningún trabajo de superestructura. La prosecución de la explotación en las secciones extremas Ferrol - Ortigueira y Luarca - Avilés debería ser objeto de un estudio especial, a emprender desde ahora dentro del marco general de las líneas de tráfico reducido y de la coordinación de los transportes y según los métodos recomendados en el estudio hecho por SOFRERAIL por cuenta de la RENFE. Sin esperar los resultados de dicho estudio, se deberían estudiar y aplicar medidas de simplificación de la explotación en estas secciones".*

Esta situación se vio además agravada por una falta de inversiones que permitieran mejorar ciertos servicios (por ejemplo, entre ciudades). En la modernización del Ferrocarril en España, que se inicia con el *Plan de Transporte Ferroviario* (1987), las inversiones que *Feve* precisaba quedaron fuera del mismo, tal y como su presidente, Martínez-Vilanova, reconocía en una entrevista (Muñoz Rubio 2005):

> *«… un problema muy importante durante estos años. De cara al exterior, en las discusiones presupuestarias ha constituido una limitación – diría incluso que una posición de debilidad – el que se negociara las cantidades destinadas a FEVE fuera de las ya comprometidas por el PTF».*

Debe además subrayarse que esta situación fue sensiblemente diferente en las redes de vía estrecha que pasaron a ser de competencia autonómica, en las que se realizaron inversiones, incluso en líneas de débil tráfico (Llevat i Vallespinosa 1996).

La extinción de *FEVE* al finalizar 2012 y la asunción de la gestión por parte de *Adif* y *Renfe Operadora*, unida a la situación que arrastraba la operación ferroviaria, tuvo un efecto imprevisto: la explotación de los servicios que, de forma más o menos precaria, se había ido manteniendo, empezó a tener problemas de regularidad por averías del material móvil y la práctica inexistencia de unidades para poder reemplazar a las averiadas. A pesar de que la situación ha ido mejorando y *Renfe Operadora* ha sacado a concurso la adquisición de nuevo material móvil, no deja de ser una nueva advertencia acerca de la precaria salud de los servicios ferroviarios de vía métrica prestados en la línea Ferrol - Gijón y del incierto futuro de esta línea, tal y como se conoce en la actualidad.

6. LA NECESIDAD DE ACTUAR

La situación que ha alcanzado la red ferroviaria de vía métrica y, en particular, la línea Ferrol – Gijón, requiere actuaciones. Por esta razón, debería redactarse y poner en marcha un plan que permita actualizar esta red y sus servicios.

No debe olvidarse que, como ya en 1979 afirmaba Moseley (Moseley 1979):

> *"El transporte rural representa la sangre que da vida a las comunidades rurales. Tiene un papel vital en el acceso al trabajo y a los servicios."*

Satisfacer la necesidad de transporte público en el ámbito rural siempre ha sido un arduo objetivo. La densidad de población es baja y, como consecuencia, la demanda de transporte también suele ser baja. En general, las soluciones convencionales de transporte público no son capaces de atender este tipo de demandas de una forma eficiente. Los ferrocarriles rurales son particularmente ineficaces en este aspecto, si bien con frecuencia son apreciados por los residentes frente a otras alternativas de transporte (Utsunomiya 2018).

Si se analiza el problema en términos meramente económicos, el cierre de algunas líneas o tramos podría parecer inevitable, ya que la inversión necesaria para mejorar los servicios en estas líneas no se justificaría, al ser demasiado alto en comparación con la reducida demanda.

Debe recordarse aquí la frase de John Stuart Mill, "*Ningún problema económico tiene una solución puramente económica*". Por ello, parece razonable que, sin eludir ninguna posibilidad, la toma de decisiones sobre estas líneas se base en un modelo que contemple diferentes criterios, no únicamente las pérdidas anuales, y que debería responder a preguntas como qué servicios se mantienen, cómo deben configurarse, qué mejoras requiere la infraestructura para poder ofrecer dichos servicios, etc.

Si ello es posible, resulta especialmente útil establecer previamente un estándar para seleccionar, en cada caso, el modo de transporte más adecuado para satisfacer una determinada demanda de transporte (Kurosaki y Alexandersson 2018).

La tecnología sigue ofreciendo soluciones para reducir los costes de mantenimiento de la infraestructura ferroviaria (Bugarín, Novales, y Orro 2004; Muramoto 2017), así como el desarrollo de vehículos ferroviarios mejor adaptados a estas condiciones de operación tan particulares. Todo ello debería contribuir a un descenso de los costes, reduciendo el saldo negativo de explotación.

Finalmente, en párrafos anteriores se han mencionado las redes de vía estrecha de Suiza e Italia. Son dos realidades, entre otras, de las que pueden obtenerse interesantes experiencias. En esta línea, cabe señalar también los cambios recientes que se han producido en el sistema de ferrocarriles locales de Japón (Utsunomiya 2016). Entre ellos, debe destacarse la puesta en marcha de servicios turísticos, cuya expansión está ayudando a compensar la disminución de la demanda en desplazamientos cotidianos. Además, estos servicios turísticos, que se difunden entre los visitantes extranjeros, ayudan a la promoción de productos locales, como el pescado fresco, verduras o productos elaborados de forma artesanal, colaborando en la revitalización de la economía de las comunidades locales.

Por otra parte, en el marco de la lucha contra la despoblación rural, se están definiendo planes maestros para la red de transporte público local, con el fin de revitalizar el transporte público y la sociedad locales. Con este tipo de medidas, desde 2013 no se ha cerrado ninguna línea de ferrocarril en Japón.

Se trata de algunas referencias que se presentan como ejemplo, que en todo caso requerirán de un estudio pormenorizado para analizar hasta qué punto son factibles y eficaces en el caso concreto de la red de vía métrica de Galicia.

AGRADECIMIENTOS

Esta ponencia está basada en el informe desarrollado para la *Asociación Transfronteriza de Municipios Eixo Atlântico do Noroeste Peninsular*, sobre la red de vía métrica en Galicia (Bugarín 2019). Los autores expresan su más profundo agradecimiento a dicha Asociación, con cuyo apoyo se realizó el citado estudio.

ABSTRACT

In recent decades, High-Speed Railway (HSR) lines have become one of the most extended and environmental-friendly ways to plan new mass transport networks. These systems are directly influenced by its operational speed generated dynamic effects and the areas where it runs through. This necessarily requires to predict ground-borne vibrations generated by trains passing-by populated areas and its influence zone.

Trends in ground-borne measurements, prediction models, and isolation systems are usually performed for maximum operation speed. This method implies the maximum dynamic forces which are suitable for structural calculations (generally developed in time domain) but not necessary for vibration related issues (emission and/or transmission). Additionally, these studies are mainly focused on urban areas where maximum operational speed are frequently far from railways service's top speeds.

Related to frequency domain, it is known that upper frequencies are not the most disturbing ones. In fact, European structural standards usually cut frequencies off at 30 Hz, so much relevant information for vibrational prediction is ignored due to it does not influence structural issues.

Moreover, current common predictive numerical models usually apply punctual loads (birth & death) that are disposed to run in certain speed conditions. This method, which is considered valid for time domain analysis, are identified to be incomplete for frequency domain components due to its discontinuous application of loads.

The implementation of contact theories in the wheel-rail interface implies a continuous load application, refining the obtained results but increasing computational cost.

In this study, different scenarios are compared varying inner and boundary conditions of a model, with the aim of validate results and optimize resources by obtaining a parametrical influence study that will show how different assumptions and cases could condition ground-borne vibrational studies results.

1. INTRODUCTION

1.1 Ground-borne vibrations generated by railways. State of the Art.

It is known that railways running along the track produces important vibrations -noise & vibration Pollution- not only in the track but its surroundings, as well as air-borne and structural noise. Assuming the common ‘noise & vibration’ binomial, it is capital to note that two different concepts are then considered.

Regarding the air-borne noise, so many consolidated and standardized methods are sufficiently defined in order to guaranty its measurement and/or prediction models. However, vibrational measurement or prediction modelling is not as standardized due its inner complex phenomena, because its transmission is made along non-homogeneous materials -ground and soils- which is definitely more difficult to analyse or mitigate.

Some particular characteristics about railway related vibrations are:

- Short term events

- Intermittent and repeated sequences due to bogies and axles passing-by. Frequency spectra variable depending on operational issues.
- Moving forces applied
- Non-linear events
- Conditioned by:
    - Track typology -slab or ballasted tracks-
    - Subgrade typology -earthworks, structures, tunnel-
    - Soil characterization
    - Track grade of maintenance

Vibrations are initially generated by wheel–rail contact, subsequently this wave propagates through track components, subgrade and soils to surrounding buildings. Vibrations effects are basically originated by:

- Rolling stock moving loads (quasi-static) and produced deformations
- Wheel and/or Rail unevenness effect
- Punctual track defects
- Axles passing-by effect
- Other track components effect

Aforementioned, one of the major needs for vibrations prediction is to accurately define the transmission media between the source and the receptor. Following image shows common way of generated vibration. As could be seen there, once vibrations are running along soil, any kind of discontinuity as layers or punctual issues, must affect the wave transmission and subsequently, the immission results.

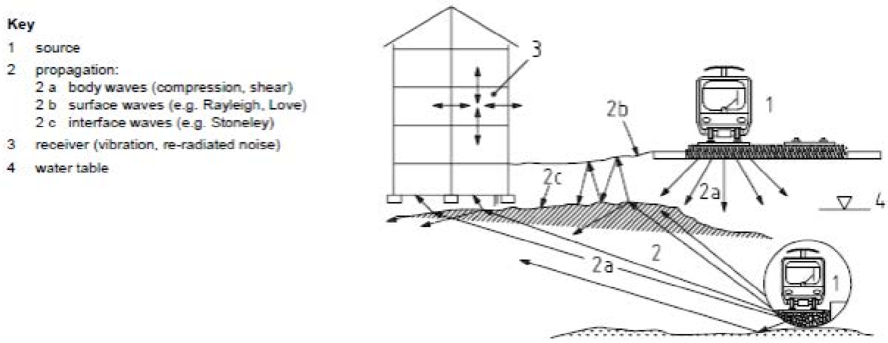

Figure 1. Generation, transmission and immission scheme. Source: ISO 14837-1:2005 Standard

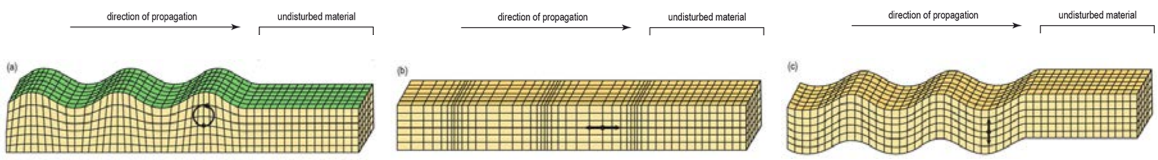
Additionale, each transmitted wave along the soil is mainly divided into three typologies, a) Surface waves, b) P-Waves and c) S-Waves. The following Table shows the main ones and its shape:



a) b) c)

Figure 2. Rayleigh, P & S waves. Source: http://www.kgs.ku.edu/Publications/PIC/pic37.html

Additionally, other capital parameter to completely analyse how these waves moves and its possible attenuation, is to study not only Time domain but Frequency domain.

- Geometrical attenuation: reduction produced by the distance between the source and the measure point. It is not related to frequency domain.
- Material typology attenuation: reduction produced by traversed materials properties. This is directly related to frequency response.

It is important to note that, nowadays, this kind of vibration phenomena is not sufficiently known or modelled due to a non-possible media total characterization.

Vibrational energy arises in structures from its foundations and is distributed througthout it as structural noise and vibrations. In fact, it is common to use empirical formulations.

1.2 Effect of vibrations on humans

With the aim of developing a regulating standard for railway vibrations, structural issues and its influence over humans should be studied. It is capital to analyse possible harmful effects.

Firstly, with the aim of determining the most annoying situations, not only time domain must be done, but a deep frequency domain study must be realized to obtain enough information to evaluate its consequences.
Secondly, one of the most used concepts to analyse frequency domain and ponder it, is the Root Mean Square acceleration -RMS- weighting, that penalizes the identified most harmful frequencies for humans.

Then, due to the wide range of perceptible frequencies, it is not possible to analyse it one by one, thereby it is necessary to agglutinate the spectrum in bands -1/3 octave bands-. Moreover, this bands could be ranged from 1 to 250 Hz for human’s perception .

Finally, based on scientific literature and experience, some reference values are the following:

- Generally, the natural frequency of the most common structures is between 5 and 30 Hz.
- The most annoying frequencies for humans are under 8 Hz.
- Although railways-related vibrations do not show a clear and defined spectrum, maximum energy peaks are generally between 40 and 80 Hz.

2. VIBRATIONAL PREDICTION STUDIES

When carrying out vibrational prediction studies or measurements some stages should be completed before starting works to reach a proper characterization of the existing situation. Previous background and the applicable standards should be determined depending on the location. This process will determine affections and/or existing limit values.

Otherwise, a structural evaluation along the surroundings of the track must be done to identify possible affections. Note that some variances could appear when analysing possible environment affection depending on applicable standard values.

In order to obtain reference values, it is necessary to obtain the existing vibrational values by at-field measuring. Every possible existing source such as surrounding tracks, roads, industrial facilities, and others will be considered.
Once the base plane is fully characterised, a future scenario modelling and prediction is started. With the aim of optimizing time scale and computational cost, a two-step sequence is generally performed:

1. First approach. Analytical models are used to reach some initial rough numbers of vibrational conditions. This kind of modelling does not need important computational resources or time to make a first approach for fencing possible structural affections.
2. Numerical modelling. With the aim of considering the most reliable prediction by modelling existing subgrade, soil or surrounding structures, a numerical specific model is developed.

Finally, some possible necessary solutions for attenuation would be tested to select the optimized system for each detected case. The following list shows presented process:

1. Background and applicable standards
2. Obtain Reference Values
3. Potential affections pre-analysis
4. Future situation analytical modelling
5. First modelling results and initial affections proposal
6. Ad-Hoc soil and structures characterization
7. Detailed numerical modelling
8. Results study and affections refinement
9. Corrective and absorption solutions where necessary are proposed

3. EXISTING STANDARDS

Only European ISO recommendations or guidelines are standardized, so each country and/or region apply its own standard.

Most extended Methods are generally related to a called *K* parameter, which was regulated by ISO 2631-2 (1989). Note that this parameter was deleted in the most recent versions of the standard.

4. MODERN PREDICTIVE MODELS

Due to recent consciousness about these vibrational issues and the increase of operational speeds with High-Speed Railways, deeper studies are necessary to predict future possible effects.

Consequently, vibrational predictive models come up as a tool to simulate railways passing-by and the vibration phenomena generated, and identify possible planification not only for new lines but for track maintenance or renewal.

In recent times, different models arose with this aim. These models are commonly subdivided into independent submodels that are finally interrelated. As represented in Figure 3, three different models are involved in the process: Vehicle model, Subgrade model and surrounding structures model (in case of existing).

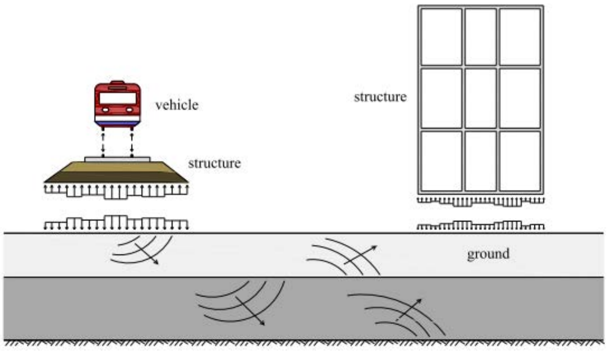


Figure 3. Submodels pipeline to complete a prediction model (Correia dos Santos et al., 2017)

4.1 Vehicle Modelling

For rolling stock modelling, the 'Quarter-car' model is the most extended. It is a Discrete Elements formulation to compose the vehicle model as shown in Figure 4.

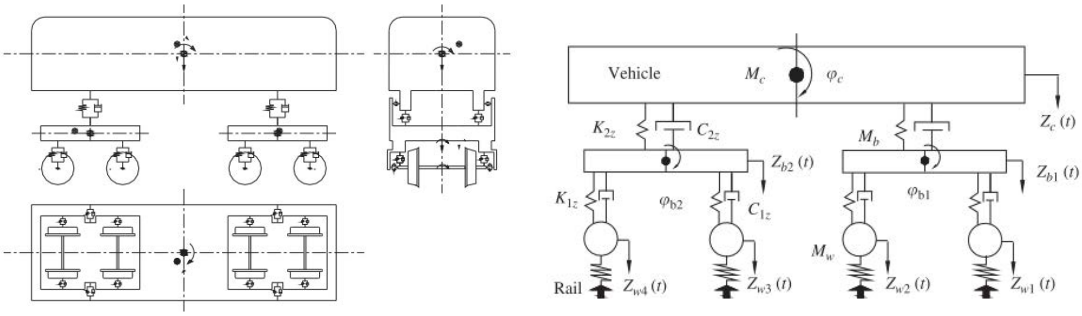

Figure 4.- Comparison between vehicle -left- and its mechanical model -right- (Xin & Gao, 2011)

These representations assume each element of rolling stock as vehicle car mass, suspended mass, unsprung mass, axles or bogies distribution.

4.2 Subgrade Modelling

Regarding track and terrain modelling, two main trends are generally developed depending on the analysis stage or needed accurate. These typologies are the analytical ones and the numerical ones.

4.2.1 Analytical Models

Analytical models (Koziol et al., 2008; Metrikine & Vrouwenvelder, 2000; Salvador et al., 2011) solve the wave equation for a 2-Dimension terrain and assuming viscoelastic layers and linear behavior soils.

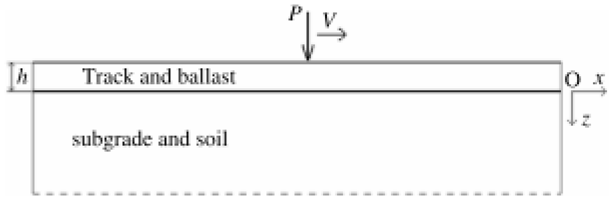

Figure 5.- Diagram for the track & soil model (Salvador et al., 2011)

These kinds of models are also able to consider the static load of the rolling stock and its harmonic without needing high computational resources or processing time.

In contrast, these models are severely limited to be considered a reliable tool to make accurate predictions to be used for planning new infrastructures because they are not able to model non-linear scenarios and punctual situations.

It could be concluded that the use of Analytical models is advisable for a vibrational first approach, initials pre-dimensioning, and/or relative comparisons between comparable track systems due to many analyses could be done in a short-term period.

4.2.2 Numerical Models

Numerical models are based in Finite Elements Method (FEM) and/or Boundary Elements Method (BEM) (Dijckmans et al., 2014; François et al., 2014; Galvín & Domínguez, 2007; Galvín & Romero, 2014; Gupta et al., 2006; Lombaert & Degrande, 2009; Romero et al., 2010, 2013), that provide precise time-domain track responses and their surroundings for accurate future planning predictions, assuming a 3-Dimension model.

Numerical models are feed through track elements geometry & materials specific properties as well as soil layers and environmental elements. These mentioned models mainly subdivided into the rolling stock FEM model and the track & soil BEM model. FEM-BEM coupling is made by Hertzian contact by applying an extra component of rail unevenness.

Usage of BEM reaches several computational savings respect FEM models by avoiding internal mesh points when calculating, and time-domain results are consciously validated by on-site measurements.

In contrast, it is necessary to note that the coupling of models is made by a discontinuous loads time-domain sequence to represent the train movement (loads birth-death process). Figure 6 shows how loads are modelled as punctual at each point depending on time. This discrete loading method commonly ballast the obtained Frequency-domain results due to the instant change of situations.

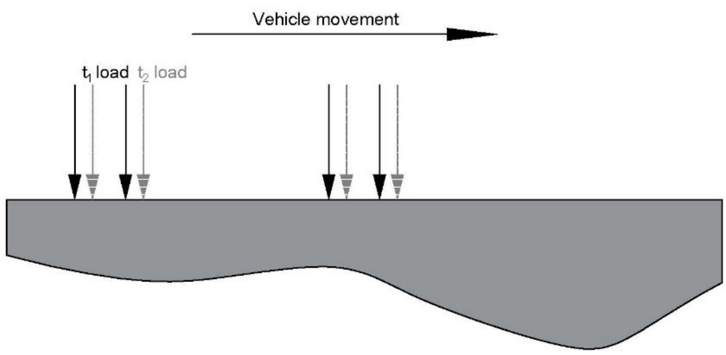

Figure 6. Common practice of numerical model's vehicle loads representation (own elaboration)

5. CONCLUSIONS

Prediction models are nowadays positioning as the elemental tool in railway networks planification and operation. These elements are able to clarify the track surroundings influence of vibrations generated by trains passing-by and also to evaluate possible means to absorb and attenuate these vibrations.

Regarding numerical models' possible future research, there is much work to do, because there are no common standards in the EU or different countries that clearly characterize this necessary process.

ABSTRACT

This paper discusses a case study in which publicly available data of a rail freight transportation firm has been gathered, cleansed, and analyzed in order to: (*i*) describe the data using statistical indicators and graphs; (*ii*) identify patterns regarding several Key

Performance Indicators; (*iii*) obtain forecasts on the future evolution of these indicators; and (*iv*) use the identified patterns and the generated forecasts to propose customized insurance products that reflect the current and future freight transportation activity. The paper illustrates the different methodological steps required during the extraction and cleansing of the data --which required the development of Python scripts--, the use of time series analysis for obtaining reliable forecasts, and the use of machine learning models for designing customized insurance coverage from the identified patterns and predicted values.

1. INTRODUCTION

Data has become an essential element for the operational development and economic growth of many organizations throughout the world. As organizations across the world reach a level of economic abundance, their capacity to efficiently and effectively manage data has become a matter for concern (Parr-Rud, 2012). As a result, organizations from all industries and fields, and those which contribute to an emerging economy are welcoming innovative solutions and methods for managing their volumes of data. For instance, organizations from the railroad freight transportation sector in the United States (U.S.) have experienced substantial data growth throughout the years. This valuable information can be used for identifying factors which can prevent an organization from reaching and maintaining economic growth. According to Samson and Previs (1999), the first train freight transport service contracted in the U.S. took place in 1827. Shipments of cargo were less frequent, and hence, the volume of standard goods being transported were minimal during this period. As a result, risks and incidents that occurred during transportation were minimal. On the other hand, train freight carrier services extend beyond transporting standard items and commodities. Train freight carriers have also committed to cautiously and effectively transport dangerous goods (DG) and hazardous materials (HAZMAT) which are essential for world economies. These materials are employed for powering vehicles, homes, and businesses, and for producing pharmaceuticals, sterilizers, disinfectants, fertilizers, and pesticides. In addition, these highly demanded items require cautious and effective handling and containment. Moreover, train freight carriers have encountered unforeseen challenges during transportation of standard items, DG, and HAZMAT. Increased risks of accidents, loss of goods, and adverse environmental consequences have been the most significant challenges. Therefore, sustaining risks awareness initiatives by assessing and anticipating risks which could occur during train shipments could prepare freight carriers for these unforeseen events. For this reason, the design of Business Interruption Insurance products for protecting the train freight industry from unforeseen circumstances and calamities is imperative.

The proposed insurance product or mechanism would parametrically pay (i.e., based on the collected data over time) when the actual performance falls below the agreed performance thresholds with respect to an established forecast. This type of mechanism would obviate the need to conduct any type of claim or forensic analysis and therefore permit the insured to recover without delay and without the peril of legal disputes.

Substantial data growth which is attributed to the railroad freight transportation sector implies that there is a high demand for the services provided by railroad freight operators.

Therefore, such organizations can profit from the abundance of valuable information extracted from databases by using data analytics not only for examining data, but also for attempting to identify patterns and for forecasting future events. In consideration of the foregoing, this paper will address the use of data analytics and machine learning methods for designing Business Interruption Insurance Products. As a result, data from a U.S. public train freight transportation organization has been extracted and analyzed by employing statistics and graphs. In addition, forecasts were processed for identifying patterns regarding key performance indicators (KPIs), and for supporting the design of business interruption insurance products aimed at safeguarding losses during train freight transportation.

Currently, data analytic methods could be considered the most efficient and effective solution for managing data (Ji and Wang, 2017). In the same manner, machine learning has contributed to the optimization of data analytic methods.

In order to create new knowledge and accomplish the goal of this study, the development of a forecasting model based on historical data that establishes the baseline performance of the freight business at the time of underwriting the policy is proposed. The predicted performance would then be compared with current performance developments.

The presented forecast method could be used for supporting the devising of customized parametric insurance policies that trigger a payout once verifiable conditions aimed at safeguarding losses during train freight transportation are satisfied. These policies could be devised by stipulating a payout that considers the real transported goods against expected transported goods over a certain period of time. In this manner, the policy would behave as a compensation for aggregate drops rather than as a payout for a momentary drop in transported cargo at a particular point in time.

The Methodology illustrates data extraction and cleansing based on the development of Python scripts, and consists of descriptive and predictive data analytics. Subsequently, time series analysis for forecasts on the evolution of these indicators have been provided, which together with previous results, are used with machine learning models for proposing customized insurance products based on identified patterns and predictive values, and for reflecting the current and future freight transportation activity. Subsequent to the Introduction, this paper is arranged as follows: Section 2: Literature Review presents a synopsis of related topics; Section 3: Problem Definition describes the problem contextualization; Section 4: Methodology introduces the tools and methodology for gathering and analyzing the data; Section 5: Results and Discussion provides a data and forecasting analysis of the future; and to conclude, Section 6: Conclusions and Further

Developments highlights the main conclusions of this investigation and proposes future research guidance.

2. LITERATURE REVIEW

The freight transportation industry continuously encounters risks such as loss of cargo due to business interruptions. Addressing these risks has posed challenges in carrying out logistics processes. Risk management has existed for decades and has been essential for logistics processes and systems. When transportation companies are faced with cargo losses, the consequences directly affect the cargo owners. For this reason, companies acquire cargo insurance that provides protection and entitlement to monetary compensation (Wu et al. 2017). Business interruptions affect both the insurance sector and global industries (Mizgier et al. 2018), forcing insurance companies to replace their business models with those that meet financial obligations as a result of an accident (Ganapathy, 2017).

However, few studies have focused on business interruption insurance although it has significant optimization and digitization potential through the use of big data and data analytics (Dong and Tomlin, 2012; Ganapathy, 2017). This literature review presents an overview of existing work on business interruption insurance and data analytics for the freight transportation industry.

According to Gagatsi et al. (2014), the devising of transportation insurance policies is an intricate process requiring extraordinary diligence from all stakeholders and affected economic sectors. Moreover, business interruption insurance products protect against losses incurred during company operational interruptions as a result of unexpected events occurring within their own sites or the suppliers' facilities. Business interruption insurance products are devised to include clauses describing explicit coverage limitations that define three crucial elements: (*i*) the premium which represents the price paid by the interested company for obtaining insurance coverage; (*ii*) the coverage limit which represents the maximum amount paid by the insurer in case of a loss; and (*iii*) the deductible which represents the monetary value of the loss absorbed by the insured company. Prior to establishing prices for customized business interruption insurance products, insurance providers must access the facilities of prospective insurance holders for assessing possible loss values (Dong and Tomlin, 2012).

Keller et al. (2018) have reported that data analytics has played a fundamental role in insurance policies allowing them to evolve from "intuitive bets" on the future to an industry based on logic calculus and decision making. They also considered that recent advances in big data analytics, artificial intelligence, and the internet of things promise to transform the role of data by understanding risks and protecting insurance product holders by providing compensation for incurred losses. According to Frees (2015), "insurance is a data-driven industry" which is linked to data and models of uncertainty. Insurance is also of a random nature, given by the very concept of payment, compensation, risks, as well as their grouping and dispersion. Understanding its benefits leads to the relationship of all factors involved giving rise to stochastic models that have correlations for measuring dependencies between random outcomes. A statistical data analysis pioneer who aimed at investigating the distribution of business interruption products was Zajdenweber (1996) from the French

Insurance Syndicate. Zajdenweber (1996) analyzed the consequences of Pareto's alpha exponent law when the tail was close to one on the actuarial risk. Pareto's law asserts that 80% of outputs results from 20% of all inputs. This implies that premium calculations for 100% insurance coverage require an uppermost limit corresponding to the highest potential loss. He also concluded that the insurer and reinsurers' financial stability requires funds for coping with annual fluctuations and unforeseen events. Dong and Tomlin (2012) explored the relationship between business interruption products and operational measures such as inventory and emergency sourcing as strategies for managing business disruption risks.

Moreover, an endogenous insurance pricing model was used for providing reliable insurance coverage and for supporting operational decisions. The results highlighted the importance of linking effective decision making and risk management practices into operational processes.

According to Frees (2015) description of the contributions of analytical and statistical methods for insurance market operations, analytical predictions are advanced data mining tools. Among the applied methodologies are the neural networks, the classification trees, and non-parametric regression statistical methods. An example of this is the methodology for calculating the Fuzzy net present value proposed by Neto et al. (2012). The net present value verifies the viability of purchasing a business interruptions insurance product for an offshore production unit. Moreover, it is the result of the discounted cash flow which gives rise to uncertainty with the available information. In Zurich, Switzerland, Mizgier et al. (2018) developed a collaborative project between Zurich Insurance and the Swiss Federal Institute of Technology. A large amount of data concerning business interruption claims from various data sources was extracted and analyzed. The results enabled Zurich Insurance to design and implement a relevant business interruption insurance service proposition for customers.

In the case of business interruption products for the freight transport industry, Zhen et al. (2016) proposed a model based on the work of Dong and Tomlin (2012). This model characterized the relationship between transport recovery and business interruption insurance when transport costs were uncertain and when transport recovery was deemed an endogenous factor. In the same manner, Li et al. (2018) developed a fine-grained transport insurance prototype based on blockchain and internet of things technologies. The insurance premium was evaluated on the basis of vehicle use and driver behavior. The insurance and payment model were implemented using an Ethereum framework by saving data from mobile sensors. Wang et al. (2018) contributed to the literature for the high-value transportation disruption including the value declared by the customer, the optimal insurance premium, and the strategy preference problem of the express logistics providers. Two types of contracts were developed, the additive and the multiplicative, which depend on actual probability of disruption where it is critical for the express logistics providers to be aware of the actual value of the load in order to maximize its profits. This proposal benefits both the transport company and the insured customers. In addition, studies have been based on data analysis that propose management improvements and support decision making in freight transport cases involving business interruption insurance. For example, Tatarinov and Kirsanov (2019) built an information support system aimed at managing the road transportation of dangerous goods based on a systematic approach that relies on guidance documents and that employs information and communication technologies for transmitting information from moving vehicles to duty vehicles. This system includes the load insurance during the transport by road organization stages. Wu et al. (2017) also addressed the management of logistics risks based on knowledge discovery in databases procedures with business analytics of descriptive, predictive, and prescriptive analysis to address load loss incidents. In relation to business interruption insurance, they conceived strategic cargo loss insurance policies where they used insurance company claim databases for not only preventing the financial losses caused by incidents, but also to avoid jeopardizing the company's competitiveness. Currently, investigative research on business interruption insurance and data analytics for the freight transportation industry remains limited and inadequate. Nonetheless, the insurance industry seems to be clear about the importance of integrating big data and data analytics into activities such as product development, portfolio analysis, underwriting operations, pricing, and loss and control. As insurers venture beyond the analysis of structured transaction data to incorporate external data of all kinds, the combination and analysis could be challenging (Breading and Garth, 2014).

3. PROBLEM DEFINITION

The case study in this research is a recognized train freight transportation company servicing the U.S. railroad industry. Its railways cover thousands of miles across the U.S. eastern contiguous territory. It operates up to 1,300 trains per day, and it transports some 6.5 million carloads of products per year. Moreover, HAZMAT constitutes 7.5% of the company's yearly cargo. As with all organizations, train freight transport has not been exempted from encountering challenges in the course of its organization's development. Train freight carriers that assess, anticipate, and are informed of the various risks which could occur during train shipments are less affected by unforeseen circumstances.

More recently the managing of emerging or accelerated data growth has become a trending concern. Train freight transport companies generate and store excessive volumes of data in their organization's internal database. Consequently, the data becomes valueless if it is not analyzed. However, by employing the analyzed railway transportation data through descriptive and predictive analytics, a forecasting model was developed. This forecasting model supports the devising of customized insurance policies by calculating the probability of transportation statistics deviation from the forecasting model. Had the railway operator and insurer accepted the customized model terms as a valid trading tool, this calculation could allow the insurer to stipulate a compensation amount if the forecasted drop materialized. This mechanism would allow the devising of parametric business interruption policies that compensate the railway operator if certain transportation KPIs deviate from expectations.

This descriptive and predictive data analytic model based on historical data will identify the patterns and will generate a forecast in order to define KPIs and thresholds. Therefore, the resulting information will support decision making strategies and present insights for devising customized business interruption insurance products. In addition, it will define the baseline performance at the time of signing the policy intended for minimizing losses occurred during train freight transportation and will protect the rail freight transportation industry from unforeseen circumstances and calamities.

4. METHODOLOGY

With the exponential growth of data from businesses, data analytic methods have been considered by experts as one of the most efficient and effective solutions for managing information (Ji and Wang, 2017). Recently, this process has been optimized by the use of machine learning algorithms that have contributed to the management of large amounts of valuable information. The machine learning algorithms are implemented for searching through a set of possible predictive models and for identifying the model that best captures the relationship between the descriptive traits and the objective feature of a data set (Kelleher et al. 2015).

Moreover, the objective of this investigation is to examine all past and current information derived from an active freight transportation company by employing a descriptive and predictive analytical methodology. With the examination results, customized insurance products that consider identified patterns and predictive values that reflect the current and future freight transportation activity could be proposed. This methodology is based on the development of Python scripts that perform data extraction, cleansing, and descriptive and predictive data analyses through data analytic techniques. Subsequently, machine learning methods will be applied for predicting the evolution of the gathered indicators.

4.1 Data Wrangling

The methodology starts with gathering and processing a large amount of raw data from the active freight transportation company which is publicly available online in a PDF format.

This process, referred to as *data wrangling*, consists of cleansing, structuring, and enriching raw data into a desired format for effective and prompt decision making (McKinney, 2012).

The following tasks were performed for generating the final structured data: (*i*) data gathering from the web; (*ii*) correction of typographical errors and standardizing product titles (also referred to as *metrics*); (*iii*) deletion of empty and duplicate entries; and (*iv*) categorizing and structuring the pre-processed data according to the metrics, weeks, and years. Subsequent to the gathering of data, the methodology approach will address performing a descriptive analysis and performing forecasts. Figure 1 presents an example of the resulting structured data gathered from previous steps. Notice that the data is categorized by metric, year, and week. For the year 2020, the gathered structured data was collected only up to the 38th week of the year and does not reflect the entire year.

```
                          Metric  Year   Value  Week
0                          Grain  2013    2672     1
1             Grain Mill Products  2013    2082     1
2        Farm Products, Ex. Grain  2013     255     1
3                   Food Products  2013    1674     1
4                       Chemicals  2013   10087     1
...                           ...   ...     ...   ...
10045              Total Carloads  2020   64783    38
10046                    Trailers  2020    2109    38
10047                  Containers  2020   57904    38
10048            Total Intermodal  2020   60013    38
10049               Total Traffic  2020  124796    38

[10050 rows x 4 columns]
```

Figure 1 – Structured data example.

4.2 Descriptive Analysis

Once the data was structured as presented in Figure 1, the descriptive analysis was initiated.

The exploration of the data was performed with data visualization techniques such as pie charts, bar charts, histograms, and time series charts. For this purpose, the methodology approach filtered the data according to the desired analysis to be performed. For example, the data was filtered by specific year(s) and/or by a specific number of weeks. However, only the first 38 weeks of the year 2020 were filtered in order to provide and perform approximate comparisons with other years within the same time period.

Subsequently, a series of statistical data analyses that included graphs and metrics were performed. Such analyses were used for extracting information that reveals the following criteria for each year: (*i*) the histogram of the total transported carloads for each product in 2019; (*ii*) the volume percentage of the 10 most transported carloads in 2019; (*iii*) the time series of transported carloads by product from 2013 to 2020; (*iv*) the mean volume of transported products per season (winter, spring, summer, and autumn of 2013 to 2020).

4.3 Predictive Analysis

The structured data was composed of a sequence of values representing each type of transported products from 2013 to 2020. As a result of the data having been categorized into weeks and years for each metric, this categorization resulted in a sequence of values over time, i.e., a time series forecasting. Given this particularity for making projections about future performance on the basis of the gathered historical and current data, i.e., the forecast, a predictive model was proposed by applying the Holt-Winters forecasting model (Chatfield and Yar, 1988), also known as the *triple exponential smoothing* for time series forecasting.

Another reason which supports the use of the Holt-Winters forecast modeling method refers to the fact that this data reveals trend and seasonality over an entire year of (52 weeks). As a result, the introduction of an additional parameter to handle seasonality is required

(Kalekar, 2004). When the model is trained with the historical data, the model becomes a machine learning method that uses previously transported volume values that support the designing of customized business interruption insurance products based on identified patterns and predictive values that protect the train freight industry form unforeseen circumstances and calamities.

Figure 2 summarizes the methodology steps beginning from the raw data extraction to its analysis and prediction of future events.

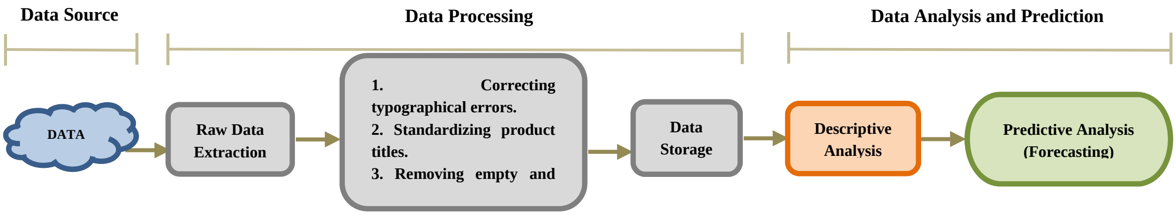

Figure 2 – Methodology Steps.

5. RESULTS AND DISCUSSION

This section provides a descriptive and predictive analysis of the train freight transportation data. In addition, a predictive model validation has been included. Moreover, this section will reveal the proposed customized insurance product functionality once all models are created. In accordance with the data structure, the following criteria was assessed for each year: (*i*) the total transported carloads for each product in 2019; (*ii*) the volume percentage of the 10 most transported carloads in 2019; (*iii*) the time series of transported carloads by product from 2013 to 2020; (*iv*) the mean volume of transported products per season (winter, spring, summer, and autumn) of 2013 to 2020; (*v*) the forecast for the year 2021, and (*vi*) the predictive model validation which included real data vs a forecast from 2019. Descriptive and predictive analytic methods were applied for completing this investigation. Furthermore, this analytical method involved monitoring data trends and patterns. The database representing the year 2019 was queried by employing a descriptive analytic method. The parsing process and descriptive analysis were developed using Python scripts.

5.1 Train Freight Transportation Descriptive Analytics

The descriptive analysis revealed the total transported carloads for each product in 2019 as depicted in Figure 3. According to the bar chart, the largest total volume carload was Coal with a total volume of 783,777 carloads. However, the least total volume carloads were Farm Products (excl. Grain) with a total volume of 9,514 carloads.

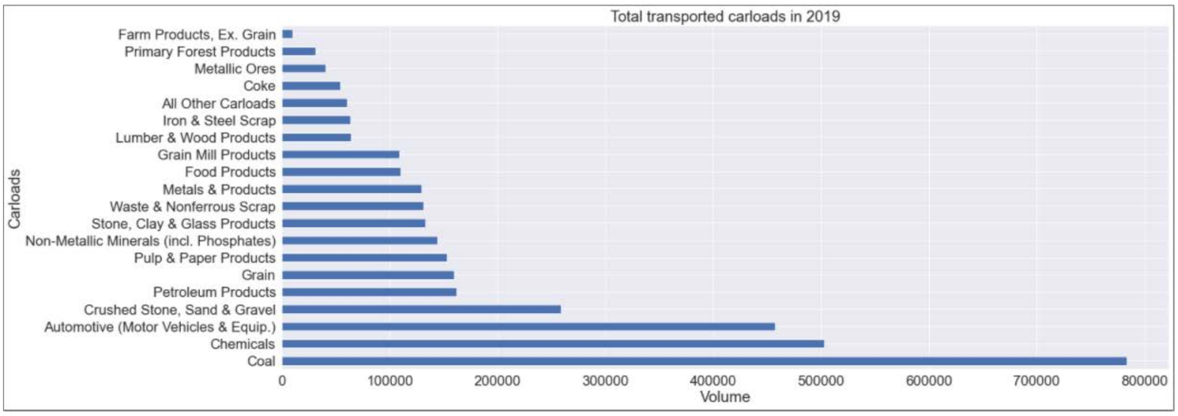

Figure 3 – Total transported carloads for each product in 2019.

Moreover, the 10 most transported carloads of 2019 are presented in Figure 4. Those carloads representing the most significant carloads were Coal with 27.1%, Chemicals with 17.4%, and Automotive (Motor Vehicles & Equipment) with 15.8%. The transport of Petroleum Products, Grain, Pulp & Paper Products, Non-metallic Minerals (Incl. Phosphates), Stone, Clay and Glass Products, and Waste and Nonferrous Scrap represented an approximate proportion of about 5% of the total.

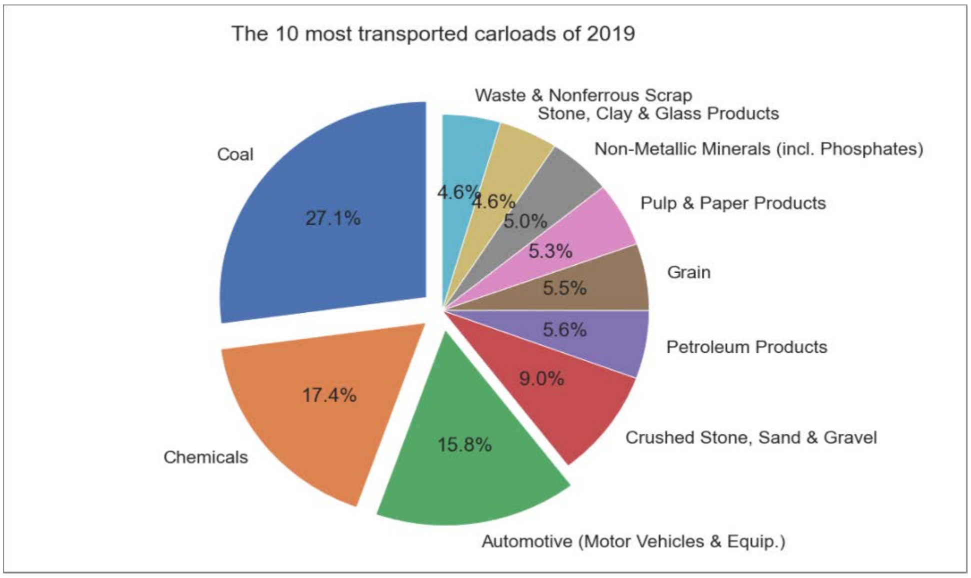

Figure 4 – Volume percentage of the 10 most transported carloads of 2019.

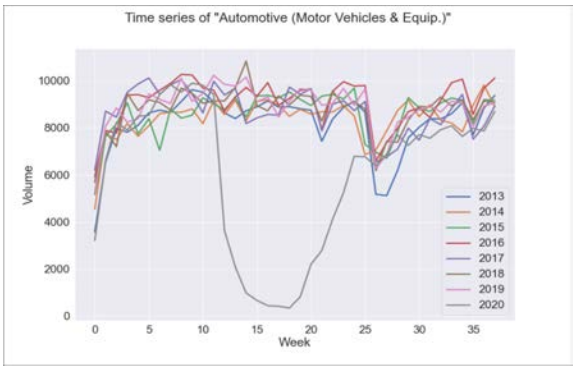
Figure 5 represents the weekly time series of four distinct transported carloads from 2013 to 2020: (*a*) Automotive (Motor Vehicles & Equipment), (*b*) Chemicals, (*c*) Coal, and (*d*) Food

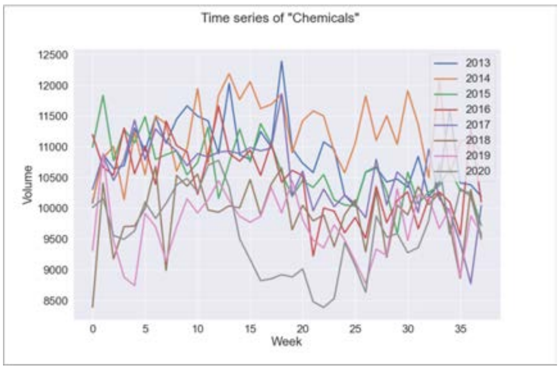
Products. The equivalent volumes of each carload per week provide a clear representation of the overall trend in the variability of each carload over the years. These graphs allow for a year-to-year behavior comparison for each week. For example, from 2013 to 2019, the Automotive (Motor Vehicles & Equipment) transported carloads maintained the same behavior week by week with approximately 2,000 units when compared to previous years. A similar trend can be observed for Food Products. Contrary to this, Coal volumes descended by almost 10,000 units in 2015. From then onward, volumes remained between 10,000 and 17,000 units until 2019. In the case of Chemicals, transported carload volumes had ascending and descending movements. During mid-2016, a decline in Chemical carloads became evident. Then in 2017, Chemical carloads began to ascend. However, during 2018 through the 38th week of 2020, Chemical carload volumes descended. Although the year 2019 collectively experienced the lowest Chemical carload activity when compared to other years, both 2017 and 2018 experienced the lowest Chemical carload points within a fractional period.

Moreover, the COVID-19 pandemic and its impact on carload volumes was also considered. The impact was more evident during week 10 of 2020. In particular, the Automotive (Motor Vehicles & Equipment), Chemicals, Coal and Food Products carloads were the most affected as a result of the COVID-19 preventive restrictions imposed by local governing authorities.

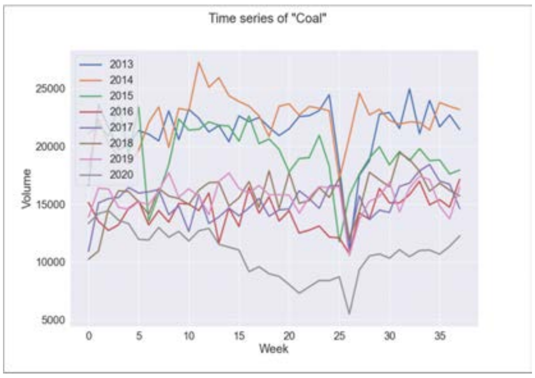
Despite the impact COVID-19 had on carload volumes, it can be observed that the need of Chemicals for producing sanitizers against COVID-19 resulted in a fast recovery for Chemicals' carload volumes. Furthermore, first necessity goods such Food Products carload volumes recovered faster than other transported goods.



(a) – Automotive (Motor Vehicles & Equip)



(b) – Chemicals



(c) – Coal

(d) – Food Products

Figure 5 – Time series of transported carloads from 2013 to 2020: (*a*) Automotive (Motor Vehicles & Equipment), (*b*) Chemicals, (*c*) Coal, and (*d*) Food Products.

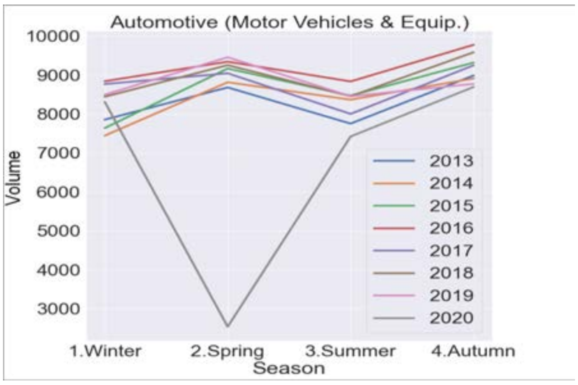
To complement the descriptive analysis, a seasonal analysis was completed. Figure 6 represents the volume of four distinct transported carloads per season (winter, spring, summer, and autumn) of 2013 to 2020 for (*a*) Automotive (Motor Vehicles & Equipment), (*b*) Chemicals, (*c*) Coal, and (*d*) Food Products. The values for each season correspond to the "Mean" value of each carload. This compact structure generates a visualization of the year-by-year changes reflected in the columns. Figure 6 (a) illustrates a variability of 2,000 units between the 7,000 to 10,000 volume unit range for the Automotive (Motor Vehicles & Equipment) carload. This variability consists of comparable seasonal behavior where carload volumes increased during winter to spring and decreased during spring to summer.

The atypical behavior of transported carloads during spring of 2020 is exhibited in Figure 6 (*a*, *b*, *c*, and *d*). This atypical behavior resulted from the unexpected COVID-19 pandemic.

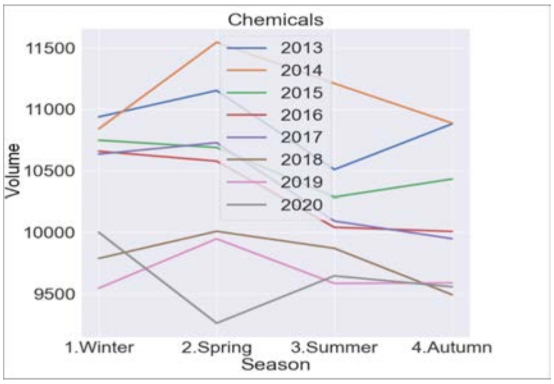
With the exception of 2020, spring was the season with the highest transported Food products carload volumes as illustrated in Figure 6 (*d*). Figure 6 (*a*, *b*, *c*, and *d*) illustrates the reactivation and recovery trend of the world economy following the COVID-19 pandemic. A similar carload volume recovery trend can be observed during autumn with the appearance of a second phase in some countries. The difference in volumes between the analyzed years remained stable since 2013 by approximately 350 units. On the other hand, Coal and Chemicals experienced greater carload volume variability from one year to the next as depicted in Figure 6 (*b*) and (*c*). Coal carload volumes for example remained at a high level from 2013 to 2015.

Although Coal carload volumes decreased between 2016 and 2017, carload volumes began ascending in 2018 and onward. This ascending behavior was particularly observed during spring of 2019 when Coal carload volumes reached its highest average volume throughout the analyzed years. Chemicals' carload volumes exhibited similar behavior in terms of year-to-year volume variability. Between 2015 and 2017,

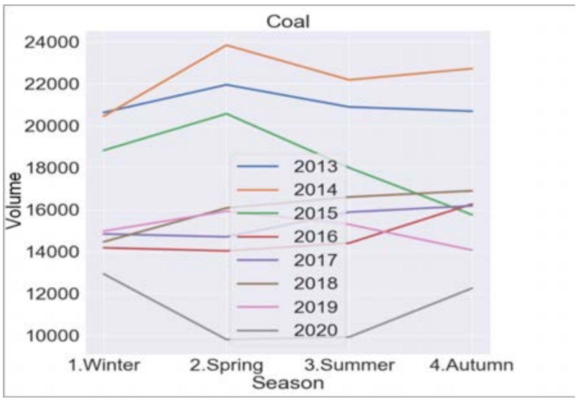
Chemicals' carload volumes followed a similar trend. A significant decrease in transported carload volumes was observed for the years 2018 and 2019. Figure 6 (*a*, *b*, *c*, and *d*) illustrates a significant decrease in transported volumes during the spring of 2020 due to the COVID-19 pandemic.



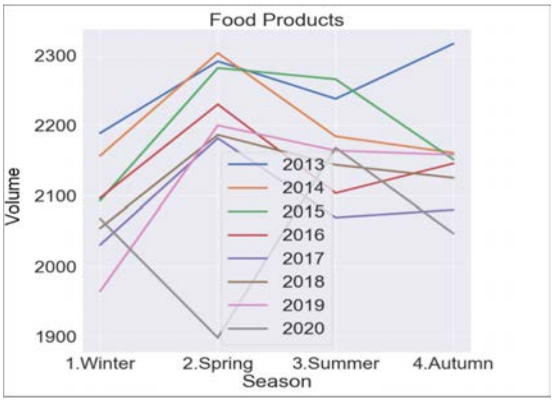
(a) – Automotive (Motor Vehicles & Equip)



(b) – Chemicals



(c) – Coal



(d) – Food Products

Figure 6 – Mean volume of transported carloads per season (winter, spring, summer, and autumn) of 2013 to 2020: (*a*) Automotive (Motor Vehicles & Equipment), (*b*) Chemicals, (*c*) Coal, and (*d*) Food Products.

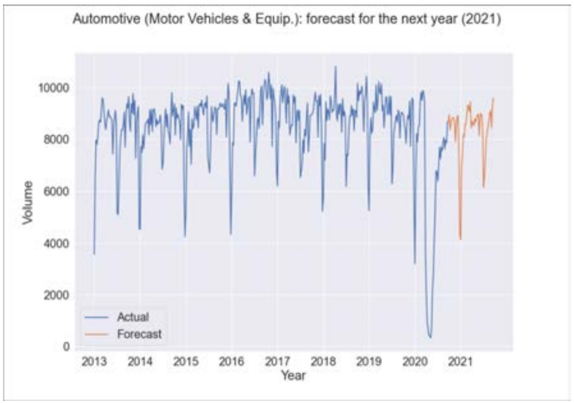
5.2 Train Freight Transportation Predictive Analytics

The Predictive analysis provided a transport carload volumes 2021 forecast for (*a*) Automotive (Motor Vehicles & Equipment), (*b*) Chemicals, (*c*) Coal, and (*d*) Food Products. The forecast can be observed in Figure 7 (*a*, *b*, *c*, and *d*).

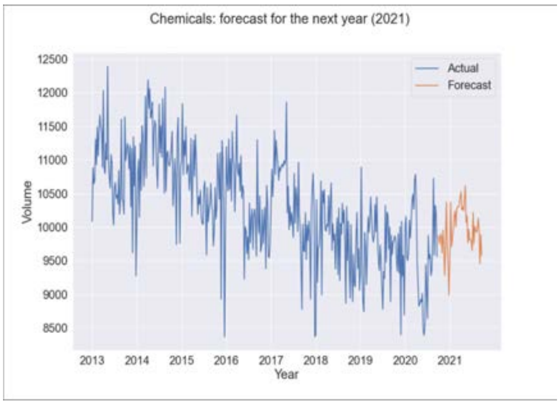
According to the one-year forecast, from week 38 of 2020 to week 38 of 2021, two significant decreases in transported carload volumes were anticipated in the Automotive (Motor Vehicles & Equipment) carloads. A decrease in transported carload volumes was expected towards the end of 2020. However, an increase in carload volumes was expected during the subsequent weeks. This increase of carload volumes is expected to maintain a stable flow until June 2021 when a decrease in carload volumes is anticipated. In the case of Chemicals, carload volumes were expected to remain stable during 2020. Then in 2021 onward, the carload volumes of Chemicals would begin an ascending trend. Chemicals' carload volumes similar to the previous year can be expected. In contrast, the transportation of Coal carload volumes descended since mid-2014. The forecast for Coal carload volumes anticipates a descending trend falling under carload volumes from the previous years.

In the case of Food Products, a comparable trend to Coal is anticipated, however, with less variability as has occurred during the previous years.

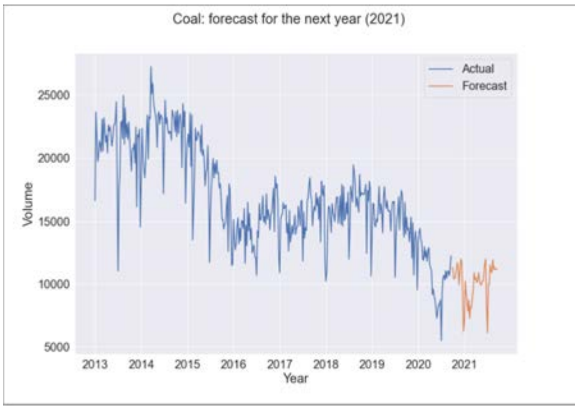
Moreover, a Predictive analysis could support decision-making by analyzing data patterns. As a result, business interruption insurance product thresholds can be set and defined with premiums established by the Insurer and the Insured in the event of exceeding thresholds.



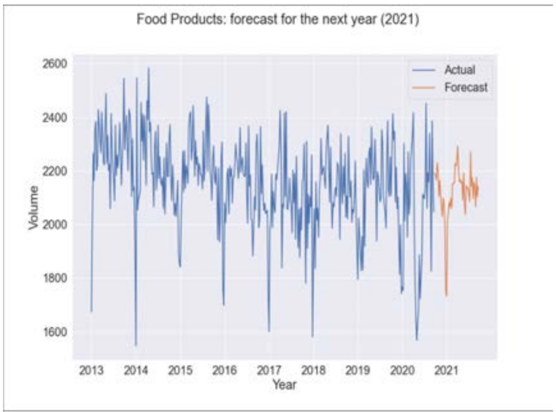
(a) – Automotive (Motor Vehicles & Equip)



(b) – Chemicals



(c) – Coal



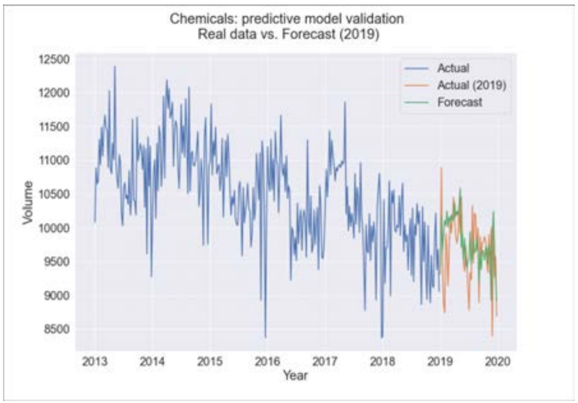
(d) – Food Products

Figure 7 – 2021 Forecast for (*a*) Automotive (Motor Vehicles & Equipment), (*b*) Chemicals, (*c*) Coal, and (*d*) Food Products.

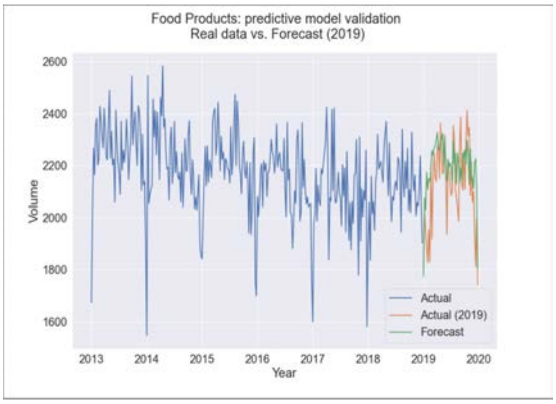
5.3 Predictive Analytics: Model Validation

The predictive model was validated with the cross-validation method which is a statistical method used for estimating the skills of machine learning models. The cross-validation method examined data from 2013 to 2019. The examined data was subsequently used as training data for this model. The validation data corresponds to the year 2019. Figure 8 (*a*) and (*b*) illustrates the predictive model validation for (*a*) Chemicals and (*b*) Food Products carloads, and compares Real Data with that of a 2019 Forecast. The comparison distinguishes actual 2019 data from predictive data that indicates what was expected to occur during 2019.

The predictive model graphs of both Chemicals and Food Products carloads exhibit the transported values for each period of the year. However, the predictive model graphs illustrate that during the first weeks of 2019, both Chemicals and Food Products carloads would have higher values than those actually obtained. Despite this difference, both the predictive model and the actual values indicate similar trends. In the second half of the year, the model values were closer to the actual values and accurately described the transported quantities of each product.



(a) – Chemicals



(b) – Food Products

Figure 8 – Predictive model validation: Real data vs. 2019 Forecast for (*a*) Chemicals and (*b*) Food Products.

Altogether, the values predicted by the model do not exactly match the actual values. In addition, as illustrated in Figure 8 (*a*) and (*b*), the model does not predict statistical data points or outliers which differ from the actual values such as volume increases and decreases.

Therefore, the validation revealed that predictive models based on the Holt-Winters forecasting method allow for predicting data behavior. Nevertheless, the model does not anticipate unexpected events. The model does however accurately predict behavior of values for each week.

5.4 Train Freight Transportation Customized Insurance Product

Once all models are created, the forecasting system will support the devising of customized insurance policies based on KPIs or metrics that trigger a compensation or payout upon satisfying the previously agreed conditions stipulated in the policies.

To understand how a customized insurance product works, the developments of the novel Coronavirus disease of 2019 or COVID-19 have been considered in this insurance policy "example". In December 2019, COVID-19 which is caused by the Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) was detected. Nevertheless, it was not until March 2020 that COVID-19 was declared an official world pandemic. Assuming that prior to the COVID-19 outbreak, an insurance policy for the transportation of Automotive (Motor

Vehicle & Equip.) carloads stipulating coverage throughout the entire year of 2020 was devised and bound, and had been in effect noting the following condition:

- *Condition: The policy begins to pay once the transported carloads fall below a threshold of 7,000 carloads.*

Under this condition, will the railway operator receive a payout? As previously illustrated in Figure 5 (a), there was a significant decrease in the transport of Automotive (Motor Vehicle & Equip.) carloads in March 2020 when COVID-19 was officially declared a world pandemic and preventive measures were imposed. It is evident that throughout weeks 10 to 25, the carloads dropped below the 7,000 carloads threshold. In such an event, a payout would be triggered as it satisfies the condition. The insured or policyholder would receive the agreed compensation limit for business losses, approximated by the drop in cargo versus the expectations derived from the forecasting model. Such a policy mechanism, while applied to different cargo types, would offer the railway operator a statistical option for hedging potential business losses due to unexpected events. The fact that the forecasting model is fixed prior to the policy being devised and bound allows for both parties to agree on the algorithm as a feasible trading mechanism.

6. CONCLUSIONS AND FURTHER DEVELOPMENTS

As businesses emerge throughout the world, data has become an essential element in their operational development and their economic growth. In this study, a series of descriptive and predictive data analysis from an existing freight transportation company was performed for devising customized insurance products aimed at identifying existing data values and patterns, examining current data, and for predicting losses that could occur during freight transportation. In this regard, Python scripts for extracting and analyzing raw data were developed. In addition, machine learning strategies for predicting events that could result with losses were adopted.

The revealed information from the analyzed data was subsequently used for adopting resolutions and supporting decision making. Moreover, the data acquired from the 10 most transported carloads revealed informative discrepancies that could prevent businesses from reaching their operational and economical potential.

The employed analytical methods in this study facilitate the designing of customized business interruption insurance products for protecting businesses from losses resulting from unexpected events or disruptions such as the COVID-19 pandemic. For example, the data analysis performed for supporting this study revealed those carload volumes that decreased during transportation and those carload volumes that recovered during the developments of the COVID-19 pandemic. Furthermore, as world economies grow and business operations thrive, data analytics is emerging in a short period of time.

In an effort to protect businesses from sustaining financial losses as a result of unexpected events and disruptions, a daily data analysis rather than a weekly analysis could possibly improve the accuracy in predicting fluctuating data behavior. Data is knowledge, and with knowledge, businesses will be predisposed with the necessary criteria for predicting operational activities, making decisions, and for acquiring reliable insurance products.

RESUMEN

El cambio climático y el previsible aumento de los fenómenos climáticos extremos, tales como olas de calor o lluvias torrenciales, supone un gran desafío para la sociedad en su conjunto y para los medios de transporte en particular. El ferrocarril, cuya infraestructura se extiende por todo el territorio, debe afrontar dicho desafío y adaptarse a su entorno para mantener su sostenibilidad y fiabilidad en el futuro.

En este contexto, y como parte del proyecto de investigación MINFECLIMA (fruto de la colaboración entre AZVI, S.A.U. y SIER en el marco de una Convocatoria de Cooperación Internacional, con financiación del CDTI proveniente del Ministerio de Ciencia, Innovación y Universidades), se pretende monitorizar ciertos aparatos de vía especialmente críticos y vulnerables (como pueden ser desvíos o aparatos de dilatación) mediante sensores in situ, buscando un sistema sencillo que sea capaz de recopilar y transmitir datos regularmente. Entre otros, se pretende recoger información sobre temperaturas en carril y desplazamientos.

Posteriormente, estos datos se podrán analizar para evaluar el comportamiento de dichos puntos críticos de la infraestructura ferroviaria, y determinar su posible vulnerabilidad frente a fenómenos extremos que se prevén más adversos y habituales en el futuro. En última instancia, se pretende contribuir a lograr un ferrocarril más resiliente y fiable.

1. INTRODUCCIÓN

Durante las últimas décadas se ha venido observando cómo las infraestructuras de transporte se ven cada vez más afectadas por fenómenos meteorológicos extremos. Olas de calor, heladas o lluvias torrenciales pueden afectar seriamente a las redes de transporte, provocando graves daños e interrumpiendo servicios esenciales para el buen funcionamiento de nuestra sociedad. De acuerdo a las previsiones más recientes, estos fenómenos no harán sino agravarse en el futuro debido al cambio climático, por lo que se prevé necesaria una gran inversión para aumentar la resiliencia de todas las infraestructuras de transporte (IPCC, 2014).

Centrándonos en las redes ferroviarias, existen todavía ciertas carencias a la hora de cuantificar los efectos de los fenómenos climáticos extremos sobre la infraestructura y el servicio, debido en parte a las incertidumbres asociadas a la propia evolución del clima en las próximas décadas. No obstante, se han llevado a cabo algunos estudios en diferentes países para tratar de poner cifras al impacto del clima sobre las redes ferroviarias. Así, por ejemplo, Duinmeijer y Bouwknegt (2004) determinaron que los factores climáticos son responsables de entre un 5 y un 10% de los fallos en los ferrocarriles de los Países Bajos, cifra que Thornes y Davis (2002) elevan hasta el 20% en el caso del Reino Unido.

Son diversos los impactos que el clima puede tener sobre la infraestructura ferroviaria. Las olas de calor, por ejemplo, pueden provocar un fallo por pandeo, un fenómeno brusco de inestabilidad de carril que altera por completo la geometría de la vía y eleva el riesgo de descarrilo (Esveld, 2001). Según datos de la Agencia Europea del Ferrocarril (ERA), sólo en el año 2018 se produjeron más de 6000 episodios de pandeo en toda la red de la UE28, y esta cifra sigue una tendencia ascendente en la última década (Villalba et al., 2020). Según Dobney et al. (2009, 2010), el coste anual de los eventos de pandeo en la red ferroviaria del Reino Unido supera los 9 millones de libras, y Quinn et al. (2017) predice que esta cifra podría doblarse hacia el año 2080. Otros estudios como los de Baker et al. (2010), Palin et al. (2013) o Villalba et al. (2020) también predicen un aumento significativo de eventos de pandeo en el futuro. Respecto a los aparatos de vía, estos elementos son el componente principal de la infraestructura ferroviaria que afecta la disponibilidad del sistema (Morant et al., 2016), donde casi el 33% de los costes totales de mantenimiento es dedicado a los desvíos y cruces (Wang et al., 2017).

Otro impacto sobre la infraestructura ferroviaria digno de mención es la inestabilidad de taludes debidas a las lluvias torrenciales. Esta clase de fallo catastrófico depende en gran medida de la distribución espaciotemporal de las precipitaciones (Corominas et al., 2005), distribución que es de prever que se modifique notablemente en los próximos años a causa del cambio climático (Manning et al., 2008).

De ahí que diversos estudios sobre resiliencia de las infraestructuras ferroviarias (Quinn, 2017; UITP, 2016) destaquen la inestabilidad de taludes y los desprendimientos provocados por lluvias como uno de los principales fenómenos a tener en cuenta en el futuro.

En este contexto, es evidente que resulta imprescindible adaptar la infraestructura ferroviaria a las condiciones cambiantes del clima. Así, organismos internacionales tales como la UIC (Quinn, 2017), la UITP (2016) o la Agencia Europea del Medioambiente (EEA, 2014) ya han establecido recomendaciones generales de adaptación al cambio climático. También es de destacar en España el informe de necesidades de adaptación al cambio climático de la red troncal de infraestructuras de transporte elaborado por el CEDEX y el Ministerio de Fomento (2013). Sin embargo, a pesar de estos esfuerzos aún no existe, a día de hoy, un marco general o metodología unificada para afrontar estos problemas, y salvo algún caso aislado (siendo Network Rail en Reino Unido el más notable), ningún gestor de infraestructura ferroviaria ha adaptado todavía sus protocolos de monitorización y mantenimiento de acuerdo a las previsiones de cambio climático, o en todo caso no ha pasado de establecer algunas líneas o principios generales.

El proyecto MINFECLIMA nace precisamente con el objetivo de contribuir a un mejor mantenimiento de la infraestructura ferroviaria para adaptarla al cambio climático. Se trata de un proyecto de investigación desarrollado por AZVI S.A.U. y SIER en colaboración con la Universitat Politècnica de València en el marco de una Convocatoria de Cooperación Internacional con financiación del CDTI proveniente del Ministerio de Ciencia, Innovación y Universidades. Una de las principales tareas del proyecto se centra en monitorizar durante un largo período de tiempo ciertos elementos de la vía especialmente críticos y vulnerables, tales como desvíos o aparatos de dilatación.

Los trabajos presentados en esta ponencia se centran en la metodología de monitorización de un aparato de dilatación, detallando el montaje realizado, el tipo de datos a recopilar y una primera aproximación a la clase de análisis que se espera aplicar sobre los mismos.

2. METODOLOGÍA

En el marco del proyecto MINFECLIMA, antes explicado, se planea monitorizar durante un largo período de tiempo varios puntos críticos de la infraestructura ferroviaria, para poder recopilar un gran volumen de datos que permita determinar con mayor precisión los impactos provocados por los fenómenos climáticos extremos.

Este plan de monitorización incluye la instalación de sensores en un aparato de dilatación para determinar su comportamiento frente a los cambios de temperatura. En este apartado se exponen las principales características del equipo de monitorización a instalar.

2.1 Sección a monitorizar

El aparato de dilatación escogido (y su junta de dilatación asociada) se encuentran en el PK 62+000 de la vía del Corredor Mediterráneo (Figura 1). El principal motivo para escoger este aparato en concreto es que se trata de un diseño bastante representativo del tipo de aparatos de dilatación instalados en la red ferroviaria de Adif.

Fig. 1 – Aparato y junta de dilatación. Fuente: elaboración propia.

Concretamente se trata de un aparato con una carrera de 500 mm, situado a la entrada de un puente ferroviario, en un tramo entre las estaciones de L'Enova Manuel y Xàtiva, en la provincia de Valencia (España). Por esta línea circulan tanto trenes de pasajeros (incluyendo cercanías y media y larga distancia) como mercancías.

2.2 Equipo de medida

Para monitorizar el aparato de dilatación mostrado en la Figura 1 se ha optado por un sistema sencillo basado en sensores de fácil adquisición y un microordenador tipo Raspberry Pi 4. Mediante este equipo se pretenden monitorizar tres variables, tal y como se recoge en la Tabla 1.

Variable	Sensores
Temperatura en carril	2 sensores de temperatura en alma de carril
Separación entre estribo y tablero del puente	2 potenciómetros de desplazamiento en junta de dilatación
Desplazamiento en puntas del aparato de dilatación	2 sensores de ultrasonidos en las puntas del aparato

Tabla 1 – Variables a monitorizar en el aparato de dilatación

Como se aprecia en la Tabla 1, para medir la temperatura de carril se sitúan dos sensores de temperatura adheridos al alma mediante un adhesivo especial. Estos sensores son simples sondas de temperatura de 5 mm de tamaño con un rango de medición de -55ºC a 125ºC. Por otra parte, para medir la apertura de la junta de dilatación se emplean dos potenciómetros de desplazamiento lineal de 100 mm de carrera. Por último, para medir los desplazamientos de las puntas del aparato de dilatación se emplean dos sensores de ultrasonidos con un rango efectivo de medición de 25 a 450 cm. La Figura 2 muestra un croquis de la localización de estos sensores, mientras que sus principales características se recogen con mayor detalle en la Tabla 2.

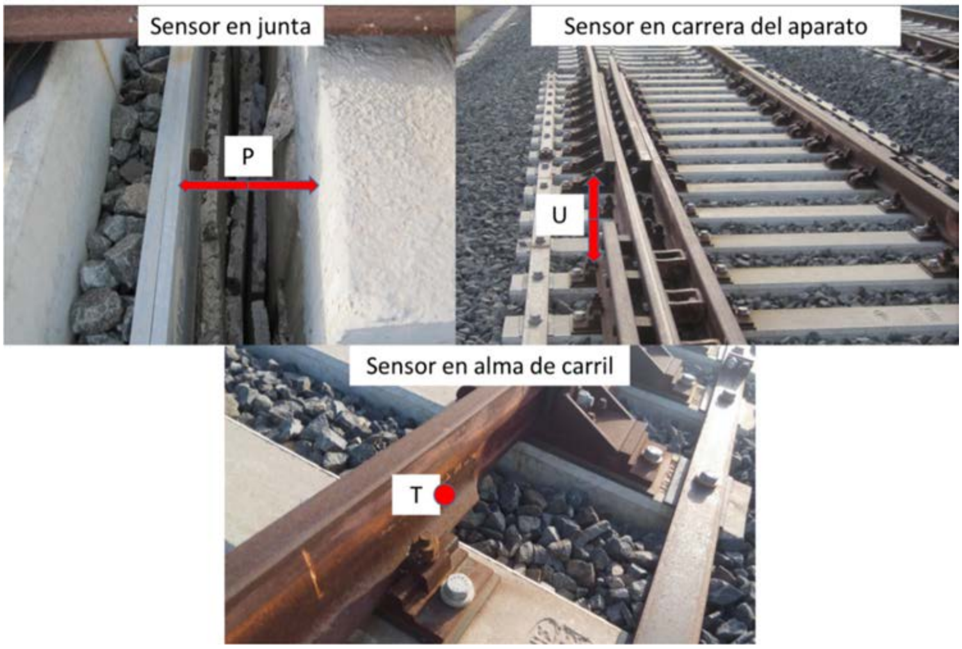

Fig. 2 – Localización de los sensores en el aparato y junta de dilatación.
P: Potenciómetro de Desplazamiento. U: Sensor de Ultrasonidos. T: Sensor de Temperatura. Fuente: elaboración propia.

Sensor de temperatura	
Rango de operación	-55ºC a 125ºC
Error (-30ºC a 100ºC)	± 1ºC
Tensión de alimentación	3-5,5 V
Dimensiones	4,95x4,95x3,94 mm
Potenciómetro de desplazamiento	
Carrera	100 mm
Linealidad	± 0,075%
Resistencia a vibraciones / impactos	15 g / 50 g
Temperatura de operación	-10ºC a 65ºC
Dimensiones	21x25x230 mm
Sensor de ultrasonidos	
Distancia de detección	25 a 450 cm
Ángulo del sensor	< 70º
Precisión	5 mm
Peso	54 g
Dimensiones	41x28,5 mm

Tabla 2 – Características de los sensores

Estos sensores se conectan a un microordenador Raspberry Pi 4 (Figura 3), que es el encargado de almacenar las señales de los sensores y enviarlas a un servidor mediante un módulo modem con antena GNSS.

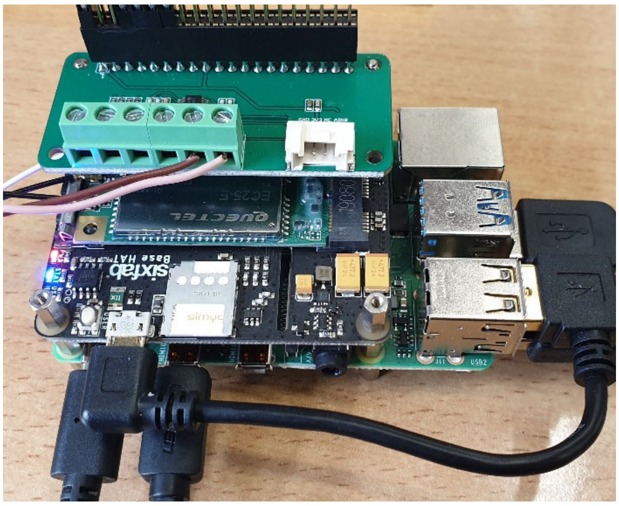

Fig. 3 – Microordenador para captación de datos

El conjunto del sistema se alimenta con una batería, que se recarga mediante paneles solares para garantizar su autonomía en campo.

2.3 Plan de monitorización

Una vez instalado el equipo, se procede a recopilar datos durante un período no inferior a 12 meses, si bien sería recomendable llegar a los 18 meses. La monitorización se realiza de forma automática de acuerdo al esquema mostrado en la Figura 4.

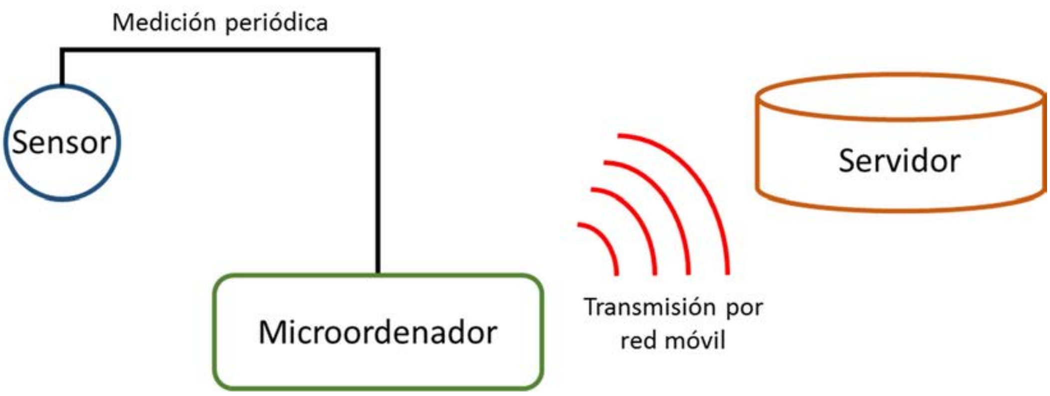

Fig. 4 – Esquema del proceso de medición. Fuente: elaboración propia.

Los sensores realizan una medición cada hora, registrando niveles de temperatura en carril, apertura de junta y desplazamiento de puntas. Estos datos se almacenan en el microordenador y se sincronizan regularmente con una base de datos habilitada a tal efecto mediante conexión 4G.

3.RESULTADOS

En este apartado se exponen los resultados que se esperan obtener a partir del montaje descrito en el apartado anterior. Cabe destacar que la labor de monitorización cubre un período extenso de un mínimo de 12 meses entre los años 2021 y 2022, por lo que se irán acumulando registros en la base de datos hasta alcanzar un volumen elevado que permita realizar un análisis exhaustivo del comportamiento del aparato de dilatación y la junta. En esta ponencia sólo se exponen, a título ilustrativo, la estructura de datos a obtener y el potencial que ofrece para futuros análisis.

3.1 Estructura de base de datos

Una vez instalado el equipo en vía, comenzará a tomar datos de forma regular siguiendo el esquema mostrado en la Figura 4. Los datos se almacenarán en una base de datos local en el propio microordenador, que se sincronizará a intervalos regulares con otra base de datos en la nube mediante la conexión 4G del sistema. Los datos se estructuran, en ambos casos, siguiendo el esquema mostrado en la Tabla 3.

Campo	Tipo de dato	Descripción
id	integer	Identificador del microordenador
tipo	string	Tipo de sensor (temperatura, distancia, etc.)
num_sens	integer	Número de sensor
dato	float	Valor de la medida
hora	float	Fecha y hora (expresada en tiempo UNIX)
synced	integer	Estado de sincronización.

Tabla 3 – Estructura de datos almacenados.

Así pues, cada registro tomado tendrá un identificador 'id' que indica desde qué microordenador se ha tomado (en el caso de que se realicen varios montajes en diversos puntos, tal y como está planificado en el proyecto MINFECLIMA), un indicador del tipo de sensor, una numeración de sensor (para distinguir entre varios sensores del mismo tipo), el valor de medición tomado, la fecha y hora en la que dicha medición se produjo (expresado en tiempo UNIX) y un indicador de sincronización con la base de datos en la nube (que tomará valores de 0 y 1 según la medición se haya o no sincronizado).

3.2 Volumen de datos y posibles análisis

Con una periodicidad de toma de datos de un registro por segundo, y asumiendo un período de toma de datos de dieciocho meses, se espera recopilar, para cada sensor instalado en vía, un total de 13150 registros. Evidentemente, este valor podría incrementarse notablemente si se aumenta la frecuencia de muestreo, cosa que se podría llevar a cabo si se estima oportuno para capturar fenómenos climáticos de evolución más rápida.

En todo caso, resulta claro que, gracias al montaje descrito en el apartado 2, será posible recopilar un extenso volumen de datos relativos al comportamiento del aparato de dilatación durante un período muy extenso, lo que permitirá plantear un análisis masivo de los mismos e identificar patrones, asociándolos a los diferentes fenómenos climáticos que se produzcan. Para analizar la información climática, se realizará una integración con los datos proporcionados por la Agencia Estatal de Meteorología (AEMET), principalmente de las estaciones climatológicas más cercanas a cada uno de los montajes de monitorización del proyecto.

Extendiendo este proceso a otros puntos singulares de la vía férrea, será posible llevar a cabo una labor concienzuda de recopilación de datos que permitirá estudiar nuevas opciones de mantenimiento que incluyan las variables climáticas y su evolución como factores fundamentales, contribuyendo así a un ferrocarril más sostenible y resiliente frente al cambio climático.

4. CONCLUSIONES

En el marco del proyecto MINFECLIMA, desarrollado por AZVI S.A.U. y SIER con la colaboración de la Universitat Politècnica de València, se pretende contribuir a mejorar la resiliencia y el mantenimiento de la infraestructura ferroviaria, aportando datos que permitan evaluar el comportamiento de puntos singulares de la vía frente a los fenómenos climáticos extremos.

En este contexto, la presente ponencia recoge un sistema sencillo y autónomo de adquisición de datos, diseñado para monitorizar temperaturas de carril y desplazamientos en un aparato y junta de dilatación. Se han expuesto las principales características del sistema, los sensores a emplear y su instalación en vía, y se ha detallado el plan de medición a aplicar, la estructura de datos que se va a generar y su sincronización automatizada con una base de datos en la nube

Está previsto que este montaje se aplique en breve y se inicie la recopilación de datos, que se extenderá durante un período de entre 12 y 18 meses entre los años 2021 y 2022. Conforme se vayan acumulando registros, será posible llevar a cabo un análisis exhaustivo de los mismos que permita identificar patrones novedosos y relacionarlos con los fenómenos climáticos extremos que se produzcan durante dicho período de medición.
En suma, la metodología descrita en esta ponencia es una de las herramientas mediante las que el proyecto MINFECLIMA aspira a aportar nuevos conocimientos y metodologías para un mantenimiento ferroviario adaptado a los desafíos del cambio climático.

AGRADECIMIENTOS

Los autores desean expresar su agradecimiento a Adif, por su permiso para instalar sensores en sus vías en el marco del proyecto MINFECLIMA y por su inestimable colaboración durante las labores de montaje de los equipos.

Ingeniero de minas, MAXAM International, Spain
Ignacio Fernández de Miguel
Ingeniero de minas, MAXAM International, Spain
Andrés Gudín Böller
Ingeniero de minas, MAXAM International, Spain

RESUMEN

Una de las piezas críticas de desgaste de la red ferroviaria es el corazón de los cruzamientos, un elemento sometido a mayores esfuerzos que las vías. Para su construcción suele emplearse acero Hadfield, con una dureza "de fábrica" en torno a 220 HBW.
MAXAM, líder europeo en la fabricación de material explosivo y sistemas de iniciación para uso civil (minería, túneles, canteras…), ha desarrollado un proceso de endurecimiento de estas piezas que permite aumentar su dureza por encima de 350-400 HBW, antes de su suministro e instalación, mediante el disparo de una carga explosiva especialmente diseñada denominada RIOMETAL.

Con esta dureza, el cruzamiento aumenta de manera notable su resistencia al desgaste, lo que implica una reducción aproximada de los costes de mantenimiento del 50%, una extensión de su vida útil de alrededor del 40% y una disminución del Coste del Ciclo de Vida (LCC) de un 20% aproximadamente, reduciéndose también el número y duración de las paradas para reparaciones, recargas de material y sustituciones.

Figura 1. Cruzamiento ferroviario

1. EL ACERO HADFIELD Y SU APLICACIÓN EN VÍAS FERROVIARIAS

Un desvío ferroviario es una construcción especial que permite a los trenes cambiar de una vía a otra para modificar su dirección. La parte fundamental de cada desvío es cruzamiento, a través del cual las vías se cruzan para luego separarse definitivamente en dos direcciones diferentes.

Dentro del cruzamiento, el elemento de mayor desgaste es el denominado corazón, donde se materializa la separación de ambas vías. El material más adecuado para la producción estos corazones es el acero austenítico al manganeso: acero Hadfield.

1.1 El acero Hadfield

El acero Hadfield es un acero austenítico al manganeso en el que la transformación martensítica de endurecimiento ha sido suprimida por una combinación de alto contenido en manganeso y carbono, y la precipitación de carburos por una alta velocidad de enfriamiento desde la temperatura de austenización.

El material es unifásico y presenta una estructura austenítica capaz de elevar su dureza desde 180 hasta 900 Brinell sin presentar transformación martensítica. Este material posee una incomparable capacidad de endurecimiento por deformación plástica y una alta resistencia a la tracción y a la compresión.

Por ello, es utilizado cuando se requiere resistencia al impacto y contra la abrasión, como en los campos del movimiento de tierra y minería (trituradoras, molinos, dientes de pala), la perforación de pozos, la siderurgia o la industria ferroviaria.
Sin embargo, es difícil de mecanizar, por lo que no son aptos para piezas que requieran alta precisión o que deban resistir la deformación plástica durante su servicio.

1.2 Cruzamientos ferroviarios

En los cruzamientos ferroviarios se emplea el acero Hadfield porque es capaz de endurecer su superficie de trabajo (es decir, aumentar su dureza superficial) bajo la presión y carga de choque que producen las ruedas de ferrocarril circulando sobre él.

Sin embargo, en los primeros ciclos de uso, puede sufrir un alto desgaste debido a que este proceso de endurecimiento no se ha producido aún.

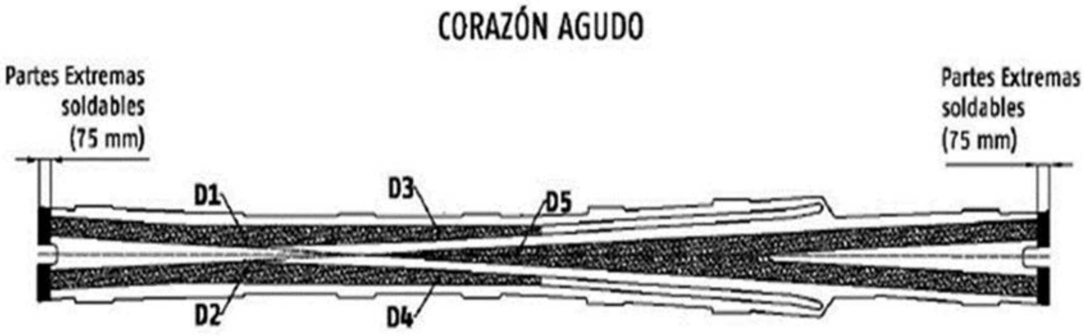

Figura 2. Ejemplo de un corazón de cruzamiento y zonas de pre-endurecimiento

Cuando los corazones de los cruzamientos se emplean sin endurecimiento previo pueden experimentar una deformación y un desgaste de unos 3 mm en las primeras semanas de servicio, hasta que logran alcanzar una dureza suficiente para minimizar este desgaste.

Este endurecimiento "natural" se produce por efecto de la deformación plástica que causan las propias cargas de operación (los trenes al pasar) sobre el acero austenítico al manganeso.

Para alargar la vida útil de los aparatos, reducir el coste de mantenimiento (recarga de material, sustitución) y optimizar su coste del ciclo de vida (LCC), los principales operadores ferroviarios especifican que, en sus vías férreas, los corazones de sus cruzamientos deben tener las bandas de rodadura endurecidas previamente a su instalación.

1.3 Pre-endurecimientos con explosivos

El proceso de endurecimiento previo a su colocación en la red ferroviaria más habitual es el endurecimiento con explosivos, patentado por primera vez en 1955.

Esta tecnología se fundamenta en la importante deformación plástica que sufre el acero al verse sometido a la onda de presión producida por la detonación del material explosivo, que aumenta drásticamente su dureza superficial.

El proceso de endurecimiento de aceros austeníticos con explosivos consiste en adherir una carga detonante a la zona de la pieza que se pretende endurecer (banda de rodadura) y hacerla detonar.

Con una sola detonación se pueden alcanzar valores de dureza Brinell superiores a 350 hasta una profundidad de unos 20 mm bajo la superficie de rodadura. Para alcanzar mayores durezas (>450 HBW), este proceso puede repetirse varias veces, normalmente hasta un máximo de 3.

Los principales operadores ferroviarios han establecido normas y criterios que incluyen los requisitos de dureza superficial y profundidad requeridos para los cruzamientos que han pasado por un proceso de pre-endurecimiento.

La Tabla 1 muestra, a modo de resumen, algunos ejemplos de requisitos exigidos en diferentes normas y regiones.

The validity of the standard	**Standard**	**Hardness after explosive hardening (HBW)**	**The explosive application depth Z (mm)**	**Length of hardening area L**	**Surface hardness test locations**
The European Union	EN 15689	321	10	100%	3, 4, 5
Switzerland	SBB 10-028-C3	321	14	100%	3, 4, 5
North America	AREMA 100-08	352	15,9	100%	1 to 7
Australia	ETA-03-03	350-415	20	100%	1 to 7

Tabla 1. Requisitos de dureza tras pre-endurecimiento según diversas normas

2. PROCESO RIOMETAL PARA PRE-ENDURECIMIENTO CON EXPLOSIVOS.

MAXAM ha desarrollado un proceso de endurecimiento de los corazones de los cruzamientos, utilizando para ello un explosivo específicamente patentado denominado RIOMETAL. Esta técnica se realiza en una instalación especialmente acondicionada en la planta de la Compañía en Páramo de Masa (Burgos).

Por este proceso han pasado, tan sólo en 2020, más de 1.100 corazones de cruzamientos producidos por los principales fabricantes europeos (Amurrio Ferrocarril y Equipos, JEZ sistemas ferroviarios, Mieres Rail, Vossloh Cogifer, Outreau Technologies…) que han sido instalados en líneas de alta velocidad, metros, ferrocarriles mineros y líneas convencionales y de mercancías de Europa, África y América.

Al tratarse de una aplicación de material explosivo, debe llevarse a cabo por personal autorizado y en un área acondicionada y autorizada para ello. En el caso de MAXAM, se realiza por artilleros de la propia compañía y bajo supervisión del departamento técnico, en el campo de tiro que hay dentro de sus instalaciones de Burgos.

2.1 Características técnicas de las láminas explosivas de RIOMETAL

Para el endurecimiento de la superficie de las piezas de acero, MAXAM emplea un explosivo laminado en bandas denominado RIOMETAL, formado por una base de pentrita muy fina embebida en una matriz plastificante.

El producto lleva una banda adhesiva que le permite adherirse a la superficie de la pieza que se quiera endurecer.

Este producto lo fabrica MAXAM para todo el mundo en su fábrica de Páramo de Masa (Burgos).

Figura 3. Láminas de RIOMETAL

Las características técnicas del RIOMETAL son las siguientes:

- Espesores de lámina: de 2 a 6 mm
- Ancho de lámina: Hasta 1.000 mm
- Longitud de banda: 10 m
- Velocidad de detonación: 6.500 m/s
- Clasificación UN: UN 0084, clase 1.1 D

Como todos los explosivos que comercializa MAXAM y en cumplimiento de la legislación vigente y del Reglamento de Explosivos, cada caja de RIOMETAL tiene su propio código de trazabilidad y, dentro de la caja, cada plantilla específica de su interior dispone de un código único de trazabilidad. Gracias a ello, podemos realizar el seguimiento de calidad en cada una de las piezas endurecidas.

2.2 Características del lugar de trabajo de los endurecimientos

Un factor fundamental para realizar este proceso es disponer de un lugar adecuado donde realizarlo, que deberá contar con su autorización correspondiente y, dado que se trata de hacer detonar explosivos al aire, deberá cumplir con los siguientes requisitos:

- Que el lugar esté alejado de zonas habitadas para evitar que la onda aérea cause molestias o daños.
- Que esté vallado y sin posibilidad de acceso de personas ajenas a la actividad
- Que cuente con un acceso adecuado para la entrada de los camiones de transporte de las piezas y los elementos de descarga (grúa)

- Que la superficie sobre la que se realiza el endurecimiento y su entorno esté limpio de cualquier elemento que pueda arder, como vegetación o embalajes, para evitar el riesgo de incendio, y contar con un sistema de extinción de incendios de seguridad.
- Deberá contar con plataformas para la colocación de las vías que permitan su perfecta nivelación y soporten el impacto de la detonación.

Figura 4. Vista general del campo de tiro de MAXAM en Páramo de Masa (Burgos)

2.3 Procedimiento operativo

Cada pieza que se pretende endurecer se identifica con un código y se diseña específicamente para ella la plantilla de explosivo que va a necesitar por medio de un programa de diseño gráfico.

A continuación, se recortan dichas plantillas a partir de los bloques de RIOMETAL que se almacenan en los depósitos de seguridad con los que cuenta MAXAM en sus instalaciones de Páramo de Masa y se les coloca la lámina adhesiva y el código de trazabilidad único y específico. Una vez está completo el lote, se embalan en cajas que, a su vez, se codifican para tener un control completo del producto explosivo que se va a utilizar en cada operación.

El día de disparo, se trasladan las cajas hasta el campo de tiro y se custodian por un vigilante de seguridad autorizado hasta que se produce su colocación y disparo.

Mientras, las piezas procedentes de la fundición son recepcionadas, identificadas, descargadas y posicionadas, prestando especial atención a su asentamiento en la cama de arena de la zona de disparo, para asegurar que la fuerza del impacto se trasmita de manera homogénea a la pieza.

Figura 5. Plantilla de RIOMETAL recortada y colocación en cruzamiento

Ya posicionadas, se revisan las piezas para detectar posibles anomalías y se limpian las superficies de contacto para proceder a la colocación del explosivo específico de cada pieza, que previamente fue recortado a medida. Esta labor la realizan artilleros especializados de MAXAM, bajo supervisión de su departamento técnico y cumpliendo con los protocolos establecidos.

Una vez finalizada la colocación de los explosivos y los sistemas de iniciación, se revisa la instalación, se asegura el perímetro de seguridad, se abandona la zona y comienza el procedimiento de disparo con la comprobación del circuito de voladura, la conexión del explosor en la caseta de disparo, la verificación final de que la zona está totalmente despejada y, si todo está bien, la detonación del explosivo en uno o más disparos secuenciados.

A continuación, los artilleros regresan al campo para comprobar que todo el explosivo ha detonado y que se puede retornar con seguridad. Cuando es así, se revisan de nuevo las piezas, se comprueban las durezas resultantes en los puntos de control de cada pieza con un durómetro portátil, se toman fotografías, que podrán formar parte del informe final de calidad, y se elabora el certificado de dureza específico.

Finalmente, se procede a la carga del material endurecido en el camión para enviarlo de vuelta a su fábrica de origen, donde será revisado de nuevo y rectificado si es necesario.

Figura 6. Secuencia de disparo

3. RESULTADOS DEL PROCESO

A lo largo de los años, MAXAM ha trabajado en el endurecimiento de más de 3.000 aparatos de ferrocarril para diferentes fabricantes internacionales.

A continuación, se recoge el estudio de los resultados obtenidos en las 1.398 piezas que endureció con el proceso RIOMETAL en sus cruzamientos de vías entre junio de 2015 y agosto de 2019.

Para ello, se recopilaron las durezas medidas y registradas en los informes de calidad en tres puntos de cada pieza: corazón, pata 1 y pata 2.

Durezas HBW	Punta	Pata 1	Pata 2	Pieza
Medio	367	361	363	**364**
Máximo	474	460	465	**474**
Mínimo	321	322	322	**321**
Percentil 10%	399	390	390	**394**
Percentil 99,5%	324	325	325	**325**

Tabla 2. Resumen resultados 1.398 piezas

La conclusión fue que, en las 1.398 piezas analizadas, se alcanzó un valor promedio de dureza de 364 HBW, con un 10% de las medidas superando, incluso los 394 HBW y el 99,5% de las medidas superando los 324 HBW.

Los resultados obtenidos se pueden ver resumidos en las siguiente tablas y gráficas que recogen los resultados obtenidos en las diferentes piezas:

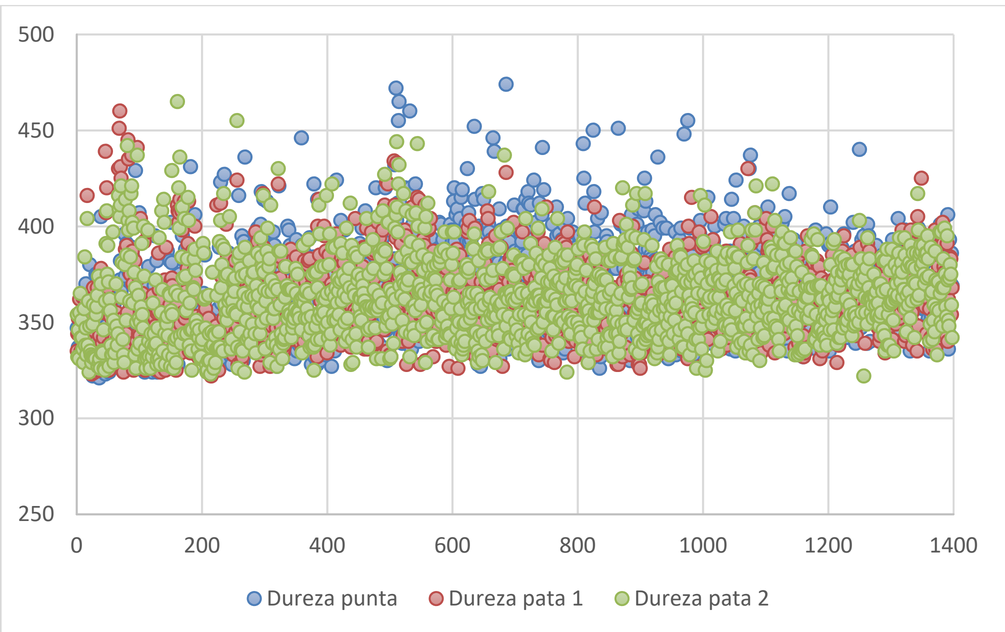

Figura 7. Resumen de resultados de dureza Brinell en punta y patas de cruzamientos

4. EJEMPLOS EXPERIMENTALES

Como ejemplos prácticos, incluimos en este artículo dos procesos de endurecimiento con una y con dos detonaciones llevados a cabo por MAXAM en 2020.

Los trabajos en campo fueron realizados por un equipo compuesto por un ingeniero, como Director Facultativo y responsable de la operación, y 2 artilleros, todos con una amplia experiencia en esta aplicación, que contaron con el apoyo externo del departamento técnico de MAXAM (TAP).

4.1 Caso 1: Endurecimiento con una detonación

Se trataba de 5 cruzamientos soldables de corazón agudo fabricados en acero Hadfield.

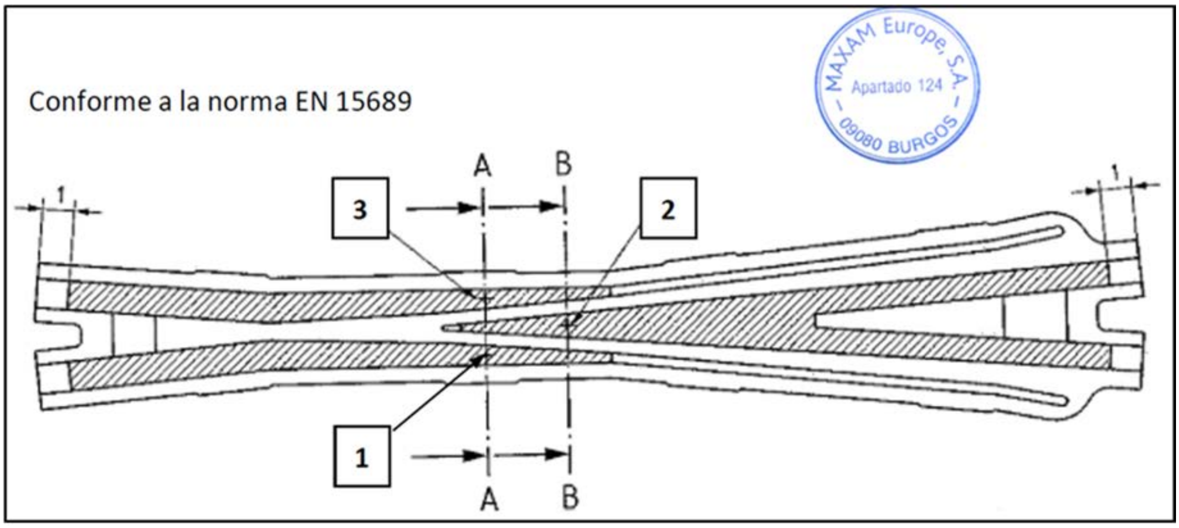

Figura 8. Esquema de cruzamiento, áreas de endurecimiento y puntos de control

En ellos se midieron la dureza inicial con un durómetro portátil calibrado modelo Equotip, de la empresa Proceq, con compensación automática, punta de carburo de tugsteno y un rango de medida de 150 a 950 HLD con una precisión de +/- 4 HLD, obteniéndose la siguiente tabla de valores:

	Pieza 1			Pieza 2			Pieza 3		
	Control 1	Control 2	Conrtrol 3	Control 1	Control 2	Conrtrol 3	Control 1	Control 2	Conrtrol 3
Medida 1 (HBW)	170,0	190	178	187	228	203	196	224	260
Medida 2 (HBW)	184,0	178	194	160	199	239	169	179	245
Medida 3 (HBW)	178,0	186	187	187	219	200	196	221	235
Valor promedio (HBW)	177,3	184,7	186,3	178,0	215,6	213,9	187,0	208,1	246,7
Valor promedio (HBW)	**182,8 HBW**			**202,5 HBW**			**213,9 HBW**		

	Pieza 4			Pieza 5			Media		
	Control 1	Control 2	Control 3	Control 1	Control 2	Conrtrol 3	Control 1	Control 2	Conrtrol 3
Medida 1 (HBW)	193,8	209,0	213,6	205,4	219,5	220,0	190,4	214,2	214,9
Medida 2 (HBW)	226,3	165,5	203,7	278,4	144,0	213,9	203,5	173,2	219,1
Medida 3 (HBW)	190,5	195,3	220,7	186,7	218,7	244,9	187,7	208,0	217,5
Valor promedio (HBW)	203,5	189,9	212,7	223,5	194,1	226,3	193,9	198,5	217,2
Valor promedio (HBW)	**202,0 HBW**			**214,6 HBW**			**203,2 HBW**		

Tabla 3. Valores iniciales 1 detonación

El endurecimiento se llevó a cabo con un único disparo. El explosivo que se empleó fue una lámina de 4,5 mm de RIOMETAL, fabricado por MAXAM, y el proceso fue llevado a cabo en el campo de tiro de MAXAM en Páramo de Masa (Burgos).

Tras el endurecimiento, se volvieron a medir las durezas siguiendo el mismo procedimiento y con los mismos equipos de medida, obteniéndose los siguientes resultados.

	Pieza 1			Pieza 2			Pieza 3		
	Control 1	Control 2	Conrtrol 3	Control 1	Control 2	Conrtrol 3	Control 1	Control 2	Conrtrol 3
Medida 1 (HBW)	340,0	334	357	367,0	363	344	358,0	373	391
Medida 2 (HBW)	343,0	359	339	351,0	371	358	367,0	391	382
Medida 3 (HBW)	338,0	365	346	355,0	359	376	364,0	384	407
Valor promedio (HBW)	340,3	352,7	347,3	357,7	364,3	359,3	363,0	382,7	393,3
Valor promedio (HBW)	**346,8 HBW**			**360,4 HBW**			**379,7 HBW**		

	Pieza 4			Pieza 5			Media		
	Control 1	Control 2	Control 3	Control 1	Control 2	Conrtrol 3	Control 1	Control 2	Conrtrol 3
Medida 1 (HBW)	371,0	354	388	367,0	347	333	360,6	354,2	362,6
Medida 2 (HBW)	384,0	357	359	352,0	384	343	359,4	372,4	356,2
Medida 3 (HBW)	382,0	349	367	356,0	369	347	359,0	365,2	368,6
Valor promedio (HBW)	379,0	353,3	371,3	358,3	366,7	341,0	359,7	363,9	362,5
Valor promedio (HBW)	**367,9 HBW**			**355,3 HBW**			**362,0 HBW**		

Tabla 4. Valores finales tras 1 detonación

Como se puede observar, en todas las mediciones (45/45) los valores de dureza Brinell obtenidos son superiores a 334 HBW, con valores puntuales superiores a 390 HBW. El valor promedio fue de 362 HBW, que supone un incremento de la dureza media del 78%. La inspección final de las piezas no detectó ninguna grieta ni deformación fuera de rango.

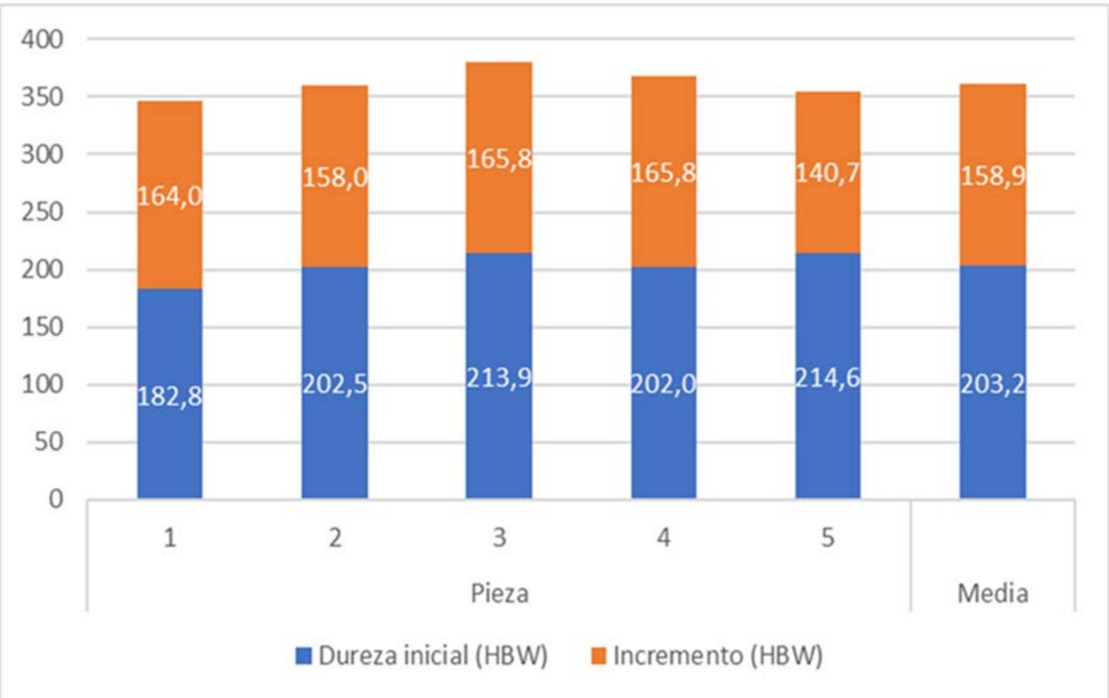

Figura 9. Incremento de dureza Brinell tras 1 detonación. Representación gráfica

4.2 Caso 2: Endurecimiento con dos detonaciones

En este caso, se trataba de endurecer una pieza con 11 puntos de control, cuyo esquema es el siguiente:

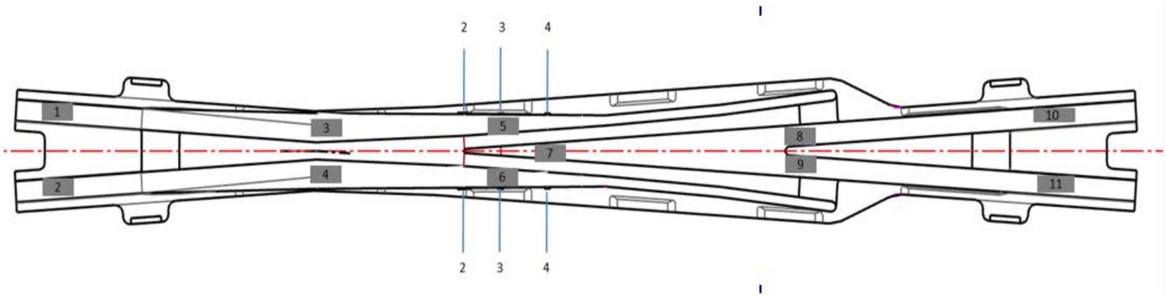

Figura 10. Esquema del cruzamiento

De cada uno de los puntos de control se tomaron 3 medidas de dureza antes y después de cada una de las detonaciones para un total de 99 valores de dureza HBW que se midieron con el mismo durómetro portátil calibrado modelo Equotip.

El endurecimiento se llevó a cabo con dos detonaciones. El explosivo que se empleó fue una lámina de 4,5 mm de RIOMETAL, fabricado por MAXAM, y el proceso fue llevado a cabo en el campo de tiro de MAXAM en Páramo de Masa (Burgos).

Los resultados que se obtuvieron fueron los siguientes:

Momento de la medida	Medidas de durezas (HBW)															
	Punto1			Valor medio	Punto2			Valor medio	Punto3			Valor medio	Punto4			Valor medio
Previo explosionado	226,0	222,0	218,0	222,0	192,0	201,0	204,0	199,0	213,0	193,0	200,0	202,0	185,0	197,0	200,0	194,0
Tras 1er explosionado	303,0	324,0	323,0	316,7	311,0	315,0	333,0	319,7	310,0	336,0	346,0	330,7	325,0	349,0	362,0	345,3
Tras 2º explosionado	350,0	352,0	351,0	351,0	356,0	351,0	354,0	353,7	355,0	351,0	352,0	352,7	**371,0**	**357,0**	**352,0**	**360,0**
	Punto5			Valor medio	Punto6			Valor medio	Punto7			Valor medio	Punto8			Valor medio
Previo explosionado	227,0	236,0	203,0	222,0	267,0	233,0	234,0	244,7	193,0	255,0	204,0	217,3	179,0	177,0	205,0	187,0
Tras 1er explosionado	321,0	372,0	340,0	344,3	323,0	333,0	331,0	329,0	319,0	318,0	343,0	326,7	345,0	323,0	345,0	337,7
Tras 2º explosionado	393,0	376,0	364,0	377,7	354,0	361,0	360,0	358,3	399,0	352,0	356,0	369,0	**354,0**	**359,0**	**354,0**	**355,7**
	Punto9			Valor medio	Punto10			Valor medio	Punto11			Valor medio	VALOR MEDIO			Valor medio
Previo explosionado	181,0	184,0	186,0	183,7	190,0	174,0	162,0	175,3	180,0	176,0	184,0	180,0	**203,0**	**204,4**	**200,0**	**202,5**
Tras 1er explosionado	338,0	330,0	341,0	336,3	333,0	339,0	345,0	339,0	335,0	343,0	349,0	342,3	**323,9**	**334,7**	**341,6**	**333,4**
Tras 2º explosionado	372,0	353,0	364,0	363,0	352,0	357,0	366,0	358,3	358,0	352,0	364,0	358,0	**364,9**	**356,5**	**357,9**	**359,8**

Tabla 5: Valores de dureza antes y tras cada detonación.

Mientras que los valores medios de dureza antes del disparo (pieza sin endurecer) variaban entre 175 y 245 HBW (media 202 HBW), la dureza superficial tras la primera detonación subía hasta 317 y 345 HBW (media 333 HBW), lo que supone un incremento de un +64,7% de la dureza superficial.

Tras la segunda detonación, la dureza media en capa punto de control osciló entre 351 y 378 HBW (media 360 HBW) lo que supone un aumento de un +7,9%.

5. CONCLUSIONES

El endurecimiento con explosivos de los corazones de los cruzamientos ferroviarios de acero Hadfield es una técnica ampliamente extendida que permite aumentar su resistencia al desgaste, lo que implica una reducción de su mantenimiento y una extensión de su vida útil.

Según los estudios realizados por los principales fabricantes de cruzamientos y operadores de líneas férreas, instalando un cruzamiento pre-endurecido se pueden conseguir las siguientes ventajas:

- **Reducción de los costes de mantenimiento** en un 50%, principalmente en los primeros meses después de su instalación.
- **Aumento de su vida útil** (carga soportada) en un 40%
- **Reducción del coste del ciclo de vida** en un 20%, considerando también el sobrecoste que supone el pre-endurecimiento del cruzamiento.

Adicionalmente, la reducción de mantenimiento y el alargamiento de su vida útil suponen una reducción del número y tiempo de paradas y estancias fuera de servicio. Todos ellos, aspectos fundamentales para los gestores de redes ferroviarias

En este documento se mostraron los requisitos exigidos para los cruzamientos pre-endurecidos con explosivos por los principales gestores de este tipo de instalaciones en diversas partes del mundo.

También se describió el proceso RIOMETAL, desarrollado por MAXAM específicamente para el endurecimiento de cruzamientos, y se mostraron los resultados experimentales obtenidos en cerca de 1.400 de los más de 4.000 endurecimientos llevados a cabo en sus instalaciones del Páramo de Masa (Burgos), donde también está su centro de producción del explosivo y el Centro de Innovación del Grupo MAXAM para todo el mundo.

Analizando tanto los datos históricos y como los últimos ejemplos, se puede afirmar que con el proceso RIOMETAL se alcanzan y sobrepasan las durezas requeridas tanto por las normas europeas como por las normas norteamericana y australiana, aún más exigentes, para la dureza superficial de los corazones de punta fija de cruzamientos ferroviarios.

NUEVOS DESARROLLOS PARA METROS LIGEROS

Raúl Parra Hermida
Director de proyectos, Metrotenerife, España
Pablo Martín Pacheco
Responsable de Informática e Ingeniería de Sistemas, Metrotenerife, España
Pablo Oromí Fragoso
Ingeniero de proyectos, Metrotenerife, España

RESUMEN

Metrotenerife es el operador del Metro Ligero de Tenerife desde su puesta en marcha en el año 2007. Asimismo, esta empresa pública perteneciente al Cabildo Insular de Tenerife lleva a cabo los estudios pertinentes para la implantación de nuevos corredores ferroviarios con el objeto de mejorar la sostenibilidad de la movilidad e incrementar la cuota de transporte público colectivo en la isla.

La experiencia que adquiere el operador de un sistema de transporte de metro ligero a lo largo de 14 años de servicio comercial le hace replantearse soluciones técnicas y tecnológicas que permitan mejorar las condiciones de seguridad de la circulación de convoyes y las acciones de mantenimiento. Metrotenerife ha desarrollado, entre otros, dos sistemas novedosos que le han permitido obtener dichas mejoras, y que están siendo además lanzados al mercado para permitir al resto de operadores poder beneficiarse de ellos. Se trata, por un lado, del SIMOVE (Sistema de Monitorización de Velocidad Embarcado), que permite supervisar de forma continua y a tiempo real la posición del vehículo y su velocidad, siendo capaz de activar de forma automática el freno de emergencia en caso de que se sobrepase el umbral de riesgo, y por otro lado la Chaqueta Aislante Extraíble para carril de garganta, un elemento de aislamiento eléctrico y acústico que por sus prestaciones permite sustituir dicho carril en tiempo reducido y sin necesidad de llevar a cabo obras de demolición y reposición de revestimientos de vía.

1. SIMOVE

1.1 Introducción

SIMOVE es un sistema de seguridad capaz de supervisar en tiempo real la velocidad del vehículo, alertar al conductor de las limitaciones de velocidad existentes en función del tramo por el que circula; y en caso de sobrepasarlas, aplicar el Frenado de Urgencia Automático del vehículo (FU en adelante).

SIMOVE está formado por dos partes: un sistema embarcado y el back office, que están comunicados vía Wi-Fi o tecnología 3G/4G. El primero es el encargado del control de velocidad, monitorización y registro de eventos. El back office recibe, gestiona y almacena la información de los equipos embarcados, además permite configurar y preparar la información para poder explotarla, en función de las necesidades del operador.

1.2 Funcionalidades de SIMOVE

Las funciones principales del equipo se han diferenciado e independizado dependiendo de la aplicación que se va a llevar a cabo, acordes a los requisitos RAMS (Reliability, Availability, Maintainability and Safety) exigidos, y para evitar que durante la fase de mantenimiento, la actualización de los parámetros de una de las funciones afecten al resto.

El sistema SIMOVE está basado en tecnología GPS para ubicar el vehículo en la línea y determinar su sentido; y en la lectura del odómetro embarcado para calcular la velocidad y distancia recorrida.

1.2.1 Control de la posición y velocidad del vehículo

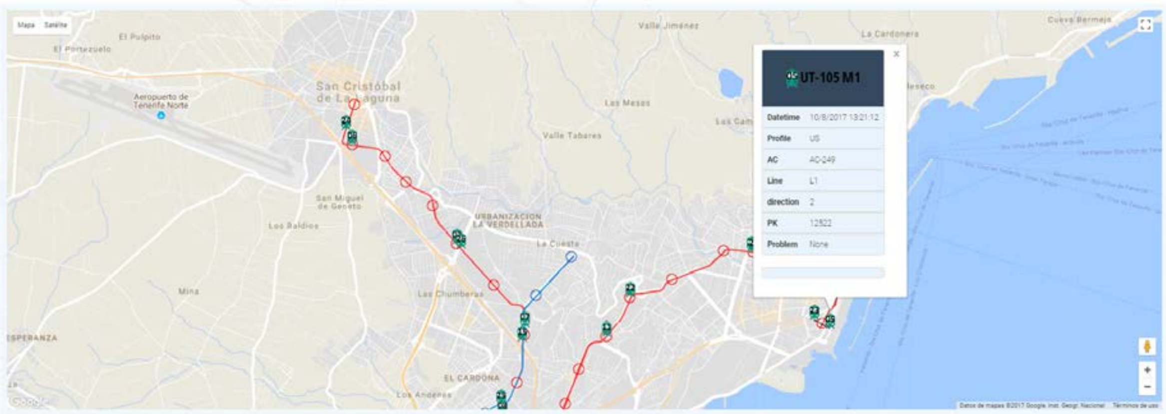

Fig. 1 - Posición de la flota operativa a tiempo real

- Seguimiento continuo de la posición del vehículo deduciendo línea y sentido de marcha.
- Seguimiento continuo de la velocidad del vehículo.
- Comparación de la velocidad del vehículo con las velocidades máximas de conducción impuestas en el tramo de la línea por el que circula y el tipo de vehículo.
- El sistema funciona en todo tipo de topologías (túneles, puentes, zonas entre edificios, etc.).

1.2.1.1 Localización del vehículo basada en tecnología GPS

La determinación de la línea y sentido del vehículo se realiza a través del GPS. Éste se activa al poner en marcha el vehículo desde la cabina de conducción, y no permite que el SIMOVE esté operativo hasta que localice un número mínimo de satélites con una potencia mínima establecidos.

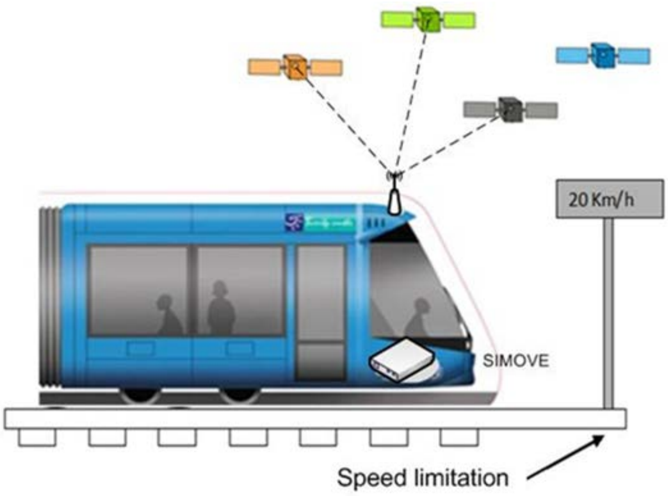

Fig. 2 - SIMOVE utiliza la constelación GPS para su localización

1.2.1.2 Localización del vehículo mediante lectura del odómetro

La conexión del SIMOVE con el odómetro embarcado permitirá el cálculo de la velocidad del vehículo, el desgaste de la rueda, la distancia recorrida desde la última posición de referencia y su ubicación sobre la línea.

1.2.1.3 Comparación con el perfil de velocidad del tramo.

Ubicado el vehículo en una línea y conociendo su sentido, el sistema compara la velocidad registrada por el odómetro, con el perfil de velocidad definido en dicho tramo. El sistema posiciona el vehículo en cada tramo con el objetivo de alertar al conductor del exceso de velocidad cuando supera el umbral de alarma, o frenando el vehículo cuando sobrepasa el umbral de emergencia.

1.2.1.4 Recreación de la posición y velocidad de la flota

SIMOVE permite efectuar una recreación de los viajes realizados por la flota completa, permitiendo al operador visualizar los desplazamientos de los vehículos en una franja temporal determinada, a modo de moviola. Esta funcionalidad permite analizar los siguientes puntos: gestión de la flota llevada a cabo por el PCC (Puesto Central de Control), gestión de incidencias por parte del PCC, análisis de eventos, etc.

1.2.2 Ratio de obtención de información.

El sistema embarcado obtiene información 3 veces por segundo. Es posible leer con frecuencias mayores. Las limitaciones son las de hardware y almacenamiento de datos

1.2.3 Aviso e información al conductor.

- El sistema embarcado está equipado con una pantalla situada en la cabina, que muestra al conductor la velocidad actual del vehículo y la velocidad máxima permitida en la sección en la que está circulando.
- Identificación del conductor mediante solicitud de usuario. El registro del conductor se realizará en ambas cabinas simultáneamente.

Fig. 3 - Registro del código de conductor

- Aviso si el conductor no se ha registrado en el sistema.
- Avisos sonoro (fichero de audio personalizable) y luminoso en la pantalla cuando la velocidad de *warning* ha sido sobrepasada. Si se alcanza el segundo umbral, denominado velocidad de emergencia, se aplicará un FU. Ambos umbrales de velocidad son parametrizables en cada una de las líneas, dirección y localización precisa.
- Aplicación de umbrales distintos dependiendo del tipo de vehículo, en adelante perfiles (por ejemplo, unidad simple, unidad doble, unidad de prueba, etc.

1.2.4 Actuación sobre el freno del tranvía.

- La orden de frenado FU se dará mediante la apertura del lazo de puertas provocado por el relé del SIMOVE.
- Tras la aplicación de un FU aparecerá en la pantalla un aviso de aplicación indicando la velocidad del tramo y la velocidad alcanzada. Posteriormente el conductor deberá reconocer el FU para poder continuar con la conducción.

Fig. 4 - Pantalla conductor en un FU

1.2.5 Aviso e información a terceras partes y/o aplicaciones.

- Los destinatarios de la información y avisos enviados por SIMOVE son completamente personalizables, así como el tipo de información que recibe cada uno de ellos.
- Publicación en un Servicio Web de los avisos de emergencia y FU en tiempo real, para poder ser explotados por terceras aplicaciones.
- Servicio Web que provee a tiempo real el posicionamiento del vehículo, el cual puede ser actualizado según parametrización para poder ser explotados por terceras aplicaciones.
- Generación de los ficheros KML conteniendo la velocidad y aceleración de cada viaje para su representación sobre interfaz GIS, aun cuando no hayan sido registrados eventos significativos.
- Envío de avisos por SMS o servicios de mensajería instantánea de las FU y otros eventos destacables a una selección de usuarios predefinida.

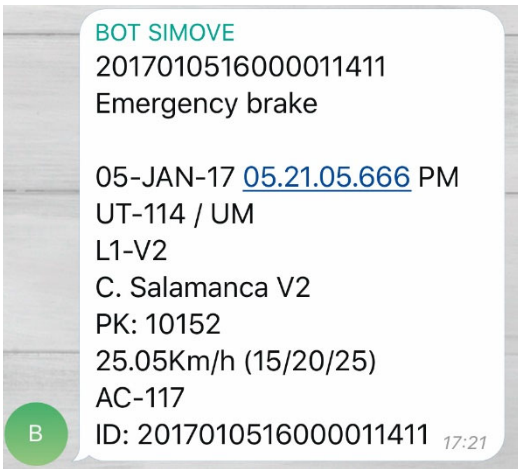

Fig. 5 - Mensaje de texto enviado a un destinario predeterminado ante un FU

1.2.6 Registro y almacenamiento.

- Registro de los datos significativos proporcionados por el sistema. Todos los datos registrables son parametrizables.
- Volcado de los mismos a un servidor central donde se almacenarán en una base de datos.
- Distintos medios de descarga de datos en el vehículo (USB, Ethernet y Wifi).
- Grabación del sonido ambiental de la cabina de conducción para verificar las alarmas acústicas en caso de exceso de velocidad.
- Informes operacionales disponibles para facilitar el análisis e investigación.
- Datos registrados:
  - Fecha/Hora.
  - Numero de vehículo y su cabina de conducción.
  - Línea y dirección de viaje.
  - Identificación del conductor.
  - Tipo de vehículo.
  - Posición GPS medida (coordenadas).
  - Posición Odómetro calculada.
  - Posición teórica (PK de la línea asociado).
  - Distancia de error entre GPS y PK asociado.
  - Velocidad GPS medida.
  - Velocidad Odómetro calculada.
  - Velocidad máxima del tramo.
  - Velocidad de alarma del primer aviso.
  - Velocidad de emergencia (2º aviso y aplicación del FU).
  - Activación de la alarma de precaución (aviso).
  - Activación del frenado automático en el vehículo.
  - Estado del conmutador de inhibición.
  - Precisión del cálculo de la posición, basada en los diferentes valores del GPS.
  - Incidencia detectada (código).
  - Número de satélites GPS encontrados.
  - Número de satélites GPS en uso.
  - Calidad de la señal GPS.
  - Activación del DGPS (corrección diferencial de GPS).
  - Relación r/n necesaria para cálculos con el odómetro (siendo r el radio de la rueda y n el número de dientes para un giro completo de la misma).
  - Distancia acumulada desde la última posición de referencia.
  - Control de las distintas versiones del software, configuración y parametrización.

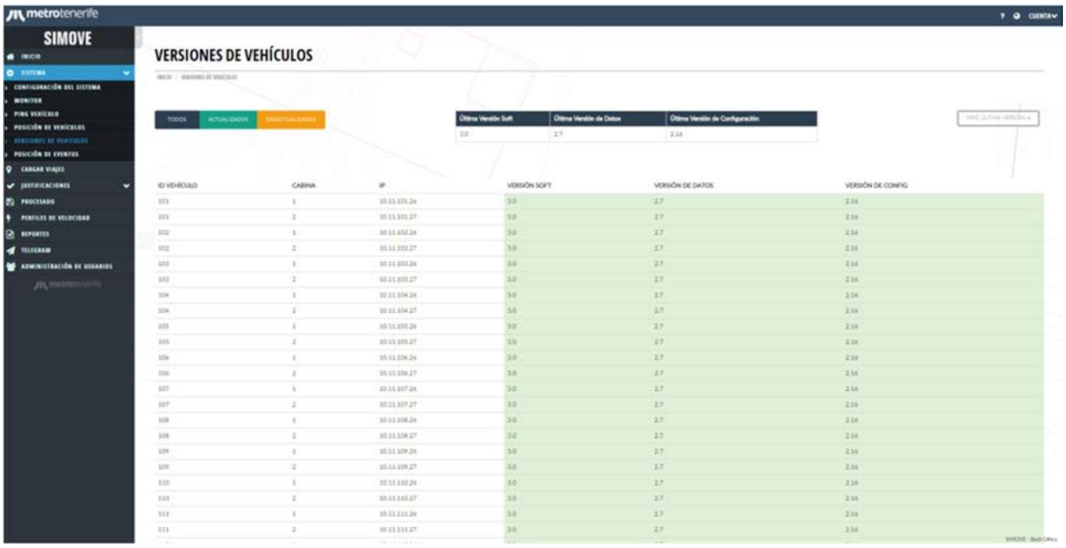

Fig. 6 - Versiones de vehículos en el back office de SIMOVE

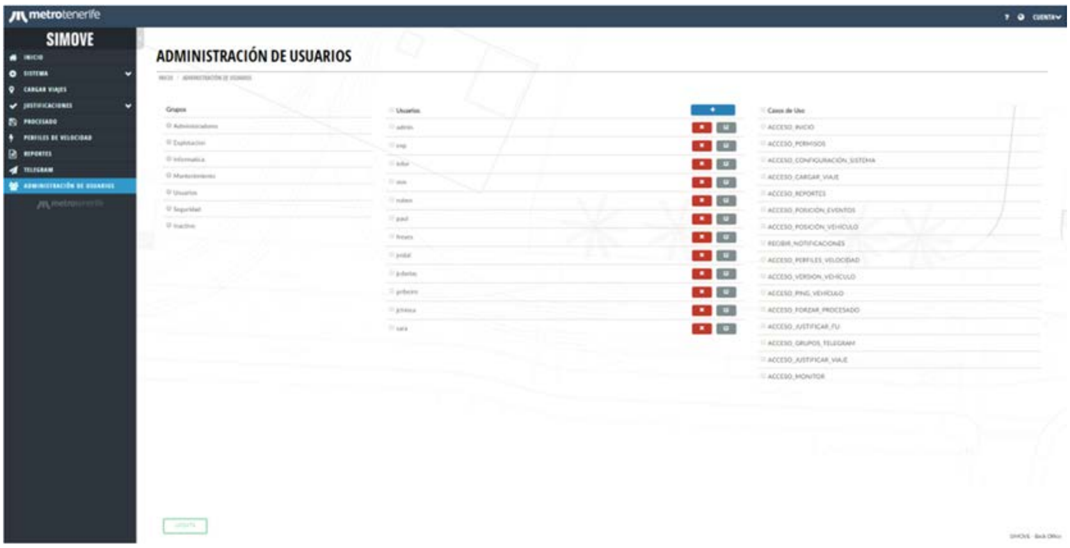

Fig. 7 - Administración de usuarios en el back office de SIMOVE

1.2.7 Mantenimiento y configuración.

- Recepción de ficheros desde el servidor central para su configuración.
- Menú de mantenimiento con código de acceso para:
    - Test de funcionamiento. Realización de pruebas periódicas que confirman el buen funcionamiento del equipo, tales como: conectividad, estado del GPS, números de pulsos, diámetro actual de rueda, etc.
    - Cambio de perfiles, unidad múltiple, unidad simple, líneas virtuales, etc.
    - Volcado de datos a memorias externas.
    - Versión de software, de datos, parametrización.
    - Identificación de unidad, cabina e IP.
    - Muestra si existen ficheros pendientes de cargar, tanto de datos como de audio.
    - Introducción del diámetro de la rueda después de su torneado o reemplazo.

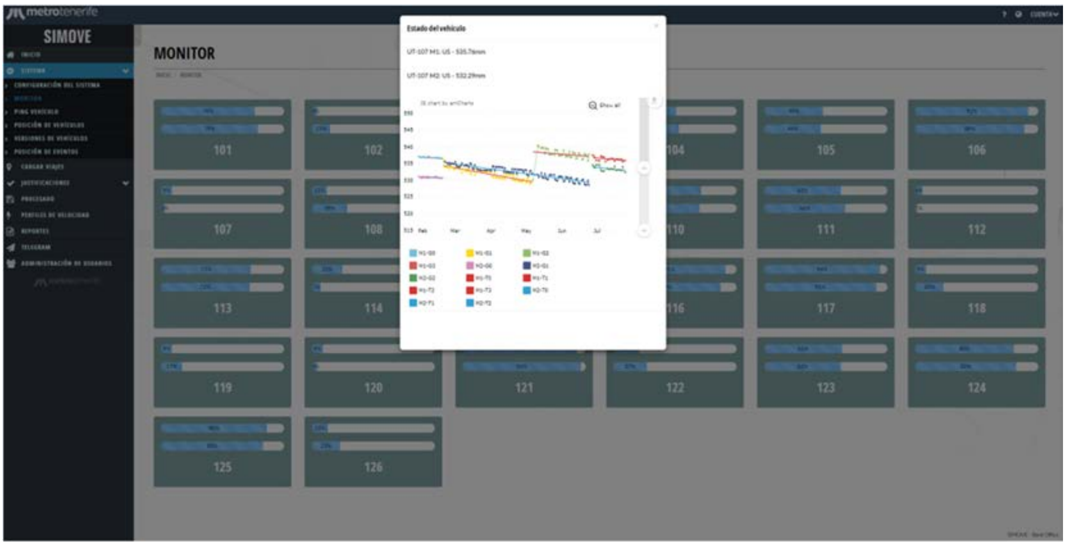

Fig. 8 - Información sobre el estado de la rueda en el back office de SIMOVE

- Actualización local o remota tanto del software como de los parámetros y tablas.
- Acceso mediante VNC al equipo embarcado desde el back office.

1.2.8 Inhibición del sistema embarcado.

- Inhibición automática del sistema en caso de que desconozca la línea/sentido y por tanto no pueda aplicar el perfil de velocidad correcto.
- Inhibición automática del sistema cuando el vehículo recorra una distancia establecida sin haber logrado reposicionarse por GPS.
- Posibilidad de inhibición manual por parte del conductor, sólo mediante autorización del operador, mediante el accionamiento del correspondiente conmutador, el cual se encuentra precintado para evitar la inhibición del dispositivo de forma no controlada.

1.2.9 Integración de la radiodifusión

El sistema puede ser integrado con la radiodifusión, de forma que controle la señal y volumen de la misma, evitando interferencias en las comunicaciones con el PCC y pasajeros. Además, si el SIMOVE emitiera avisos sonoros, estos prevalecerán sobre los sonidos de radiodifusión, que serían bloqueados durante el tiempo de duración de dichos avisos

2. CHAQUETA AISLANTE EXTRAÍBLE PARA LÍNEAS DE METRO LIGERO

2.1 Introducción

En líneas ferroviarias urbanas tipo LRT (L*ight Rail Transit*), con trazados en superficie, los carriles suelen implantarse en plataformas reservadas o compartidas, embebidos generalmente en revestimientos de pavimento rígido y en revestimientos verdes (césped natural o artificial); esto se debe a que en entornos urbanos existe en muchos casos la necesidad de transitar sobre la plataforma tranviaria (por ejemplo: cruces con calzadas de vehículos, calles peatonales…, etc.) y también por cuestiones de integración visual y paisajismo. La existencia de canalizaciones metálicas soterradas en entornos urbanos (canalizaciones de servicios) obliga a aislar los carriles debido a que éstos forman parte del circuito eléctrico de alimentación de los tranvías (circuito de retorno) y pueden afectar a las canalizaciones por el efecto de las corrientes vagabundas; por otro lado, es conveniente también aislar acústicamente el carril para disminuir la emisión de ruidos causados por la rodadura ferroviaria. Ambas circunstancias han llevado a la generalización del empleo de chaquetas aislantes que envuelven inferior y lateralmente al carril en este tipo de líneas.

En el marco de las operaciones de mantenimiento de una línea de metro ligero, la sustitución de carriles desgastados representa un quebradero de cabeza para los operadores de estos sistemas de transporte público. Con las soluciones actuales de aislamiento, la sustitución de carriles cuando llegan al final de su vida útil conlleva la demolición de los revestimientos, ya que tanto los carriles como sus sujeciones se encuentran embebidos en el revestimiento. En ese escenario, la sustitución de carriles conlleva un conjunto de inconvenientes que se citan a continuación:

- Coste para el operador por los trabajos de demolición y posterior reposición de pavimentos, operaciones éstas que no generan ningún valor añadido a la plataforma tranviaria, siendo por lo tanto una inversión sin rentabilidad
- Generación de residuos RCD (residuos de construcción y demolición), los cuales son generalmente trasladados a vertedero debido a su difícil reciclado.
- Plazo de ejecución de las operaciones de demolición y reposición, con interferencias para el servicio comercial de transporte
- Molestias al entorno urbano por ruidos, polvo, desvíos de tráfico, etc.

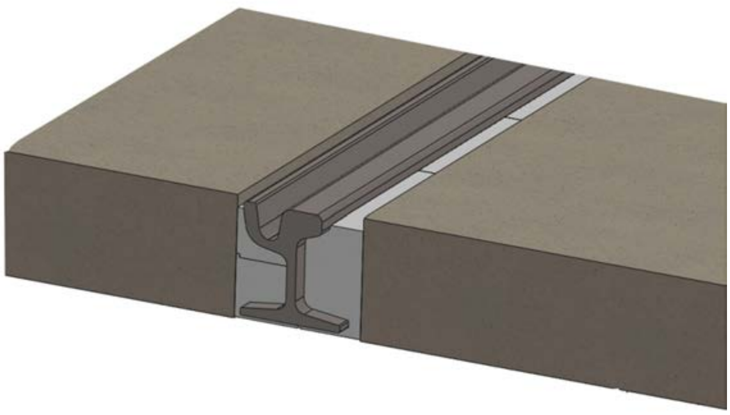

Fig. 9 - Solución habitual de chaqueta aislante de carril

2.2 Chaqueta Aislante Extraíble

Para solventar estos inconvenientes Metrotenerife ha desarrollado y obtenido la patente en España (OEPM) y en Europa (EPO) de un diseño de chaqueta aislante de carril que permite la sustitución de los carriles desgastados sin necesidad de afectar al revestimiento.

La Chaqueta Aislante Extraíble cumple con el cometido de aislamiento eléctrico y acústico que presentan el resto de soluciones del mercado, pero introduce la novedad de poderse retirar fácilmente para extraer el carril antiguo y volver a colocarse una vez reemplazado el carril nuevo, volviendo a cumplir con su tarea de aislamiento. La retirada de la chaqueta y su reposición no requieren de trabajos de obra civil tales como demolición o construcción, aportando por tanto un claro beneficio para el operador en los términos indicados anteriormente. Adicionalmente, este diseño concreto de chaqueta aporta otras ventajas en términos de fabricación respecto a otras soluciones constructivas, pues reduce el volumen de material empleado y además elimina la necesidad de uso de caperuzas de protección de la sujeción, hechas habitualmente en plástico, proporcionando por tanto beneficios medioambientales.

Metrotenerife comenzó con las pruebas de la nueva chaqueta en el año 2016, y desde entonces ha implantado esta solución constructiva en sus líneas durante las operaciones de sustitución de carril, obteniendo resultados satisfactorios hasta la fecha.

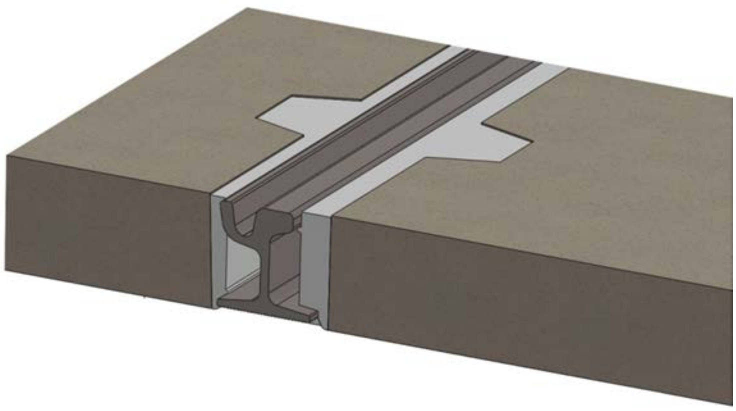

Fig. 10 - Solución chaqueta aislante extraíble de Metrotenerife

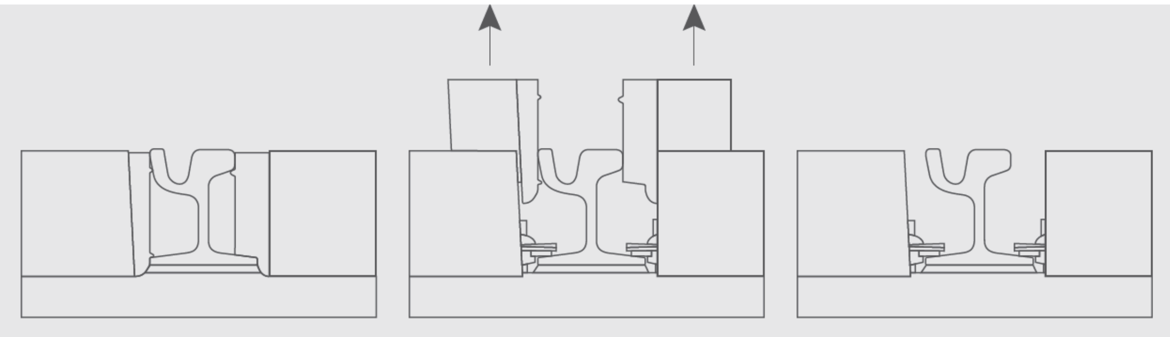

Fig. 11 - Extracción vertical y sustitución del enchaquetado sin necesidad de demoler el revestimiento

2.3 Solución polivalente

La solución de chaqueta aislante extraíble permite ser instalada en los diversos tipos de revestimientos empleados habitualmente en las líneas de metro ligero, tanto pavimentos rígidos como revestimiento verde (césped). Además, también permite ser instalada en cruces con calzadas de vehículos, en cuyo caso se añade un perfil metálico de protección de la interfaz entre chaqueta y revestimiento para evitar daño y erosión de ambos materiales, una solución empleada también en las soluciones constructivas habituales del mercado actual.

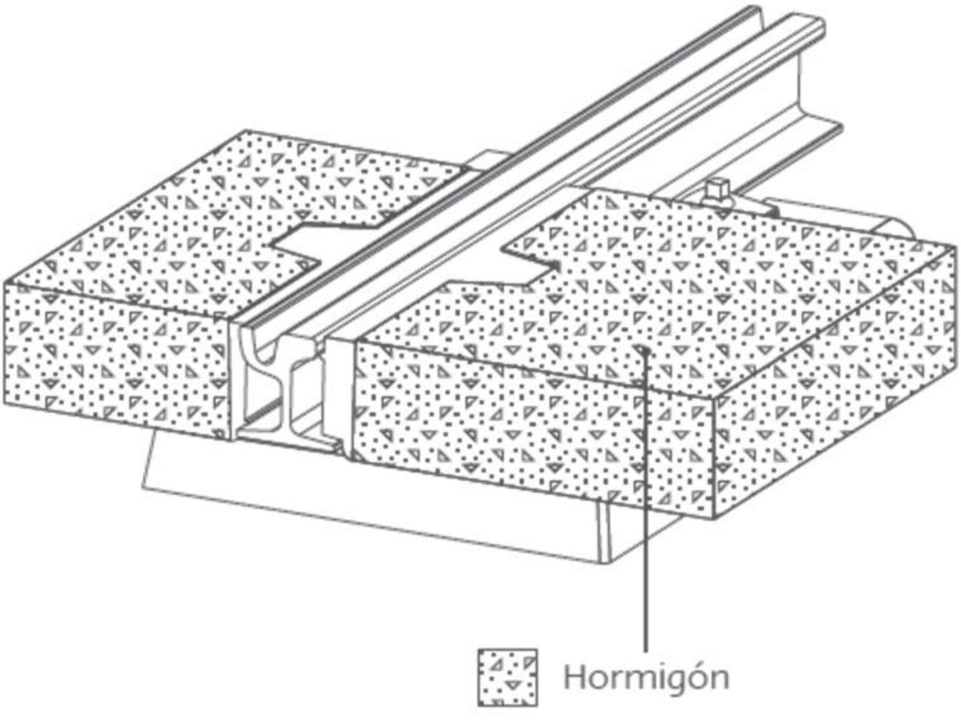

Fig. 12 - Instalación con revestimiento de hormigón, sin cruce con circulación rodada

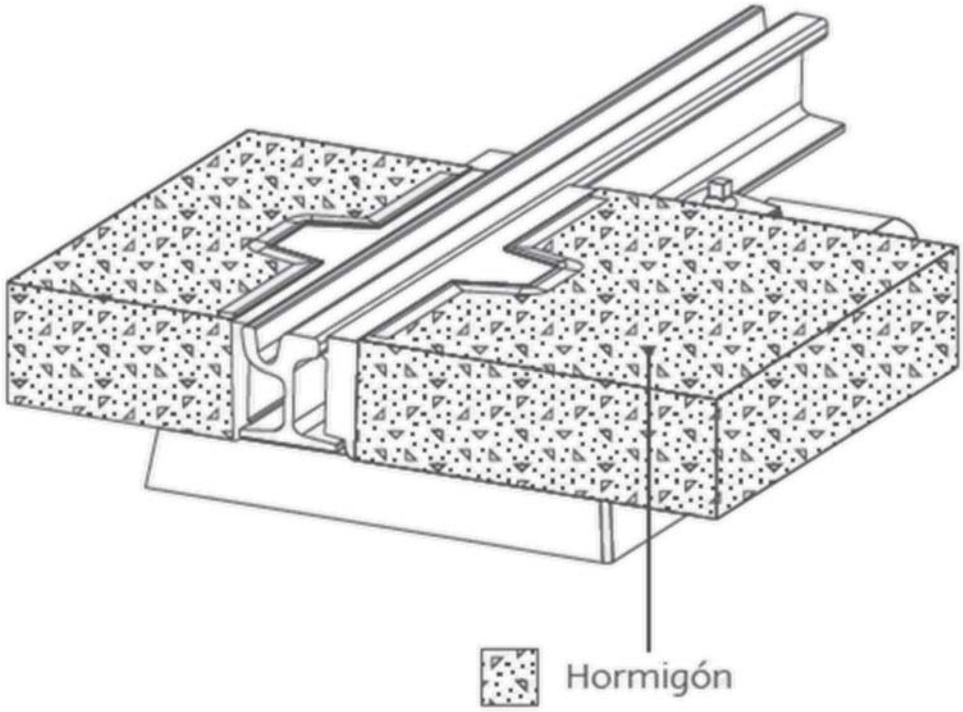

Fig. 13 - Instalación con revestimiento de hormigón, en cruce con circulación rodada (con perfil metálico de protección)

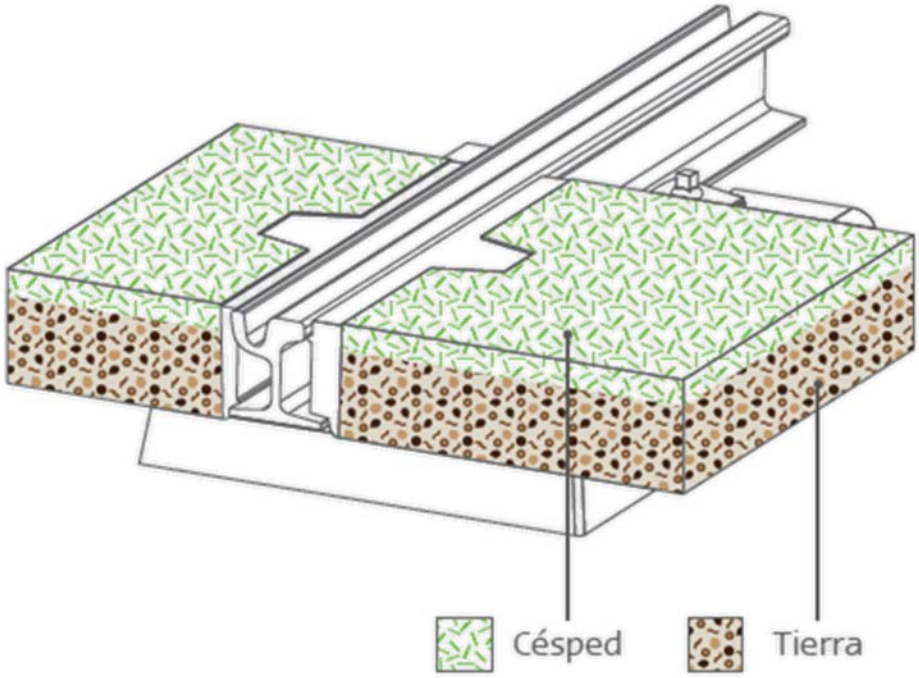

Fig. 14 - Instalación en revestimiento verde (césped)

		
Revestimiento de hormigón	Cruce con calzada	Revestimiento verde

Tabla 1 – Instalación con diversos revestimientos

2.4 Ventajas

Por tanto, la chaqueta aislante extraíble aporta las siguientes ventajas respecto a los modelos de chaqueta actuales del mercado:

- Menor coste de fabricación, al necesitar menor volumen de material
- Reducción del número de elementos a emplear en el conjunto de aislamiento, al eliminar la caperuza de protección de la sujeción, ya que la propia chaqueta cubre la sujeción
- Mejoras en afección medioambiental, al eliminar el uso de caperuzas plásticas
- Reducción de costes para el operador al eliminarse los trabajos de demolición y posterior reposición de pavimentos, operaciones éstas que no generan ningún valor añadido a la plataforma tranviaria
- Reducción de residuos RCD (Residuos de Construcción y Demolición) emitidos por las operaciones de sustitución de carril con soluciones estándar
- Reducción de los plazos de ejecución de las operaciones de demolición y reposición
- Reducción de las interferencias sobre el servicio comercial de transporte, al reducirse el plazo y eliminarse trabajos de obra civil en la plataforma ferroviaria
- Reducción de molestias al entorno urbano por ruidos, polvo, desvíos de tráfico provocados por la demolición y reposición en las soluciones estándar.

ESTUDIO EXPERIMENTAL DE LA PISADA DE PASAJEROS AL MOMENTO DE BAJAR AL ANDÉN DESDE UN TREN URBANO

Sebastian Seriani

RESUMEN

El metro de Santiago de Chile es hoy en día uno de los medios de transporte más usado por los capitalinos, es por esto que muchos pasajeros con movilidad reducida (PMR) lo prefieren. Sin embargo, en las líneas del metro podemos encontrar distintas brechas verticales (BR) que se generan entre el tren y el andén. Estas BR dificultan los PMR para subir y bajar del tren generando un cambio en su pisada, afectando su estabilidad. Esta estabilidad se puede representar con distintas variables como la fuerza de rechazo y amortiguamiento, los rangos de recorrido de cada componente de pisada y el área generada por estos rangos de recorrido.

El objetivo de este artículo es estudiar, de forma experimental, el efecto de la BR en la pisada de PMR en el espacio tren-andén de estaciones de metro. Para esto, se llevó a cabo la construcción de experimentos a escala real que representan la transición tren-andén en el Laboratorio de Dinámica Humana de la Universidad de los Andes. Para obtener los datos, se ocupó una placa de fuerza Bertec y un software Bertec Acquire 4, el cual permite entre otras cosas obtener la fuerza en el eje z y los centros de presión en el eje x y eje y.

Los resultados muestran que a mayor BR, mayor es la inestabilidad en PMR. Además, también se observó como PMR cambian su estrategia de pisada al tener que enfrentar BR mayores a 11 cm, dado que cambiaron totalmente el ángulo de inclinación con el cual las personas posicionan su pie al bajar, de manera de poder hacer el proceso con mayor estabilidad. Se espera que en futuros experimentos se logre expandir el alcance de este tipo de estudios, al implementar más instrumentación y un mayor número de participantes.

1. INTRODUCCIÓN

Al igual que en otras ciudades del mundo, en Santiago de Chile, el transporte público más importante es el tren urbano o metro. Este sistema es el principal esqueleto que conecta todas las redes de la capital, cuenta con 7 líneas y conexiones a las otras redes de trasporte público, como buses suburbanos y Red Metropolitana de Movilidad (ex – Transantiago). Este a la vez presenta una característica esencial, que es tener accesibilidad universal, logrando que pasajeros con movilidad reducida (PMR) puedan usarlo sin problemas, sin ninguna restricción y de forma autónoma (Subsecretaría de Transportes, 2013; Ministerio de Vivienda y Urbanismo, 2010; 2016). La accesibilidad universal se debe entender como lo estipulado en la Ley de accesibilidad universal, contexto normativo en el cual se debe regir, inspirar y alcanzar:

> "Avanzar hacia un país inclusivo y moderno, que otorgue a todos iguales oportunidades de cumplir metas y aspiraciones personales: Un desafío a la arquitectura, urbanismo, programas y proyectos públicos a incorporar las condiciones necesarias para que nuestras ciudades, edificios, plazas y parques tengan posibilidades de acceso y uso para todos sus habitantes" (Ministerio de Vivienda y Urbanismo, 2010).

Esta cita explica a grandes rasgos, que en Chile se esta dando un importante impulso al diseño de ciudades para cumplir con todas las normativas vigentes. Por consiguiente, los diferentes sistemas de transporte público tienen el desafío de adaptarse a la accesibilidad universal para que los pasajeros puedan no solo acceder a este sino también utilizarlo (Tyler, 2002). La accesibilidad hoy es un término amplio y relativo, imprescindible tanto para conseguir una igualdad de oportunidades efectiva para todas las personas, como para optimizar el diseño de un entorno (Alonso, 2007). Sin embargo, hay dos tipos de diseños que son importantes de mencionar al hablar de accesibilidad en el transporte público: existen diseños de accesibilidad que están pensados para pasajeros con discapacidad y otros para PMR. Por ejemplo, los ascensores o rampas son una ayuda para pasajeros con discapacidad que requieren de una silla de ruedas como herramienta para poder moverse, sin embargo el uso de escaleras con pasamanos o escalones menos altos son soluciones que se buscan para dar accesibilidad a PMR. Por lo tanto, PMR son capaces de desenvolverse en entornos de transporte público sin accesibilidad universal, pero no por eso es menos importante buscar diseños que le mejoren la calidad de vida.

En trenes urbanos, los problemas de accesibilidad se concentran en la interfaz tren-andén, el cual presenta mayores riesgos de accidentes para PMR (Seriani y Fernández, 2015). En el caso del metro en Santiago, se ha utilizado un material de caucho como relleno para reducir la brecha horizontal entre el andén y tren (ver Fig. 1 - izquierda). Por otro lado, para reducir la brecha vertical (BR) algunas estaciones de metro han introducido andenes elevados.

A modo de ejemplo, la estación Green Park en el metro en Londres tiene un andén elevado que se extiende en una parte del andén y tiene una longitud total de 27 m (ver Fig. 1 - centro), por lo que este elemento cubre el segundo y tercer vagón y un total de cuatro puertas (dos dobles y dos individuales). A pesar de las diferentes medidas para mejorar la accesibilidad universal en dicha interfaz (Ministerio de Vivienda y Urbanismo, 2010; 2016), las soluciones se limitan a diferentes factores como el diseño del andén (por ejemplo, andenes curvos), puertas del tren (por ejemplo, número y ancho de puertas) y piso del tren (por ejemplo, material), y por lo tanto no pueden implementarse en todas las estaciones. Como consecuencia, algunas estaciones aún tendrán un BR, que es un valor fijo considerando el tipo de tren y el diseño de la interfaz en cada estación (ver Fig. 1 - derecha) (Oyanedel, 2020). Para ahondar en diseños de BR, estudios realizados por Fernández et al. (2010; 2015) buscó simular flujos unidireccionales en el que participantes suben y bajan de 3 BR distintas: 0 cm, 15 cm y 30 cm. Los resultados muestran un mejor diseño estaría dentro del rango de 0 cm a 15 cm. Esto abre un rango en el que este estudio busca trabajar y ver cómo se comporta el proceso de pisada para PMR.

Fig. 1 – BR en estaciones de metro: material de caucho (izquierda), andén elevado (centro), BR existente (derecha)

Para poder dar soluciones que mejoren la accesibilidad universal en la interfaz tren-andén, se necesita estudiar el efecto de la BR en la pisada de PMR. Mas específicamente, este articulo busca estudiar de forma interdisciplinaria como afecta la BR en la inestabilidad de PMR para un proceso de bajada desde el tren al andén, combinando conocimientos de transporte y kinesiología mediante instrumentación y métodos de estudio. Los objetivos específicos son los siguientes: (a) definir variables relevantes de estudio que afectan el proceso de pisada de PMR al enfrentar una BR, (b)definir un método para medir las variables relacionadas a la estabilidad de un proceso pisada, (c) simular en el Laboratorio de Dinámica Humana de la Universidad de los Andes (LDH en adelante) pasajeros que bajan una BR en un experimento a escala real, (d) analizar los datos obtenidos en el experimento para ver como varia la estabilidad de una PMR en distintas BR.

Este artículo está estructurado en cinco secciones, comenzando con la introducción. En la sección 2 se presentan los estudios existentes relacionados con la BR. En la sección 3, el método se explica en base a experimentos de laboratorio. En la sección 4, se presentan los resultados seguidos de la discusión y las conclusiones de la sección 5.

2. ESTUDIOS EXISTENTES SOBRE EL PROCESO DE PISADA

Podríamos decir que, en estaciones de metro, subir y bajar por diferentes BR es algo que pasajeros realizan a diario. Sin embargo, esta tarea locomotora tan cotidiana es bastante exigente para PMR, especialmente considerando sus restricciones de movilidad en sus extremidades inferiores. Enfrentar BR puede ser muy difícil, por lo que urge una manera, forma y solución que no demande tanto esfuerzo físico ya que sería una ayuda significativa en la calidad de vida de personas con impedimentos físicos. Además, recuperar la locomoción es un factor clave que ayuda a un paciente regresar a su casa después de una lesión (Startzell et al., 2000). Se puede identificar que la marcha al pasar una BR se pude separar en el ascenso y descenso de ésta, lo cual es significativamente una tarea compleja para PMR, que demanda un esfuerzo físico y también a su vez el uso de cierta capacidad motriz, siendo una potencial causa de pérdidas de equilibrio y caídas (Hashish et al., 2017).

El proceso de pisada es un proceso o secuencia de movimientos del pie por el cual una persona se mueve hacia adelante, se puede dividir en dos fases principales: (a) amortiguamiento, el cual corresponde cuando el pie hace contacto con el suelo, tomando toda la carga del cuerpo en el tobillo de este pie, (b) rechazo, el cual se define como el abandono de este pie del suelo, instancia en que la última parte en perder contacto corresponde a los dedos. Para estudiar dicho proceso, se debe analizar el desplazamiento del centro de masa (COM) que representa el grado de balanceo del cuerpo en diferentes direcciones. También es importante el centro de presión (COP), el cual se refiere al desplazamiento, calculado por los cambios de posición del punto de fuerzas de reacción del suelo, representando la estrategia de marcha y la estabilidad del cuerpo. En este sentido se puede calcular la estabilidad dinámica (DGS) como un parámetro que tiene en cuenta simultáneamente el COM y su velocidad instantánea, por lo que es una buena forma de medir pérdidas de equilibrio y caídas. Además, el ángulo de inclinación del pie existente en dos planos, el antero posterior y plano medio lateral, es un parámetro difícil de medir e tiempo real, pero esta directamente relacionado con la inestabilidad. Por su parte, la placa de fuerza es un instrumento para medir las fuerzas de reacción del suelo generadas por un cuerpo que pasa o esta sobre este. Generalmente son usadas para cuantificar el equilibrio, la marcha y otros parámetros de la biomecánica. Dicha placa se complementa con cameras VICON, las cuales son utilizadas como instrumento para registrar los movimientos de las personas tridimensionalmente mediante el uso de pines de metal reflectantes, generalmente con aplicaciones médicas y deportivas (Bhatt et al., 2011).

A partir de las definiciones anteriores, un estudio realizado por Song et al. (2020) analizó cómo las personas descienden por un escalón. Los resultados arrojaron que a mayor complejidad de la tarea cognitiva o manual que se realiza al bajar la escalera menor es la velocidad de la pisada, pero no afectó DGS ni tampoco el ángulo de inclinación. Lo anterior dado que se creía que la marcha ocurre inconscientemente y no involucra funciones cerebrales superiores. Los resultados dicen que las tareas cognitivas y manuales en paralelo requieren recursos adicionales, demostrando el peligro que es hacer tareas en paralelo mientras se descienden escalones. También es importantes destacar cómo afecta llevar cargas externas a la hora de descender o ascender por un escalón. Un pie soporta el peso de todo el cuerpo, el otro pie avanza al siguiente escalón generando una desigualdad en la carga y por consiguiente un aumento en la velocidad medio lateral del COP (Anker et al., 2008), y también mayor desplazamiento de este durante el inicio de la pisada (Vieira et al., 2016).

Por otra parte, un estudio realizado por Wang y Gillette (2020) buscó investigar el efecto de carga simétrica y carga asimétrica externa en las extremidades inferiores durante el proceso de descenso y acenso de escalones. Los resultados indicaron que llevar carga de manera asimétrica es lo que más daña la estabilidad seguido por la carga simétrica. En ambos casos este parámetro se vio más perjudicado a la hora del descenso y manteniéndose relativamente normal en el acenso.

En base a los estudios anteriores, poder medir la estabilidad es una de las características más importantes que ayudan a las personas a intuir caídas, además de poder completar acciones secundarias mientras esta está en desplazamiento. Dadas todas las formas de establecer qué es la estabilidad, una forma empírica, práctica y con bastante literatura de respaldo para medir, es mediante desplazamiento del COP (Huang y Brown, 2013). La obtención del COP se logra médiate el uso de una placa de fuerza, la cual entrega un punto en milímetros de donde se sitúa el COP en dicha placa, situando un eje cartesiano imaginario donde el punto 0,0 está justo en el centro de ésta. El uso de la placa es una técnica relacionada con la cuantificación del balanceo postural o movimiento plano medio lateral de una persona de pie. Ayuda a medir el balanceo real de cada pie o el balanceo de todo el cuerpo. Los desplazamientos del COP es una de las medidas más comunes de balanceo corporal (Lafond et al., 2004). La interpretación empírica más extendida de las medidas típicas del balanceo de la postura plano medio lateral es que un mayor balanceo significa mayor inestabilidad, lo que se considera una indicación de un sistema de control postural deteriorado. Este razonamiento se basa en muchos experimentos sobre el envejecimiento y las condiciones patológicas que, de hecho, han observado una mayor influencia en esas condiciones. Sin embargo, se debe tener en cuenta que puede que no siempre sea así (Lafond, et al., 2004).

El valor del desplazamiento COP depende, de dónde pisa la persona en la placa de fuerza. Un procedimiento típico en el análisis del COP es eliminar el valor medio de los datos ya que este es generalmente por el largo del pie, generando la presencia de una tendencia.

Si bien se podría argumentar que la tendencia en sí misma podría brindar información valiosa sobre la señal (Zatsiorsky y Duarte, 2000), el problema es que la mayoría de las medidas que se usan deben asumir que la señal es estacionaria. Una señal es estacionaria si sus propiedades estadísticas (como la media y la varianza) no cambian a lo largo del tiempo. Por lo tanto, para eliminar la tendencia de los datos puede ser necesario en ciertos casos aplicar un filtro de paso alto a los datos con una frecuencia de corte relacionada con el período de adquisición de datos (Witt et al., 1998).

Por otro lado, la velocidad media expresa la velocidad promedio del desplazamiento del COP, calculada simplemente como la variable de trayectoria total (el desplazamiento total) dividida por el período total. Esta variable generalmente se conoce como velocidad, pero como es un escalar, debería llamarse velocidad propiamente tal. La velocidad media resultante es la velocidad calculada en forma vectorial considerando cada dirección, es decir, la raíz cuadrada de la suma de la velocidad al cuadrado de la dirección antero posterior y la dirección plano medio lateral. Otra forma de medir el balanceo postural es calcular el área que abarca los datos del COP en el plano antero posterior y el plano medio lateral usando una curva en un plano (por ejemplo, un círculo o elipse) o un polígono (por ejemplo, un rectángulo). Un método común para ello es calcular una elipse de predicción, que se encuentra ajustando una elipse a los datos utilizando conceptos del procedimiento estadístico conocido como análisis de componentes principales. Una elipse de predicción del 95% es un intervalo de predicción para los datos de COP de modo que existe un 95% de probabilidad de que una nueva observación se encuentre dentro de la elipse. De la interpretación del COP se puede decir que, a mayor área de desplazamiento durante un determinado tiempo, mayor será la inestabilidad y también el balanceo (movimiento plano medio lateral) de la línea dejada por el desplazamiento del COP de una persona avanzando rectamente. Entre menos recta sea esta línea, mayor será su inestabilidad.

En conclusión, la información bibliográfica indica que, dada la literatura expuesta y a pesar de los avances encontrados hasta la fecha sobre el proceso de pisada y sus variables asociadas, se requiere un estudio sobre el comportamiento de la estabilidad para distintas BR en la interfaz tren-andén. Se debe estudiar en conciso cómo afecta la variación de BR en la estabilidad dinámica de PMR que tiene que descender por ésta desde un tren urbano, lo cual será el objetivo principal de este artículo.

3. MÉTODO EXPERIMENTAL

3.1 Diseño experimental en laboratorio

Para el diseño experimental se realizaron mediciones de las 7 líneas de la red de metro en Santiago, eligiendo 3 estaciones por cada línea, dando una muestra de 21 estaciones (correspondientes al 15% de la red). En terreno se recolectó datos de cada estación en ambos sentidos durante la semana del 4 de diciembre de 2019.

En la Tabla 1 se muestran las BR observadas por este estudio, se agrupa las estaciones por su línea correspondiente, y cada estación se divide en dirección 1 y 2, correspondiente a cada andén, respectivamente. Las BR están en un rango de valores entre 0 y 12,5 cm. En el caso de BR = 0 cm corresponde a las nuevas líneas 3 y 6, donde los trenes nuevos tecnología de puertas en andenes y el tren se dirige sin conductor (de forma automatizada). El caso de 12,5 cm corresponde a la línea 2, donde se utilizan trenes más antiguos.

Para medir las BR en cada estación, se utilizó elementos de medición directa (por ejemplo, una huincha de medir) al momento que el tren se detenía próximo al andén. Se seleccionó la puerta más crítica de un tren, entendida como la puerta que está próxima a la salida o entrada del andén, y por ende la que probablemente utilizan PMR, ya que este tipo de pasajeros tienden a fatigarse al desplazarse en trayectos largos (Tyler, 2002).

Línea	Nombre Estación	Dirección 1	Dirección 2
		BR [cm]	BR [cm]
Línea 1 (L1)	Estación Central	1,5	1,7
	Pedro de Valdivia	0,0	1,3
	Los Dominicos	1,5	1,7
Línea 2 (L2)	Vespucio Norte	12,5	1,8
	Parque O'Higgins	10,5	1,7
	La Cisterna	1,7	1,7
Línea 3 (L3)	Puente Cal y Canto	6,0	6,0
	Irarrázaval	5,5	5,3
	Plaza Egaña	4,5	5,5
Línea 4 (L4)	Tobalaba	6,3	4,2
	Quilín	2,7	3,0
		4,0	5,0
	Hospital Sótero del Río	2,2	4,7
Línea 4A (L4A)	La Cisterna	6,5	4,0
	Santa Rosa	4,7	4,0
	Vicuña Mackenna	1,7	1,7
Línea 5 (L5)	Blanqueado	11,0	9,0
	Ñuble	6,6	8,0
	Vicente Valdés	6,0	1,6
Línea 6 (L6)	Lo Valledor	5,3	5,0
	Franklin	5,5	5,5
	Los Leones	5,0	5,0

Tabla 1 – Dimensiones brecha vertical (BR) observadas en las estaciones de metro en Santiago

Para realizar el experimento se tuvo que construir un piloto a escala real en el Laboratorio de Dinámica Humana (LDH) de la Universidad de los Andes, basado en los datos de BR que se mencionan en la Tabla 1. El piloto consta de 6 cajones de maderas independientes entre sí, cinco de estos serían “el tren” y el otro restante correspondería al “andén”. Es importante mencionar que el cajón del andén es de suma importancia, ya que en él está la placa de fuerza, por lo que su diseño debió ser especial, meticuloso y más complejo. La decisión de construir los cajones de forma independiente se tomó, principalmente, porque de esta manera se resolvería el problema de que estos no fueran a quedar perfectamente apoyados al piso, generando movimientos indeseados mientras los participantes estuviesen caminando sobre ellos en el experimento. Además de esto, transportar y almacenar el piloto en el LDH sería mucho más cómodo. Una vez montado el piloto, fue sujetado con 4 ligas entre sí como muestra la Fig. 2, generando una sola estructura rígida con los 5 cajones correspondientes al “tren”. De esta manera se podía trasladar la placa a cada nivel distinto de BR de una manera fácil y rápida. Cabe destacar que el diseño del cajón correspondiente al andén era el más importante en este estudio, ya que cualquier falla generaría ruidos en los datos. Esto debido a la sensibilidad de la placa de fuerza durante las mediciones. Se hizo una base solida y pesada de planchas de madera para la placa de fuerza, de esta manera el peso ayudaría a que no se generasen vibraciones y así trabaría por separado al cajón.

Fig. 2 – Piloto para la experimentación en el LDH: pasajero pisando la placa de fuerza (izquierda), movimiento de cajón “andén” para diferentes BR (derecha)

Los escenarios para simular la bajada de pasajeros desde el tren al andén se muestran en la Tabla 2, cuyos valores están en el rango de observaciones de estaciones del metro de Santiago reportadas en Tabla 1.

Escenario	Cajón “Tren”			
	Ancho (m)	Largo (m)	Alto (cm)	Brecha vertical (cm)
1	0,80	1,50	13,00	0,00
2	0,80	1,50	16,75	3,75
3	0,80	1,50	20,50	7,50
4	0,80	1,50	24,25	11,25
5	0,80	1,50	28,00	15,00
	Cajón “Andén”			
	Ancho (m)	Largo (m)	Alto (cm)	Nivel (cm)
Todos	0,80	1,50	13,00	0,00

Tabla 2 – Escenarios que representan BR en el LDH

Por motivos de la pandemia (COVID 19), no fue posible reclutar PMR para el experimento.

Lo anterior porque las pruebas se llevaron en los meses que la ciudad de Santiago se encontraba con medidas de cuarentena y con un número alto de casos activos. Por lo mismo, se optó por buscar personas sanas y simular mediante casos una reducción en su movilidad.

Los participantes del experimento fueron 5 hombres jóvenes de 26 años, entre ellos un rango de altura de 172,4 ± 7,7 cm, con masa corporal de 70,4 ± 9,7 kg. Los criterios de exclusión de participantes (no podían participar) fueron la incapacidad de seguir las instrucciones, afecciones de inestabilidad cardíacas, reemplazo de articulaciones de miembros inferiores, artritis, diabetes, problemas de visión o cualquier otro problema neuromuscular que pueda evitar que los participantes puedan ejecutar el ensayo forma segura y efectiva. Los participantes no podían estar bajo prescripción de un medicamento en los últimos siete días y además no debían tener experiencia de anomalías al caminar en los últimos tres años.

Todos los participantes reportaron tener el pie derecho dominante, y lo definen como la pierna preferida para patear una pelota de fútbol. Con esto último podemos lograr reducir errores en los resultados, asegurando que la persona usó su pie más diestro para bajar desde el tren al andén (Gribble et al., 2007).

Respecto a los escenarios, se consideraron 4 casos de estudio (ver Fig. 3) para casa situación de BR definida en la Tabla 2. En cada caso se buscó simular algún tipo de características de PMR en los participantes añadiendo cierto factor de movilidad reducida. En cada caso se afrontó el proceso de amortiguamiento, es decir la bajada del tren al andén. Para dar mayor validez a los datos se efectuaron 3 repeticiones por cada proceso de pisada. En resumen, se consideró cinco participantes en 4 casos, con 5 BR diferentes, en la modalidad de bajada considerando 3 repeticiones por caso. Esto dio un total de 300 archivos .csv los cuales almacenaron en un proceso de pisada completo de principio a fin.

Fig. 3 – Casos a considerar en los experimentos de laboratorio: bota ortopédica (superior izquierda), carga simétrica (superior derecha), carga asimétrica (inferior).

En resumen, se consideraron los siguientes casos:

- Caso 1: En el primer caso cada participante hizo el experimento sin factores que afecten su movilidad. Esto para tener una medición base de sus perfiles y ver cómo se comporta su centro de presión en la normalidad. Esto fue tomado más adelante como la estabilidad "normal" para después poder comparar estos valores con los valores obtenidos por los otros casos.
- Caso 2: Cada integrante utilizó una bota ortopédica en el pie derecho, lo cual le dio menor movilidad en sus articulaciones, tratando de simular a una persona con problemas o lesiones en sus extremidades inferiores.
- Caso 3: Cada integrante cargó con el 20% de su masa corporal distribuida de manera simétrica en su mano derecha e izquierda, para simular un pasajero con dos bolsos de compras (siguiendo el estudio de Wang y Gillette, 2020).
- Caso 4: Cada integrante cargó con el 20% de su masa corporal distribuida de manera asimétrica en su mano derecha, buscando simular un pasajero con un solo bolso de compras de mayor carga (siguiendo el estudio de Wang y Gillette, 2020).

3.2 Medición de variables

La forma en que la placa de fuerza entrega los datos es a través del software Bertec. Una vez ya instalada la placa en el piloto y listo el participante para el experimento llega el momento de elegir qué datos se desea grabar.

El software en sí es sencillo y amigable para poder trabajar con la placa de fuerza. Éste permite, entre otras cosas, poner el nombre al archivo, ver gráficos en tiempo real de la pisada, su tipo de extensión (.CVS), para luego poder trabajar con estos en Python. Para el nivel de detalle que se necesita se usó 100 hz para no crear archivos extremadamente grandes. Una de las cualidades más importantes del programa es que tiene un filtro de auto-zero digital, lo que permitió eliminar todo tipo de ruidos adicionales que se produjeron por vibraciones del ambiente. El valor que se ocupó como filtro fue 4 kgf o 39,2 N en el eje z el cual es el recomendado por el desarrollador y viene listo de fábrica. Este valor de magnitud no tiene relación con el COP, pero al usarlo como filtro, se eliminaron todos los puntos de COP asociados a los valores menores a 4 Kgf en el eje z. Lo anterior afecta directamente al área y la velocidad, ya que los registros que se filtraron creaban puntos extra que no correspondían al proceso de pisada propiamente tal y “ensuciaban” los resultados.

Mediante distintas librerías Python, se generó un código para obtener valores por cada proceso de pisada. Para esto el código se ubicó en la misma carpeta que todos los otros archivos. Este automáticamente leyó cada valor de pisada y generó matrices asociadas al nombre de cada archivo. Estas matrices fueron de dimensiones (3, n), siendo n el largo del archivo, donde la primera columna es la fuerza en el eje z (Fx Z), mientras que la segunda columna es el COP-antero posterior y la tercera columna es el COP-plano medio lateral.

Un ejemplo de los datos de salida del código usado en Python se muestra en la Fig. 4. Los valores obtenidos por cada archivo fueron:

- Área elipse 95 % confianza (cm^2)
- Largo de movimiento antero posterior (cm)
- Largo de movimiento plano medio lateral (cm)
- Velocidad movimiento antero posterior (cm/s)
- Velocidad movimiento plano medio lateral (cm/s)
- Suma de ambas velocidades al cuadrado (cm/s)

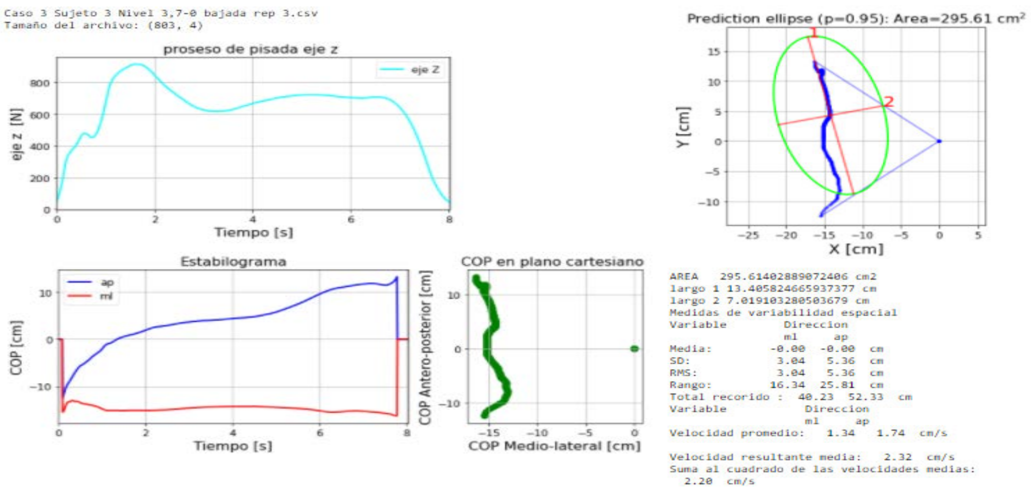

Fig. 4 – Ejemplo de datos de salida del código en Python con filtro a 4 kgf

Una vez ya leídos todos los archivos por el código, se traspasaron los valores obtenidos de cada uno a una planilla de Excel donde se promediaron las 3 repeticiones hechas en cada BR y caso para los 5 participantes. Una vez completada la planilla, se exportaron sus datos en Power-BI, la cual es una plataforma que permite hacer operaciones y visualizarlos de forma adecuada. De esta manera, estudiar como varía la estabilidad de los participantes en cada caso del experimento al cambia las BR. Estos valores obtenidos fueron combinados entre si mediante la obtención de las siguientes variables de comparación por caso (de ahora en adelante VC). Se da este carácter de comparación debido a que ni una variable por si sola puede darnos mucha información, pero al ver como varían entre ellas podemos dar con información útil.

La VC1 (ver ecuación 1) es de gran ayuda para estudiar el comportamiento del área formada por la elipse de 95% confianza. A mayor largo del pie mayor será su recorrido antero posterior, y por ende mayor el área de la elipse. Haciendo esta división se logra llegar a un valor donde las características físicas del pie del participante no afectan los datos.

$$VC1 = \frac{Área\ elipse\ (cm^2)}{Largo\ de\ pie\ (cm)} \quad (1)$$

El rango medio lateral representa la estabilidad. A mayor rango medio lateral menor estabilidad durante el proceso de pisada. Al comparar BR distintas el rango de movimiento antero posterior va a variar, y por ende es necesario compararlo con el medio lateral en una razón expresada en ecuación 2.

$$VC2 = \frac{Medio\ lateral\ (cm)}{Antero\ posterior\ (cm)} \quad (2)$$

La división en ecuación 3 relaciona que tan grande fue la velocidad de la pisada en el plano antero posterior, en comparación al rango de movimiento antero posterior. Si este valor aumenta, se debe a que la estabilidad disminuye. A menor rango antero posterior se le atribuye un menor ángulo de inclinación en el plano antero posterior. Este ángulo es con el que se entra y sale del proceso de pisada. Al sentir inestabilidad ante una BR, el participante busca entrar con un ángulo de inclinación más cercano a los 90 grados. Por ello, no se tiene un rango de movimiento antero posterior menor. Además, si a esto se le agrega que este rango antero posterior se lleva a cabo a una velocidad igual o mayor es porque la persona busca salir rápido de la situación para lograr estabilidad rápidamente antes de caerse, comúnmente visto en personas que se tropiezan al bajar escaleras o que no puede controlar su velocidad en este proceso.

$$VC3 = \frac{Vel.\ antero\ posterior\ (cm/s)}{Antero\ posterio\ (cm)} \quad (3)$$

En la ecuación 4 se repite la lógica anterior de VC 3, sin embargo en este caso se ve la relación del vector de velocidad que se compone por velocidad del plano antero posterior del plano medio lateral, por lo que se hace una comparación con el área de la elipse.

$$VC4 = \frac{\sqrt{vel.AP^2 + vel.ML^2}\,(\frac{cm}{s})}{Área\ elipse\ (cm^2)} \quad (4)$$

Las variables de comparación VC 2, VC 3 y VC 4, son divisiones de variables con unidades distintas. Estos VC no se exponen por su unidad resultante ya que no tienen un sentido físico.

Más bien se exponen como divisiones ya que lo que se busca es ver como estas se comportan entre si y si su relación aumenta o disminuye al variar las BR. Las VC se comparan utilizando gráficos de cajas, los cuales se usan para grupos de puntuaciones en escala. De esta manera, permite estudiar las características de distribución de un grupo de puntuaciones, así como el nivel de las puntuaciones. Las puntuaciones se ordenan de menor a mayor, y se forman cuatro grupos de igual tamaño a partir de las puntuaciones ordenadas. Es decir, el 25% de todas las puntuaciones se colocan en cada grupo. Las líneas que dividen los grupos se denominan cuartiles y los grupos se denominan grupos de cuartiles. Por lo general, se etiqueta estos grupos del 1 al 4 comenzando por la parte inferior. En los resultados además se añadió un punto circular que da el promedio de los datos, así también poder ver una tendencia de este lo que agrega una mayor comprensión de estos. Cada punto le corresponde al promedio de las 3 repeticiones hecha por cada participante.

4. RESULTADOS

4.1 Caso 1 (base)

Los resultados de este caso son de gran importancia, ya que son los que sentarán las bases para el resto de los casos. En la Fig. 5 se observa que el VC 1 (razón entre el área de la elipse y el largo del pie) presenta una leve pero constante disminución a medida que aumenta la BR. Se esperaba ver un aumento del área de la elipse, ya que al aumentar la BR los participantes debiesen haber presentado un cambio negativo en su estabilidad. De hecho, esto si sucedió, sin embargo 4 de los 5 participantes cambiaron su estrategia de pisada al afrontar BR más grandes. Para cambiar la estrategia se debe disminuir el ángulo de inclinación en el plano antero posterior. Es decir, que el pie derecho buscó estar en una posición más cercana a los 90 grados al llegar al andén. Si bien en este estudio no se pudo medir el ángulo de inclinación, podemos deducir si esta variable disminuyo o aumento relacionando las demás VC del caso base.

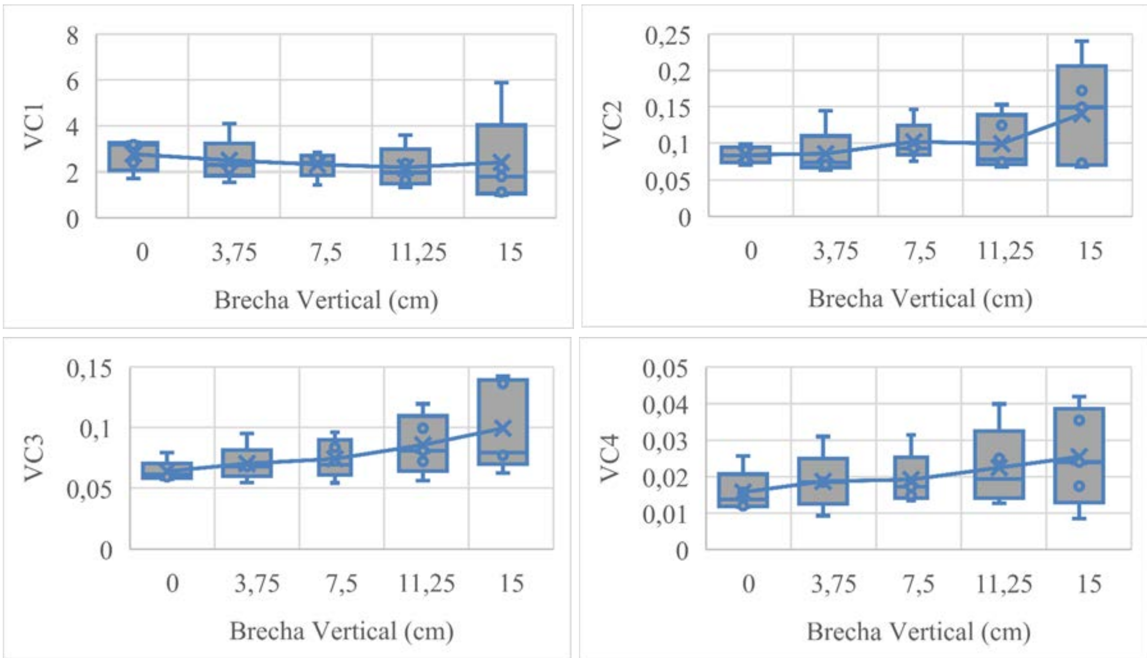

Fig. 5 – VC para cada BR en el Caso 1 (base)

Respecto a VC2 (razón entre el medio lateral y antero posterior) la Fig. 5 muestra un constante pero pequeño aumento de inestabilidad. Esto quiere decir que la estabilidad plano medio lateral se vio afectada de manera negativa al aumentar la BR. El mayor salto se puede ver entre la BR 11,25 cm y BR 15 cm. En el caso de VC 3 (razón entre la velocidad del movimiento antero posterior y antero posterior) y VC4 (razón entre la velocidad del movimiento antero posterior, velocidad del movimiento medio lateral y área de elipse), la Fig. 5 muestra una clara tendencia al aumento de la inestabilidad. Esto comprueba que el ángulo de inclinación del plano antero posterior disminuyó constantemente al aumentar la BR. Como se explico anteriormente esto se debe a que los participantes cambiaron su estrategia de pisada.

Los gráficos obtenidos para el caso 1 fueron utilizados como la base de comparación en los siguientes casos. Se hace hincapié en mencionar que todas las VC se comportaron como se esperaba, a excepción de la VC1. En esta se esperaba ver un crecimiento en vez de una disminución, sin embargo, al analizarla y ver como se comportó el resto podemos entender que la razón está en el cambio de estrategia de pisada. Se puede dar como conclusión del Caso 1 que, a mayor BR, mayor fue la inestabilidad, en donde BR = 15 cm fue la más perjudicial para los participantes.

4.2 Comparación de casos

En el Caso 2 (bota ortopédica), los resultados de la Fig. 6 no muestran una tendencia tan clara como en el Caso 1 (base). Los valores en promedio se mantuvieron sin variaciones extremas. Es decir, algo en la bota ortopedia aportó cierta ayuda a los participantes.

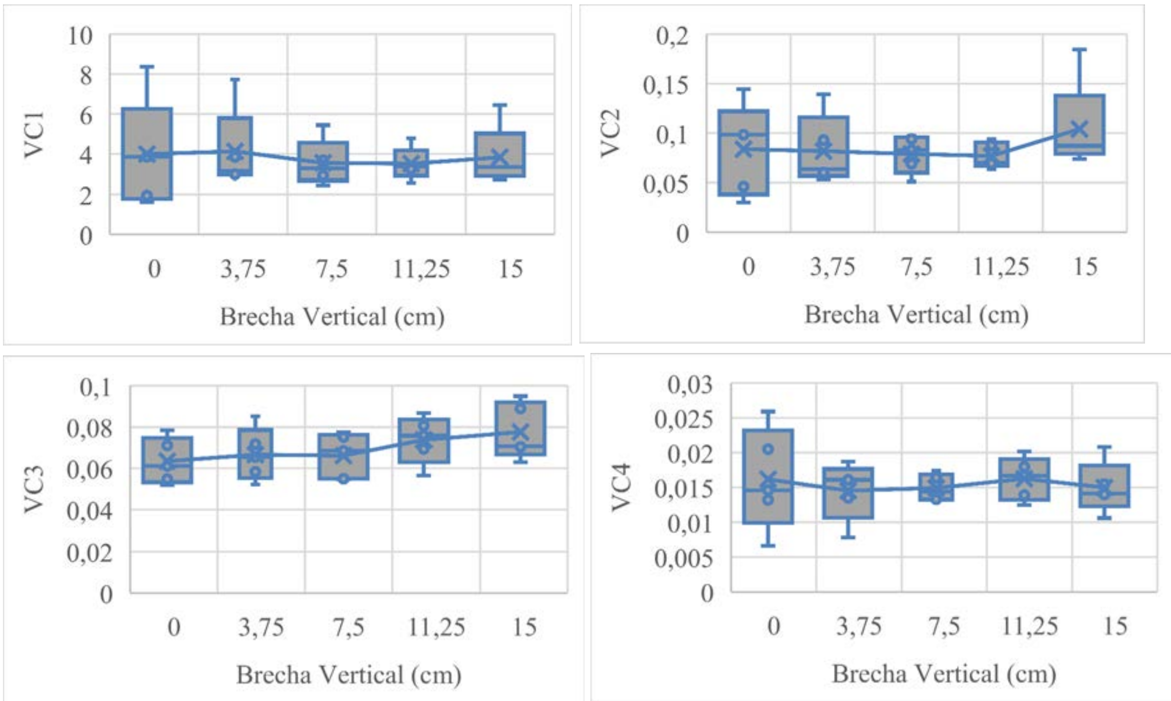

Fig. 6 – VC para cada BR en el Caso 2 (bota ortopédica)

Las botas ortopedias son usadas en caso de lesiones o roturas producidas en las extremidades inferiores y a diferencia de los yesos clínicos estas pueden ser removidas, para ayudar al paciente. Su construcción es mayormente de plástico de alta densidad y tela acolchadas para no producir heridas en la piel de quien la usa. Estas botas restringen toda la movilidad en la pantorrilla, tobillo y dedos del pie, generando una dificultad al caminar. Una posible razón de está poca variación en los valores obtenidos para cada VC se debe a que la suela de la bota es curva, lo cual afecta el plano antero posterior y plano medio lateral. Esta curvatura lo que genera es que el COP tienda a centrarse durante todo el proceso de pisada, disminuyendo sus rangos antero posterior y medio lateral, y por ende las VC no mostraron una tendencia clara de mayor inestabilidad al aumentar las BR. Esto no significa que esta mayor inestabilidad no sucedió, sino que el método empleado basado en el COP no logró medir bien las pisadas con este tipo de suela con curvatura.

En la Fig. 7 se observa que el Caso 3 (carga simétrica) es una versión más inestable comparada al Caso 1. Esto debido al peso extra añadido a los participantes el cual correspondió al 20% de su peso. Esta inestabilidad se hizo notorio en las últimas BR, lo cual tiene una explicación clara, pues a mayor BR el peso que llevaba cada participante genera una aceleración, y por ende los participantes tuvieron que hacer un esfuerzo mayor para mantenerse estables (reflejado en las VC2 y VC3).

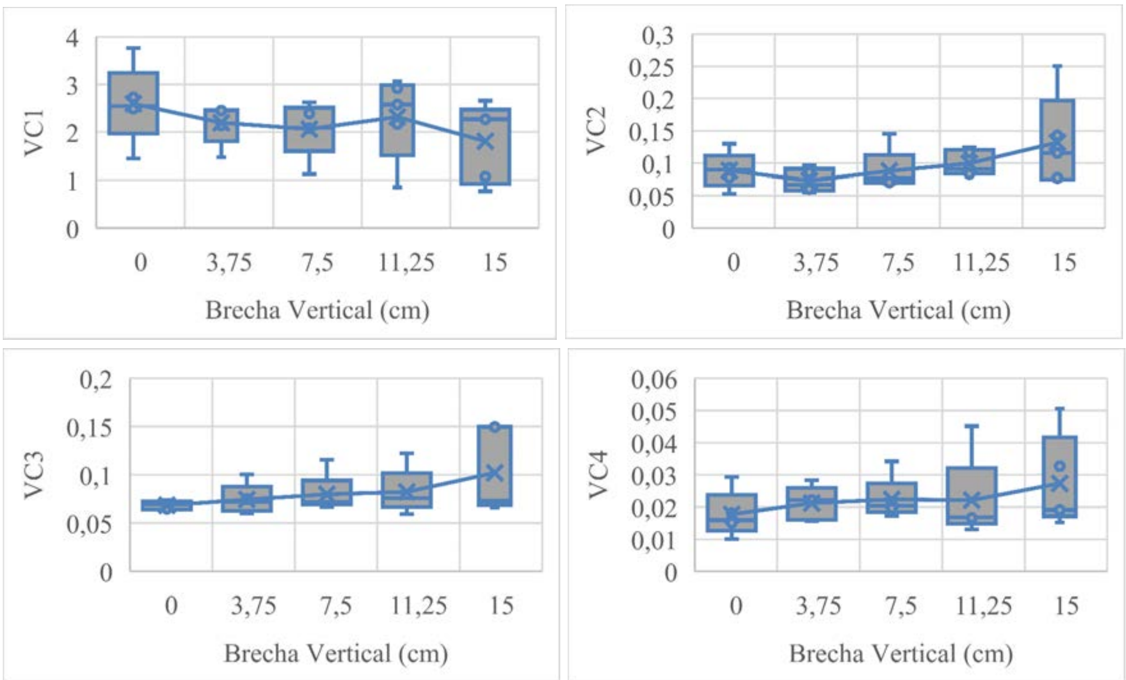

Fig. 7 – VC para cada BR en el Caso 3 (carga simétrica)

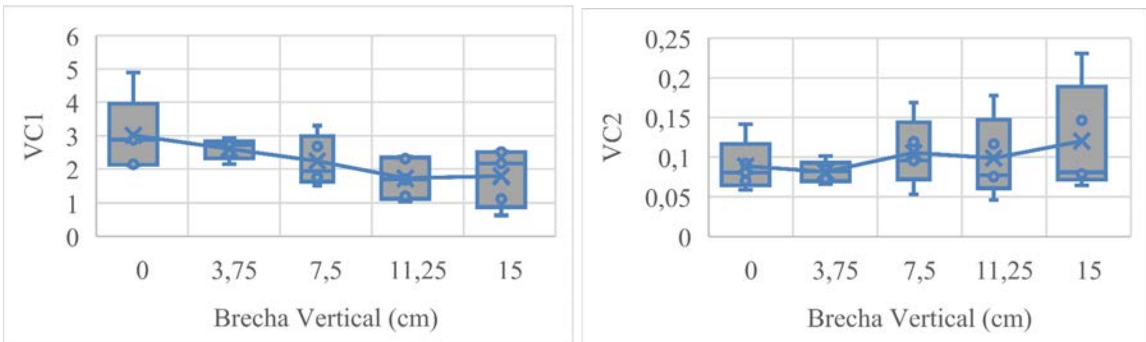
En el Caso 4 (carga asimétrica) la Fig. 8 muestra tendencias similares al Caso 3. La VC2 marca un aumento similar al Caso 3, lo que implica que la estabilidad plano medio lateral se vio afectada de manera negativa al aumentar las BR. Sorprende que la variación fue menor a las del Caso 1 y al Caso 3. Sin embargo, un nuevo fenómeno se observó (y también en el Caso 3) durante la inspección visual de los gráficos de pisada. Este fenómeno se mostró en desplazamientos del COP erráticos y anormales en un 3,5% de archivos correspondientes a BR = 15 cm. También este fenómeno se observó para BR = 11,25 cm. Los participantes presentaron desplazamiento como se observa en la Fig. 9 donde se aprecia que, en vez de hacer un desplazamiento lineal, se genera un desplazamiento en forma de "V". La inestabilidad generada fue tan alta que la amortiguación se hizo primero con los dedos del pie. Este fenómeno se considera común en un proceso de salto, pero no de pisada. Luego, el peso pasó a los talones para después continuar con un proceso "normal" de pisada.



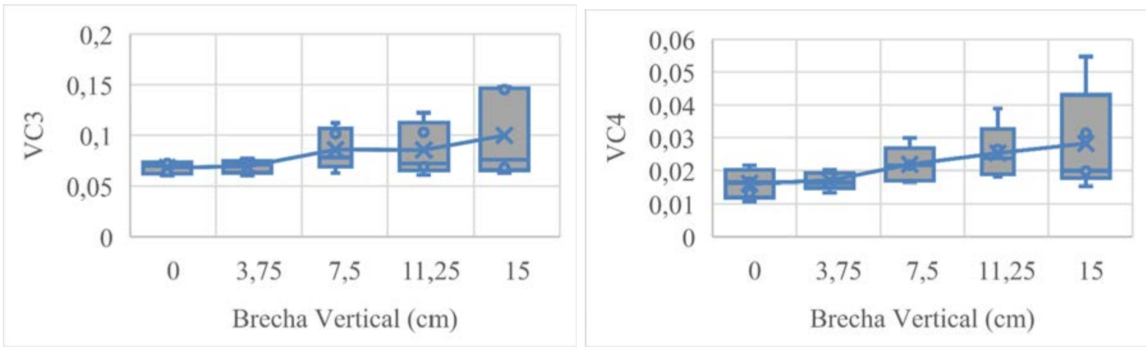


Fig. 8 – VC para cada BR en el Caso 4 (carga asimétrica)

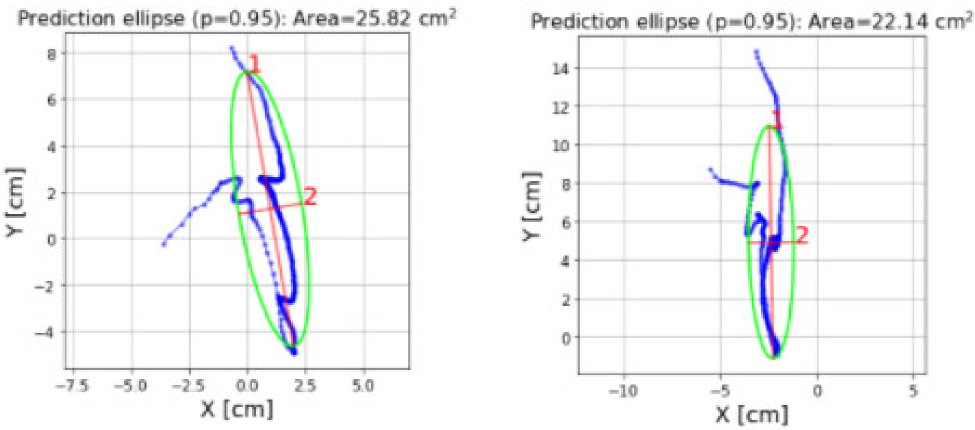

Fig. 9 – Desplazamiento del COP en forma de "V": Caso 4 (izquierda) y Caso 3 (derecha)

5. CONCLUSIONES

Este artículo se centró en estudiar las variables que afectan la estabilidad de PMR al enfrentar distintas BR, para luego construir un piloto experimental que pudiera determinar una forma eficaz de medir las variables asociadas a la pisada en el proceso de bajada desde un tren urbano a un andén. La metodología expuesta se basó en el diseño del piloto a escala real que permitió simular y medir este proceso de pisada. Una vez obtenidos los datos necesarios para poder ver el movimiento COP y el área de la elipse de 95% de confianza, se obtuvieron los valores suficientes para llegar a las 4 variables comparadas (VC), y así observar como varían en 4 casos diferentes para 5 escenarios de BR (realizando 3 repeticiones de pisada).

Los 4 casos distintos de estudio, permitieron dar una muestra de datos para estudiar el impacto de BR en la inestabilidad de PMR. El Caso 1 (base), entregó más información, dado que los resultados fueron los puntos de comparación para el resto de los casos. De los resultados se puede desprender que el área de la elipse no es la mejor manera de medir inestabilidad, puesto que los participantes del experimento tomaron cambios de estrategia para distintas BR, lo cual generó un cambio en el ángulo de inclinación del plano antero posterior de su pisada.

En el Caso 2 la suela curva de la bota ortopédica no permitió que se pudiera medir correctamente el desplazamiento del COP. Esto hace sentido ya que una suela curva genera que la persona tenga menos posibilidad de caer o resbalarse y así contrarrestar el efecto negativo de esta bota en su movilidad

Los Casos 3 y 4, dieron un fenómeno nuevo. Entregaron datos de inestabilidad mayores al Caso 1, y además mostraron desplazamientos erráticos para BR = 11,25 y BR = 15 cm. Esto demuestra que BR mayores a 15 cm no son aptos para PMR.

Una de las áreas que este estudio no pudo profundizar y puede ser fuente de inspiración para investigaciones en el futuro es hacer mediciones de COP y COM simultaneas en los participantes. De esta manera se puede lograr la obtención del ángulo de inclinación en el plano antero posterior y medio lateral, logrando tener datos empíricos de sus valores durante un proceso de pisada. Para esto debería usarse un sistema más complejo de medición, lo que añadiría una cantidad de tiempo necesaria para llevar a cabo el experimento. Sin embargo, se recomienda este camino ya que este artículo es más bien exploratorio y parte desde las bases, por lo que un estudio que expanda la experimentación realizada sería un excelente complemento para esta línea de estudio.

Por otra parte, la mayor limitación que se tuvo en este estudio, y es además la razón principal de porque los datos no mostraron tendencias claras en algunos casos como se esperaba. El número reducido de participantes que se pudo congregar para ser parte del experimento en el LDH fue un punto complejo de solucionar. Esto debido al marco de la pandemia del COVID19 que está atravesando el país y el mundo en este momento.

Se concluye que los resultados entregados para determinar el cambio de estabilidad en PMR en distintas BR, dan evidencia que a mayor BR se genera de manera directa y indirecta una mayor inestabilidad. Si bien no se logró dar con un diseño final o entregar valores absolutos de BR, los resultados permiten comparar escenarios y casos, los cuales dejan entre ver que nos es posible tener rangos de BR mayores a 15 cm en personas sanas (Caso 1) y rangos de BR mayores a 11,25 cm en PMR, puesto que causaría una alta inestabilidad en el proceso de pisada al bajar desde un tren urbano al andén.

AGRADECIMIENTOS

Los autores quisieran agradecer a quienes participaron de los experimentos en el Laboratorio de Dinámica Humana de la Universidad de los Andes. Este estudio tiene el apoyo de ANID (Chile) FONDECYT Proyecto 11200012.

METHODOLOGY FOR THE DEVELOPMENT OF RAILWAY OPERATING PLANS

Sergio Quintero González
Fundación de los Ferrocarriles Españoles – FFE- Spain
Sergio Martín Cabo
Fundación de los Ferrocarriles Españoles – FFE – Spain

ABSTRACT

The main objective of this paper is to determine the methodology to be followed for the optimization of railway transport services supply in a railway line selected as scope of the study.

To carry out this optimization, it is vitally important to have a high-quality database, which includes consolidated technical information. This database will be made up of different items, which will refer to aspects related to the infrastructure (equipment, alignments, slopes, speeds, etc.) and to its traffic type (passengers, freights or mixed).

Furthermore, a geographic database must be considered, in order to the railway line will be digitized from a satellite image, and on which all the items included in the database that are relevant for the development of the operating plan will be spatially captured.

Once the data is collected, gear simulations are carried out with commercial times and the calculation of energy consumption for each rolling stock. This allows us to know the commercial times that would be registered on the line with different trains and consumption, in order to determine the optimal material that would be of interest for commercial exploitation.

Through the elaboration of traffic meshes, the economic balance of the operator is calculated for different service offers, until the one that the operator considers optimal is obtained. Likewise, it provides production results and operating costs.

This methodology focuses on the maximization of the railway transport capacity to attract potential passengers from other modes that could be more environmentally aggressive. For this reason, the reduction of the energy consumption by taking advantage of braking energy is a key issue.

The main objective of carrying out a railway operating plan is to promote the use of rail transport by improving the service, both quantitatively and in terms of quality, by reducing travel and waiting times, increasing supply and reducing operating costs.

Therefore, to carry out said optimization of existing or newly created passenger services, an analysis of the current situation of both services and infrastructure must be carried out, an estimate of the demand that would involve the incorporation or elimination services, and finally an economic analysis.

1. ANALYSIS OF CURRENT AND FUTURE SITUATIONS

To perform a good optimization of services, it is vitally important to have a quality database, which includes revised and consolidated technical information. To do this, an analysis of the infrastructure to be exploited and the railway material available or the new material that will be available in the service must be carried out.

This base will be made up of numerous indicators, which will refer to aspects related to infrastructure (equipment, alignments, slopes, speeds, etc.) and to the traffic that develops on it (travelers, goods or mixed).

There must also be the existence of a reference cartographic base, where the layout will be digitized from a satellite image, and on which all the aspects contained in the database that are relevant for the elaboration of the data will be spatially captured.

This allows to create relevant tools so that the operator can optimize and manage the strategy for the operation of the line

2. TRAVEL TIME CALCULATION

Once the type of material destined for railway operations has been analyzed and defined, the commercial times are calculated.

To do this, minimum speed simulations have to be carried out, obtaining the minimum times and energy consumption that each service would have. Once these minimum times have been obtained, the commercial progress must be calculated taking into account the commercial and recovery margin defined in the UIC 541-1.

To obtain these times and consumptions, the simulation model will be based on an integration model. These types of models are basically based on three different approaches to estimate train movement: (i) a function of time, (ii) a function of distance, and (iii) an event-based model.

The best method used is based on the second option (function of distance) for estimating motion as well as energy. For this, it can be stated that energy consumption is the applied force necessary to move the vehicle a certain length:

$$E = \int F(s) \cdot ds \quad (1)$$

From the above formula it can be highlighted that:

- In each process of acceleration of the train there is a consumption of energy, because the positive acceleration implies a tractive force.
- In each deceleration process a certain amount of energy is generated in the brake, because negative acceleration implies a retarding force, which depending on its type can be dissipated in the form of heat or transformed into electrical energy and returned to network.

The way that is chosen to model the movement of a train is to calculate all the forces that act on the vehicle point to point. In this case, it corresponds to each meter, that is, in each meter of a defined line (Origin-Destination) the forces to which it is subjected are determined and / or the forces exerted on it are estimated.

The forces acting on the motion of a vehicle are:

a) Drag (R*av*).

$$R_{av} = A + B \times V + C \times V^2 \quad (2)$$

Where: *V* is the trains speed (km/h). A, B and C are the mechanical, air intake and aerodynamic coefficients that depend on the physical characteristics of the train *(daN, daN/(km/h) and daN/(km/h)^2).*

b) Resistance due to the curve (R*c*).

$$R_c = M_{car} \times \frac{600}{R} \rightarrow R_c = M_{car} \times \frac{800}{R} \quad (3)$$

Where: M_{car} is the mass of the loaded trains *(tons)* and R is the curves radius measured in metres *(m).*

c) Resistance due to slopes (R*p*).

$$R_p = M \times g \times i \quad (4)$$

Where: M mass of the train *(tons)*, g is gravity *(m/s^2)*, i is the slope *(mm/m)*

d) Traction or brake force (F*t*/F*d*).

The traction curve and the brake curve are in function of the speed (effort-speed curve) and depend on the train power and the adherence. Both curves are parameters provided by the manufacturer.

Next, it is showed an actual example of the effort-speed curve.

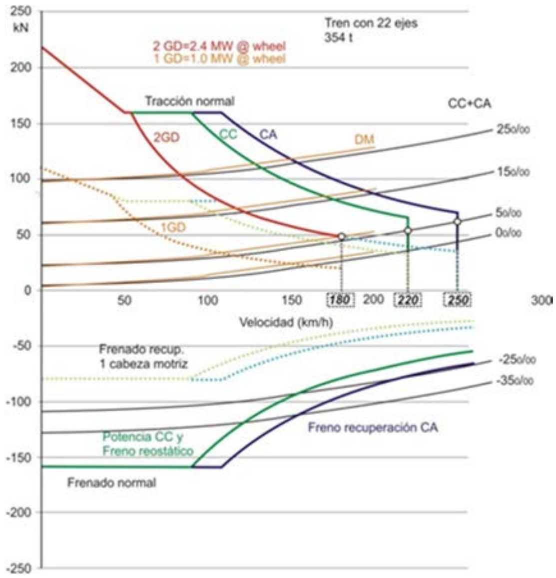

Figure 1. Example of the effort-speed curve

Knowing the forces exerted by the vehicle, both traction and braking, the energy consumption and the energy dissipated in the brake, essentially, are estimated with the following equations:

$$E_c = \int F_t(s) \cdot ds \;\; o \;\; E_R = \int F_d(s) \cdot ds \qquad (5)$$

Where: Ec is the energy consumed by the train (kWh), Er is the energy dissipated in the brake (kWh), Ft Tractive force (daN), Fd is the force exerted by the brake (daN), and ds is the differential of length.
The resultant of all the forces exerted and / or applied on the vehicle is the force used to estimate the acceleration (or deceleration)

$$F_{tot} = R_{av} + R_c + R_p + F_t + F_t = M_{tot} * \frac{dv}{dt} \qquad (6)$$

The M_{tot} parameter corresponds to the total mass of the vehicle considering the rotating masses.

Knowing the total force at a point, the acceleration, the speed, and the travel time are calculated using the equations of uniformly accelerated rectilinear motion.

This allows us to know the commercial times that would be recorded on the line with different trains and their consumption, in order to determine the optimal material that would be of interest for commercial exploitation.

3. DEMAND

Once the new travel times and the services to be implemented are known, it is essential to have a demand study for the different means of transport that currently serve this corridor, and to know the induced demand that will be captured from them. thanks to the improvements and possible changes proposed.

In order to carry out this demand study and find out the number of travelers they will have on the new services implemented, the current demand for the different media, their travel times and their frequencies is first analyzed.

In passenger transport there is a differential factor of the utmost importance, since, to move from one place to another, the traveler must not only pay the price of the ticket, but must also "contribute" their own time. People perceive that their time has value, and they implicitly "monetize" it or convert it into the equivalent of money. This total cost is what is called generalized cost, and it is what allows us to determine which means of transport each traveler will use.

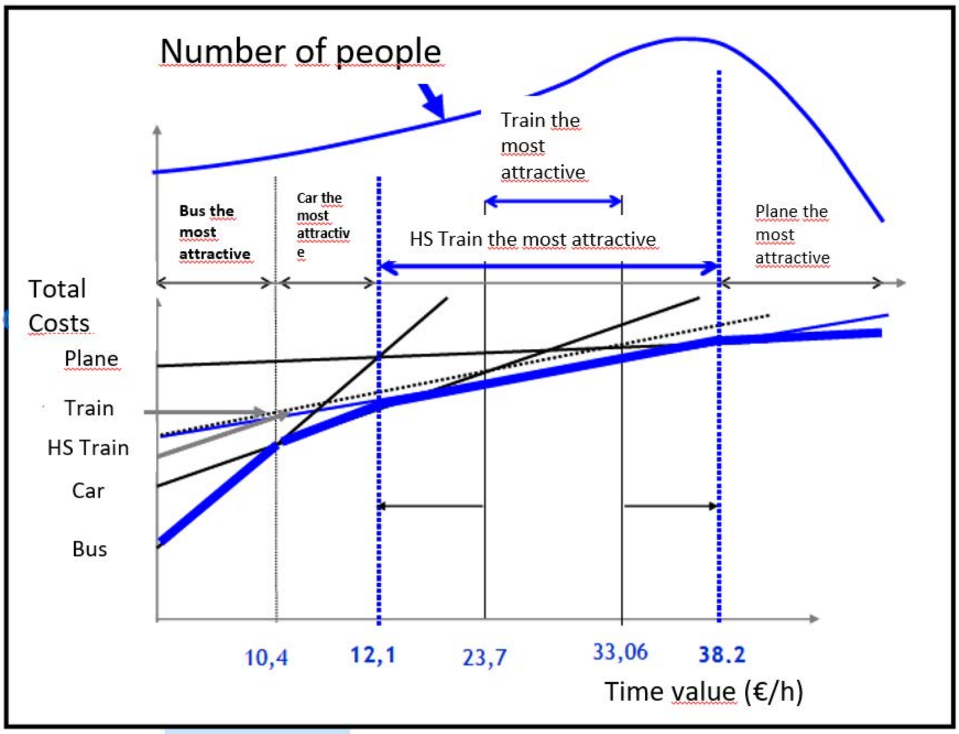

Figure 2. Generalized cost in various modes of transport as a function of the value of time. Effect on the competitiveness of the train of an increase in its speed.

To verify the demand data obtained, a study of generalized costs has been carried out, which is detailed below.

The parameters to take into account for the calculation of said generalized cost are:

a) Frequency
b) Time

To make the trip, in addition to the travel times of each means of transport, the waiting times, information and ticket purchase, travel and terminal times are taken into account.

$$Tt = Tb + Tdt + Te + Tv \quad (7)$$

Where:

Ticket time (Tb): It is the time used to get informed, get the tickets ...).
Travel time and terminal (Tdt): It is the time used to arrive and leave the terminal and to travel through it. The centrality of the stations and their limited dimensions will be taken into account.
Waiting time (Te): It is the time taken to wait for a transport offer. On average, the wait time is the inverse of the frequency.
Travel time (TV): The bus and car travel times will include the possibility of traffic jams, considering an average of 5 minutes throughout the journey.

c) Perceived Time

In each of the phases of the trip, time has a different value for each person, which coincides with personal experience. For example, the time is longer when the user has a bad time or is uncomfortable.

In this way, a modulation coefficient of perceived time is applied to the times, which introduce comfort, ergonomics, the perception of safety, etc. into the model.
The formula for the total perceived time would then be:

$$Tptot = \beta \times Tb + \delta \times Tdt + \Phi \times Te + \upsilon \times Tv \quad (8)$$

These coefficients depend on physical, utility or psychological factors:

- Physical factors: If the user is uncomfortable, without air conditioning, with noise.
- Useful factors: If you can take advantage of the time during the trip.
- Psychological factors: fear, uncertainty, insecurity.

The coefficients will have a value greater or less than 1 to homogenize the duration of time.

The higher these coefficients, the time "gets longer"

The cost of the time spent on the trip is calculated by multiplying the total time by the Value of time, VT (€ / hour).

$$Ct(€) = Tptot \times VT \qquad (9)$$

The total cost of the trip is the sum of the monetary costs and the cost of the time used, so the total general cost will be:

$$Ci = (Cmd + Cmo) + Ct \qquad (10)$$

Cmd: Direct monetary cost (€).
Cmo: Cost related to the station. They are considered transports from the origin and to the destination.
Ci: Generalized cost

Next, the modal split is calculated according to each mode of transport and its generalized cost:

$$Pi = e\ (-\gamma * Ci)\ \in e\ (-\gamma * Ci) \qquad (11)$$

Pi: Probability of choosing the medium "i"
Ci: Generalized cost of the trip in the medium "i"
n: Number of means of transport
γ: Model calibration parameter

Once the number of travelers per year is known, it is necessary to make a daily distribution, taking into account the usual oscillations such as weekends, times of greater load, oscillations between roundtrip directions, etc., in order to be able to size the fleet for the biggest daily commuter tip.

4. ESTABLISHMENT OF SERVICES

When preparing the best services according to the expected demand, it is necessary to define the analysis scenarios, calendars, service periods and patterns-types of schedules.

- Calendars: the "service calendars" of seasons of the year (for example, vacation, non-vacation) will be defined, indicating the number of weeks per year for each; as well as the peak, valley and flat periods defined for each season for standard days:

a) Monday to Friday; b) Saturdays, and c) Sundays and holidays. In the case of tips, it will indicate which is the dominant traffic direction at the tip.

- Hourly periods: Four time periods can be defined according to the classification of the hours: a) peak (with distinction of the two senses); b) flat; c) valley; and d) super-reduced.
- <u>Service patterns</u>: Various patterns (origins-destinations of trains and stops) to be associated with each of the time periods will be defined by technical assistance. These patterns will be defined for one hour and one direction, considering in principle that the schedules are cadenced and symmetrical. The most suitable minute of symmetry will be analyzed to optimize the rotations in all the headers.
- <u>Types of services:</u>
    - Stops service: This type of service is characterized, as its name indicates, by making stops at all stations on the line.
    - Semi-direct Service: It is characterized by making stops only at certain stations on the line. These stations have been determined based on the demand of each one of them, in order to support the dependencies that have the greatest demand.
    - Direct service: Direct services are those that are performed only between the main stations

In addition to the type of services mentioned above, it is also necessary to analyze whether it is convenient to establish optional stops

These stops are characterized by making it only in those dependencies in which passengers are going to get on or off.

With this type of service, which was in force at Renfe in the 1980s, it is intended to guarantee the reliability of the line's services by eliminating the stoppage of the train in those dependencies in which, in that specific service, there were no passengers who were to get on or off the train. In this case, the drivers, through the controller, will know those optional stops in which it is necessary to stop the train to allow passengers to get off. As for the ascent, it will be the driver, as the stations pass, who will make the stop depending on the presence of travelers on the platform.

- Thanks to this type of service you get:
- - The survival of those stops whose number of passengers is small or even null, which have the possibility of disappearing.
- - Reduction of travel times that can translate into margins for economical driving.
- - Fuel savings that may be due both to economical driving, as well as to the reduction of braking and acceleration due to the reduction in the number of stops, in case of switching from a service with stops to a service with optional stops.

- - Reduction of CO_2 emissions, which is given by the reduction of energy consumption.
- - Savings in maintenance of both the rolling stock and the track, due to less wear and tear due to reduced braking and acceleration.

It should be noted that each time a service is modified, the demand analysis must be carried out again, since each small change can cause an increase or decrease in the number of travelers on the operation.

5. SCHEDULE COORDINATION

Schedule design is a method by which energy consumption can be reduced at no additional cost. This makes this measure one of the best methods to reduce energy consumption.

It should be clarified that, in order to achieve these energy savings, in addition to applying the compatibility of schedules, the use of the regenerative brake is a crucial condition for any energy reduction in terms of schedules.

There are three aspects to be taken into account to reduce energy consumption. The first of them is related to (i) time frames and their compatibility with eco-driving previously explained; while the second and third are related to the (ii) coincidence between the departures, or between (iii) the departures and arrivals of the trains at a station respectively.

These aspects are described below.

- Time frames used to perform eco-driving:

Carrying out efficient and economical driving consists of exploiting advantages offered by the existing time frames in the schedules, in order to reduce energy consumption.

On the other hand, train schedules need "regularity margins" to be more robust and reliable.

That margin is often longer than the time required to perform eco-driving, therefore, it is possible to allow a small amount of time to do an eco-driving in the sections where there are no time requirements, and distribute the rest of the time between the points of the sections that require punctuality. Another possibility is to reduce the times in the stops in order to add these times to the margins necessary to carry out economical conductions.

- Avoid simultaneous departures:

The different tracks of the same station are normally fed by the same substation, even in some cases several stations are fed by the same substation. Therefore, if there is a simultaneous output of different trains, there is an increase in the peak power required in the substation, as shown in the following figure.

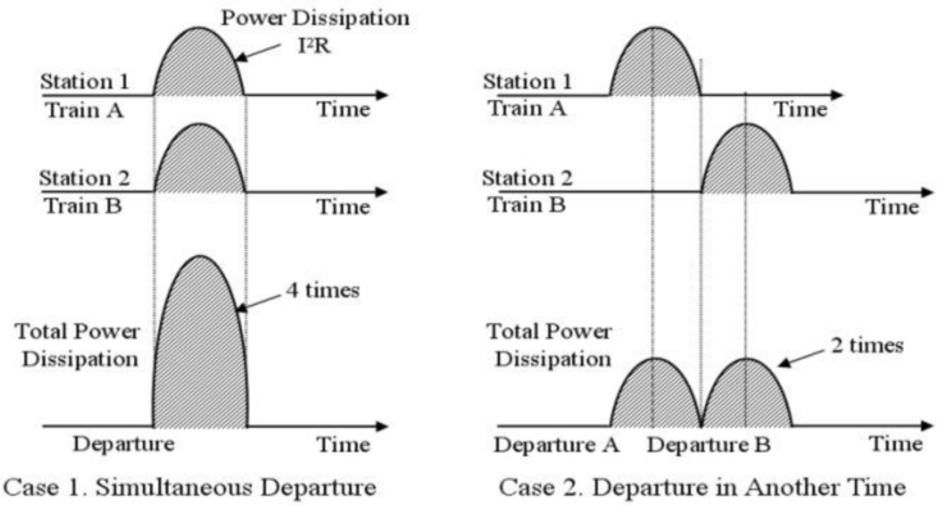

Figure 3. Power peaks due to train departures. Source: K.M. Kim et al. (2010).

This also implies an increase in ohmic losses, and therefore an increase in the energy required. In addition, the installation of a higher capacity substation is required, which translates into an increase in investment costs.

- Simultaneous arrivals and departures at the same station:

On a line with frequent stops and trains with regenerative braking, if trains depart and arrive at the same time at the same station, greater energy savings would be achieved, since the energy regenerated by the brake of the incoming train at the station can be used by the trains leaving said station in their acceleration process, as shown in the following figure.

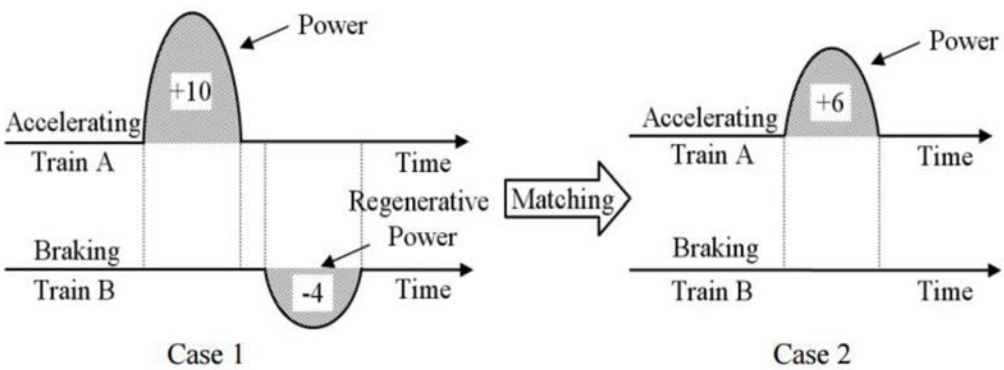

Figure 4. Power peaks in substations due to departures and arrivals. Source: K.M. Kim et al. (2010).

Timetable compatibility can help reduce energy consumption and costs, both energy and facilities, with similar travel time and almost no investment.

6. MESH CREATION

Once the services have been created and the demand known, multiple different supply scenarios configured with different type patterns (calendars, time periods, service patterns, schedules, symmetry minutes) will be carried out in order to obtain a range of possible solutions to achieve an optimal exploitation plan.

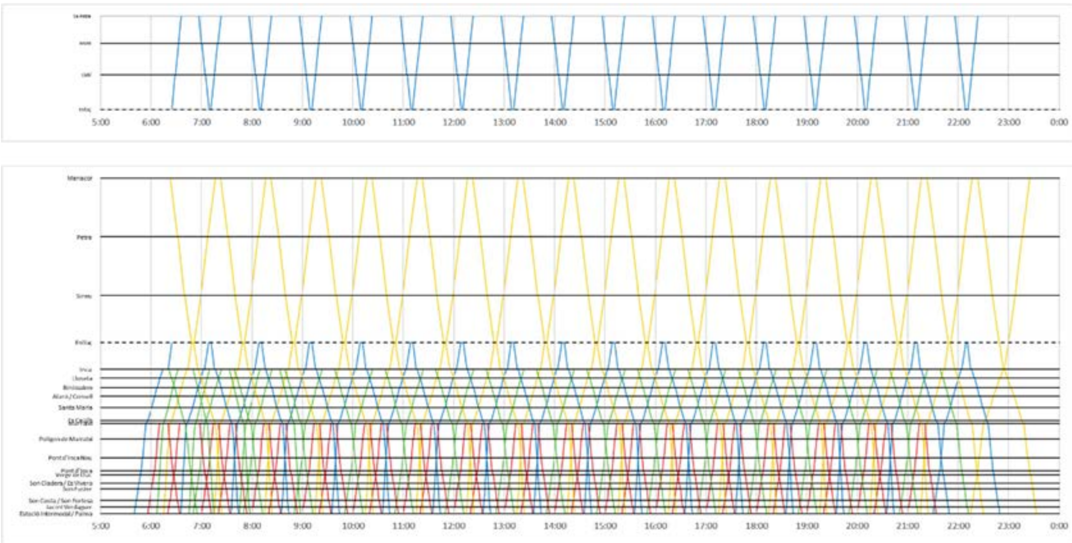

Figure 5. Daily mesh of an exploitation plan

Finally, with the N different scenarios, having a range of solutions (different meshes), a comparison will be made between them, in such a way that the advantages obtained with each one are revealed, keeping the mesh whose offer in squares meets with the planned mobility.

Through the elaboration of circulation meshes, the economic balance of the operator is calculated for different service offers until the one that the operator considers optimal is obtained. Similarly, it provides production results and operating costs.
In addition, apart from seeking a maximization of transport capacity to attract travelers in other more aggressive ways with the natural environment, other objectives are prioritized such as reducing energy consumption by taking advantage of braking energy.

The (annual) results to be obtained for each scenario are as follows:

- Production data: trains, trains.km, cars kilometer, seats, seats.km. Minutes of driver driving and minutes of accompanying personnel.
- Matrix of seats offered for each relationship

7. ECONOMIC ANALYSIS

Each calculated scenario assumes costs and monetary income that will be influenced by the following parameters:

- Energy cost: It is the cost of the energy that would be needed to carry out all the services. For this, the characteristics of the train and the reference prices for the cost of energy are taken into account.
- Maintenance: It will be taken into account whether it has its own workshop or not, and the cost of fixed and variable maintenance of the trains, the latter influenced by the number of kilometers carried out annually.
- Personnel costs: It is a cost closely related to the increase or decrease in services, since if there is a facility with many frequencies, it will be necessary to incorporate more personnel on the staff.
- Other costs: These are those related to financial expenses, possible contingencies and compensation, cleaning costs and all those costs related to the operation.
- Fare income: are those obtained from the sale of tickets either at the box office, agencies or on the internet portal.
- Special income: These are those related to advertising on the internet portal, on tickets and on the trains themselves.

With these parameters obtained and knowledge of all the previously known variables, the final income statement will be made, obtaining a balance between Expenses and Income for each of them.

COSTS		
Fixed costs	**Total**	**%**
Train Maintenance	240.197,13 €	50%
Energy	94.089,60 €	20%
Rolling Stock Amortization	4.429.571,99 €	919%
Financial expenses	2.214.786,01 €	460%
Variable costs	**Total**	**%**
Variable Maintenance Trains	481.889,70 €	100%
Energy	1.720.579,07 €	357%
Personnel cost	732.390,53 €	152%
Selling Costs	385.240,89 €	80%
Other Costs	308.962,35 €	64%
TOTAL COSTS	**10.607.707,27 €**	

INCOME		
Income	**Total**	**%**
Fare income	12.646.444,50	97%
Special income	194.918,35	3%
TOTAL REVENUE	**12.841.362,85 €**	

Earnings Before Interest and Taxes (EBIT)	**2.233.655,58 €**

Figure 6. Example of an income statement

Therefore, the optimal scenario to implement will be the one in which the Benefit for the operator is the highest possible, that is, the one in which the income is greater than the expenses.

Profesor de Ferrocarriles , Universitat Politècnica de València

RESUMEN

El proceso de liberalización del transporte ferroviario de viajeros impulsado por la Unión Europea y su consiguiente incorporación al ordenamiento español ha permitido que desde el 14 de diciembre de 2020 se materialice la incorporación de nuevas empresas ferroviarias a la operación de servicios de alta velocidad y larga distancia. Aunque a fecha de hoy en España solo está operando la empresa RIELSFERA, cuyo accionista al 100% es el operador SNCF, en el corredor Madrid-Barcelona existe otra, ILSA (INTERMODALIDAD DEL LEVANTE, S.A.), que es un consorcio formado por los accionistas de la aerolínea española Air Nostrum (franquicia de Iberia) y la compañía ferroviaria Trenitalia, que tiene previsto operar a corto plazo en el corredor Madrid-Levante.

Esta liberalización supone, naturalmente, un aumento de circulaciones en los tramos citados, siendo de esperar que este aumento se extienda también a los tramos que en un futuro se abran a la competencia. En principio, el total de nuevos servicios añadidos a los que ya realizaba RENFE OPERADORA, al menos a corto y medio plazo, no parece suponer un problema para la operación, ya que la capacidad de las líneas está diseñada para soportar un mayor número de composiciones. Sin embargo, el problema se plantea en el resto de las infraestructuras, como son las estaciones de viajeros, tanto a nivel de circulaciones como de viajeros, pues éstas están diseñadas con un número de vías y con unas longitudes de andenes no tan generosas. Por ello, la nueva situación está obligando al administrador de infraestructuras a realizar una serie de modificaciones e incluso nuevas instalaciones que puedan facilitar el movimiento de los viajeros que se incorporan a los nuevos servicios, así como a la operatoria del mayor número de trenes involucrados, sobre todo en lo que concierne a su operación en estacionamientos.

Pues bien, en el nuevo escenario de la liberalización, el paquete de capacidad marco propuesto a los candidatos ofrece la posibilidad de competir con la variable “frecuencias” para atraer a clientes a este proceso, pero, en nuestra opinión, adolece de importantes incertidumbres a sumar a las propias del incremento del tráfico ferroviario.

A las dificultades indicadas hay que añadir que, para desarrollar una tarea tan compleja, las empresas deben demostrar la solvencia técnica y económica suficiente, realizando las correspondientes demostraciones de capacidad para desarrollar un proyecto empresarial de esta magnitud, sobre todo cuando los grupos candidatos, además, pueden ser de nueva creación.

Por supuesto, también cobra especial importancia estudiar en profundidad el nivel de los cánones a aplicar a las nuevas empresas que entren en el mercado español en función de la cuota de mercado abarcado pues, de alguna manera se tiene que abordar el sostenimiento económico de los servicios comerciales por líneas convencionales que en la actualidad son sostenidos por los ingresos procedentes de la explotación comercial del que ha sido, hasta ahora, el operador único de las líneas de Alta Velocidad.

1. ESTUDIO DEL NUEVO ESCENARIO

Ante la liberalización efectiva de los servicios comerciales, de acuerdo con las directrices de la Unión Europea y la Comisión Nacional de los Mercados y la Competencia, el administrador de infraestructuras español debe asegurar una gestión eficiente del tráfico ferroviario y garantizar un acceso no discriminatorio a las mismas.

Esta obligación se extiende no sólo a las vías, sino también a todos los espacios en las estaciones dedicados a las actividades de los operadores de transporte.

Para ello, ADIF Alta Velocidad elaboró una oferta de capacidad marco para el corredor Madrid - Levante (Valencia y Alicante), vinculando la capacidad de la línea con el estacionamiento en las estaciones de viajeros. Esta capacidad marco queda agrupada en 3 paquetes con las características siguientes:

Paquete A	1 tren/hora Madrid- Valencia 1 tren/hora Madrid- Alicante
Paquete B	1 tren/2 horas Madrid- Valencia 1 tren/2 horas Madrid- Alicante
Paquete C	4 trenes/día Madrid-Alicante/Valencia

Tabla 1. Capacidad marco. Fuente Adif AV.

Los paquetes son asignados a la empresa ferroviaria u otro candidato que se comprometa a una mayor utilización en un periodo de 10 años.

Centrándonos en el tramo Madrid-Valencia del corredor la variación de capacidad queda ofertada según las siguientes tablas:

Surcos/día (ambos sentidos)	Capacidad líneas	Servicios actuales	Capacidad marco	Incremento
Madrid-Valencia	184	36	52	+ 44%

Tabla 2. Variación en la capacidad actual y ofertada. Fuente Adif AV.

Surcos/día (ambos sentidos)	Servicios actuales	Paquetes propuestos				
		A	B		C	
		Surcos	Surcos	%	Surcos	%
Madrid-Valencia	36	32	16	31%	4	8%

Tabla 3. Configuración de la capacidad marco propuesta. Fuente Adif AV.

2. EXPLOTACIÓN EN LA ACTUAL INFRAESTRUCTURA. VALOR DE LA INFRAESTRUCTURA.

2.1. Algunos conceptos a tener en cuenta

La diferente caracterización y funcionalidad de la red plantea un problema ante la capacidad de absorber el aumento de circulaciones adjudicadas y futuras, que es el *"valor de la infraestructura"*, valor que aumentará cuanto mayor sea la posibilidad de transporte que ofrezca y cuanto más atractivas y menos costosas sean las condiciones de acceso a este transporte.

Para los operadores, el valor potencial generado por la operación está compuesto, básicamente, por el producto de dos factores:

- El valor de cada surco, valor dependiente del número de viajeros que puede transportar un tren que utiliza el surco y del margen económico que esos viajeros pueden aportar al operador del servicio. Cuando estos viajeros estén dispuestos a pagar una cantidad mayor por su billete y cuanto el transporte resulte menos costoso para el operador del servicio, más valor tendrá el surco, y por ello más valor potencial tiene la infraestructura.
- El número de surcos en un periodo de tiempo queda definido como la capacidad de circulación de la línea.

La maximización del valor de la infraestructura puede venir por la combinación más adecuada de los factores anteriores pudiéndose obtener con un menor número de surcos con mayor valor unitario, o con un mayor número de surcos pero de menor valor cada uno.

El aumento del valor de la infraestructura puede venir, tanto del aumento de la capacidad (número de surcos por periodo), como de la capacidad de cada tren, apoyándose en parámetros y condiciones de la infraestructura, o mejorando las condiciones económicas para el operador.

El valor del surco depende del número de plazas por cada tren, del ingreso que potencialmente puede aportar cada viajero y del coste que supone. El número de plazas por tren y los ingresos o costes unitarios deben referirse a los aspectos en que vienen condicionados por la infraestructura, por sus parámetros y por su explotación.

El valor de un surco se inscribe en el ámbito de la operación del servicio, donde existen puntos sobre los que actuar para que cambie el valor del tren, pero la propia infraestructura condiciona el valor del tren. Así, y por lo que se refiere al número de plazas ofertadas por tren, si se aceptan trenes más anchos, más altos o largos por así permitirlo ADIF, con un mismo tren podrán transportarse muchos más viajeros. ADIF, al fijar estas condiciones de admisión de los trenes, aumenta el valor de cada surco permitiendo al operador que aumente la capacidad del tren que lo utiliza.

La potencialidad en términos de valor que ofrece la infraestructura puede ser aprovechada o no por el operador de servicios en función de su estrategia y su diseño operativo (por ejemplo, puede no estar interesado en aumentar la capacidad de cada tren para así ofrecer más frecuencia en una relación origen-destino en la que la demanda sea muy sensible a este factor), pero si el administrador no hace posible el aumento de la capacidad de cada tren (por no permitirlo los parámetros de la línea) se está privando al operador de la posibilidad de explotar este tipo de trenes y, por ello, limitando potencialmente su competitividad frente a otros modos de transporte.

Pero la capacidad no sólo se limita a las composiciones que pueden circular por una línea o tramo. La capacidad está también relacionada con el resto de las infraestructuras como son las estaciones, vías de apartado, centros de mantenimiento, etc. En el caso de los centros de mantenimiento, en la actualidad existen centros de mantenimiento que corresponden a Renfe Operadora, en los cuales se realizan las tareas correspondientes a la puesta a punto de trenes y las reparaciones necesarias para el cumplimiento de la normativa correspondiente, con el fin de realizar el transporte de viajeros de forma segura y confortable. Cabe resaltar también que estos centros de mantenimiento deben estar homologados y su personal debe estar en posesión de la correspondiente habilitación que le permita realizar este tipo de trabajos por lo que las nuevas empresas ferroviarias, en caso de utilizar centros propios para este mantenimiento, deberán estar en condiciones de poseer dichas habilitaciones.

2.2. Aplicación a algunos casos prácticos

Como ilustración de lo comentado anteriormente se trae a colación aquí algunos ejemplos sencillos que pueden servir de referencia para entender el tipo de cambios a los que nos referimos, que se deben analizar e introducir en las infraestructuras ferroviarias existentes.

Se trata de los casos de las estaciones de transporte de viajeros de Valencia Joaquín Sorolla y Madrid Puerta de Atocha. Aquí, de una forma esquemática se presentan dos problemáticas de distinta naturaleza, que ocurren en la actualidad y que merecen la pena su consideración por las ventajas que se derivarían de su tratamiento:

Estación Madrid-Puerta de Atocha

La estación es el origen de las líneas de alta velocidad con destino a Barcelona - frontera francesa, Levante y Andalucía. Las vías de circulación de entrada y salida (2 vías) de la estación desde Andalucía y Levante, a fecha de hoy, son las mismas desde la bifurcación de Torrejón de Velasco, que está situada en el p.k. 28,8, siendo su origen la estación de Madrid-Puerta de Atocha.

La existencia de limitaciones permanentes de velocidad a la salida de la estación tiene mucha influencia en la capacidad de la línea, todo ello sin tener en cuenta las incidencias que puedan producirse, además, como consecuencia de situaciones degradadas.

Otro punto a considerar es la disposición de las vías en la estación. Según el esquema siguiente encontramos una diagonal que "cizalla" las 4 vías de entrada y salida y que da acceso a la base de mantenimiento y vías de apartado de Cerro Negro produciéndose paradas técnicas que repercuten en retrasos, tanto a las circulaciones de entrada como a las de salida. En el gráfico siguiente se observa la disposición de las vías así como el ejemplo del recorrido que realiza una composición desde una vía de estacionamiento (vía 6 A) hasta la aguja de entrada de la citada base.

La distancia existente entre la vía de estacionamiento y las agujas de entrada a la base es de 2,441 kilómetros y la limitación de velocidad máxima existente en el trayecto oscila entre los 30 y 50 km/h. El tiempo invertido que pueden emplear las composiciones, teniendo en cuenta la actuación del diferímetro, es el siguiente:

- Establecimiento del itinerario: 3 minutos.
- Recorrido de la composición: 2 minutos.
- Liberación del itinerario : 3 minutos.

Esto, claramente penaliza la duración del viaje con un tiempo de espera que puede llegar a 8 minutos debido a la citada maniobra, que se debe realizar en espacios de tiempo donde la afección a la circulación sea mínima.

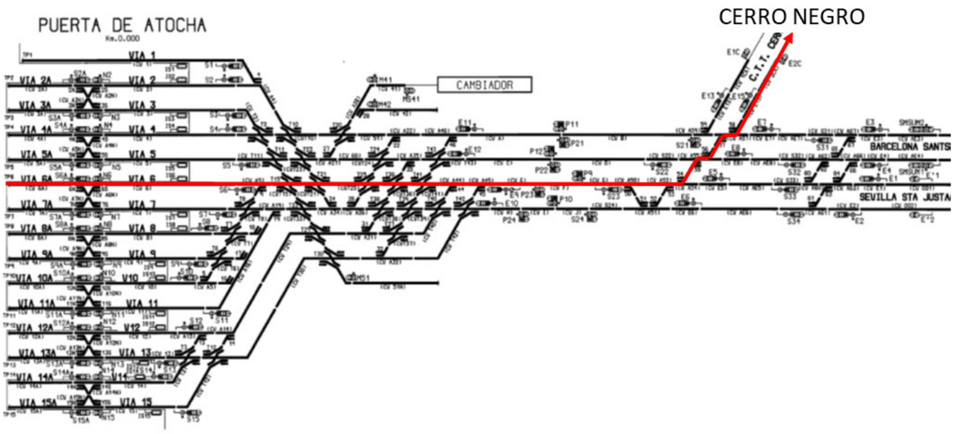

Figura 1. Interferencia en las circulaciones Madrid-Puerta de Atocha. Fuente: ADIF.

Estación Valencia Joaquín Sorolla

En el caso de esta estación (estación provisional, con el "peligro" que tiene la expresión de provisionalidad) se plantea el problema de estacionamiento tanto para circulaciones en doble composición como para el estacionamiento de una circulación en composición simple en vía ocupada. La estación cuenta con 9 vías de estacionamiento, 6 vías de ancho estándar (1.435 mm.) y 3 vías de ancho ibérico (1.668 mm). En la tabla siguiente se muestra la longitud de los andenes de la estación:

Ancho vía	Vía	Longitud andenes
Estándar	1	227 m.
	2	
	3	409 m.
	4	
	5	227 m.
	6	
Ibérico	7	185 m.
	8	374 m.
	9	400 m.

Tabla 4. Longitud de andenes de la estación Joaquín Sorolla. Fuente: ADIF.

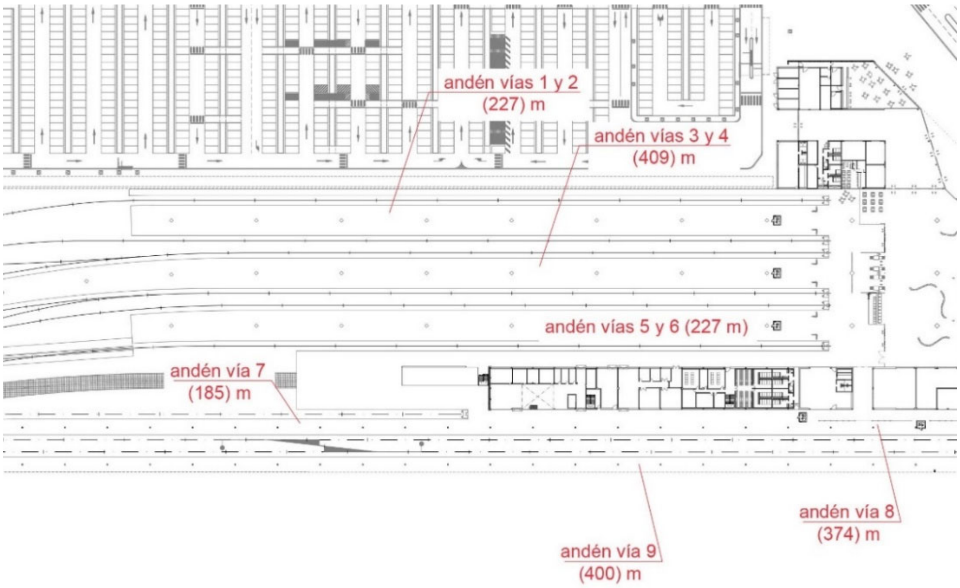

Figura 2. Disposición de vías de estacionamiento en la estación de Joaquín Sorolla. Fuente: ADIF.

Según las dimensiones de los andenes, sólo se pueden estacionar trenes que circulen en doble composición en las vías 3 y 4 y no pudiendo estacionar ningún tren sobre vía ocupada por otro. En la actualidad la estación utiliza las vías de estacionamiento como vías de apartado par material rodante fuera de servicio, lo que reduce la capacidad de las vías.

3. FINANCIACIÓN DE SERVICIOS COMERCIALES EN LÍNEAS CONVENCIONALES.

Otro tema que, aunque sea brevemente conviene que sea tratado, por su relevancia, es el de la financiación de los servicios comerciales operados por Renfe Operadora en las líneas convencionales. En estos momentos el resultado positivo de los servicios prestados por la empresa en Alta Velocidad, después de la liquidación de los correspondientes cánones, compensa los resultados negativos de todos los demás negocios de viajeros y de mercancías.

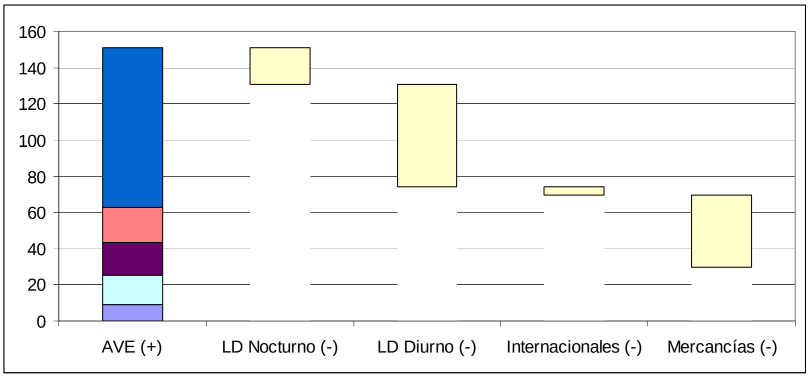

Figura 3. Contribución del AVE a la financiación de servicios comerciales de Renfe. Fuente: García, 2019.

4. CONCLUSIONES

El aumento de circulaciones, sumadas a las efectuadas por el operador actual, no presenta problemas por el aumento de surcos concedidos ya que la capacidad de la línea está calculada para soportar un mayor número de composiciones. El problema se plantea más bien en el resto de las infraestructuras, como son las estaciones de viajeros, diseñadas con un número de vías y con unas longitudes de andenes que obligan al administrador de infraestructuras a realizar una serie de modificaciones en sus instalaciones e incluso la construcción de nuevas que puedan soportar el aumento de viajeros y el aumento de trenes estacionados.

Con la liberalización el paquete de capacidad marco ofrece la posibilidad de competir con la variable “frecuencias” para atraer a clientes, pero este proceso nace con importantes incertidumbres añadidas al del propio negocio por incremento del tráfico ferroviario. Un aumento de frecuencias requiere, además de realizar las correspondientes solicitudes de capacidad técnica y económica, desarrollar un proyecto empresarial por parte de los grupos candidatos, el cual debe ser analizado con especial atención si, además, se trata de grupos de nueva creación.

La posible demanda de viajeros, bien inducida o nueva ante los nuevos operadores, puede ocasionar un descenso de clientes en el actual operador, lo que obligaría a realizar una política económica de búsqueda de captación de clientes, como puede ser lanzamientos de ofertas, bajadas de precios, etc. Frente a este descenso de los ingresos se debe estudiar a fondo la manera de sostener los servicios comerciales en las líneas convencionales y que no están soportadas por Obligaciones de Servicio Público. Se debería estudiar minuciosamente el nivel de los cánones a aplicar a las nuevas empresas que entren en el mercado español, en función de la cuota de mercado abarcado para, manteniendo la competitividad de los mismos, ver si resulta posible colaborar en el sostenimiento de los servicios convencionales, tal como se estaba haciendo hasta la entrada de los competidores.

ANÁLISIS DE LAS ENSEÑANZAS EN VEHÍCULOS Y TRANSPORTES EN LAS TITULACIONES DE INGENIERÍA INDUSTRIAL Y AFINES

Felipe Jiménez Alonso
Catedrático de Universidad, Universidad Politécnica de Madrid, España

RESUMEN

La presencia de asignaturas relacionadas con el Transporte y los Vehículos en las diferentes Escuelas de Ingeniería de España es muy dispar, aunque existen líneas bastante comunes.
El presente estudio, promovido desde el Foro de Ingeniería del Transporte (FIT) pretende mostrar la enseñanza en vehículos terrestres y transportes en general en el ámbito de las titulaciones de Ingeniería Industrial y afines con el fin de establecer un punto de partida que promueva el diálogo entre profesores, determinar puntos comunes y dispares entre Universidades, y así establecer contenidos prioritarios en cada caso, así como promover la creación de nuevos materiales de estudio.

Debe tenerse en cuenta que la Orden CIN/351/2009, de 9 de febrero, por la que se establecen los requisitos para la verificación de los títulos universitarios oficiales que habiliten para el ejercicio de la profesión de Ingeniero Técnico Industrial, no fija ningún conocimiento obligatorio relativo a transportes o vehículos. Sin embargo, la Orden CIN/311/2009, de 9 de febrero, por la que se establecen los requisitos para la profesión de Ingeniero Industrial, establece que es obligatorio que los alumnos alcancen "Conocimientos sobre métodos y técnicas del transporte y manutención industrial".

Según el requisito anterior, no existen directrices de obligado cumplimiento en relación con estas materias en las titulaciones de Grado y sólo se plantean exigencias en el Máster en Ingeniería Industrial.

Por otra parte, en muchos casos, las fronteras entre Ingenierías resultan difusas por lo que el presente estudio puede recoger algunas titulaciones con sesgos más o menos centrados en la Ingeniería Industrial, pero con contribuciones de otras ramas de la ingeniería. En total, se han analizado 52 Universidades, 92 titulaciones de Grado y 88 titulaciones de Máster para mostrar un escenario, dinámico por otra parte, de este tipo de enseñanzas.

1. INTRODUCCIÓN

La presencia de asignaturas relacionadas con el Transporte y los Vehículos en las diferentes Escuelas de Ingeniería de España es muy dispar, aunque existen líneas bastante comunes.
Desde el Foro de Ingeniería del Transporte (FIT) se lanzó la iniciativa de analizar esta situación, tanto en el ámbito de la ingeniería Civil como Industrial. Este artículo comprende estas últimas y se pretende mostrar la enseñanza en vehículos terrestres y transportes en general en el ámbito de las titulaciones de Ingeniería Industrial y afines con el fin de establecer un punto de partida que promueva el diálogo entre profesores, determinar puntos comunes y dispares entre Universidades, y así establecer contenidos prioritarios en cada caso, así como promover la creación de nuevos materiales de estudio.

Las enseñanzas de transportes en Ingeniería Industrial vienen condicionadas, al menos en parte y para las titulaciones de Máster en Ingeniería Industrial, por la Orden CIN/311/2009, de 9 de febrero, por la que se establecen los requisitos para la profesión de Ingeniero Industrial, establece que es obligatorio que los alumnos alcancen "Conocimientos sobre métodos y técnicas del transporte y manutención industrial". Sin embargo, la Orden CIN/351/2009, de 9 de febrero, por la que se establecen los requisitos para la verificación de los títulos universitarios oficiales que habiliten para el ejercicio de la profesión de Ingeniero Técnico Industrial, no fija ningún conocimiento obligatorio relativo a transportes o vehículos. Según los requisitos anteriores, no existen directrices de obligado cumplimiento en relación con estas materias en las titulaciones de Grado y sólo se plantean exigencias en el Máster en Ingeniería Industrial.

Sobre ese marco, se ha procedido al estudio de la presencia de materias sobre vehículos y transporte terrestre en las titulaciones de Grado en Ingeniería de Tecnologías Industriales y Máster en Ingeniería Industrial. Por otra parte, dado que, tradicionalmente, los ámbitos del transporte y los vehículos han estado vinculados a áreas de Ingeniería Mecánica (además de Ingeniería del Transporte), el estudio se ha extendido a las titulaciones de Grado y Máster en Ingeniería Mecánica. Sin embargo, la importancia de otros ámbitos con vinculación a la Ingeniería Industrial, tanto tecnológicos (electrónica, control, eléctrico, etc.) como de gestión, logística o fabricación, hace que otras titulaciones también incluyan materias vinculadas a vehículos o sus componentes y sistemas. Este hecho ha sido tenido en cuenta, aunque asignaturas transversales como, por ejemplo, medios de fabricación, solo se han considerado si se orientan específicamente a vehículos terrestres. De igual forma, aspectos como asignaturas sobre motores de combustión han sido excluidas al haber recaído en áreas de conocimiento específicas. Sin embargo, sí se han incluido tecnologías de vehículos eléctricos y sistemas electrónicos al tener una fuerte vinculación con el ámbito vehicular. Adicionalmente, se han analizado titulaciones específicas de vehículos y transportes.

Por último, debe recalcarse que, en muchos casos, las fronteras entre Ingenierías resultan difusas por lo que el presente estudio puede recoger algunas titulaciones con sesgos más o menos centrados en la Ingeniería Industrial, pero con contribuciones de otras ramas de la ingeniería. Así, en total, se han analizado 52 Universidades, 92 titulaciones de Grado y 88 titulaciones de Máster para mostrar un escenario, dinámico por otra parte, de este tipo de enseñanzas.

2. TITULACIONES GENERALISTAS DE INGENIERÍA INDUSTRIAL

2.1 Grado en Ingeniería en Tecnologías Industriales GITI

Se han analizado 31 titulaciones de GITI, de las cuales solo 11 incluyen en sus planes de estudios alguna asignatura sobre vehículos o transportes (Tabla 1). De hecho, resulta relevante mencionar que, de esas 11, en 6 solo hay una asignatura mientras que en 1 hay 2 y en 4 hay 3 o más, totalizando 22 asignaturas entre las que prima el carácter optativo. Es decir, la presencia es escasa en este tipo de titulaciones con un perfil relativamente generalista, si bien, en aquellas Escuelas donde se han introducido, lo han hecho con una presencial relevante.

OVIEDO	POLITÉCNICA DE MADRID
SEVILLA	

Tabla 1 – Titulaciones de GITI con asignaturas sobre vehículos o transportes

En cuanto al número de créditos, suelen ser asignaturas relativamente largas, con 9 de 6 créditos y 6 de 4,5 créditos, promediando 4,7 créditos por asignatura. En cuanto a las temáticas tratadas, se suelen centrar en aspectos relacionados con los vehículos fundamentalmente, bien automóviles o bien ferrocarril. La Figura 1 muestra estas distribuciones.

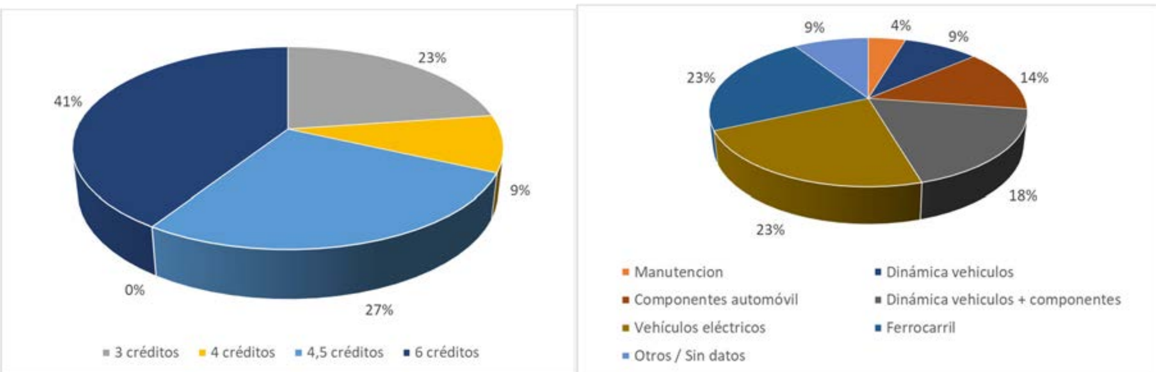

Fig. 1 – Número de créditos y temáticas de las asignaturas en GITI

2.2. Máster en Ingeniería Industrial (MII)

Se han analizado 47 titulaciones, de las cuales, en 44 se incluye alguna asignatura sobre transportes o vehículos (Tabla 2), identificando un total de 71 asignaturas (38 obligatorias, con una denominación bastante extendida de “Ingeniería del Transporte”, y 33 optativas). Esta mayor presencia viene motivada por las prescripciones incluidas en la Orden CIN/311/2009 donde se establecen que deben incluirse nociones de medios de manutención en los estudios de Ingeniería Industrial. Sin embargo, el tratamiento dado en cada titulación es diferente y, si bien en muchos casos se circunscriben a esos conocimientos, en otros casos, se incluye en la asignatura otros aspectos relacionados con el transporte, los automóviles o el ferrocarril, mientras que otras titulaciones incluyen en sus planes de estudios una carga superior, tanto en créditos totales como en número de asignaturas. En la Figura 2 se observa la distribución del número de asignaturas sobre estas temáticas en los planes de estudios, considerando algunos casos particulares en los que no existe una asignatura específica, sino que los conocimientos de transportes están integrados en otras materias. Tales situaciones son, por ejemplo, en la titulación de MII ofertada por la UNIVERSIDAD DE DEUSTO, en cuya asignatura obligatoria “Logística y Manutención Industrial” incluye un bloque sobre Gestión de la Distribución, aunque luego ofertan una Intensificación en Ingeniería de Automoción con 3 asignaturas de créditos sobre temas específicos. De igual modo, en la titulación de la UNIVERSIDAD DE LAS ISLAS BALEARES, se incluyen temas de métodos de transporte y manutención industrial en la asignatura “Calidad Industrial”, y temas sobre Infraestructuras de transporte y comunicación en la asignatura “Construcción y Explotación Industriales”. Lo mismo sucede en la UNIVERSIDAD DE LAS PALMAS DE GRAN CANARIA, donde la asignatura “Diseño, construcción y explotación de plantas industriales” incluye como uno de sus bloques temáticos la ingeniería de transporte. Por último, la UNIVERSIDAD DE VALLADOLID, incluye la asignatura obligatoria “Ingeniería de la construcción y del transporte” con una parte dedicada a construcción y otra a transporte que comprende aspectos de manutención industrial y vehículos.

Tabla 2 – Titulaciones de MII con asignaturas sobre vehículos o transportes

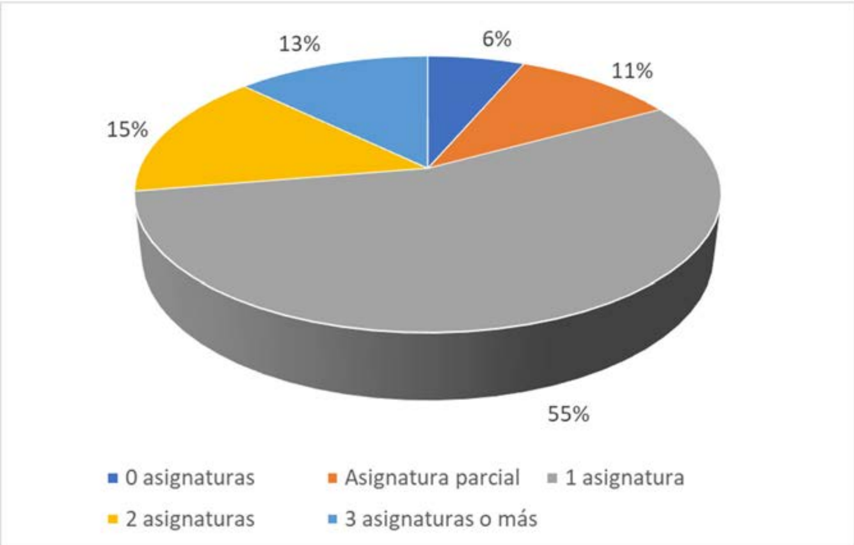

Fig. 2 – Número de asignaturas en las titulaciones de MII

La carga horaria asignada a dichas asignaturas está bastante repartida, más polarizada hacia asignaturas de 3 créditos, aunque también hay un número significativo de asignaturas entre

4,5 y 6 créditos. El promedio por asignatura resulta de 4,1 créditos, inferior al caso de las titulaciones de GITI y GIM. En cuanto al reparto de temas, más de la mitad de las asignaturas incluyen los temas de manutención, bien de forma exclusiva o bien juntamente con aspectos de transporte, vehículos automóviles y/o ferrocarriles. En el caso de las asignaturas obligatorias, el sesgo hacia asignaturas cortas de 3 créditos es mayor, con lo que el promedio de créditos por asignatura cae a 3,5 créditos, mientras que la distribución de temas se focaliza aún más en los contenidos de manutención, bien solos o con otros temas. Las Figuras 3 y 4 muestran estas distribuciones.

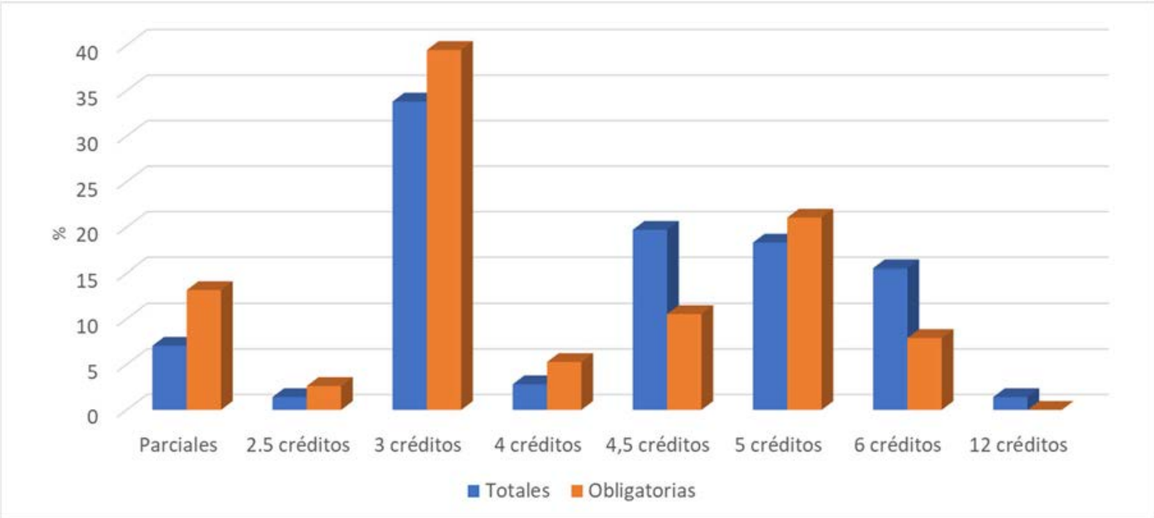

Fig. 3 – Número de créditos de las asignaturas en MII

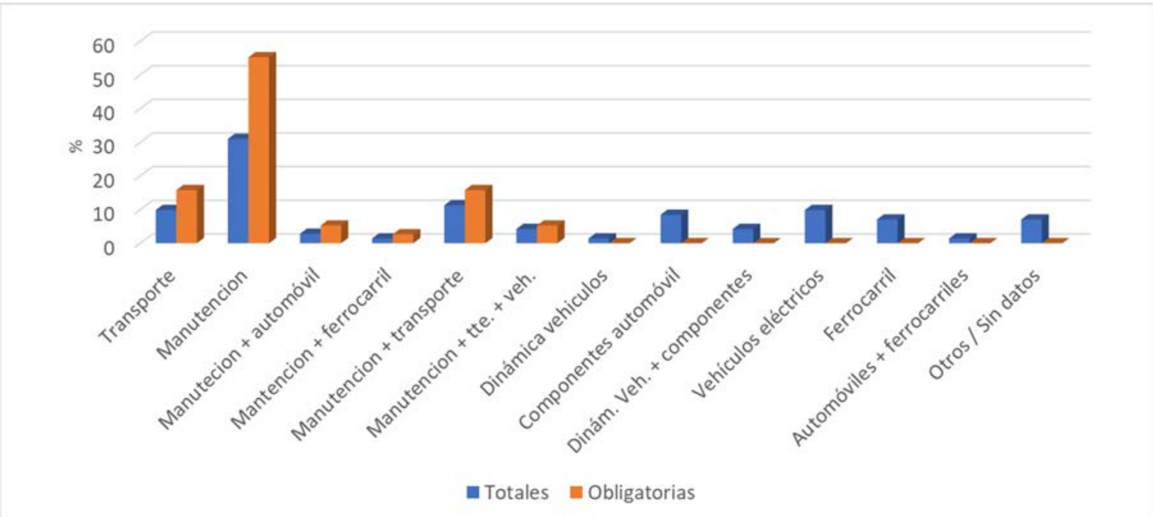

Fig. 4 – Temáticas de las asignaturas en MII

Como se observa en la Figura 4, tanto en las asignaturas totales como en las obligatorias, el tema de medios de manutención es el más incluido en los programas, desapareciendo los programas exclusivamente de vehículos o componentes de los mismos, tanto de automóviles como de ferrocarriles en las asignaturas obligatorias. También se observa que la combinación más usual con los temas de manutención es aquella de aspectos de transporte como temas de modos de transporte, tráfico o demanda de transporte. En cuanto al resto de asignaturas que no incluyen mención a los medios de manutención, los más usuales son los referentes a componentes de los automóviles y ferrocarriles, aunque resulta interesante remarcar la presencia de un número notable de asignaturas sobre vehículos eléctricos y sus componentes, si bien la cifra se encuentra algo sesgada por la oferta de la UNIVERSIDAD POLITÉCNICA DE CARTAGENA de 4 asignaturas sobre esta temática en un Bloque de asignaturas optativas, impartidas por grupos de Ingeniería de Sistemas y Automática, Ingeniería electrónica, e Ingeniería eléctrica.

Si bien no se han indicado las dobles titulaciones ofertadas a partir de la de Máster en Ingeniería Industrial, sí resulta relevante por su orientación hacia los temas que competen a este estudio citas las siguientes impartidas por la UNIVERSIDAD PONTIFICIA DE COMILLAS

- Doble Máster Universitario en Ingeniería Industrial y en Ingeniería para la Movilidad y la Seguridad (epígrafe 5.1.)
- Doble Máster Universitario en Ingeniería Industrial y en Sistemas Ferroviarios (epígrafe 5.3.)

3. TITULACIONES ESPECIALISTAS DE INGENIERÍA MECÁNICA

3.1. Grado en Ingeniería Mecánica (GIM)

En este caso, se han analizado 48 titulaciones, de las cuales, 21 de ellas incluyen asignaturas relacionadas con transportes o vehículos (Tabla 3), totalizando 33 asignaturas, la mayoría de ellas, de carácter optativo y siendo lo más común el incluir una única asignatura en el plan de estudios en 17 de las 21.

OVIEDO	ROVIRA I VIRGILI

Tabla 3 – Titulaciones de GIM con asignaturas sobre vehículos o transportes

A pesar de esta presencia limitada en los planes de estudios, las materias son relativamente importantes en los mismos con una carga promedio de 5,1 créditos por asignatura, predominando aquellas de 5 y 6 créditos. Los contenidos se centran mayoritariamente en aspectos de componentes de vehículos o sobre estos componentes junto a su dinámica. La Figura 5 muestra estas distribuciones.

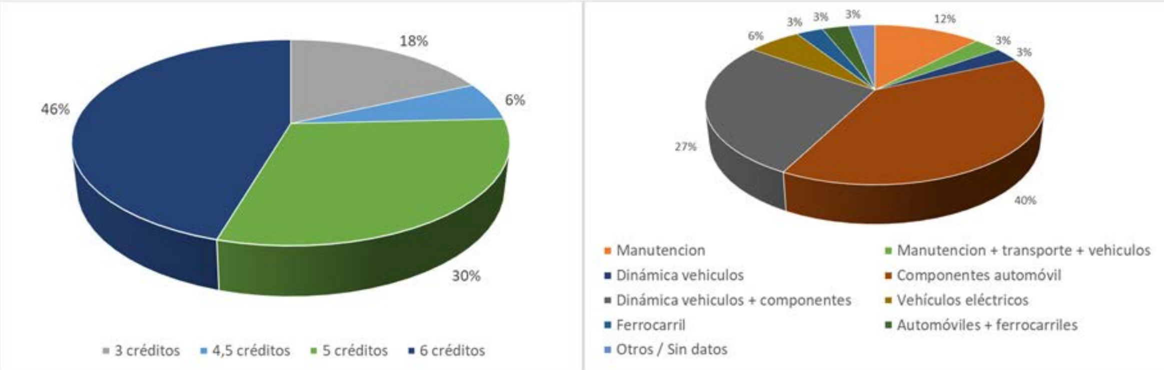

Fig. 5 – Número de créditos y temáticas de las asignaturas en GIM

Resulta un caso especial la titulación de GIM ofertada por la UNIVERSIDAD CATÓLICA SANTA TERESA DE JESÚS DE ÁVILA, donde se incluyen 9 asignaturas sobre vehículos automóviles, todas ellas optativas de 5 créditos: "Evaluación de Daños de Vehículos", "Sistemas Eléctricos del Automóvil", "Procesos y Técnicas de Reparación en Vehículos", "Estructuras Constructivas en Vehículos", "Reconstrucción de Accidentes de Tráfico", "Automóviles", "Proceso de Pintado de Vehículos", "Suspensión y chasis" y "Sistemas de freno", lo que hace crecer notablemente la proporción de asignaturas relativas a componentes del vehículo.

3.2. Máster en Ingeniería Mecánica (MIM)

Dentro de este apartado, se han analizado 7 titulaciones, de las cuales 5 tienen asignaturas relacionadas con transportes o vehículos (Tabla 4), totalizando 14 asignaturas. Se incluye en este grupo, las titulaciones con una denominación más amplia que MIM como son las de Máster en Ingeniería Mecánica, Diseño, Construcción y Fabricación de la Universidad de Oviedo y Máster Universitario en Ingeniería Mecánica Aplicada y Computacional de la Universidad Pública de Navarra.

ZARAGOZA	POLITÉCNICA DE VALENCIA
PAÍS VASCO	PÚBLICA NAVARRA
POLITÉCNICA DE MADRID	

Tabla 4 – Titulaciones de MIM con asignaturas sobre vehículos o transportes

En este caso, las asignaturas son más cortas que en estudios como GITI o GIM, con un promedio de 3,5 créditos por asignatura. En cuanto a las temáticas tratadas, aunque hay una dispersión mayor que en el caso de GITI, se focalizan, al igual que en esos estudios de Grado y en los GIM, en aspectos relacionados con los vehículos y menos con aspectos de transporte en general o aspectos de manutención englobados dentro de las enseñanzas de MIM establecidos por la Orden CIN/311/2009. La Figura 6 muestra estas distribuciones.

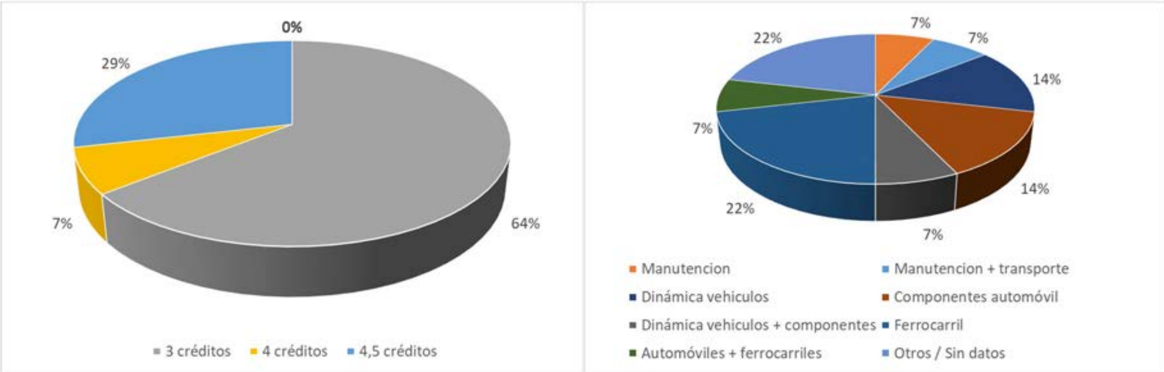

Fig. 6 – Número de créditos y temáticas de las asignaturas en MIM

4. OTRAS TITULACIONES ESPECIALISTAS (NO ORIENTADAS EXCLUSIVAMENTE AL TRANSPORTE)

También se han identificado otras titulaciones que, sin ser específicas de transportes o vehículos exclusivamente, ni ser titulaciones generalistas como las anteriormente citadas de GITI, MII, GIM, y MIM, sí incluyen una carga, cuanto menos, semejante, a la que se encuentra en aquellas. Se dividen en dos bloques en función de la relevancia de los temas que nos ocupan.

4.1. Titulaciones en las que el transporte o los vehículos forman una parte esencial de la misma o de un itinerario

- Máster Universitario en Ingeniería de Máquinas y Transportes, de la UNIVERSIDAD CARLOS III DE MADRID, con las asignaturas obligatorias de “Ingeniería del Transporte” e “Ingeniería de Vehículos”, incluyendo aspectos de transporte en general, automóviles y ferrocarril,
- Máster en Sistemas Inteligentes en Energía y Transporte, de la UNIVERSIDAD DE MÁLAGA y la UNIVERSIDAD DE SEVILLA, con las asignaturas optativas “Sistemas inteligentes de transporte y tecnologías avanzadas de vehículos”, que incluye modelos, simulación, sistemas de control y ensayos, y “Sistemas ferroviarios y tracción eléctrica”
- Máster Universitario en Investigación en Eficiencia Energética y Sostenibilidad en Industria, Transporte, Edificación y Urbanismo, de la UNIVERSIDAD DEL PAÍS VASCO, donde su orientación al transporte se focaliza más en sistemas de propulsión.
- Máster Universitario en Eficiencia Energética en la Edificación, la Industria y el Transporte, de la UNIVERSIDAD POLITÉCNICA DE MADRID, con un módulo dedicado a transporte de 16 créditos, incluyendo las asignaturas “Eficiencia Energética en el Transporte”, “Energía e impacto Medioambiental del Transporte”,

"Movilidad y Transporte", "Vehículos automóviles y ferrocarriles", éstas dos últimas del itinerario específico.

4.2. Otras titulaciones en las que se incluyen asignaturas de transporte o vehículos

- Grado en Ingeniería Eléctrica, de la UNIVERSIDAD DE CANTABRIA, que incluye una asignatura optativa de 6 créditos sobre "Vehículos Eléctricos e Híbridos".
- Grado en Ingeniería Electrónica, Robótica y Mecatrónica, de la UNIVERSIDAD DE MÁLAGA, con la asignatura "Mecanismos y Mecánica de Vehículos" de 6 créditos que incluye aspectos de dinámica y componentes de automóviles
- Grado de Arquitectura Técnica, de la UNIVERSIDAD JAUME I DE CASTELLÓN, con la asignatura "Gestión de recursos humanos y técnicos en la edificación", obligatoria de 6 créditos que incluye temas sobre medios de manipulación de cargas.
- Máster en Ingeniería Mecatrónica, de la UNIVERSIDAD DE MÁLAGA, con la asignatura optativa "Simulación numérica del flujo alrededor de vehículos" de 5 créditos sobre aspectos aerodinámicos de los vehículos.
- Máster en Hidráulica Ambiental, de la UNIVERSIDAD DE MÁLAGA, con la asignatura optativa "Movimiento fluido alrededor de vehículos" de 6 créditos sobre aspectos aerodinámicos de los vehículos.
- Master en Ingeniería Electrónica, Robótica y Automática, de la UNIVERSIDAD DE SEVILLA, con la asignatura " Control en vehículos" de 5 créditos, impartida desde el área de Ingeniería de Sistemas y Automática.

Por último, citar que la titulación Máster en Diseño Avanzado en Ingeniería Mecánica" de la UNIVERSIDAD DE SEVILLA no incluye materias específicas relacionadas con vehículos.

5. TITULACIONES ESPECÍFICAS SOBRE TRANSPORTES O VEHÍCULOS

Debido, entre otros factores, a la gran demanda por parte de las empresas de conocimientos y formación en diferentes aspectos de los transportes y los vehículos en el ámbito industrial, han surgido un número relevante de titulaciones orientadas específicamente a estos aspectos. Estas titulaciones suelen ser de Máster, aunque existen algunas excepciones de titulaciones de Grado. En el estudio no se han incluido menciones a cursos de menor entidad en cuanto a duración como cursos de especialización, salvo en aquellos casos en los que, con la concatenación de varios se pueda alcanzar un título de Grado o Máster. Esta simplificación da una visión parcial del escenario formativo en estas áreas ya que deja de lado toda la oferta más puntual de corta duración. Sin embargo, esta decisión está soportada por el hecho del alto dinamismo de este tipo de formación que cambia de un curso al siguiente y no resulta una oferta estable en el tiempo estando, en muchos casos, motivada por necesidades puntuales en lugares o momentos concretos.

5.1. Titulaciones específicas sobre transportes

Este bloque de titulaciones versa sobre aspectos del transporte que, en muchos casos, están rozando la frontera de la Ingeniería Industrial, aunque se mantiene una carga relevante de aspectos derivados de la misma como la organización, aspectos energéticos y la logística. Se trata de titulaciones Máster con la excepción de una titulación de Grado. Se describen a continuación:

- Grado en Ciencias del Transporte y la Logística, de la UNIVERSIDAD CAMILO JOSÉ CELA, enfocado a aspectos logísticos y de distribución de mercancías.
- Máster Universitario en Movilidad Urbana, Tecnología y Ecotransporte, de la UNIVERSIDAD CAMILO JOSÉ CELA, que trata aspectos de logística, impacto ambiental, energía, etc.
- Máster Universitario en Ingeniería del Transporte Terrestre y Logística, de la UNIVERSIDAD DE JAÉN, con asignaturas sobre transporte por ferrocarril, por carretea, ambas infraestructuras y logística.
- Máster Universitario en Sistemas de Transporte, de la UNIVERSIDAD DEL PAÍS VASCO, orientado a políticas, organización, gestión y modelización del transporte.
- Máster Universitario en Planificación, Economía y Operación del Transporte Urbano y Metropolitano, de la UNIVERSIDAD PABLO OLVIDE, con un enfoque que incluye temas de movilidad, estudios de mercado, modelización y economía del transporte.
- Máster Universitario en Cadena de Suministro, Transporte y Movilidad, especialidad de Transporte y Movilidad, de la UNIVERSIDAD POLITÉCNICA DE CATALUNYA , sobre movilidad y aspectos de economía del transporte y planificación.
- Máster Universitario en Transporte, Territorio y Urbanismo, de la UNIVERSIDAD POLITÉCNICA DE VALENCIA, sobre temas de urbanismo, infraestructuras y explotación.
- Máster en Ingeniería para la Movilidad y la Seguridad, de la UNIVERSIDAD PONTIFICIA DE COMILLAS, que combina aspectos tecnológicos de sensores, sistemas de asistencia, sistemas de retención, biomecánica y propulsión eléctrica, con otros como simulación, dinámica o logística. También se oferta el Doble Máster Universitario en Ingeniería Industrial y en Ingeniería para la Movilidad y la Seguridad con las asignaturas “Dinámica vehicular”, “Sistemas de Asistencia y Tecnología de Sensores”, “Sistemas de retención y seguridad integrados”, “Movilidad sostenible”, “Estructuras ligeras”, “Sistemas de Propulsión Eléctrica”, “Vehículo Autónomo”, “Biomecánica del daño”, “Logística y Transporte Global” y “Resistencia al Choque”.

5.2. Titulaciones específicas sobre automoción

Se ha identificado una amplia oferta en el campo de la formación en automoción, tanto en nivel de Grado, pero, sobre todo, en nivel de Máster. El enfoque de estos estudios da un mayor peso a los ámbitos tecnológicos de los vehículos, aunque, en muchos casos, se extienden a los ámbitos de fabricación, explotación, comerciales, etc.

Titulaciones de Grado:

- Grado en Ingeniería del Automóvil, de la UNIVERSIDAD ANTONIO DE NEBRIJA, que incluye asignaturas específicas sobre automoción en los semestres 6, 7 y 8 como Teoría de Vehículos, Vehículos Eléctricos, Instrumentación y Electrónica del Automóvil, y Sistemas y componentes.
- Grado en Ingeniería de la Automoción, de la UNIVERSIDAD DE VIC-UNIVERSIDAD CENTRAL DE CATALUNYA, con asignaturas específicas sobre automoción en los cursos 2, 3 y 4 como reglamentación, estructuras, instrumentación, electrónica, sistemas y fabricación.
- Grado en Ingeniería en Automoción, de la UNIVERSIDAD DEL PAÍS VASCO, que incorpora asignaturas específicas de automoción desde el primer curso con una línea temática semejante a los casos anteriores.
- Grado en Ingeniería de la Automoción, de la UNIVERSIDAD POLITÉCNICA DE CATALUNYA, que centra las asignaturas específicas en los dos últimos cursos, con una línea temática semejante a los casos anteriores.

Titulaciones de Máster:

- Máster en Ingeniería de Vehículos de Competición, de la UNIVERSIDAD ANTONIO DE NEBRIJA, único máster centrado en este tipo especial de vehículos.
- Máster Universitario en Ingeniería de Componentes de Automoción, de la UNIVERSIDAD DE BURGOS, muy focalizado hacia el diseño, materiales, cálculo estructural y sistemas electrónicos.
- Máster Universitario en Ingeniería de Automoción Sostenible, de la UNIVERSIDAD DE DEUSTO, con 4 módulos muy centrados en aspectos de propulsión, aunque no de forma exclusiva: Automoción y Tecnologías de motores, Tren de Potencia, Electromovilidad y Vehículos de próxima generación
- Máster Universitario en Diseño y Fabricación en Automoción, de la UNIVERSIDAD DE DEUSTO, que incluye aspectos de vehículo y de su fabricación y diseño.
- Máster Universitario en Dirección de Producción en Empresas del Sector de Automoción, de la UNIVERSIDAD DE NAVARRA, estudios menos técnicos que otros antes citados y más enfocado a aspectos de gestión.
- Máster Universitario en Ingeniería de Automoción, de la UNIVERSIDAD DE VALLADOLID, centrado en los diferentes sistemas del vehículo y su diseño y comportamiento, e incluyendo aspectos de fabricación.

- Máster Universitario en Ingeniería de la Automoción, de la UNIVERSIDAD DE VIGO, con un tronco común que incluye Tecnologías y Procesos, Mantenimiento y Medioambiente en la Automoción, Aprovisionamiento, Logística y Técnicas de Calidad, y Financiación, Sistemas de Prevención y Recursos Humanos, y 2 especialidades: Tecnologías Automoción y Procesos de Automoción
- Máster Universitario en Ingeniería de la Automoción, de la UNIVERSIDAD EUROPEA DE MADRID, con 5 módulos: Ingeniería de Vehículos y Motores, Subsistemas y herramientas de diseño, Proyectos de automoción, Sostenibilidad y legislación, e Ingeniería de fabricación.
- Máster Universitario en Ingeniería de Automoción, de la UNIVERSIDAD POLITÉCNICA DE CATALUNYA, orientado a profundizar en cada uno de los sistemas del vehículo, principalmente.
- Máster en Ingeniería de Automoción, de la UNIVERSIDAD POLITÉCNICA DE MADRID, que incluye 5 módulos (Módulo de Ingeniería de los Vehículos, Módulo de Gestión, Módulo de Impacto Socioambiental, Módulo de Ingeniería de Fabricación, y Módulo de Entrada al Sector) y conforma 3 especialidades: diseño en automoción, vehículos híbridos y eléctricos, y vehículos autónomos y conectados.

5.3. Titulaciones específicas sobre ferrocarriles

La oferta de estudios sobre ferrocarril es mucho más limitada que en el caso de automoción. En concreto, se han identificado 2 titulaciones de Máster y otras 2 titulaciones planteadas de forma modular para poder adquirir diferentes cualificaciones, siendo la más alta, la de Máster. Se describen a continuación:

Titulaciones de Máster:

- Máster en Ingeniería de Sistemas Ferroviarios, de la UNIVERSIDAD CARLOS III DE MADRID, que incluye 4 grandes bloques temáticos: fundamentos de ingeniería ferroviaria, señalización y tracción ferroviaria, seguridad y mantenimiento.
- Máster Universitario en Sistemas Ferroviarios, de la UNIVERSIDAD PONTIFICIA DE COMILLAS, que incluye 4 bloques temáticos: señalización y sistemas de control, rodante material, infraestructura y gestión. Adicionalmente, se oferta el Doble Máster Universitario en Ingeniería Industrial y en Sistemas Ferroviarios con las siguientes asignaturas del ámbito ferroviario: Normativa ERTMS Y RAMS, Señalización Ferroviaria, Planificación y programación, Sistemas avanzados de diseño y control de tráfico, Sistemas de control y supervisión, Electrificación, Elementos del material rodante, Ferrocarriles metropolitanos, urbanos y de cercanías, Obra civil y Estaciones, Alta Velocidad e Intercity, Dinámica de material rodante y freno y Mecánica de catenaria.

Cursos con estructura modular:

- Programa de módulos conducentes a titulaciones de Experto Profesional, Experto Universitario o Máster en Ingeniería y Mantenimiento Ferroviario, de la UNIVERSIDAD NACIONAL DE EDUCACIÓN A DISTANCIA, que incluye 15 módulos sobre vehículos, infraestructuras, comunicaciones, subestaciones, ciberseguridad, mantenimiento, etc.
- Programa de módulos conducentes a titulaciones de Experto Profesional, Experto Universitario o Máster en Ingeniería y Gestión del Transporte Terrestre, de la UNIVERSIDAD NACIONAL DE EDUCACIÓN A DISTANCIA, que incluye 14 módulos, principalmente centrados en los aspectos ferroviarios como alta velocidad, explotación y material rodante e infraestructuras ferroviarias, pero también tratando Infraestructuras y vehículos del transporte terrestre, transporte interurbano, urbano y metropolitano, y transporte de mercancías y logística

6. CONCLUSIONES

La prospectiva de las enseñanzas en transportes y vehículos dentro de las titulaciones de Ingeniería Industrial y afines ha demostrado que la presencia es mayor en títulos de MII y de GIM, siendo más residual en titulaciones más generalistas como GITI. La mayor presencia en MII viene motivada por las directrices marcadas por la Orden CIN/311/2009. Sin embargo, a pesar de la menor presencia en GITI y GIM, son las dos titulaciones en las que se han detectado asignaturas con mayor contenido en créditos con los promedios más altos. El enfoque y las temáticas tratadas también son diferentes en las titulaciones, siendo prioritarios aspectos de vehículos y sus componentes en GITI, GIM y MIM, mientras que se en el MII se focaliza hacia transportes y medios de manutención prioritariamente. En cuanto a formación específica, la limitada formación en aspectos de ferrocarril contrasta con la alta oferta en automoción, no solo de ámbitos técnicos sino también de otra índole como fabricación o administración. Esta alta oferta, sin embargo, no tiene su reflejo en titulaciones regladas.

Sin duda, este análisis pone de manifiesto que se trata de materias claramente aplicadas por lo que su presencia natural está en cursos de Máster y resultan muy proclives a formación especializada. Sin embargo, sí resulta relevante apreciar la alta dispersión entre los enfoques empleados en diferentes Universidades para una misma titulación, tanto en número de asignaturas, créditos de las mismas o contenidos impartidos. La tendencia a asignaturas cortas, sobre todo las obligatorias en Máster, obligan a una selección muy parcial en un ámbito tan amplio como es el transporte terrestre y sus vehículos, con lo que quedan, en muchos casos, aspectos que no son ni introducidos. Afortunadamente, en titulaciones como GITI, MII o MIM, entre los planes de estudios que incorporan alguna asignatura sobre transporte, hay un porcentaje relevante de casos en los que existe más de una asignatura (entre el 33% para los planes de MII y el 66% para los planes de MIM), lo que permite complementar enfoques y tratar, por ejemplo, en una materia aspectos de transporte y manutención y en otra aspectos de vehículos, como combinación más usual, así como introducir tecnologías novedosas como sistemas electrónicos o vehículos eléctricos.

AGRADECIMIENTOS

Se desea agradecer la colaboración de los profesores que han revisado las versiones iniciales del documento sobre análisis de las enseñanzas de transportes y vehículos y han contribuido con correcciones, ampliaciones o aportando información más detallada.

Universidad de Burgos

RESUMEN

En la sociedad actual necesitamos poner en marcha planes de formación orientados a la educación a la movilidad sostenible para garantizar un devenir mejor a las generaciones futuras. La manera en la que se ha comunicado y educado en la movilidad sostenible no ha sido completa hasta ahora. La mayoría de los estudios y proyectos formativos se han centrado en la seguridad de los niños, el tráfico callejero, las reglas de tráfico o fomentar comportamientos más saludables como andar o ir en bici al cole, por lo que existe la necesidad de ampliar las temáticas a tratar para fomentar el cambio de actitudes.

En este articulo, presentamos los resultados más relevantes de una experiencia basada en la técnica de gamificación que promueve la educación a la movilidad sostenible en las aulas de la escuela primaria. Este nuevo método formativo, dirigido a niños entre 10-12 años, permite la aplicación de metáforas de juego para tareas de vida real en entornos no lúdicos con el fin de aumentar la motivación al cambio de actitudes.

La intervención didáctica se ha desarrollado con el uso de la plataforma ClassCraft y se han creado actividades especificas que considerasen todos los componentes de la movilidad sostenible: ambiental, económica y social.

El análisis inicial ha demostrado que la percepción sobre la movilidad sostenible estaba orientada hacia los problemas medioambientales y muy poco hacia los componentes social y económico. Después de la experiencia, se han evaluado los conocimientos adquiridos sobre el tema y los cambios de actitud de los niños demostrando que, con el uso de la herramienta gamificada ClassCraft y actividades bien estructuradas sobre todos los aspectos de la movilidad sostenible, los alumnos han adquirido nuevos conceptos que clarifican la importancia de los componentes social y económico, empezando a desarrollar una conciencia sobre cómo ser parte activa en el cambio de sus conductas.

1. INTRODUCIÓN

Los niños son los ciudadanos del futuro y, por lo tanto, la educación y el sentimiento de ser parte de una comunidad juegan un papel fundamental en la configuración de nuestra sociedad futura. El reconocimiento del papel de la educación como un facilitador clave para el desarrollo sostenible y la movilidad sostenible ha ido creciendo constantemente. Facilitar y promover medios y hábitos de movilidad más sostenibles es un objetivo de creciente importancia para las ciudades de todo el mundo.

La manera en la que se ha comunicado y educado en la movilidad sostenible no ha sido completa hasta ahora. La mayoría de los estudios y proyectos formativos se han centrado en la seguridad de los niños, el tráfico callejero, las reglas de tráfico, fomentar comportamientos más saludables como andar o ir en bici al cole (Tabibi, 2009). Existe la necesidad de ampliar tanto las temáticas a tratar para fomentar el cambio de actitudes, así como las herramientas que puedan ser útiles.

El principal objetivo de nuestro estudio ha sido observar y evaluar el uso de técnicas de gamificación como clave para el impulso del aprendizaje y el cambio hacia hábitos de movilidad sostenible.

Para demostrar los cambios en el aprendizaje sobre la movilidad sostenible y el cambio de hábitos nos hemos centrado en los siguientes objetivos específicos:

- Evaluar la percepción que los alumnos tienen respecto a la movilidad sostenible.
- Evaluar el grado de conocimiento conseguido a través de la experiencia.

Después de la introducción, en el apartado 2 se presenta una revisión de la literatura relativa a como movilidad sostenible ha sido tratada con niños, así como a la gamificación y a su aplicación en temas de movilidad. En el apartado 3 se presenta la metodología adoptada y se describe el caso de estudio. En el apartado 4 se presentan los resultados obtenidos.

Finalmente, en el apartado 5 se presentan las conclusiones, junto con las limitaciones que el estudio ha encontrado y las posibles futuras líneas de investigación.

2. REVISION DE LITERATURA

Para el desarrollo de esta investigación es importante describir cómo, en la sociedad actual, se considera y se aborda el tema de la educación en movilidad sostenible relacionada con niños.

Al mismo tiempo es importante analizar la gamificación y su aplicación en temas de movilidad. La gamificación ha demostrado su potencial como un elemento socio-técnico estratégico para aumentar la participación y el compromiso, y promover comportamientos sostenibles, como el hábito ético, social, ecológico o saludable (Bielik et al., 2012). A continuación, analizaremos dichos aspectos de forma independiente.

2.1 La Movilidad sostenible y la infancia

Para entender cómo educar a la movilidad sostenible es necesario preguntarse porque es fundamental ocuparse de ese tema.

Durante la Conferencia de las Naciones Unidas sobre Medio Ambiente y Desarrollo (Keating, 1993), los niños fueron reconocidos como un grupo importante para el desarrollo de un ambiente sostenible. Dado que las actitudes hacia el medio ambiente ya comienzan a desarrollarse en la infancia, puede ser imperativo centrarse en los niños y los jóvenes (Lyons y Breakwell, 1994) para abordar el transporte en el futuro.

El transporte ha estado dominado tradicionalmente por campos como la ingeniería, por lo tanto, muchos de los conceptos centrales para la movilidad sostenible siguen siendo competencia de los especialistas técnicos en lugar de estar en manos de los consumidores, de los responsables de la toma de decisiones o de los jóvenes estudiantes (Schweitzer, Marr, Linford, y Darby, 2008).

Existe un creciente cuerpo de investigación sobre las actitudes de los adultos hacia los automóviles y el medio ambiente (Beirão y Cabral, 2008; Gärling, 2004; Joireman, Van Lange, y Van Vugt, 2004). Sin embargo, ha habido muy poca investigación sobre las actitudes de los niños hacia los automóviles y a la movilidad. Una excepción notable es un informe de investigación escocés sobre cómo los niños y los jóvenes consideran la sostenibilidad en relación con su transporte personal (Davison, Reed, Halden, y Dillon, 2003). Los resultados obtenidos demostraron que la mayoría de los niños conocían bien los problemas de transporte sostenible, pero sus conocimientos no necesariamente tuvieron un impacto en el cambio de actitudes.

Si bien la investigación sobre movilidad en general es muy amplia, existe una falta particular de investigación de movilidad en relación con los niños. Las pocas investigaciones realizadas se han centrado principalmente en los viajes de los niños a la escuela (Kerr et al., 2006; Mackett, Gong, Kitazawa, y Paskins, 2007; McMillan, Day, Marlon, Alfonzo, y Anderson, 2006; Pooley, Turnbull, y Adams, 2006).

Los niños desempeñan un papel fundamental en la movilidad sostenible, no solo por sus estilos de vida actuales dependientes de los automóviles, sino también por su capacidad única de ser "agentes de cambio" (Chawla, 2009; Chawla, 2007; Heft y Chawla, 2006; Malone, 2013, 2015; Sharpe y Tranter, 2010) para sus propias necesidades de viaje, así como las opciones de viaje de sus hogares en general (Tranter y Sharpe, 2012) para lograr vecindarios sostenibles ahora y asegurar los cambios necesarios para un futuro sostenible.

Cambiar el comportamiento de la movilidad personal en respuesta al cambio climático representa un gran desafío para los científicos sociales y los profesionales, dada la naturaleza integrada de la movilidad en la vida diaria (Barr, 2018). Los intentos por comprender, gobernar y promover una movilidad más sostenible han tendido a centrarse en la toma de decisiones individuales y los cambios en el comportamiento, como la reducción del uso de automóviles y el aumento del uso de caminatas, ciclismo y transporte público.

El comportamiento individual juega un papel importante en el transporte sostenible, sin embargo, los hábitos de movilidad diaria son difíciles de cambiar.

A lo largo de los años ha ido creciendo el interés sobre la relación entre movilidad sostenible y niños. Por ejemplo, históricamente, textos clave como “El niño en la ciudad” de Ward (1978) comenzaron a plantear la cuestión sobre cómo los niños se mueven en el espacio público. Del mismo modo, las series clásicas de estudios empíricos de Hillman et al. en 1971 y 1990 (Hillman, Adams, y Whitelegg, 1990) atrajeron la atención al hecho de que los niños se comprometen de hecho con la movilidad y los viajes. Para muchos niños en países desarrollados, sus vidas giran en torno a un territorio urbano expandido a medida que acceden diariamente a amplias áreas de la ciudad para asistir a actividades escolares, deportivas, educativas y culturales (Karsten y van Vliet, 2006). Esto forjó el camino para un número más amplio de estudios empíricos de los patrones de viaje de niños y jóvenes a través de los países industrializados occidentales que replicaron el estudio de Hillman y documentaron patrones similares de cambios en la movilidad de los niños, incluidos los de países como Dinamarca (Fotel y Thomsen, 2004), Italia (Rissotto y Tonucci, 2002), Suecia (Sandqvist, 2002) y Nueva Zelanda (Collins y Kearns, 2001).

Se están lanzando muchas iniciativas de base y participativas a nivel local que brindan soluciones de abajo hacia arriba que apoyan la libertad de movimiento de los niños (por ejemplo, pedibus, trenes de bicicletas, voluntarios en los cruces de peatones, viajes compartidos entre padres y similares). Sin embargo, cualquier programa innovador y costoso, introducido de arriba hacia abajo por las ciudades para aumentar la seguridad vial y la movilidad independiente de los niños tiene más probabilidades de tener éxito si se combina con iniciativas dirigidas a cambiar las actitudes de los padres y los niños, y a aumentar la conciencia de los ciudadanos sobre este tema. En este sentido, Gilbert, Whitzman, Pieters, y Allan (2017) afirman que no hay un lugar mejor que la vida diaria de los niños en edad escolar para originar un cambio en las actitudes hacia una movilidad más sostenible.

En Europa y América del Norte, la movilidad de los niños ha recibido una mayor atención pública y académica (Mikkelsen y Christensen, 2009). En España hay varios ejemplos de buenas practicas educativas en lo que se refiere a la movilidad sostenible. Destacan las iniciativas de “Camino escolar seguro” en Barcelona, Granollers, Madrid, San Sebastián, Segovia, Viladecans y Zaragoza. “Con Bici al Cole” o el programa de Educación Ambiental de Segovia, “Pies para que os quiero: movilidad y camino escolar”. Estos programas pretenden inculcar y promover, en los niños de primaria y en la comunidad en general, los hábitos de cuidado del entorno y de la salud propia mediante la incorporación de conceptos y conductas relacionados con la movilidad sostenible haciendo que la calle se convierta en un lugar propicio para convivir (Ferrando, Molinero, y Peña, 2007).

Para que cualquier actividad educativa para la movilidad sostenibilidad se traduzca en cambio de comportamiento y práctica en la vida diaria, es fundamental complementarlos con otras estrategias. Para una promoción eficaz de los viajes activos, es necesario combinar una gama de proyectos de infraestructura y no infraestructura. Davison, Werder, y Lawson (2008) destacaron el importante papel que desempeñan los programas comunitarios de educación en resultados exitosos de rutas seguras a proyectos escolares en los EE. UU. De manera similar, McDonald y Aalborg (2009) enfatizaron que la infraestructura por sí sola no es suficiente para políticas de viaje activo, además educar y alentar a las familias y los niños es esencial para lograr un cambio de comportamiento. En países como Dinamarca, Holanda y Alemania, la educación en viajes activos se ofrece más allá del plan de estudios formal y está respaldada por una amplia capacitación práctica, que se traduce en una práctica diaria para los niños y las comunidades en general (Faherty y Morrissey, 2014; Schwanen et al., 2012).

2.2 Gamificación y movilidad sostenible

Los juegos serios, los juegos persuasivos, así como las interacciones gamificadas, han demostrado ser herramientas útiles no solo para crear conciencia sobre un tema, sino también para promover una actitud o un cambio de comportamiento. La idea clave es aumentar la motivación de las personas para tomar ciertas decisiones, o llevar a cabo ciertas tareas que son instrumentales para alcanzar objetivos valiosos, convirtiéndolos en experiencias divertidas y gratificantes. La sostenibilidad ambiental es un área de aplicación donde los enfoques de gamificación han sido ampliamente aplicados, que van desde el ahorro de energía (Cowley, Moutinho, Bateman, y Oliveira, 2011; Orland et al., 2014; Shiraishi et al., 2009), la movilidad sostenible (Gabrielli et al., 2013; Holleis et al., 2012; Kazhamiakin, Marconi, Martinelli, Pistore, y Valetto, 2016; Kazhamiakin et al., 2015) y otras cuestiones ambientales como las misiones ambientales comunitarias (Lee et al., 2013), la gobernanza participativa de los barrios urbanos (Coenen, Merchant, Laureyssens, Claeys, y Criel, 2013) o el descubrimiento de la ciudad educativa (Hamari, Koivisto, y Sarsa, 2014). La gamificación para la conciencia ambiental y la sostenibilidad ha resultado exitosa en varios de esos casos; sin embargo, su impacto es a menudo transitorio y tiende a disminuir con el tiempo (Hamari et al., 2014), a menos que se refuerce con las motivaciones oportunas (Weiser, Bucher, Cellina, y De Luca, 2015), y los elementos y la mecánica de diseño del juego correspondientes (Khoshkangini, Valetto, y Marconi, 2017).

El uso de técnicas de gamificación en el ámbito de la movilidad sostenible, como forma para incentivar cambios de comportamiento voluntarios hacia soluciones de movilidad sostenible, se ha difundido mucho en estos últimos años en relación con la difusión de las Smart City en Europa (Kazhamiakin et al., 2015; Khoshkangini et al., 2017).

Una ciudad inteligente (Smart City) es una ciudad eficiente y avanzada de alta tecnología que conecta personas, información y elementos de la ciudad mediante el uso de nuevas tecnologías para crear una ciudad sostenible, más ecológica, competitiva e innovadora, y una mayor calidad de vida (Bakıcı, Almirall, y Wareham, 2013).

La mayoría de los estudios y aplicaciones desarrolladas están dirigidas a adultos. Merugu, Prabhakar, y Rama (2009) ilustran una aplicación para reducir la congestión del tráfico. Hoh et al. (2012) proponen gamificación de pareja y crowdsourcing para incentivar a los ciudadanos a compartir información sobre plazas de aparcamiento en la ciudad. Gabrielli et al. (2014) describen una metodología de diseño para la gamificación y la aplican a los estudios de caso realizados en cuatro ciudades europeas. Buningh, Martijnse-Hartikka, y Christiaens (2014) implementaron un sistema gamificado para estimular a los empleados de la empresa a elegir medios sostenibles de transporte para trabajar. Wells et al. (2014) proponen un modelo de gamificación para motivar a los usuarios a adoptar una movilidad sostenible, que rastrea los comportamientos de movilidad de las personas y propone desafíos modulados sobre la base de su progreso actual. De manera similar, la plataforma Tripzoom (Bie et al., 2012) se utilizó en tres ciudades europeas (Poslad, Ma, Wang, y Mei, 2015) para identificar los patrones de comportamiento de los ciudadanos en materia de movilidad, y luego propuso y recompensó soluciones de movilidad personalizadas y gamificadas que mejoran las emisiones de CO_2, la salud de los jugadores y el tiempo.

En el otoño de 2014, dentro del proyecto STREETLIFE EU, se llevó a cabo un experimento para evaluar el impacto de las recomendaciones de movilidad sostenible y los incentivos de gamificación en el comportamiento de movilidad de los pasajeros que necesitan viajar rutinariamente al centro de la ciudad en automóvil (Kazhamiakin et al., 2015). Se proporcionaron mecanismos para integrar e implementar políticas a nivel de ciudad dentro de un conjunto de servicios de movilidad inteligente: como servicios de planificación de viajes y recomendaciones de rutas que los ciudadanos utilizan habitualmente. Además, se proporcionaron mecanismos para incentivar a los ciudadanos a tomar decisiones de acuerdo con esas políticas de movilidad, mediante la gamificación. Este estudio puede permitir a un diseñador de gamificación concebir juegos que aumenten el conocimiento de los ciudadanos sobre las políticas y servicios de movilidad sostenible existentes y nuevos en la ciudad, y los motiva a adoptar las soluciones de TIC habilitantes correspondientes para obtener estatus y reputación en el juego y ganar recompensas (ya sean virtuales o materiales).

Por lo tanto, la gamificación puede desempeñar un papel clave y triple en este contexto: apoyar la sostenibilidad de las iniciativas de educación ambiental a largo plazo, promover el compromiso de la comunidad en general y fomentar la creatividad y la participación activa. Ya hay algunos ejemplos exitosos que aprovechan la gamificación para promover estilos de vida sostenibles en niños y padres (González, 2016; Hu, Fico, Cancela, y Arredondo, 2014; Jones, Madden, y Wengreen, 2014).

Sin embargo, hay algunos ejemplos de enfoques de gamificación que se dirigen específicamente a la educación ambiental de los niños. Por ejemplo, ECOMobile implementa un enfoque de aprendizaje situado para el aprendizaje de las ciencias del ecosistema, que puede aprovecharse para organizar excursiones a entornos de estanques locales (Kamarainen et al., 2013). Su combinación de una experiencia gamificada de realidad aumentada ha demostrado ser muy efectiva para que los niños comprendan e interpreten las mediciones de la calidad del agua.

Beat the Street (“Beat The Street - Delivered By Intelligent Health,” 2007) y Kids-Go-Green (Marconi et al., 2018) son unas aplicaciones similares en sus objetivos. La iniciativa "Beat the Street" es un plan de viaje activo, una experiencia propuesta en Reino Unido. La iniciativa convierte a toda la ciudad en un juego. De hecho, involucra a una comunidad local de personas dentro de una competición que los anima a caminar o andar en bicicleta en su vecindario, utilizando tecnología de rastreo y un esquema de recompensa. Este juego se ha aplicado también en las escuelas para promover la movilidad activa y sostenible de los niños, pero estudios preliminares muestran que el cambio inducido fue muy limitado (Coombes y Jones, 2016). Esto podría deberse al hecho de que Beat the Street no fue diseñado específicamente para niños, ni para integrarse en el entorno escolar y su programa didáctico. La mecánica del juego, las recompensas y la experiencia del usuario en Beat the Street están diseñadas para involucrar a una población de jugadores genéricos.

Mientras, Kids-Go-Green (Marconi et al., 2018) está diseñado específicamente para ser significativo y atractivo para los niños pequeños en un entorno educativo, como la escuela. Tiene como objetivo aumentar la conciencia y cambiar el comportamiento de los niños y sus familias con respecto a los hábitos de movilidad activa y sostenible. Además, busca provocar un compromiso a corto plazo hacia hábitos de movilidad diferentes, específicamente en lo que se refiere al viaje del hogar a la escuela, lo que eventualmente conduce a una actitud a largo plazo, mediante el aprovechamiento del potencial de las iniciativas educativas gamificadas. Kids-Go-Green se ha desarrollado como una aplicación web a la que se puede acceder desde cualquier navegador web y que se puede utilizar en la escuela por medio de pantallas grandes, pizarras interactivas, tabletas inteligentes u ordenadores.

3. METODOLOGÍA

Para hacer un diagnóstico sobre la percepción y el conocimiento de los alumnos sobre la movilidad sostenible, antes y después de la experiencia didáctica con la plataforma ClassCraft, la investigación se ha subdividido en 4 grandes fases:

1. Diseño de un cuestionario de conocimiento inicial y final, con preguntas de caracterización socioeconómica, hábitos de movilidad y propias del tema de estudio;
2. Diseño de las actividades en la plataforma de juego ClassCraft;
3. Recolección de datos, donde se han recogido las respuestas del cuestionario efectuado de modo presencial, antes y después de la experiencia;
4. Análisis de los resultados, donde se han analizado las respuestas de los estudiantes, antes y después de la experiencia, obteniendo con ellos la percepción previa y los conocimientos finales sobre el tema.

3.1 Diseño del cuestionario

Los cuestionarios se centraban sobre los conocimientos de los aspectos ligados a la movilidad sostenible a través de 38 preguntas de diversa tipología: algunas de respuesta con elección múltiple, otras de respuestas abierta, algunas de preferencias y otras de ranking. Para estructurar este tipo de cuestionario hemos tenido como referencia las encuestas utilizadas para estudiar la percepción del usuario sobre la calidad del servicio de transporte público (dell'Olio, Ibeas, y Cecín, 2010; dell'Olio, Ibeas, y Cecin, 2011; Rojo, Gonzalo-Orden, dell'Olio, y Ibeas, 2011; Rojo, Gonzalo-Orden, dell'Olio, y Ibeas, 2012).

Las 38 preguntas presentan diferentes temáticas:

- de carácter socioeconómico: se pregunta cuántos miembros tiene la familia, qué trabajo tienen los padres, dónde viven, si tienen coche y bicicletas.
- análisis de los hábitos de movilidad: cómo van al colegio, si utilizan la bici, los motivos de los desplazamientos y las diferentes modalidades de movilidad presentes en la ciudad.
- definición de algunas palabras y conceptos clave asociados a la movilidad sostenible como: carril bici, zonas peatonales, transporte colectivo, coche compartido, ciudad sostenible, transporte sostenible, *bike sharing*.

Este cuestionario, sin la parte inicial de caracterización socioeconómica, se ha propuesto después de la experiencia didáctica con técnicas de gamificación para evaluar los cambios en los conocimientos de los alumnos.

Para entender mejor los resultados hablaremos de *cuestionario inicial* cuando nos referimos a los datos antes de la experiencia didáctica y *cuestionario de verificación* cuando nos referimos a los datos después de la experiencia didáctica.

3.2 Diseño de las actividades en la plataforma ClassCraft

Inspirada en los videojuegos de rol o juegos de rol (por ejemplo, World of Warcraft), la primera versión de ClassCraft fue concebida por Shawn Young en enero de 2011.

Aunque inicialmente ClassCraft se desarrolló para la gestión de la clase en la escuela secundaria, hay ejemplos de su uso en la educación primaria (Mora Márquez, Camacho Torralbo, y Torralbo, 2019).

Se trata de una aplicación web, ya creada, que permite a los profesores dirigir un juego de rol en el que sus alumnos encarnan diferentes personajes. Los Role-Playing Game (RPG) se podrían definir como un sistema para crear historias basadas en una serie de reglas (Grande-de-Prado, Baelo, García-Martín y Abella-García, 2020). En este caso la idea es que los alumnos estén involucrados en un juego donde la evolución de su personaje está relacionada a sus capacidades escolares y de colaboración en clase.

El juego funciona en un motor web en tiempo real, por lo que los eventos del juego se envían en tiempo real a los dispositivos de otros usuarios, como en un videojuego normal en línea (Sanchez, Young, y Jouneau-Sion, 2017). ClassCraft no está relacionado con una materia escolar específica, y la duración del juego depende de las expectativas del maestro (desde unas pocas horas de clase hasta todo el año). Los estudiantes juegan durante las horas escolares y fuera de clase (Sanchez et al., 2017).

ClassCraft es una plataforma muy visual y atractiva que permite crear un mundo de personajes (magos, sanadores y guerreros) que deberán cooperar y participar en misiones para ir ganando puntos y monedas con el que mejorar su equipo. El objetivo, es ir avanzando de forma colaborativa a la vez que aprenden y desarrollan su conocimiento. Los maestros tienen acceso a una interfaz donde pueden elaborar una historia, crear un conjunto de actividades que los alumnos deben resolver para obtener puntos y recompensas. El estudiante tiene un perfil privado en línea donde puede ver cuántas insignias ha recibido, cuáles son las actividades, etc. Se supone que los estudiantes deben desarrollar lo que el maestro propuso y luego recibir puntos y distintivos que reconocen su trabajo.

Las reglas del juego son bastante simples. Un estudiante que demuestre un comportamiento positivo en la clase puede ganar "Puntos de experiencia (XP)". Si un estudiante “rompe” las reglas de la clase, perderá “Puntos de salud (HP)”, su energía vital en el juego, y eventualmente, caerá en la batalla.

En nuestro caso, se ha construido una historia donde los alumnos eran superhéroes llamados a salvar a los habitantes de una isla contaminada. Se han elaborado y presentado, en la plataforma, actividades de varias tipologías: crucigramas, sopas de letras, mensajes cifrados, imágenes, mapas conceptuales, problemas matemáticos, videos informativos y documentales, historias, discusiones en chat, ejemplos reales. En total el mapa de la historia con las actividades se componía de 48 etapas. Para resolver cada tarea los niños tenían a disposición un tiempo y podían recibir diferentes recompensas (XP y GP) si terminaban antes del tiempo dado o después.

3.3 Recolección de datos del caso de estudio: realización de la Encuesta antes y después de la experiencia

Los protagonistas de la investigación han sido alumnos de 5º de primaria del Colegio Marista Liceo Castilla de Burgos. El total de la muestra objeto de estudio se corresponde con 75 alumnos divididos en tres clases (25 cada una). Todos los estudiantes se incluían en el rango de edad 10-11 años, con una ligera prevalencia en el género de los niños sobre las niñas y observamos que esta tendencia se mantiene en las tres clases. En el total había un 53% de niños y un 47% de niñas.

La experiencia se enfocó como una actividad extracurricular y se planearon algunos encuentros presenciales para no interferir en el desarrollo de las actividades curriculares.

Para la realización de las encuestas, los alumnos han tenido a su disposición 60 minutos para responder a cada una, siendo ayudados por sus profesores, que solo tenían la posibilidad de ayudarlos desde el punto de vista práctico (cómo contesto) y no conceptual (qué significa). Se garantizó en todo momento el anonimato y la confidencialidad de las respuestas. Los cuestionarios se han suministrado antes de la experiencia y después de tres meses de actividades.

4. RESULTADOS

El análisis de los cuestionarios se ha hecho conjuntamente, las mismas preguntas se formularon antes de llevar a cabo la actividad gamificada y después. Por comodidad dividimos los resultados en tres grandes partes:

- la caracterización de los hábitos y percepción de movilidad de los alumnos;
- la evolución de los conocimientos básicos de movilidad sostenible.
- el análisis del aprendizaje con técnicas de gamificacion antes y después de la actividad.

El objetivo principal es ver cómo ha evolucionado su forma de pensar con el fin de evaluar y validar la efectividad de la actividad. Hay que tener en cuenta que en esta experiencia las actividades no eran obligatorias.

4.1 Caracterización de los hábitos y percepción de movilidad de los alumnos

A continuación, analizaremos y compararemos los hábitos y percepción sobre la movilidad antes y después de la actividad gamificada.

Analizamos la percepción de las distintas formas para ir al colegio, qué tipo de transporte hay en la ciudad, qué opiniones tienen respecto a diferentes temas relacionados con el ambiente, la contaminación y la sostenibilidad, y qué prioridades tienen a la hora de desplazarse.

Con el fin de establecer si las costumbres de movilidad están influenciadas por la zona donde viven, se preguntó acerca del lugar de residencia, teniendo en cuenta que la ubicación del colegio es periférica (respecto al centro de la ciudad) y se encuentra conectada con una de las vías principales de entrada/salida a la ciudad.

Aquí hay bastante heterogeneidad con prevalencia de niños que viven en el centro de la ciudad el 37%, pero se registra un porcentaje parecido, aunque inferior de niños que viven en la periferia un 30% o en pueblos un 22%.

También la posesión de coche es un factor importante que incide en los hábitos de movilidad de los alumnos y sus familias.

Se registra cómo la mayoría de los hogares tienen 2 coches, con un total de 155 coches en los 75 hogares, lo que supone una tasa de motorización de 2,07 coches por hogar.

La mayoría de los hogares (el 96%) tienen al menos una bici y la mayoría de ellos la usan una vez a la semana (el 40%) o más de una vez por semana (el 42%). Dos de ellos la usan a diario. La mayoría de ellos la usan para jugar y para desplazarse.

Se preguntó cuántas formas (modos o combinación de modos) distintas pueden elegir para ir desde casa al colegio. El intento de las preguntas es averiguar cuántas posibles formas de ir al colegio conocen, independientemente de si la utilizan o no.

Para ir al colegio, la mayoría de los alumnos se desplaza de forma habitual en coche (más del 60%) o a pie (el 21%) y un pequeño porcentaje se desplaza en bici (el 11%) y en bus (el 7%). Los niños van al colegio principalmente acompañados por sus padres y madres, y en forma menor con abuelos y hermanos. Se registra, después de la experiencia, un incremento de opciones de respuestas, esto quiere decir que en la actividad los alumnos han aprendido, recordado o conocido nuevos modos de transportes que han ampliado su visión. Los incrementos más importantes los tenemos en los siguientes modos: bici, pedibus, bus y a pie. Todos ellos son modos de transporte sostenible y por lo tanto desde este punto de vista podemos concluir que la actividad ha sido muy efectiva. Como era lógico también se incrementa el número de personas que eligen el coche y curiosamente baja el número de personas que eligen el modo combinado a pie + bus. La mayoría de los alumnos usa también medios de transporte distintos del coche, pero hay un 21,3% de alumnos que solamente usa el coche para sus desplazamientos. Como modos alternativos prevalecen los desplazamientos a pie, en bus, en tren y en bici. Entre los motivos de desplazamientos prevalecen: ir de compras, visitar amigos y familiares y hacer recados.

Conocer los modos de transporte público es un aspecto importante para poder favorecer su uso. Para verificar su nivel de conocimiento se preguntó qué medios de transporte público existen en la ciudad de Burgos. Globalmente el número de alumnos que conocen los diferentes modos de transporte público presentes en la ciudad aumenta de una forma importante después de la actividad gamificada. Las escaleras mecánicas, el tren y las bicis de alquiler, son los modos de transporte público que más incremento tienen respectivamente de un 29%, un 18% y un 14%, pero también se incrementa el número de alumnos que conocen el taxi (3%) y el bus (2%) (que es el modo de transporte publico más conocido por los alumnos). Hay que destacar que un número mínimo de alumnos indican la presencia del tranvía (1 alumno tanto antes como después de la actividad) y del metro (2 alumnos tanto antes como después de la actividad) en la ciudad de Burgos que actualmente no existen. Globalmente se puede concluir que también este objetivo se ha alcanzado con la actividad y por lo tanto los alumnos han incrementado de forma significativa su conocimiento de los modos de transporte publico de su ciudad.

4.2 Evolución de los conocimientos básicos de movilidad sostenible

En este apartado analizaremos las preguntas comunes de los cuestionarios considerando las referidas a los conocimientos básicos de movilidad sostenible antes y después de la actividad gamificada.

En los conocimientos empezamos por los *carriles bici*. Antes de las actividades, los alumnos demuestran conocer los carriles bici un 70%, pero lo que se pretende es ver si tras la actividad gamificada comprenden su utilidad. En la actividad gamificada, los alumnos aprenden que la bici no debe ser únicamente un modo de transporte para actividades de ocio y este logro es importante. También se incrementan de un 5% las respuestas donde los alumnos dicen que el carril bici favorece el uso de la bici e incrementa la seguridad de los ciclistas. Estos conceptos son importantes y evidencian el progreso de los alumnos en el aprendizaje de su función. Disminuye un 9% el número de alumnos que dicen que los carriles bici sirven para ir más rápido y que sirven para pasear los fines de semana y en el tiempo libre. También demuestran entender mejor que el carril bici no sirve para que lo usen los peatones y que no es una infraestructura que estorbe o perjudique al peatón. Globalmente podemos decir que con esta actividad se han logrado unos resultados muy satisfactorios.

Exactamente lo mismo pasa con las *zonas peatonales*, demuestran conocer su presencia en la ciudad de Burgos un 70%. Cuando se pregunta sobre la utilidad de las zonas peatonales, la mayoría opina que sirven para que los peatones puedan circular libremente, un 70%, también para que no haya coches en ellas un 50% y para que haya más espacio público un 38% y para reducir la contaminación un 26%.

Después de la actividad gamificada los mayores incrementos se obtienen justamente en las dos opciones menos elegidas (para que haya más espacio público incrementa del 4% y para reducir la contaminación incrementa del 3%). Esto es muy positivo puesto que nos demuestra que las actividades gamificadas han ayudado a entender mejor estos conceptos menos populares entre los alumnos.

A continuación, analizamos las respuestas relativas a algunas definiciones: *transporte colectivo, coche compartido, ciudad sostenible, transporte sostenible, bike sharing.*

En todos se analiza la frecuencia de respuesta desagregada por clase y total, y los porcentajes de variación del total de respuestas.

Para verificar si los alumnos conocían el significado de *transporte colectivo* se les dio a elegir entre tres definiciones:

Definición 1: Es un medio de transporte público que tiene unos horarios y rutas establecidos. Unos ejemplos son los coches, motos, furgonetas y camiones.
Definición 2: Es un medio de transporte público que tiene unos horarios y rutas establecidos. Unos ejemplos son los autobuses, trenes, tranvías, etc.
Definición 3: Es un medio de transporte que usan solo las personas que no tienen su coche.

Antes de la actividad, la mayoría de los alumnos eligieron la definición 2 un 65%, otros alumnos eligieron la definición 1 un 20% y la 3 un 15%. Después del juego sube el numero de los alumnos que eligen la respuesta correcta y en las otras el número baja, sobre todo en el caso de la definición 1 que podemos considerar como incorrecta.

Analizamos los datos considerando la variación de porcentaje en su percepción respecto al concepto de *transporte colectivo*: se ve cómo después de la actividad se incrementa en un 22% el número de alumnos que eligen la definición 2 y baja un 17% el número de alumnos que eligen la definición 1 y un 5% los que eligen la 3. También en este caso podemos concluir que la actividad ha sido efectiva en el conocimiento de las características y funciones del transporte colectivo.

Para verificar si los alumnos conocían el significado de *coche compartido* se les dio a elegir entre tres definiciones:

Definición 1: Consiste en compartir un coche con otras personas por un tiempo limitado.
Definición 2: Consiste en compartir un coche con otras personas, pero solo cuando no tengo mi coche disponible.

Definición 3: Consiste en compartir un coche con otras personas para ir al trabajo, al colegio, de viaje, etc. Con esta práctica se pueden reducir los atascos y la contaminación en las ciudades.

La mayoría de los alumnos conocen el significado de coche compartido y lo asocian principalmente a la definición 3 que es la más correcta.

Después de la actividad gamificada el número de alumnos que elige la definición correcta se incrementa sensiblemente. La variación del porcentaje demuestra que se incrementa en un 28% el número de alumnos que eligen la definición 3 y baja un 18% el número de alumnos que eligen la definición 1 y un 10% los que eligen la 2. También en este caso se puede comprobar la efectividad de la actividad.

Para verificar si los alumnos conocían el significado de *ciudad sostenible* se les dio a elegir entre tres definiciones:

Definición 1: Es una ciudad donde sus habitantes cuidan el medio ambiente sin dañarlo, desarrollan sus actividades económicas creando una ciudad respetuosa, de bienestar e igualitaria entre todos.
Definición 2: Es una ciudad donde sus habitantes cuidan el medio ambiente sin dañarlo y sin desarrollar actividades económicas de ningún tipo, siendo de esta manera muy respetuosos con el medio ambiente.
Definición 3: Una ciudad sostenible es una ciudad en la que sus habitantes no se encargan de cuidar el medio ambiente y desarrollan sus actividades económicas sin respetar el entorno, creando una sociedad desigualitaria y de poco bienestar.

Es evidente que la definición correcta es la 1 y la 3 es la que es totalmente incorrecta.

La definición 2 es la que normalmente la gente suele considerar puesto que se fija en el factor medioambiental ignorando las otras dos dimensiones de la sostenibilidad.

Si miramos a las frecuencias de respuestas los resultados parecen no satisfactorios, pero realmente esto se debe a que, en la primera encuesta, antes de la actividad gamificada algunos niños eligieron más de una definición, cosa que se limitó en la encuesta después de la actividad.

Por ello es interesante analizar el resumen de los resultados por porcentaje, se puede ver como el número de alumnos que elige la respuesta correcta se incrementa un 6% y disminuye el número de alumnos que eligen las otras dos definiciones, respectivamente del 4% por la definición 2 y de un 2% para la 3. Podemos considerar el resultado es satisfactorio, aunque el objetivo habría sido que el número de alumnos que eligen la definición 2 bajase de forma sustancial. Por lo tanto, la actividad puede mejorarse en este sentido incidiendo sobre estos puntos.

Para verificar si los alumnos conocían el significado de *transporte sostenible* se les dio a elegir entre tres definiciones:

Definición 1: El transporte sostenible consiste en utilizar cada uno su coche para ir al colegio, al trabajo, etc.
Definición 2: El transporte sostenible consiste en utilizar todos los modos de transporte disponibles en la ciudad.
Definición 3: El transporte sostenible ayuda a reducir los efectos negativos sobre el medio ambiente y consiste en utilizar modos de transporte menos contaminantes.

En este caso la definición correcta es la 3. La 1 y la 2 son incorrectas, aunque la 2 podemos considerarla menos incorrecta que la 1.

Después de la actividad gamificada la elección de la definición 3 se incrementa un 20%, disminuyendo también la elección de ambas definiciones 1 y 2. La elección de la definición 1 disminuye de un 13% y la de la 2 más de un 7%. También en este caso se puede comprobar la efectividad de la actividad.

Para verificar si los alumnos conocían el significado de *bike sharing* se les dio a elegir entre tres definiciones:

Definición 1: Es un servicio de transporte de pago en el que las bicicletas se ponen a disposición en varios puntos de la ciudad para que la gente las utilice, pudiéndola coger en un punto y dejándola en otro distinto.
Definición 2: Es un servicio para viajes de corta distancia en una zona urbana como alternativa al transporte público, que se coloca en varios puntos de la ciudad y es gratuito.
Definición 3: Es un servicio para que la gente utilice la bicicleta como un transporte público más, que te permite utilizar la bicicleta por el tiempo que quieras.

En este caso la definición correcta es la 1 aunque la 2 y la 3 aportan algunos conceptos importantes que se intenta transmitir en la actividad gamificada. En la definición 2 se insiste en el carácter urbano y en su gratuidad que son características que se pueden imponer a un servicio de *bike sharing*, mientras en la 3 se insiste en que el *bike sharing* es un transporte público, pero que las bicis se pueden tener el tiempo que cada uno quiera.

Tras la actividad, en porcentaje, la elección de la definición 1 disminuye un 10%, mientras la 2 y la 3 se incrementan un 6% y un 4% respectivamente. Puede parecer, a primera vista, que los resultados no demuestren un alto porcentaje de mejora después de la actividad, como para las nociones anteriores. Se considera oportuno, para futuras investigaciones, incidir más en una definición más clara de lo que es *bike sharing* y proporcionar más actividades al respecto.

4.3 Análisis del aprendizaje con técnicas de gamificación antes y después de la actividad
En los apartados anteriores hemos comentado los resultados de los cuestionarios describiendo la caracterización de los hábitos y percepción de movilidad de los alumnos y la evolución de los conocimientos básicos de movilidad sostenible antes y después de la actividad didáctica con técnicas de gamificación.

En este apartado compararemos más en el detalle el grado de conocimiento inicial y final de los alumnos. Para tal fin, a las preguntas de conocimiento se ha añadido una puntuación en función de las respuestas dadas. El recuento de esa puntuación en el cuestionario inicial y en el final nos permite definir numéricamente el nivel base del que el alumno empieza y el nivel final una vez que la actividad gamificada haya terminado.

A continuación, se propone una tabla que resume los resultados más relevantes (Tabla 1).

	Nº	% ALUMNOS	SUMA PUNTOS	% PUNTOS
Alumnos que mejoran	50	66,67	225	80,36
Alumnos que se quedan igual	3	4,00	0	-
Alumnos que empeoran	22	29,33	-55	19,64

Tabla 1 - Resumen de las puntuaciones de los dos cuestionarios antes y después

En la primera columna se puede apreciar que el número de alumnos que mejora su nivel es superior al número de alumnos que empeoran. En términos de porcentaje se puede observar como el 66,67% de los alumnos mejoran su puntuación (segunda columna).

Globalmente se puede observar en la tercera y cuarta columna como los que mejoran lo hacen mucho más (80,36%) que los alumnos que empeoran su puntuación (19,64%).

La justificación de esto quedará más clara más adelante, cuando consideremos los resultados relacionados con otros factores: como la satisfacción, el tiempo dedicado, el número de actividades desarrolladas, etc. A partir de dichas relaciones, explicaremos cómo esta circunstancia tiene un rol relevante en el éxito de esta metodología. La Figura 1 representa visualmente los resultados de los 75 alumnos, expresados en la tabla anterior, ordenados en función de la variación de puntuación (DELTA PUNTUACION = PFINAL – PINICIAL).

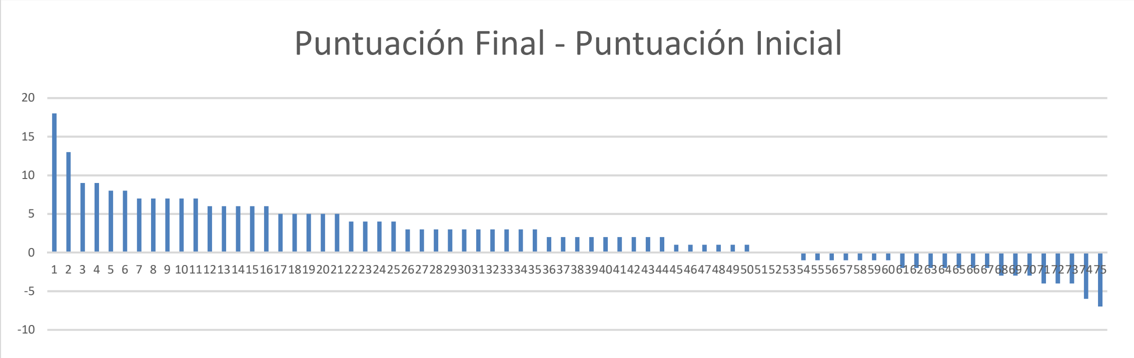

Fig. 1- Variación de puntuación entre los cuestionarios

Con el fin de analizar la relación entre la puntuación final y otras variables relevantes se proponen una serie de modelos de regresión lineal múltiple (9 modelos del MR1-MR9). En estos modelos se relaciona la puntuación final (PFINAL), alcanzada a través del cuestionario de verificación (final) que es nuestra variable dependiente, con las variables que hemos obtenido a través de la plataforma de ClassCraft, que nos indican el tiempo que cada jugador ha dedicado al juego, así como el nivel de satisfacción global del juego (SAT_GLOB) (Tabla 2).

En concreto utilizaremos las siguientes variables:

- desde la plataforma: el nivel del juego alcanzado por el alumno (NIV_JU), los puntos alcanzados en la plataforma de Classcraft al final del juego (P_JU), el número de actividades terminadas dentro de Classcraft (N_ACT), el número de conexiones (N_CON).
- Desde el cuestionario final en concreto las preguntas: los accesos semanales (ACC_SEM), las horas semanales dedicadas (HOR_SEM), el nivel de satisfacción global (SAT_GLOB).

	MR1	*MR2*	*MR3*	*MR4*	*MR5*	*MR6*	*MR7*	*MR8*	*MR9*

Tabla 2 - Resumen de los modelos de regresión

Como se puede observar en los modelos (Tabla 2) existe una correlación positiva entre todas las variables consideradas y la puntuación final alcanzadas por los alumnos. Además, en todos los casos los parámetros asociados a la variable dependiente considerada son estadísticamente significativos a más del 95% del nivel de confianza.

En el MR1 se calcula un modelo de regresión para predecir la puntuación final obtenida a través del cuestionario de verificación en función del nivel del juego alcanzado. Se obtiene una regresión significativa ($F(1,74) = 140,877$, $p < ,000$), con un R^2 de ,656. La predicción de la puntuación final es igual a 2,275 * (NIV_JU).

En el MR2 se calcula un modelo de regresión para predecir la puntuación final obtenida a través del cuestionario de verificación en función de los puntos alcanzados en la plataforma de ClassCraft al final del juego. Se obtiene una regresión significativa ($F(1,74) = 115,891$, $p < ,000$), con un R^2 de ,610. La predicción de la puntuación final es igual a 0,003 * (P_JU).

En el MR3 se calcula un modelo de regresión para predecir la puntuación final obtenida a través del cuestionario de verificación en función del número de actividades terminadas dentro de ClassCraft. Se obtiene una regresión significativa ($F(1,74) = 82,476$, $p < ,000$), con un R^2 de ,527. La predicción de la puntuación final es igual a 0,849 * (N_ACT).

En el MR4 se calcula un modelo de regresión para predecir la puntuación final obtenida a través del cuestionario de verificación en función del número de conexiones a ClassCraft. Se obtiene una regresión significativa ($F(1,74) = 134,726$, $p < ,000$), con un R^2 de ,645. La predicción de la puntuación final es igual a 0,655 * (N_CON).

En el MR5 se calcula un modelo de regresión para predecir la puntuación final obtenida a través del cuestionario de verificación en función de los accesos semanales a ClassCraft. Se obtiene una regresión significativa ($F(1,74) = 301,488$, $p <, 000$), con un R^2 de ,803. La predicción de la puntuación final es igual a 6,179 * (ACC_SEM).

En el MR6 se calcula un modelo de regresión para predecir la puntuación final obtenida a través del cuestionario de verificación en función de las horas semanales dedicadas a ClassCraft. Se obtiene una regresión significativa ($F(1,74) = 259,502$, $p < ,000$), con un R^2 de ,778. La predicción de la puntuación final es igual a 12,194 * (HOR_SEM).

En el MR7 se calcula un modelo de regresión para predecir la puntuación final obtenida a través del cuestionario de verificación en función del nivel de satisfacción global con la actividad. Se obtiene una regresión significativa ($F(1,74) = 350,162$, $p < ,000$), con un R^2 de ,826. La predicción de la puntuación final es igual a 10,008 * (SAT_GLOB).

En el MR8 se calcula un modelo de regresión múltiple para predecir la puntuación final obtenida a través del cuestionario de verificación en función del nivel de satisfacción global con la actividad y de las horas semanales dedicadas a ClassCraft. Se obtiene una regresión significativa (F(1,74) = 364,131, p < ,000), con un R^2 de ,909. La predicción de la puntuación final es igual a 6,207 * (SAT_GLOB) + 6,219 * (HOR_SEM).

En el MR9 se calcula un modelo de regresión múltiple para predecir la puntuación final obtenida a través del cuestionario de verificación en función del nivel de satisfacción global con la actividad y de los accesos semanales a ClassCraft. Se obtiene una regresión significativa (F(1,74) = 453,112, p < ,000), con un R^2 de ,925. La predicción de la puntuación final es igual a 5,934 * (SAT_GLOB) + 3,355 * (ACC_SEM).

Analizando los modelos MR1, MR2 y MR3 podemos concluir que indudablemente los alumnos que han aprendido más son los que han alcanzado un nivel del juego más alto, los que han totalizado más puntos y los que han terminado un número mayor de actividades. Esto es muy importante, porque valida la eficacia del método empleado y sobre todo justifica que los alumnos que no han mejorado y que hasta en algún caso han empeorado su rendimiento son los alumnos que se han quedado a un nivel inferior, han completado un número inferior de actividades y han sacado por lo tanto menos puntos.

Analizando los modelos MR4, MR5 y MR6 podemos observar cómo el tiempo dedicado tiene un impacto directo también en el rendimiento final del alumno. Se demuestra que los alumnos que se conectaron más veces, los que accedieron un mayor número de semanas y los que dedicaron más horas semanales también han aprendido más. Si unimos estos resultados con los anteriores, podemos concluir que el rendimiento de los alumnos está directamente relacionado con las actividades desarrolladas y con el tiempo dedicado. Si miramos con más detalle, podemos ver que los modelos MR5 y MR6 son los que presentan mejor R^2 ajustado de entre los 6 primeros modelos. Esto nos indica que para aprender los alumnos no solamente necesitan conectarse muchas veces, sino que es importante que cada semana dediquen algo de tiempo a las actividades.

El modelo MR7 pretende medir si el grado de satisfacción con la aplicación y con el juego afecta positivamente al aprendizaje. Como se puede ver podemos concluir claramente que es quizás lo más importante. Cuanto más atractivo sea el juego y cuanto más satisfechos estén los alumnos con él, más aprenderán.

Los últimos dos modelos (MR8 y MR9) combinan el efecto de la satisfacción con el tiempo dedicado. Como se puede ver la combinación de las dos cosas hace que los alumnos aprendan más.

5. CONCLUSIONES

En este articulo se describen los resultados de una experiencia educativa basada en la gamificación con el fin de mejorar la percepción de la sociedad sobre los problemas alrededor de la movilidad sostenible. El proyecto se ha diseñado para formar a alumnos de 10-12 años.

Se muestran las principales conclusiones obtenidas del presente trabajo teniendo en cuenta los objetivos generales y específicos que nos hemos planteado, valorando además el cumplimento de los mismos.

El objetivo general planteado ha sido el de observar y evaluar el uso de técnicas de gamificación como clave para el impulso del aprendizaje y el cambio hacia hábitos de movilidad sostenible. A éste hemos añadidos unos objetivos específicos que juegan un papel relevante, al servir como vehículo para conseguir el objetivo general. El nivel de cumplimiento tanto del objetivo general como de los específicos ha sido satisfactorio.

La revisión de la literatura, tanto en la parte de la gamificación como en la de educación en movilidad sostenible, nos ha servido como base para entender mejor esta metodología de enseñanza y verificar su uso en el campo de la educación. También hemos comprobado que hay poca investigación sobre cómo proporcionar temas de movilidad sostenible a niños de primaria, en nuestro caso entre los 10 y 12 años, y los tipos de metodologías de enseñanza usados a tal fin.

Podemos decir que nuestra experiencia ha contribuido a la comprensión del efecto que este tipo de metodología puede tener para mejorar la percepción de los conceptos de movilidad sostenible en todas sus vertientes.

En concreto, antes de la actividad gamificada propuesta se puede concluir que los niños poseen un conocimiento básico sobre el tema. Deducimos que los niños, antes de su participación en la actividad educativa, se centran únicamente en los aspectos ambientales de la movilidad sostenible, ignorando completamente los aspectos sociales y económicos. En definitiva, sus conocimientos parecen estar sesgados a la componente medioambiental.

Si comparamos los datos después de la actividad gamificada propuesta podemos concluir que los niños amplían sus conocimientos sobre la movilidad sostenible incluyendo también los conocimientos relativos a las componentes sociales y económicas que la movilidad sostenible favorece.

Consideramos nuestra investigación un punto de partida para futuras investigaciones, que deberán tener en cuenta las siguientes cuestiones:

- Se necesitan estudios futuros para determinar si nuestros hallazgos pueden generalizarse a una población más amplia. Se podrían dar diferentes resultados al considerar otras poblaciones y al comparar los resultados.
- El posible reflejo de los resultados en la modalidad de transporte adoptada en los viajes diarios a la escuela de los niños, adoptando modalidades sostenibles para llegar a la escuela.
- Un cuestionario de seguimiento que mida si los conceptos adquiridos se mantienen después de que finalice la actividad del juego.
- Un cuestionario para los padres en lo que se pueda verificar cómo el comportamiento sostenible también se generaliza a otros contextos, como el tiempo libre y los viajes familiares.
- Las opiniones de los docentes sobre la experiencia.

AGRADECIMIENTOS

Nos gustaría agradecer el Colegio Marista Liceo Castilla de Burgos y sus profesores por su disponibilidad y colaboración en el desarrollo de la aplicación práctica de la metodología expuesta en este artículo.

ENSEÑANZA DE LA MOVILIDAD SOSTENIBLE A TRAVÉS DE LA LITERATURA INFANTIL

Marta Miguel-Borge
Universidad de Burgos
Ana María Aguilar López
Universidad de Burgos

RESUMEN

El diseño de nuestras ciudades y su organización, en general, se ha centrado en el vehículo motorizado y ha dejado muy poco espacio para peatones o ciclistas. Algunas de las consecuencias de esta movilidad urbana son altos niveles de contaminación, congestión, emisión de gases de efecto invernadero, ruido... La necesidad de cambio en el diseño de la movilidad urbana se contempla en el objetivo 11 de los Objetivos de Desarrollo Sostenible (ODS) 2030 promovidos por Naciones Unidas.

La comunidad educativa es fundamental para propiciar cambios de comportamiento que puedan beneficiar en un futuro no muy lejano a toda la sociedad. Claro está que no es la única forma, pero sí una de las de mayor peso. Teniendo esto en cuenta, este trabajo mostrará cómo la literatura infantil puede ser una buena herramienta para transmitir conceptos que pueden resultar complejos para los niños. Esta disciplina cuenta con diferentes recursos que permiten dar a conocer las ventajas de la movilidad sostenible en las materias escolares. En nuestro caso, vamos a ver cómo la literatura puede ayudarnos a fomentar esa necesidad de cambio entre los alumnos de 4.º y 5.º de primaria.

Para conseguirlo, hemos trabajado con alumnos del Grado en Maestro de Educación Primaria dotándoles de la formación general en recursos para transmitir diferentes conceptos a través de la narrativa infantil y, en paralelo, les hemos formado en movilidad sostenible. A continuación, les hemos guiado en la creación de material didáctico para poder llevarlo a las aulas de primaria con el objetivo de transmitir la necesidad de una movilidad sostenible en nuestras ciudades. En este trabajo se mostrarán algunos de los recursos generados.

1. INTRODUCCIÓN

Debemos cambiar la forma en la que nos movemos de forma habitual por nuestras ciudades y comenzar a ser conscientes de los beneficios y la necesidad de ser menos contaminantes y más eficientes. Cada uno de nosotros tenemos la responsabilidad de cuidar nuestro planeta y hacer que las ciudades sean más inclusivas y sostenibles, donde todos tengamos cabida y respiremos un aire más limpio. Para ello buscaremos un cambio de movilidad urbana que implique favorecer los desplazamientos a pie, en bicicleta y en transporte urbano sostenible.

1.1 Las ciudades y la movilidad sostenible

La movilidad urbana está basada principalmente en el consumo de combustibles fósiles que pone en riesgo la salud de los individuos y del medio ambiente (Calvo, 2013). En muchas de estas urbes sus habitantes respiran aire contaminado proveniente, en gran medida, del transporte motorizado, en especial, el privado. Este es causante de muchas de las emisiones de CO_2 a la atmósfera y, por tanto, del calentamiento global. Este problema de contaminación afecta directamente a nuestra salud, provocando enfermedades de tipo respiratorio, daños cardiovasculares o daños en el sistema nervioso que afectan en especial a personas enfermas, niños y ancianos, los sectores más vulnerables de nuestra población. En la Unión Europea el 74% de sus habitantes viven en ciudades y el 40% de las emisiones de CO_2 de transporte son causadas por la movilidad urbana (Diez et al, 2018).

Para reducir de forma considerable esta contaminación debemos cambiar de forma urgente nuestra forma de movernos. Para propiciar que una ciudad sea sostenible debemos diseñar medidas que incrementen la calidad del aire y del agua, reduzcan la contaminación acústica y generen espacios para los peatones, además de conseguir ciudades más amigables para todos (Torres-Porras y Arrebola, 2018). Para valorar los beneficios de las políticas de movilidad propuestas, así como de los cambios en nuestra forma de movernos, podemos recurrir a diferentes técnicas de modelización (Gonzalo-Orden et al, 2012). Son muchas las instituciones nacionales e internacionales, organismos públicos y privados los que buscan educar por y para la sostenibilidad y que proponen nuevos modelos de movilidad implicando directamente a la ciudadanía (Prieto y Cid, 2009).

No es posible lograr un desarrollo sostenible sin transformar radicalmente la forma en que construimos y administramos los espacios urbanos. Mejorar la seguridad y la sostenibilidad de las ciudades implica garantizar el acceso a viviendas seguras y asequibles y la mejora de los asentamientos marginales. También incluye realizar inversiones en transporte público, crear áreas públicas verdes y mejorar la planificación y gestión urbana de manera que sea participativa e inclusiva (ONU, 2015). El nuevo diseño urbano pasa por recuperar un modelo de ciudad compacta, con servicios de proximidad, amplias zonas peatonales y con un buen sistema de transporte público, para mejorar la calidad de vida y la calidad ambiental (Martín Carretero, 2016). Además, debemos favorecer el uso de la bicicleta con una buena red que carriles bicis, donde prime más la calidad que la extensión de los mismos. El carril bici tiene que ser seguro, conectado, accesible, directo, atractivo, conveniente, integrado con el sistema de transporte público y las instalaciones de estacionamiento de bicicletas ubicadas lógicamente y diseñadas para minimizar los robos (Gonzalo-Orden et al, 2014).

Debemos perseguir un uso muy ocasional del transporte privado, reducir su velocidad máxima en la ciudad y promover el uso de un transporte público más sostenible y menos contaminante. La reducción de la velocidad de los vehículos de motor conduce a calles más amigables y promueve un aumento de los desplazamientos a pie y en bicicleta. Adicionalmente, es una medida clave para reducir los atropellos y, en caso de que ocurran, la probabilidad de muerte de los peatones involucrados en esos accidentes (Gonzalo-Orden et al, 2016, 2018).

Otra ventaja de la movilidad sostenible a pie, en bicicleta o en transporte público es el desarrollo de la vida social de la ciudad a través de un contacto más directo entre las personas que participan en ella. Esta idea de hacer más participativa a la ciudad es el objetivo que persigue Francesco Tonnuci (2006) que desde 1991 trabaja en su proyecto *La ciudad de los niños*. Este autor considera que a los niños y niñas se les está privando de experiencias fundamentales para su desarrollo al no disponer de tiempo libre ni de un espacio público compartido. La idea es que los niños interactúen con otras personas más allá de su núcleo familiar, creando conciencia de barrio, donde todos nos conocemos. Además, se reduce la contaminación ambiental, las emisiones de gases de efecto invernadero a la atmósfera y se mejora la seguridad vial.

1.2 Movilidad sostenible y educación

Se precisan medidas y actuaciones que nos ayuden a concienciarnos de la necesidad de este cambio y por eso es fundamental la educación cívica y el ejemplo de todos. Necesitamos la colectividad social para conseguir avances en la movilidad sostenible (Torres Castejón, 2014). “Sin participación ciudadana no puede haber movilidad sostenible” (Carbonell, 2014). En este punto consideramos que un núcleo muy importante de actuación son los centros escolares y sus formadores. Educar a los maestros, a los alumnos y a sus familias en movilidad sostenible es una estrategia fundamental para que no se comentan los errores del pasado, fomentando la autonomía y la seguridad de todos. Dado el carácter obligatorio de los desplazamientos de la vivienda al colegio de los niños en edad escolar, hace que el realizar un proyecto sobre movilidad sostenible sea más factible. Hay que tener en cuenta que estos itinerarios los realizan además de los menores, los padres, los profesores y el personal de administración y servicios. Se trata de un entorno que engloba a un sector importante de la población y que viene avalado por el entorno educativo.

Una forma de hacerlo es diseñando caminos escolares sostenibles, donde los protagonistas deben desplazarse a pie o en bicicleta principalmente, “un proyecto de autonomía infantil está inexorablemente vinculado a la promoción de los modos no motorizados” (Román, 2011). En el diseño y puesta en funcionamiento de un camino escolar hay muchos actores, en primer lugar, los niños, ellos van a ser los grandes beneficiarios a corto y largo plazo, los desplazamientos al colegio van a incentivar su autonomía, prevenir la obesidad infantil, socializar fuera del entorno familiar, conocer su ciudad y explorar. Por otro lado, estarían las familias, sin ellas cualquier proyecto de camino escolar sería un fracaso. La mayor dificultad con la que contamos es el miedo de los padres y madres a dejar a los menores ir al colegio solos, les preocupan los accidentes y la inseguridad en las calles. Debemos convencerles de los beneficios que conlleva la autonomía de sus hijos y trabajar con ellos sus temores. Por último, tenemos a los docentes. Es fundamental que se reflexione en las aulas sobre movilidad sostenible, un cambio de los que los profesores pueden ser partícipes y se pueden sentir protagonistas del mismo. El equipo docente es el que hará de intermediario entre los alumnos, las administraciones y las familias. Esto será posible si desde las aulas se trabaja este concepto y se realizan actividades relacionadas con la autonomía y la movilidad (Román, 2011). Para implementar este tipo de proyectos en un colegio se puede trabajar desde cualquier disciplina (lengua y literatura, Ciencias Sociales, Ciencias Naturales, Matemáticas…).

Por ese motivo, vemos cómo la literatura dirigida a niños a través de los recursos que nos ofrece, puede convertirse en una gran aliada, ya que conecta con el mundo infantil y cuenta con unas características cercanas al niño.

1.3 La literatura como medio para llegar a los niños

La literatura es de suma importancia para el ser humano, surge por la necesidad de este de contar historias, de dejar constancia de ellas a las generaciones venideras para promover determinadas conductas y como un aprendizaje de la vida. (Colomer et al., 2018). De hecho, es el único animal que tiene la capacidad de fabular (Vallejo, 2020). La literatura presenta textos abiertos que permiten la interpretación y la comprensión del mundo, al tiempo que logra desarrollar el pensamiento. De hecho "cualquier narración, infantil o no, refleja la sociedad de su época y está repleta de reflexiones sobre las personas que pueden incluir valoraciones y mensajes más o menos intencionados y más o menos explícitos" (Colomer et al., 2018).

La literatura cuenta con una serie de rasgos y funciones que hacen que esta disciplina sea idónea para trabajar con los niños. Destaca, entre otras cualidades, su carácter lúdico cercano al mundo infantil y a su mundo interior. Provoca la reflexión en los más pequeños, la construcción de su propio pensamiento, el acceso a la representación de la realidad y la socialización, el contacto con otras personas que desembocará en cambios generados por ese contacto. Así mismo, la literatura se relaciona con los juicios de valores. La función axiológica tiene que ver con esas historias abiertas donde los niños son capaces de hacer su propia interpretación, con temas transversales, los valores humanos y que dejan a la imaginación del niño elaborar su propio pensamiento crítico (Guimarães, 2013). Además, nos ofrece una serie de personajes que se identifican con los lectores, los protagonistas suelen ser niños o adolescentes cuyas preocupaciones e intereses suelen coincidir con el lector al que va dirigida la historia (Gutiérrez, 2016). Por estas razones, creemos que puede ser un buen recurso para transmitir las ideas que persigue la movilidad sostenible e involucrar a niños y docentes en este cambio tan necesario.

2. LA MOVILIDAD SOSTENIBLE Y LA LITERATURA INFANTIL

En este apartado mostraremos algunos materiales y ejemplos de aplicación donde podemos ver cómo la narrativa es la protagonista para acercar la movilidad sostenible a los niños.

El Ministerio para la transición ecológica y el reto demográfico pone a disposición de los usuarios una serie de recursos para trabajar la movilidad sostenible. En muchos casos, estos vienen dados a través de la literatura infantil. Es el caso de *Caperucita camina sola* (Gea21, 2010), un cuento-exposición que pretende devolver la autonomía a los niños y que caminen por la ciudad donde se aboga por devolver el espacio que les ha sido arrebatado por el "coche feroz". En este cuento se repiten las fórmulas tradicionales, pero adaptándolo a la problemática que aquí se presenta, para más adelante, analizar los problemas de obesidad, contaminación urbana, diseño urbano… Otro recurso que hemos encontrado es *Detective de lo nunca observado. La movilidad urbana: el camino escolar* (Monterrubio et al, 2004) donde se busca incentivar que los niños lleguen al cole caminando, desarrollen su autonomía, fomenten las relaciones sociales y conozcan el barrio. En él se comienza con la lectura dramatizada del cuento *¿Sois vosotros los Reyes Magos?*, con el que se pretende introducir cómo una misma realidad se ve de manera diferente por parte de los adultos y de los niños. Con este recurso presentan el elemento mágico para acercar la narración a los más pequeños. En el 2005, el Ayuntamiento de Segovia lanza una propuesta titulada *Tras las huellas del camino escolar* donde la motivación e introducción del tema corre a cargo de un cuento, *La niña de la nube* (Monterrubio et al, 2005). En él, se muestra la invisibilidad de algunos colectivos, en el diseño de las ciudades y que afectan directamente a su movilidad urbana. También en 2005, la Diputación de Guipúzcoa edita una unidad didáctica titulada *¡Muévete!, una unidad didáctica sobre la movilidad sostenible* (Prieto de Blas y Cid, 2005) que propone la lectura de una serie de cuentos que se pueden relacionar con el tema de la movilidad sostenible. En estos casos, aunque se trata de libros de corte más informativo, cuentan con un personaje literario cercano al mundo infantil que facilitará el aprendizaje.

La Dirección General de Tráfico (DGT) lanza el *Proyecto Stars* que busca promocionar la movilidad sostenible a la escuela e incrementar la autonomía infantil. Así mismo, propone establecer un programa paneuropeo de acreditación y compartir el conocimiento entre ciudades, regiones y centros educativos. Se recomienda que las intervenciones sean continuadas en el tiempo para provocar el cambio que se pretende conseguir y de esta forma dejar el vehículo privado motorizado como forma de movilidad muy ocasional. Entre los recursos que nos ofrece encontramos herramientas literarias que nos permiten poner en contacto a los más pequeños con la necesidad de un cambio de comportamiento para movernos por las ciudades. Por ejemplo, *Clara tiene dos caminos*, editado por el Ayuntamiento de Madrid (2009). Clara tiene una edad parecida a los lectores lo que permite que se identifiquen con ella y se vean capaces de crear sus caminos "de la risa" y no "de la prisa". El elegir un camino u otro repercute en la conservación del planeta. Se muestran conceptos como el cambio climático, el efecto invernadero, los gases que provocan este efecto y qué podemos hacer para bajar los niveles de contaminación. Otro cuento que nos ofrecen es el de *Silvia y su triciclo* (Gómez y Urberuaga, 2013), que tiene que ver con las dificultades que encuentran muchos ciclistas a la hora de utilizar el carril bici ya que su mal diseño apenas deja sitio para que peatón y bicicleta puedan coexistir. Un buen diseño pasa por proporcionar suficiente sitio para cada usuario. En la novela infantil *La bicicleta* *crecedera de Óscar* (Gómez, 2013) los niños, liderados por Carlota, son los motores del cambio. En *La selva de Mario* (Frabetti, 2011) se equipara la ciudad a la selva donde hay que tener cuidado con los distintos vehículos motorizados que transitan por ella.

3. PROPUESTA. OBJETIVOS Y METODOLOGÍA

Como parte de la evaluación de la asignatura de *Didáctica de la literatura infantil y de la animación a la lectura y la escritura* de cuarto curso del Grado en Maestro de Educación Primaria se planteó este proyecto para fomentar la movilidad sostenible mediante la implicación de los alumnos en un problema real. Este proyecto contó con la financiación y ayuda que ofrece el centro de cooperación de la Universidad de Burgos.

Queríamos saber si desde nuestra asignatura podíamos diseñar materiales didácticos para trabajar la movilidad sostenible en la etapa de educación primaria. Como objetivos de nuestra intervención en el aula, marcamos los siguientes:

- Formar a los futuros maestros de educación primaria en movilidad sostenible.
- Ayudar y guiar a estos universitarios en el diseño de propuestas didácticas centradas en la movilidad sostenible a través de la narrativa infantil como recurso principal.
- Utilizar estas propuestas en las aulas de primaria para promover esta movilidad.

Comenzamos con la creación de grupos cooperativos formados por entre tres y cinco miembros. A continuación, se reservaron dos clases prácticas para la formación, con el apoyo de expertos, en movilidad sostenible y para marcar los contenidos esenciales que debería tener la unidad didáctica. En paralelo, se acordó con el CEIP Río Arlanzón de Burgos que las propuestas didácticas irían destinadas a 4º y 5º curso de primaria.

Debido a la COVID-19 nuestros estudiantes universitarios no pudieron tener contacto directo con las aulas de primaria por lo que se readaptaron las propuestas para poder ser grabadas en vídeo simulando una clase real. Como complemento se prepararon diversos materiales que fueron entregados a los profesores del colegio junto a los vídeos, así como guías con los diferentes pasos a seguir para poner en funcionamiento las propuestas.

4. EJEMPLOS DE APLICACIÓN

A continuación, se exponen tres de las propuestas diseñadas y que utilizan la narrativa infantil como recurso literario.

Propuesta 1: *Movilidad sostenible por mi ciudad. El camino al colegio*.
Los objetivos relativos a la literatura infantil son conocer e identificar personajes literarios; diseñar un camino escolar acompañados por alguno de estos personajes y trabajar el texto descriptivo. Los objetivos en movilidad sostenible son aprender en qué consiste dicha movilidad; promover el pedibús y el bicibús y desarrollar la autonomía de los niños.

Esta propuesta está basada en un artefacto literario titulado *En el Bosque* (Matute y Odriozola, 2017). Esta pequeña caja contiene una serie de cartas con personajes, reales e imaginarios, ubicados en un bosque y que les permite a los niños ir construyendo su propio camino y contar sus propias historias. A través de este recurso, los alumnos universitarios diseñaron cartas que representaban el camino desde la casa hasta el colegio. De esta forma pretenden que los niños creen su propio camino al cole, observando qué establecimientos encuentran y escogiendo los personajes que quieren que los acompañen en el trayecto al colegio. Esta propuesta se inicia con una actividad para saber qué medios de transporte conocen para desplazarse por la ciudad, cómo vienen los niños al cole, si su forma de desplazarse es sostenible o no y si les gustaría cambiar la forma en la que vienen al cole:

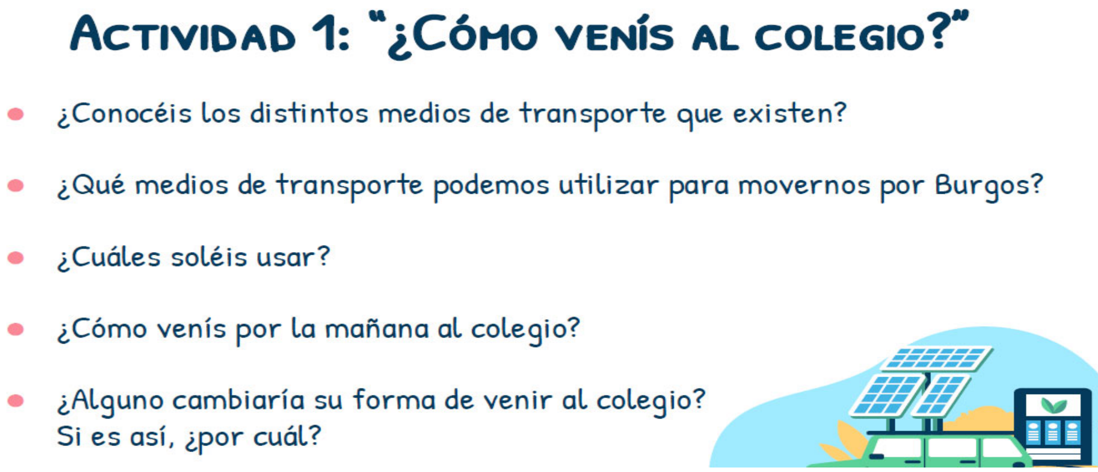

Fig 1. - Actividad de conocimientos previos. Realizada por María Gil, Miriam Morquillas, Paula Perdigones y Ana Saiz.

Con este ejercicio se pretende que los niños reflexionen sobre cómo nuestras acciones diarias son capaces de afectar a nuestro planeta y de las posibilidades que tenemos para poder cambiarlo. La siguiente actividad es un vídeo donde Lola, la protagonista, parece no estar muy contenta con ir en coche al colegio, le gustaría ir más en bicicleta o andando como hacen algunos de sus compañeros. Lola mandará una carta a la clase para que los niños propongan ideas para convencer a su madre para ir al cole con sus compañeros sin necesidad de utilizar el coche.

Fig. 2. - Lola va al colegio. Fotograma del vídeo realizado por María Gil, Miriam Morquillas, Paula Perdigones y Ana Saiz.

Lo más probable es que la protagonista represente la realidad de muchos de los alumnos, que de forma habitual acuden al centro escolar en coche. Las soluciones que le pueden dar a Lola se pueden aplicar para sus propios desplazamientos. Los alumnos escribirán a Lola una carta donde pondrán sus propuestas. Una vez que ellos hayan dado soluciones para que Lola vaya al colegio andando o en bicicleta, el docente les propondrá diseñar su propio camino al colegio, que se fijen en qué establecimientos se encuentran y con quiénes se cruzan. Para completar su camino deberán elegir alguno de los personajes literarios que les sean familiares (Tintín, Matilda, Jerónimo Stilton, Alicia, el Grinch…).

Propuesta 2: ***El futuro en tus manos.***
Los objetivos que se persiguen acerca de la literatura son reconocer textos e historias interactivas. En cuanto a los objetivos de movilidad sostenible se trata de concienciar a los alumnos de la importancia de esta movilidad, el gran impacto que puede tener en el medio ambiente y recordarles que nuestros actos tendrán repercusión en un futuro.

En este caso, la fuente literaria de inspiración va a ser *Pesadillas* de R. L. Stine que presentan una lectura interactiva donde el lector es quien elige qué ocurre en la historia. En publicaciones más actuales destaca ¡*Resuelve el misterio!* de Lauren Magaziner con el mismo tipo de lectura y que tiene gran éxito entre los jóvenes lectores. En este caso, los alumnos universitarios titularon su historia interactiva *El futuro está en tus manos*.

Fig. 3. - Lola va al colegio. Fotograma del vídeo realizado por Sergio Pellón, Javier Rodríguez y Jorge Sanz.

Para ello, se creó una historia de corte futurista donde nuestro planeta es prácticamente inhabitable por lo que se decide enviar a un grupo de tres personas al pasado, concretamente al año 2020, año en el que aún estamos a tiempo de salvarlo. En esta historia los alumnos de primaria deberán decidir cómo sigue la historia para preservar la Tierra y que sea habitable. El cómo nos desplazamos será importante para llegar al final de la historia con éxito. Además, los alumnos, a medida que avanzan en la lectura, realizarán *El manual de las buenas decisiones* donde apuntarán cuáles son las mejores opciones para cuidar el mundo y hacer que no haya cambios irreversibles en el planeta.

Propuesta 3: ***Voy al cole en bici*.**

El objetivo literario es el reconocimiento e identificación de las partes de un cuento. En cuanto a los objetivos en movilidad sostenible se persigue concienciar del grave problema que supone la contaminación en las ciudades; proponer alternativas para reducir la contaminación procedente de los distintos medios de transportes y promover y fomentar los desplazamientos por la ciudad en bicicleta. Esta propuesta se inicia con una actividad en la que se evalúan los conocimientos previos para contextualizar el tema:

Fig. 4. - Actividad previa realizada por Ángela Hernando, Jimena Manso, Mónica Merino, y Lorena Villagra.

El recurso literario con el que se va a trabajar es un cuento de Gianni Rodari titulado *El flautista y los automóviles* de su libro *Cuentos para jugar* (1993). Este cuento se basa en *El flautista de Hamelín*, pero en vez de ratones, esta ciudad está invadida de coches. Rodari diseña tres finales alternativos para solucionar el problema. A los alumnos se les va a pedir que inventen su propio final. Entre todas las posibilidades de movilidad sostenible que surgen de la actividad, se decidió trabajar el desplazamiento en bici. En este caso, los alumnos tendrán que proponer su propio carril bici, añadir o inventarse las señales y solucionar algunos de los problemas que presenta el carril bici actual:

Fig. 5. - Situación real del carril de Burgos. Información localizada por Ángela Hernando, Jimena Manso, Mónica Merino, y Lorena Villagra.

Para ponerse en contacto con los alumnos decidieron enviar un vídeo en formato de informativos, donde contaban todo lo acontecido sobre el carril bici.

5. CONCLUSIONES

En este proyecto hemos podido verificar que es posible crear material para trabajar la movilidad sostenible a través de la asignatura *Didáctica de la Literatura Infantil y de la animación a la lectura y escritura* que se imparte en 4.º de grado en Maestro de Educación Primaria.

Queda demostrado que la narrativa infantil es un buen recurso para trabajar esta temática ya que presenta unas características muy cercanas a la naturaleza del niño que hace que pueda servir de estímulo, de medio de reflexión, de desarrollo del pensamiento crítico…

Los alumnos universitarios se han formado en movilidad sostenible y han sido capaces de transmitir estas ideas a los alumnos de primaria. Todos ellos se han concienciado de la importancia de cuidar el medio ambiente y cambiar nuestros hábitos de movilidad.

La experiencia ha sido un éxito, los alumnos han estado muy involucrados en sus respectivos proyectos educativos. El proyecto se adaptó a los cambios inesperados por la pandemia del COVID-19. El estado de alarma sanitaria no nos permitió acceder al colegio, y tampoco que las actividades se llevaran a cabo en un tiempo determinado. Imprevistos como el confinamiento de clases, de tutores o de alumnos universitarios, hizo que no se pudieran llevar las propuestas cuando correspondía, dejando libertad a cada tutor del colegio para hacerlo cuando pudiera. No obstante, los futuros maestros desarrollaron material y propuestas didácticas que llegaron a los alumnos de primaria.

Todo esto abre nuevas líneas de trabajo, donde se pueda profundizar, no solo en el desarrollo de propuestas educativas relacionadas con la narrativa, sino también con otros géneros literarios y con la medición de los conceptos aprendidos y cambios de comportamiento sobre la movilidad sostenible.

AGRADECIMIENTOS

Este trabajo forma parte del proyecto *Integración de la movilidad sostenible en la educación primaria a través de la dramatización* de la II Convocatoria de Proyectos de Innovación Docente y Transformación Social en Aprendizaje y Servicio (ApS) para el Curso Académico 2020-2021 de la Universidad de Burgos y subvencionado por el Vicerrectorado de Internacionalización, Movilidad y Cooperación, el Vicerrectorado de Estudiantes de la Universidad de Burgos y el Ayuntamiento de Burgos.

Finalmente, los autores quieren agradecer al CEIP Río Arlanzón, Asociación Andando Burgos, DGT Burgos, AMPA Torre de Babel y a los alumnos de la asignatura de *Didáctica de la literatura infantil y de la animación a la lectura y la escritura* del Grado en Maestro de Educación Primaria, su colaboración en el desarrollo del estudio.

LA INGENIERÍA DEL TRANSPORTE EN LA UNIVERSIDAD ESPAÑOLA: ESTRUCTURACIÓN DE LAS ENSEÑANZAS Y DESCRIPCIÓN DE CONTENIDOS EN TITULACIONES VINCULADAS A LA INGENIERÍA CIVIL

José María Díaz y Pérez de la Lastra
Profesor de Transportes. Universidad de Cantabria. España

RESUMEN

Para los que no es ajeno el mundo universitario, no es ninguna sorpresa el afirmar que la adaptación de los títulos universitarios españoles al Espacio Europeo de Educación Superior –EEES- ha supuesto una reforma profunda en la concepción de múltiples aspectos que abarcan desde el "diseño" de las titulaciones y la verificación oficial de las mismas hasta las metodologías docentes utilizadas o evaluación de los alumnos.

En el ámbito de la "Ingeniería Civil" –como en otras muchas ingenierías- una de las principales diferencias que separa la forma de "diseñar" los títulos que habilitan para las profesiones reguladas de "Ingeniero Técnico de Obras Públicas" y de "Ingeniero de Caminos, Canales y Puertos" antes y después de los cambios suscitados por el EEES, estriba en la manera de entender el cómo proporcionar la formación adecuada en las bases teóricas y en las tecnologías propias de estas Ingenierías: mientras en la situación anterior se determinaban las materias troncales de obligatoria inclusión en todos los planes de estudios, con descripciones de contenidos, créditos y vinculación a áreas de conocimiento, en la situación posterior se plasman los requisitos formativos en forma de adquisición de competencias, dando una mayor libertad y flexibilidad en la configuración de las materias (denominaciones, contenidos, duración).

Ante esa falta de referentes comunes que caracterizaban los planes de estudio en el pasado, el presente trabajo pretende ofrecer una "fotografía" actual y un análisis de cómo las Escuelas que ofertan títulos en el ámbito de la "Ingeniería Civil" han integrado en sus planes de estudio los contenidos ligados a la Ingeniería e Infraestructura de los Transportes, tanto de los Grados como de los Másteres que habilitan para el ejercicio de las profesiones arriba mencionadas. El objetivo no es otro que promover una "discusión" sobre la realidad actual de las enseñanzas en esta materia y sobre la necesidad o no de homogeneizar materias y contenidos. Para ello se han analizado los contenidos de un total de 209 asignaturas (68 de Máster y 141 de Grado) incardinadas en 13 títulos oficiales de Máster y 30 de Grado impartidos en las universidades públicas españolas.

1. ANTECEDENTES

En el pasado Congreso de Ingeniería del Transporte (CIT 2018) celebrado en Gijón en junio de 2018, este mismo autor presentó una ponencia bajo el título "La enseñanza universitaria en España de la Ingeniería del Transporte en el ámbito de la Ingeniería Civil".

En dicho trabajo se analizó con carácter general y global el papel de la enseñanza de la Ingeniería del Transporte en la diversidad de itinerarios formativos que habilitan para el ejercicio de profesiones reguladas de Ingeniero Técnico de Obras Públicas -en cada una de sus tres especialidades- y de Ingeniero de Caminos, Canales y Puertos. Para ello se realizó, en primer lugar, una introducción en la quedaron patentes los cambios más relevantes ligados a la adaptación de las enseñanzas al EEES y en concreto las de Grado y Máster en el ámbito de la "Ingeniería Civil" que habilitan para ejercer las profesiones reguladas mencionadas; para, a continuación, avanzar sobre el cómo esos cambios han afectado a la enseñanza de las disciplinas ligadas a la "Ingeniería del Transporte". Tras ello, se realizó un repaso muy sintético de los contenidos de las asignaturas englobadas en el campo de la Economía, Planificación y Explotación del Transporte, a las que se sumaron las de la Logística y la Intermodalidad, así como la Movilidad y el Transporte Urbano. Y finalmente se abordó un estudio de los recursos puestos a disposición del desarrollo de la docencia de la "Ingeniería del Transporte", en concreto el relativo al personal docente. El objetivo de aquel trabajo estaba orientado a perfilar una hipotética necesidad de coordinar las enseñanzas en este campo de la ingeniería que facilitase y garantizase el paso o tránsito entre los grados y los másteres, así como una homogeneización –que no uniformidad- en las condiciones de acceso a ambas profesiones.

Algunos elementos clave de aquel trabajo que pueden servir para "arrancar" y entender mejor el desarrollo de la presente ponencia, fueron los siguientes:

- En primer lugar, el proceso de adaptación al EEES conllevó un cambio en el diseño de los títulos, pasando de lo que era una determinación de las materias troncales de obligatoria inclusión en todos los planes de estudios a una nueva situación en la que se plasman los requisitos formativos en forma de adquisición de competencias.
- En segundo lugar, se ha pasado de una situación en la que la habilitación para el ejercicio de profesiones reguladas se obtenía con una única titulación a otra situación en la que la habilitación para algunas profesiones conlleva la consecución de dos títulos, uno de Grado y otro de Máster. Es el caso de la profesión "Ingeniero de Caminos, Canales y Puertos" cuya formación se "diseñaba" desde el primer curso de la titulación que habilitaba para dicha profesión mientras que en la actualidad su formación, a través de un Máster, toma como punto de partida un título de Grado diseñado para ejercicio de otra profesión. Además, los estudiantes que acceden actualmente al Máster lo hacen con perfiles diversos como consecuencia de la mención o especialización realizada en sus estudios del Grado que les habilita para la profesión de Ingeniero Técnico de Obras

Públicas, lo que implica necesariamente la existencia de diferencias en la forma de asimilar determinadas materias, especialmente las tecnológicas.

- Y, en tercer lugar, como consecuencia de lo anterior, se da la circunstancia que entre las competencias que recoge la Orden CIN/307/2009 de 9 de febrero, para la obtención del Grado que habilita para ejercer la profesión de Ingeniero Técnico de Obras Públicas, no existe referencia alguna a las diferentes disciplinas englobadas en la “Ingeniería del Transporte” en el tronco común de los títulos ni en el “Módulo de Tecnología Específica” de la especialidad de “Hidrología”. De ello pueden derivarse posibles “carencias” de competencias esenciales con las que algunos graduados acceden al Máster que habilita para la profesión de Ingeniero de Caminos, Canales y Puertos y que muy pocos centros universitarios en donde se imparte el Máster tratan de paliar mediante asignaturas complementarias que corrijan la situación.

Con estos antecedentes, el Foro de Ingeniería de los Transportes (FIT) quiso ofrecer a sus socios una “fotografía” lo más actual y concreta posible de cómo las diferentes Escuelas han decidido integrar en sus planes de estudio las asignaturas y contenidos ligados a la Ingeniería e Infraestructura de los Transportes en títulos universitarios oficiales, tanto de los Grados que habilitan para el ejercicio de las profesión de Ingeniero Técnico de Obras Públicas como de los Másteres que lo hacen para la profesión de Ingeniero de Caminos, Canales y Puertos. Y para ello, el autor de esta ponencia elaboró un documento que pudiera concebirse como material de trabajo para a posteriori promover una “discusión” sobre la realidad actual de las enseñanzas en esta materia.

Dicho documento se puso un año más tarde, en septiembre de 2019, a disposición de los socios del Foro de Ingeniería de los Transportes a través de su WEB. La información recogida en el mismo correspondía a 209 asignaturas (63 de Máster y 147 de Grado) incardinadas en 13 títulos oficiales de Máster y 30 títulos oficiales de Grado impartidos en un total de 22 universidades públicas españolas. Las disciplinas tratadas son las tradicionales de Economía, Planificación y Explotación del Transporte (más otras que se han ido incorporando en las últimas décadas como la Logística y la Intermodalidad o la Movilidad y el Transporte Urbano); las de Ingeniería de Carreteras (incluyendo la Ingeniería de Tráfico o la Seguridad Vial); la Ingeniería Ferroviaria y la Explotación Ferroviaria; y la Planificación y Explotación Portuaria.

La información asociada a cada una de las asignaturas hace referencia a la universidad en donde se imparte; al título que la acoge; el curso académico en el que están situadas dentro del Plan de Estudios de la titulación; el carácter obligatorio u optativo de las asignaturas; y el número de créditos que tienen asignados. Y tras ello le siguen los temarios y contenidos de todas y cada una de dichas asignaturas. La información aportada es la misma que aparece en las “Guías Docentes” de las mismas que ofrecen en “abierto” las universidades.

Toda la información recogida en este documento y actualizada al curso 2020-21 es la que se ha manejado y analizado para la redacción del presente trabajo. Antes de la celebración del CIT 2021 se ofrecerá de nuevo a través de la WEB del Foro de Ingeniería de los Transportes, la actualización elaborada del mismo.

2. DATOS DE SITUACIÓN

Antes de entrar en el análisis de cómo las Escuelas que ofertan títulos en el ámbito de la "Ingeniería Civil" han integrado en sus planes de estudio los contenidos ligados a la Ingeniería e Infraestructura de los Transportes, se ofrecen algunos datos generales sobre la implantación en España de Grados y Másteres que habilitan, respectivamente, para las profesiones reguladas de Ingeniero Técnico de Obras Públicas (según especialidad ligada a la tecnología específica cursada) y de Ingeniero de Caminos, Canales y Puertos.

* Este título está siendo sustituido, curso a curso, a partir del 2020-21 por el Grado en Tecnologías de Caminos, Canales y Puertos, sin docencia aún en materia de Transportes.

Tabla 1 – Títulos habilitantes en el ámbito de la Ing. Civil. Universidades públicas.

Aunque son un total de 25 universidades, 22 públicas y 3 privadas, las que ofertan algunos de esos títulos de Grado y Máster, en este estudio repararemos únicamente en las primeras. En la Tabla 1 se muestra resumida, en una primera toma de contacto, la oferta de títulos de Grado y Máster en la universidad pública española. La oferta actual es de 30 títulos de Grado y 13 de Máster.

De entre los títulos de Grado, 26 ofertan la especialidad de Construcciones Civiles, 19 la de Hidrología y 16 la de Transportes y Servicios Urbanos. Son 13 de las 22 universidades públicas las que ofertan las 3 especialidades. Y de entre las 13 universidades que ofertan el Máster, una carece de la especialidad en Construcciones Civiles (Castilla-La Mancha); a dos de ellas le ocurre lo mismo con la de Hidrología (Burgos y Cantabria); y en tres no se imparte la de Transportes y Servicios Urbanos (Cantabria, Oviedo y Politécnica de Cartagena). La Universidad de Cantabria es la única que, ofreciendo el Máster, tan solo ofrece un Grado con una especialidad (Construcciones Civiles). Es verdad que hay otras 3 universidades (Coruña, Politécnica de Valencia y Politécnica de Cataluña) que imparten el Máster y tienen un Grado con la única especialidad de Construcciones Civiles, pero además de éste ofertan otro Grado con las 3 especialidades.

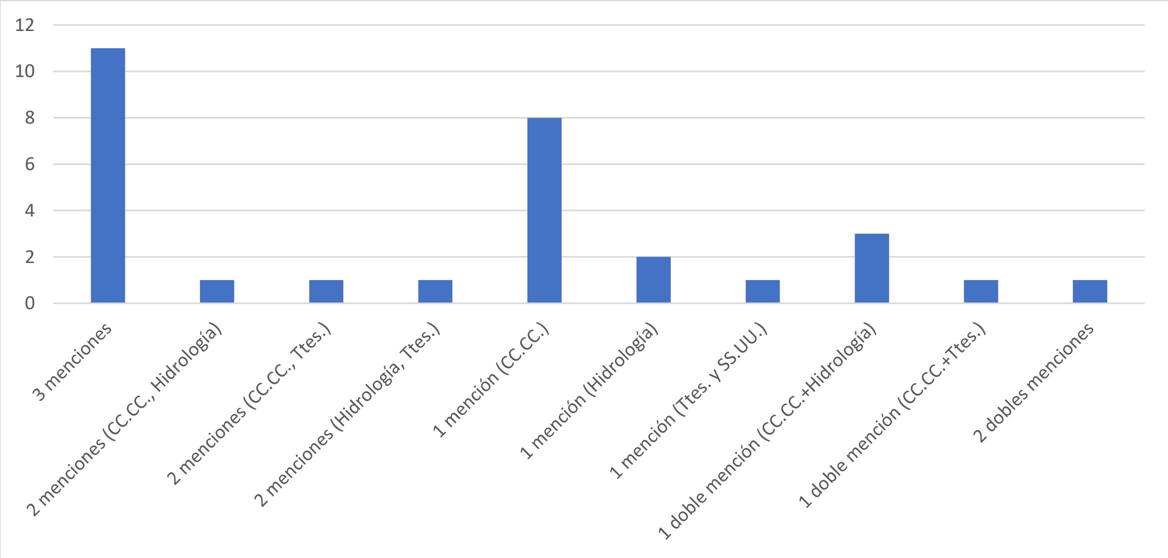

Figura 1 – Número de Grados según especialidades ofertadas

En la Figura 1 se plasma qué especialidades o menciones abordan los 30 Grados impartidos en las universidades públicas, destacando muy por encima de los demás los Grados con las tres especialidades -11 en total- y los 8 que plantean tan solo la especialidad de Construcciones Civiles. De entre los primeros hay que destacar que 8 de ellos se imparten en centros en donde también se imparte el Máster. Los Grados de 5 de los centros en donde se imparte el Máster (Burgos, Cantabria, Castilla-La Mancha, Oviedo y Politécnica de Cartagena) no se imparten las 3 especialidades.

En lo que respecta a los 8 títulos que solo tienen la especialidad de Construcciones Civiles, la mitad de ellos corresponden a centros que también imparten el Máster (Coruña, Cantabria y las Politécnicas de Cataluña y Valencia). En los 4 casos se trata de Grados cuyas enseñanzas han sido diseñadas para formar un itinerario orientado al propio Máster. Como ya se hizo referencia más arriba, salvo el caso de Cantabria, en el resto de los centros también se imparte otro Grado con las 3 especialidades.

Hacer notar finalmente de esta misma figura, que aparece al final un único título de Grado con 2 dobles menciones: Construcciones Civiles + Hidrología y Construcciones Civiles + Transportes y Servicios Urbanos. Corresponde al Grado en Ingeniería Civil que se imparte en la Escuela Técnica Superior de Ingeniería Civil de la Universidad Politécnica de Madrid y que desde el curso 2020-21 está en proceso de extinción.

Para finalizar este apartado de introducción general, y en lo que a los másteres se refiere, tan solo reflejar que únicamente 3 de los 13 títulos impartidos no tienen contempladas especialidades en los mismos. Es el caso de las 3 universidades andaluzas: Cádiz, Granada y Sevilla. Las otras 10 titulaciones abordan diferente número de especialidades, desde las 2 que se proponen desde la Universidad de Oviedo a los 11 “perfiles de intensificación” de la Politécnica de Valencia. Aun así, la mayoría de ellas, en número de 6, contemplan 3 especialidades, menciones o intensificaciones, siempre ligadas a la ingeniería de la construcción, la ingeniería del agua y la ingeniería del transporte y el territorio.

3. DATOS GENERALES EN TORNO A LA INGENIERÍA E INFRAESTRUCTURA DE LOS TRANSPORTES

Después de haber situado en el apartado anterior lo relacionado a las características generales de los títulos de Grado y Máster en el ámbito de la Ingeniería Civil en España y las especialidades que pueden seguirse en los mismos, llega el momento de abordar la docencia objeto de este trabajo, la ligada a la Ingeniería e Infraestructura de los Transportes. Las disciplinas que serán tratadas en este campo de la ingeniería son las tradicionales de Economía, Planificación y Explotación del Transporte (aquí se incorporarán también otras que se han ido incorporando en las últimas décadas como la Logística y la Intermodalidad o la Movilidad y el Transporte Urbano); las de Ingeniería de Carreteras (incluyendo la Ingeniería de Tráfico o la Seguridad Vial); la Ingeniería Ferroviaria y la Explotación Ferroviaria; y la Planificación y Explotación Portuaria.

En este apartado se estudiará dicha docencia de forma conjunta para en apartados posteriores individualizar los análisis de cada una de esas 4 disciplinas. Serán un total de 209 asignaturas las estudiadas, 141 correspondientes a estudios de Grado y 68 a estudios de Máster. En la Figura 2 se muestra una primera aproximación del reparto por disciplinas de esas 209 asignaturas, diferenciando a su vez las que se imparten en el Grado que habilita para la profesión de Ingeniero Técnico de Obras Públicas o el Máster que habilita para la de Ingeniero de Caminos, Canales y Puertos.

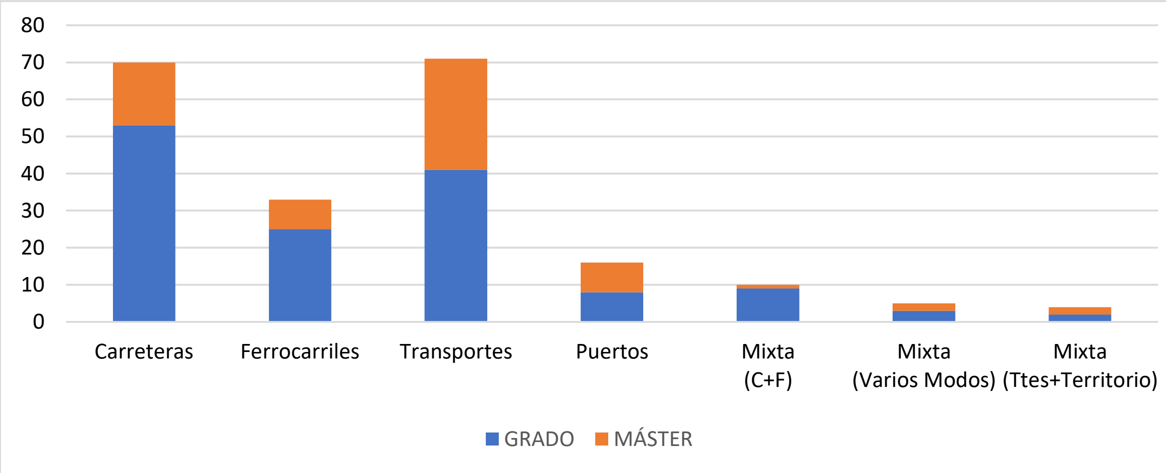

Figura 2 – Número de asignaturas según disciplinas

Aunque más adelante se profundizará sobre el carácter (troncal, obligatorio de especialidad u optativo) de dichas asignaturas, su tamaño en créditos y su ubicación en los planes de estudio de las titulaciones, baste adelantar que son la Ingeniería de Carreteras y la Ingeniería del Transporte las que agrupan las dos terceras partes de las asignaturas, siendo la primera la más importante en los títulos de Grado (su presencia es obligatoria en las especialidades de Construcciones Civiles y de Transportes y Servicios Urbanos) y la segunda en los de Máster (competencias en esa materia han de recogerse obligatoriamente en sus planes de estudio). Más reducida es la presencia de asignaturas ligadas a la Ingeniería Ferroviaria (25 asignaturas en los 30 Grados y 8 asignaturas en los 13 másteres) y más aún a la Explotación Portuaria, en este caso siempre insertadas dichas asignaturas en especialidades de Grados o Másteres. También se explicitan, finalmente, las asignaturas cuyos contenidos pertenecen a diferentes disciplinas y que se han denominado “Mixtas”, y que en muchos de los casos tienen la “misión” de satisfacer en una misma asignatura diversas competencias exigibles a la titulación. Las que mayor importancia tienen -sobre todo en los Grados- son las que engloban contenidos de Carreteras y Ferrocarriles (C+F) y de menor entidad las que asumen otras posibles combinaciones de las diferentes disciplinas o la que forman la Ingeniería del Transporte y la Ordenación del Territorio, esta última fuera del alcance de nuestro trabajo por sí misma.

	Carreteras	Ferrocarriles	Transportes	Puertos	Mixta Carretera + Ferrocarril	Mixta (Varios Modos)	Mixta Transportes + Territorio
GRADO	53	25	41	8	9	3	2
MÁSTER	17	8	30	8	1	2	2
TOTAL	70	33	71	16	10	5	4

Tabla 2 – Número de asignaturas según tipo de enseñanza oficial y disciplinas

Un siguiente paso para avanzar un poco más en el conocimiento de ese conjunto de 209 asignaturas y las disciplinas que las engloban, consiste en analizar el carácter de las mismas. De esa manera, se hablará de materia "troncal" cuando la misma haya de ser cursada obligatoriamente por todos los alumnos de una titulación; se denominará "Obligatoria de Especialidad" a toda aquella materia que, no siendo obligatoria para todos los alumnos de una titulación, sí haya de cursarse obligatoriamente en las menciones o especialidades de un Grado o en las intensificaciones, especialidades o perfiles de un Máster; y se hablará de "Optativa de Especialidad" y de "Optativa Genérica" cuando su elección corra a cargo por alumnos de una especialidad concreta o de cualquier especialidad, respectivamente.

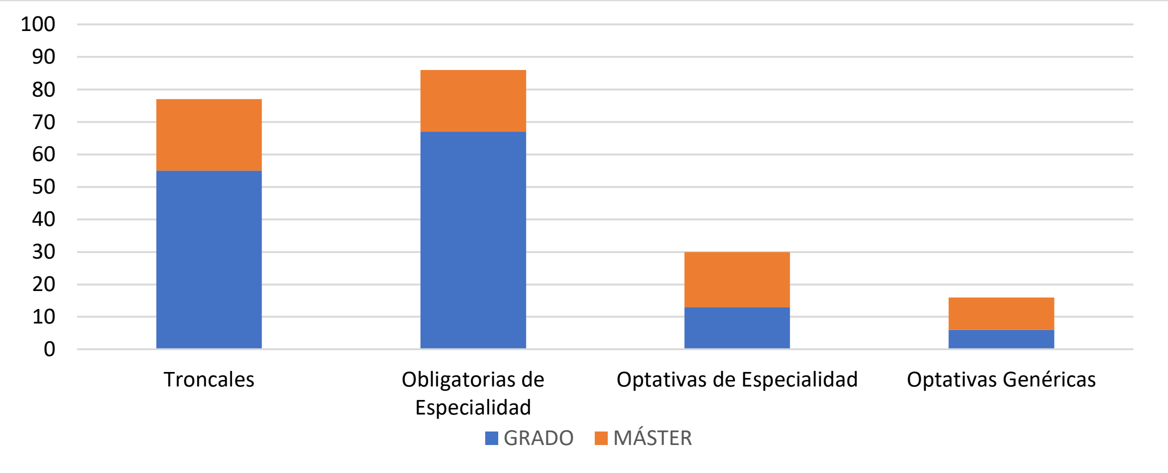

Figura 3 – Número de asignaturas según su "carácter" y tipo de enseñanza oficial

Con esta forma de caracterizar las asignaturas de un plan de estudios, se presentan en la figura 3 los datos que engloban al conjunto de asignaturas que forman parte de este trabajo. A primera vista podría pensarse que hay una buena "carga" de troncalidad en las titulaciones ofrecidas, tanto en los Grados como en los Másteres. Pero en referencia a los Grados, se veía en el apartado anterior que muchos de estos títulos solo ofrecen al alumno una única mención o una doble mención y en los que todas las asignaturas pueden considerarse "troncales" porque todas son obligatorias para todos los alumnos.

Es por ello que en la Figura 4 que se presenta a continuación puede apreciarse cómo cambia radicalmente el porcentaje de "troncalidad" en las dos situaciones presentadas: la primera de ellas corresponde al conjunto de los 30 Grados estudiados en este trabajo -con sus 141 asignaturas ya reseñadas- y la segunda a los 11 Grados que ofertan las 3 especialidades o menciones. Y es que son solo 6 Grados los que, ofreciendo las 3 especialidades en España, aportan "troncalidad" a las materias englobadas en la Ingeniería e Infraestructura de los Transportes. Corresponden esos Grados a las Universidades de La Coruña, Santiago, Sevilla y las Politécnicas de Cataluña, Madrid y Valencia. Son 10 las asignaturas troncales situadas en los planes de estudio de esas 6 titulaciones de Grado: las disciplinas de la Ingeniería de Carreteras, Ingeniería Ferroviaria e Ingeniería del Transporte aportan 2 asignaturas cada una; y las otras 4 asignaturas son con contenidos "mixtos" de Carreteras y Ferrocarriles.

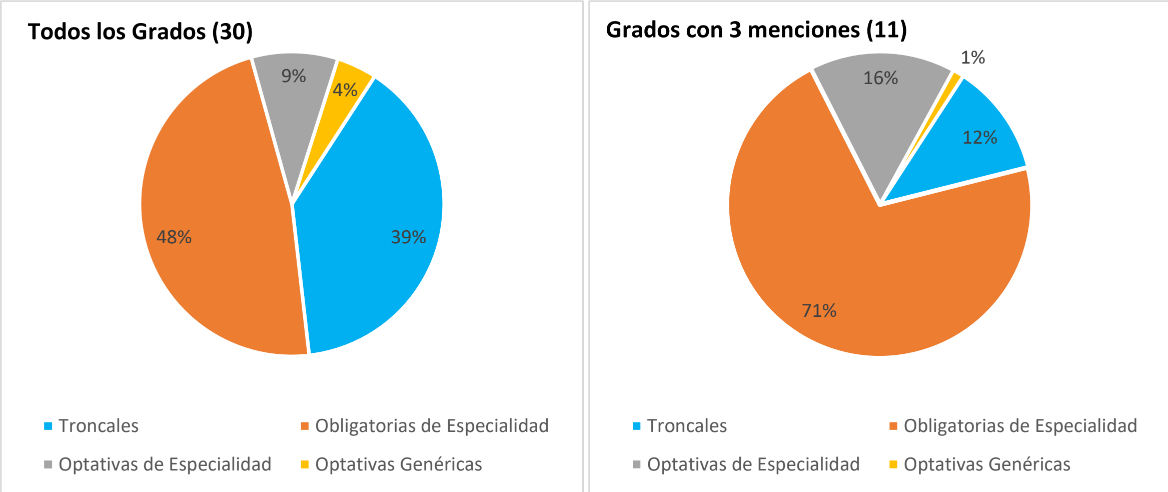

Figura 4 – Comparativa del reparto porcentual de asignaturas según su carácter para el conjunto de los Grados estudiados y los que ofertan las 3 menciones

De todo lo anterior se puede colegir que las materias cuyos contenidos pertenecen a la Ingeniería e Infraestructura de los Transportes no forman parte de la formación generalista de un futuro ingeniero técnico de obras públicas y tan solo de la formación de su itinerario de especialidad. Y eso conduce a realizar la siguiente pregunta, ¿cómo tratan las diferentes especialidades la presencia de estas materias?

En la tabla 3 que se muestra seguidamente aparece reflejado, para cada una de las menciones o especialidades de las titulaciones que habilitan para la profesión mencionada, el número de Grados en cuyos planes de estudio se recogen asignaturas ligadas a las diferentes disciplinas en que se ha dividido en este trabajo la Ingeniería e Infraestructura de los Transportes. Como ya se hizo anteriormente, además de mostrar las "monodisciplinares" (Carreteras, Ferrocarriles, Transportes y Puertos) se han incorporado las de las materias que comparten contenidos de 2 o más disciplinas y que se han denominado "Mixtas".

	Titulaciones de Grado en la que está presente	Carreteras	Ferrocarriles	Transportes	Puertos	Mixta Carretera + Ferrocarril	Mixta (Varios Modos)	Mixta Transportes + Territorio
Mención en Construcciones Civiles	26	22	19	10	0	6	1	1
Mención en Hidrología	19	8	6	3	0	5	0	0
Mención en Transportes y SS.UU.	16	14	10	16	5	5	2	1

Tabla 3 – Grados con asignaturas obligatorias de las diferentes disciplinas por tipo de mención

A la vista de esa tabla llama la atención que no todas las titulaciones de Grado con especialidad o mención en Construcciones Civiles o Transportes y Servicios Urbanos tengan asignaturas obligatorias "puras" de Carreteras y Ferrocarriles. Hay que recordar que la

"*Orden CIN/307/2009 de 9 de febrero*" en la que se plasman los requisitos formativos de los Grados que habilitan para la profesión de Ingeniero Técnico de Obras Públicas, se recogen como competencias para ambas menciones la "*Capacidad para la construcción y conservación de carreteras, así como para el dimensionamiento, el proyecto y los elementos que componen las dotaciones viarias básicas*"; y la "*Capacidad para la construcción y conservación de las líneas de ferrocarriles con conocimiento para aplicar la normativa técnica específica y diferenciando las características del material móvil*". Y la solución en varios casos para dar cumplimiento a las exigencias normativas es la de diseñar asignaturas con contenidos de dos o más disciplinas, y en concreto, para el caso reseñado más arriba, la de asignaturas con contenidos de Carreteras y Ferrocarriles.

Para comprobar que eso es así, se introduce a continuación la tabla 4 en la que se muestra de nuevo, para cada una de las menciones o especialidades de los Grados, el número de ellos en cuyos planes de estudio hay asignaturas con contenidos únicos o parciales de cada una de las 4 disciplinas.

	Titulaciones de Grado en la que está presente	Carreteras	Ferrocarriles	Transportes	Puertos
Mención en Construcciones Civiles	26	26	25	12	0
Mención en Hidrología	19	13	11	3	0
Mención en Transportes y SS.UU.	16	16	15	16	5

Tabla 4 – Grados con asignaturas obligatorias que acogen contenidos –total o parcialmente- de las diferentes disciplinas, por tipo de mención

La visualización de esta nueva tabla permite comprobar que la totalidad de los Grados que ofertan la mención de Construcciones Civiles y la de Transportes y SS.UU. acogen contenidos de Carreteras y, en el segundo de los casos, también de Transportes. Aparentemente hay una universidad cuyo título de Grado carece de contenidos obligatorios de Ferrocarriles. Y a efectos de este trabajo es así, pues aunque tiene una asignatura obligatoria denominada "Sistemas e Infraestructuras del Transporte" con un único tema genérico de Ferrocarriles, para este estudio ha sido considerada de Carreteras pues tiene 12 temas de esta disciplina en la que recorre todos los bloques habituales de la misma.

Al margen de estas disquisiciones, sí puede ser importante hacer hincapié en un hecho que puede tener trascendencia para aquellos alumnos que tras la realización de un Grado que habilite para la profesión de Ingeniero Técnico de Obras Públicas con la especialidad de "Hidrología", quiera hacer el Máster que habilita para la de Ingeniero de Caminos, Canales y Puertos. La realidad actual en España es que solo 13 de los 19 Grados que contienen esa mención, tienen asignaturas con contenidos de Carreteras (y 5 de ellas de carácter "Mixto" al repartir dichos contenidos con los de Ferrocarriles) y por tanto hay 6 Grados, impartidos en otras tantas universidades, que en dicha especialidad carecen de asignaturas obligatorias de Carreteras. Dos de esas universidades tienen la posibilidad de "solucionar" esa carencia con una asignatura en sus másteres respectivos, pero el resto no, ya sea porque su Máster no tiene esa posibilidad o porque carece de Máster y tienen que hacerlo en otra universidad. Teniendo en cuenta que solo 3 másteres de los 13 que se imparten en la universidad pública de España tienen asignaturas obligatorias de Carreteras y en general no de carácter básico sino de complemento a lo estudiado en el Grado; y que son muy pocas –un total de 4- las que imponen asignaturas con complementos de "nivelación" de conocimientos, se puede llegar a la sencilla conclusión de que hay muchas posibilidades de que alumnos que han realizado el Grado en alguna de esas universidades lleguen posteriormente a habilitarse para la profesión de Ingeniero de Caminos, Canales y Puertos sin haber recibido contenidos de Carreteras. Y si son 6 los Grados en lo que ocurre esa situación con la disciplina de Carreteras, llega al número de 8 si la que se analiza es la de Ferrocarriles, llegando a las mismas conclusiones. No es tan importante con la disciplina de Ingeniería del Transporte por la obligatoriedad de incluir contenidos de la misma en los Másteres.

Para terminar este apartado se aportarán también algunos datos de carácter global sobre los másteres que habilitan para la profesión de Ingeniero de Caminos, Canales y Puertos. Más arriba se ofrecieron dos figuras en las que se visualizaban el número de asignaturas según tipo de "disciplina" y según "carácter" de las mismas. En la tabla 5 que sigue se muestra de forma conjunta el número de másteres que dan cabida a las diferentes disciplinas de la Ingeniería e Infraestructura de los Transportes y el número de asignaturas de cada disciplina. Además, se ha hecho discriminando dichas asignaturas según el carácter troncal, obligatorio de especialidad u optativo que ya se utilizó con anterioridad.

	Carreteras		Ferrocarriles		Transportes		Puertos		Mixta	
	Másteres	Asignaturas	Másteres	Asignaturas	Másteres	Asignaturas	Másteres	Asignaturas	Másteres	Asignaturas
Troncales	3	3	2	2	13	15	0	0	2	2
Obligatorias de Especialidad	5	7	3	3	3	4	3	3	2	2
Optativas de Especialidad	3	5	2	2	3	6	3	4	0	0
Optativas Genéricas	2	2	1	1	4	5	1	1	1	1

Tabla 5 – Nº de másteres y asignaturas según su "carácter" y disciplinas de los contenidos

Teniendo en cuenta que son 13 los másteres impartidos en la universidad pública española, de la primera impresión de los datos se deduce la escasa presencia de troncalidad de la Ingeniería de Carreteras (tan solo en 3 másteres) y de la Ingeniería Ferroviaria (en 2 másteres). Mayor presencia, pero aun así escasa, en aquellos másteres que tienen una especialidad en "transportes". En apartados anteriores se aportaba el dato de que 10 de los 13 másteres impartidos participaban del hecho de tener especialidades. Pues de todos ellos, 9 másteres tienen la opción de seguir una especialidad en el campo del "Transporte". Es por ello que sigue resultando insuficiente que a pesar de ser numerosos los másteres con itinerarios de intensificación en el campo del transporte, son solo 5 los másteres que acogen obligatoriamente asignaturas de Ingeniería de Carreteras y 3 los que hacen lo propio con las de Ingeniería Ferroviaria. Con todo lo comentado vuelve a hacerse más crítica la situación comentada con anterioridad referida a los Grados: la práctica totalidad de la formación en estas dos disciplinas dependerá de lo recibido en los estudios de Grado. Reiterar por ello, el hipotético problema al que se pueden enfrentar los alumnos que cursen la mención de Hidrología cuando en sus planes de estudios de sus grados no exista troncalidad en estas disciplinas; o la carencia a la que se pueden encontrar -incluso en las otras 2 menciones- cuando los conocimientos en estas 2 disciplinas se solventen con asignaturas únicas que comparten contenidos de ambas. Y esto ocurre en 8 de los 30 Grados impartidos.

Finalmente volver a incidir de la presencia de troncalidad en todos los másteres de contenidos de Ingeniería del Transporte para cumplir con lo dispuesto en la Orden CIN/309/2009 de 9 de febrero por la que se establecen los requisitos formativos de los Másteres que habilitan para la profesión de Ingeniero de Caminos, Canales y Puertos, donde se recogen como competencias los "*conocimientos de la ingeniería y planificación del transporte, funciones y modos de transporte, el transporte urbano, la gestión de los servicios públicos de transporte, la demanda, los costes, la logística y la financiación de las infraestructuras y servicios de transporte*". Y la inexistencia de troncalidad para contenidos en Planificación y Explotación Portuaria, cuya presencia en los planes de estudio de los másteres quedan prácticamente limitados a itinerarios de especialización.

4. LA INGENIERÍA DE CARRETERAS

Ya se ha comentado anteriormente que la presencia de contenidos de la disciplina "Ingeniería de Carreteras" está principalmente recogida en las enseñanzas de Grado y muy escasamente en las de Máster. Seguidamente se adentrará en el análisis de esta disciplina discretizando la información según el tipo de titulación impartida.

4.1 La Ingeniería de Carreteras en los estudios de Grado

En referencia a los estudios de Grado, son 53 las asignaturas cuyos contenidos son íntegramente de esta disciplina. Su reparto es el siguiente:

- 2 asignaturas troncales en planes de estudio que incorporan las 3 menciones (los Grados en Ingeniería Civil de la UPM y de la Universidad de Sevilla).
- 17 asignaturas troncales en un total de 12 Grados que incorporan en sus planes de estudio 1 o 2 menciones (salvo en 2 de estos Grados, todos los demás tienen al menos la mención de Construcciones Civiles).
- 4 asignaturas obligatorias en la especialidad de Construcciones Civiles en Grados con las 3 especialidades.
- 1 asignatura obligatoria en la especialidad de Hidrología en un Grado con las 3 especialidades (Alicante).

- 13 asignaturas obligatorias en la especialidad de Transportes y Servicios Urbanos en 9 Grados con las 3 especialidades.
- 6 asignaturas obligatorias que se imparten tanto en la especialidad de Construcciones Civiles como en la de Transportes y SS.UU. de 4 Grados con las 3 especialidades.
- 1 asignatura obligatoria que se imparte tanto en la especialidad de Hidrología como en la de Transportes y SS.UU. en 1 Grado con las 3 especialidades.
- 1 asignatura optativa que se imparte en la especialidad de Construcciones Civiles
- 5 asignaturas optativas en la especialidad de Transportes y SS.UU. de 4 Grados distintos.
- 3 asignaturas optativas no ligadas a especialidad alguna de 3 Grados distintos.

Del análisis de esta información viene a corroborarse algo que ya se adelantó en apartados anteriores: la Ingeniería de Carreteras -como el resto de disciplinas aquí tratadas- tiene su principal encaje en las especialidades de los Grados o en la troncalidad de Grados con una única mención (lo que hace que todo el plan de estudios de ese Grado esté ya orientado a la especialización), generalmente la de Construcciones Civiles, o con dos menciones, siendo en todos los casos una de ellas la de Construcciones Civiles.

Respecto al tiempo asignado para la impartición de las asignaturas, el conjunto de las 53 estudiadas tienen un "tamaño" promedio de 5,89 créditos, abundando mayoritariamente las que tienen 6 créditos. De hecho, el promedio de las troncales y obligatorias se encuentra en esa cantidad, que disminuye algo en el caso de las optativas.

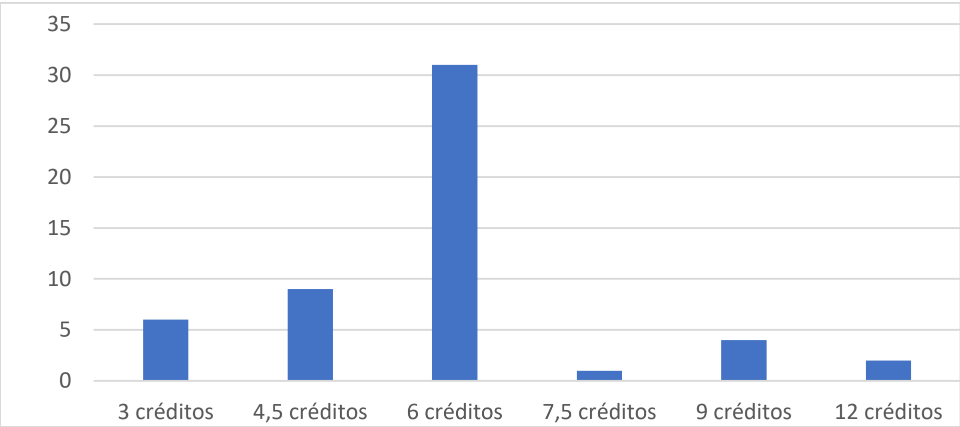

Figura 5 – Tamaño asignaturas de "Ingeniería de Carreteras" en Grados

En cuanto a los contenidos de las asignaturas, se han estudiado aquellas que se ofertan con carácter troncal o son obligatorias de las diferentes especialidades, principalmente de las de Construcciones Civiles o Transportes y SS.UU., dado que las optativas normalmente ponen su acento en cuestiones muy específicas y apenas suponen un 15% del total de asignaturas ofertadas en los Grados. Con carácter general, la inmensa mayoría de asignaturas tratan 4 aspectos esenciales de esta disciplina, normalmente en una única asignatura y en ciertos casos, en dos: ingeniería de tráfico; diseño geométrico; suelos, explanaciones y drenaje; y firmes y pavimentos. De forma más superficial, hay ciertas asignaturas que se introducen en la conservación y explotación de carreteras; en las dotaciones, señalización…; o en la seguridad vial.

En la figura 6 que aparece a continuación se muestra la importancia de esos bloques temáticos por su presencia en los contenidos de esas 43 asignaturas que de forma obligatoria -ya sea por troncalidad o en los itinerarios de especialidad- se ofertan en los Grados bajo la disciplina de la "Ingeniería de Carreteras".

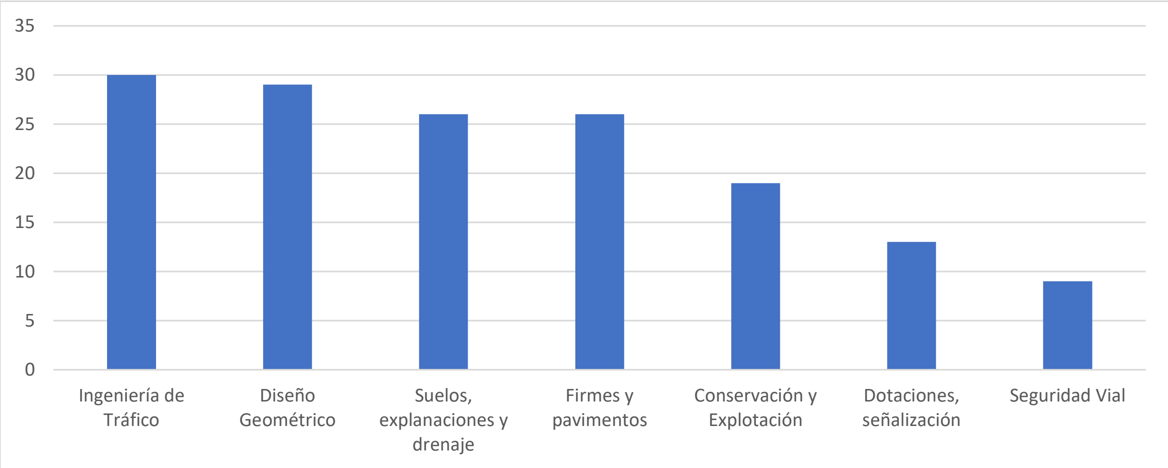

Figura 6 – Nº de asignaturas con presencia de los distintos bloques temáticos en Ingeniería de Carreteras

Como se indicaba al comienzo del apartado, todo lo reseñado hasta el momento se ha referido a asignaturas de Grado cuyos contenidos obedecen solamente a los de la disciplina de Ingeniería de Carreteras. Pero además de estas 53 asignaturas tratadas existen otras 12 asignaturas con contenidos parciales de esta disciplina. La inmensa mayoría, en número de 9, son asignaturas mixtas de Carreteras y Ferrocarriles, todas ellas troncales -6- u obligatorias -3- de las especialidades de Construcciones Civiles o Transportes y SS.UU. Su "tamaño" promedio es algo superior a las anteriores pues alcanza los 6,7 créditos, aunque mayoritariamente (7 asignaturas de las 9 mencionadas) son de 6 créditos. Y en cuanto a los contenidos que abordan de esta disciplina, son mucho más reducidos por tener que compartir "espacio" con Ferrocarriles, concentrándose en los bloques básicos de esta materia (Ingeniería de tráfico, Diseño geométrico, Suelos, explanaciones y drenaje, y Firmes y pavimentos) y sin presencia de las demás. Por lo general, las dos disciplinas comparten al 50% el temario de las asignaturas, aunque en un par de ellas predominan los contenidos de Carreteras -aproximadamente un 75%- y en una prevalecen los Ferrocarriles con un porcentaje semejante.

Finalmente, en lo relativo al Grado, existen otras 3 asignaturas que entremezclan contenidos habituales de la Ingeniería de Carreteras con los de Ingeniería del Transporte e incluso en una de ellas con los de Ingeniería Ferroviaria, de las que no se entra en valoración por su escasa incidencia en el panorama global de esta disciplina.

4.2 La Ingeniería de Carreteras en los estudios de Máster

Entrando en el análisis de la enseñanza de la Ingeniería de Carreteras en el ámbito de los Másteres, se acude de nuevo a la tabla 5 ya mencionada anteriormente, donde quedaba meridianamente clara la casi inexistencia de troncalidad de esta disciplina en los 13 másteres impartidos en España. Son solo 3 asignaturas de un total de 17 y salvo una, en la Universidad de Cádiz, que aborda temas básicos de Ingeniería de Tráfico y Trazado, las demás inciden específicamente en la seguridad vial y la explotación y conservación de carreteras.

La mayoría de las asignaturas (12 de ese total de 17) pertenecen a la especialidad de Transportes de diversas titulaciones, 7 de carácter obligatorio y 5 optativas. Las 2 restantes son optativas no sujetas a especialidad. Ninguna de las asignaturas tiene contenidos básicos de la disciplina (salvo una de la Universidad de Sevilla que ejerce de "nivelación" de conocimientos para los alumnos que no la cursaron en el Grado) e inciden, principalmente, en la Seguridad Vial (en 6 casos), en la conservación y explotación de carreteras (en 3 asignaturas), en el diseño de intersecciones, enlaces y glorietas (en 3 asignaturas) o en aspectos avanzados de ingeniería de tráfico (en 5 casos).

Antes de terminar este apartado dedicado a la Ingeniería de Carreteras, se presenta en la figura 7 cómo ha sido la evolución de la carga docente troncal en los planes de estudio que conducen a formar ingenieros de caminos, canales y puertos.

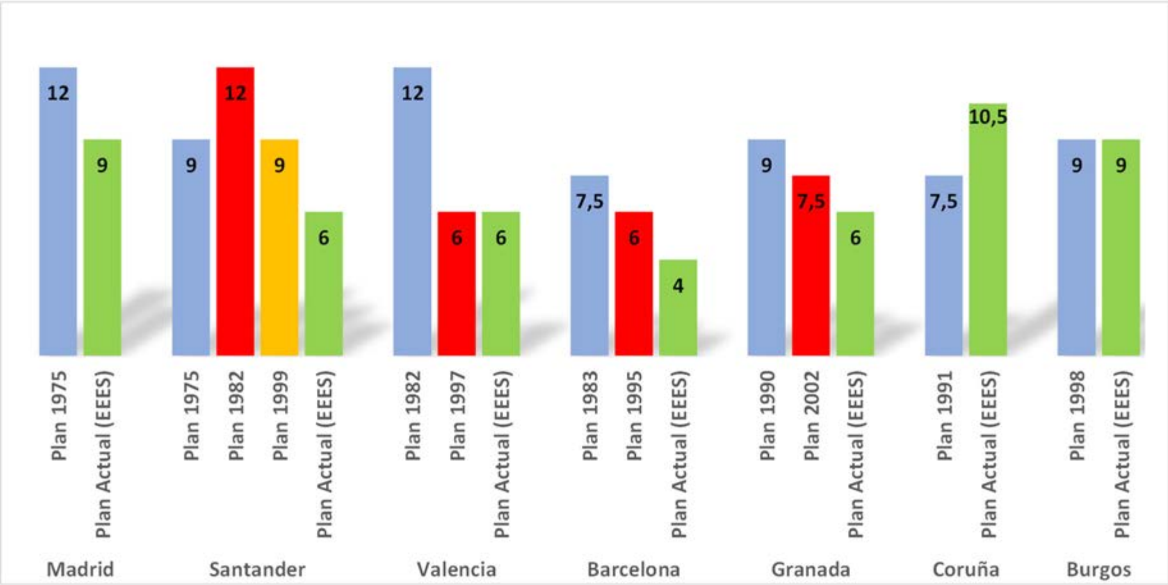

Figura 7 – Evolución del número de créditos de asignaturas troncales de Ingeniería de Carreteras en diversas Escuelas

Dado que en los primeros planes de estudio las asignaturas eran en su mayoría anuales y su carga docente se medía en "horas/semana" y que posteriormente en muchas escuelas se dio el paso a asignaturas cuatrimestrales que se "medían" de la misma forma para finalmente pasar a estructuras de planes con "créditos" y "créditos ECTS", se ha tomado para esta comparativa como valor del "crédito" el equivalente a 10 horas de docencia en aula, y asignando una duración de 15 semanas para las asignaturas cuatrimestrales y de 30 semanas para las anuales. Y dado que en el ámbito del EEES en España es necesario obtener un título de Graduado que habilita para la profesión de Ingeniero Técnico de Obras Públicas y uno de Máster para la de Ingeniero de Caminos, Canales y Puertos, los datos referentes a los actuales planes de estudio (EEES) son la suma de la troncalidad del Grado (y/u obligatoriedad en la mención de Construcciones Civiles) y del Máster en la disciplina de Ingeniería de Carreteras.

A la vista de la figura es más que evidente la pérdida de peso que esta disciplina está viviendo en los sucesivos planes de estudio de los últimos 20 años. Incluso con el incremento de duración total de los estudios, que salvo una excepción ha pasado de 5 a 6 cursos, contabilizando el Grado y el Máster, la tendencia decreciente es acentuada en la mayor parte de las Escuelas, y en especial en las de más “solera”.

5. LA INGENIERÍA FERROVIARIA

Al igual que ocurría con las asignaturas englobadas en la Ingeniería de Carreteras, las ligadas al campo ferroviario (ver de nuevo la tabla 2) están también más presentes en las enseñanzas de Grado que en las de Máster y tanto en unas como en otras, el número de asignaturas de la disciplina ferroviaria son aproximadamente un 50% inferior al de las carreteras.

5.1 La Ingeniería Ferroviaria en los estudios de Grado

En los estudios de Grado, son 25 las asignaturas cuyos contenidos son íntegramente de esta disciplina. Su reparto es el siguiente:

- 2 asignaturas troncales en planes de estudio que incorporan las 3 menciones (los Grados en Ingeniería Civil de la UPM y de la Universidad de Sevilla).
- 13 asignaturas troncales en un total de 13 Grados que incorporan en sus planes de estudio 1 o 2 menciones (salvo en 2 de estos Grados, todos los demás tienen al menos la mención de Construcciones Civiles).
- 3 asignaturas obligatorias en la especialidad de Construcciones Civiles en Grados con las 3 especialidades.
- 5 asignaturas obligatorias en la especialidad de Transportes y Servicios Urbanos en Grados con las 3 especialidades.
- 2 asignaturas obligatorias que se imparten tanto en la especialidad de Construcciones Civiles como en la de Transportes y SS.UU. de Grados con las 3 especialidades.

Es evidente que la Ingeniería Ferroviaria en el ámbito del Grado se ubica principalmente en las especialidades o en la troncalidad de Grados con una única mención. Salvo en una universidad, como ya se avanzaba al comentar la tabla 4, tiene cabida obligatoria en todos los Grados con menciones en Construcciones Civiles o en Transportes y SS.UU, en unos casos con asignaturas cuyos contenidos son exclusivos de esta disciplina (las que se acaban de relatar) o lo son de forma parcial (se hará mención de ello algo más adelante en este apartado). Es significativa también la ausencia total de asignaturas optativas -con contenido exclusivo ferroviario- en los Grados.

Respecto al tiempo asignado para la impartición de las asignaturas, el conjunto de las 25 estudiadas tienen un "tamaño" promedio de 5,58 créditos, 19 de ellas de 6 créditos.

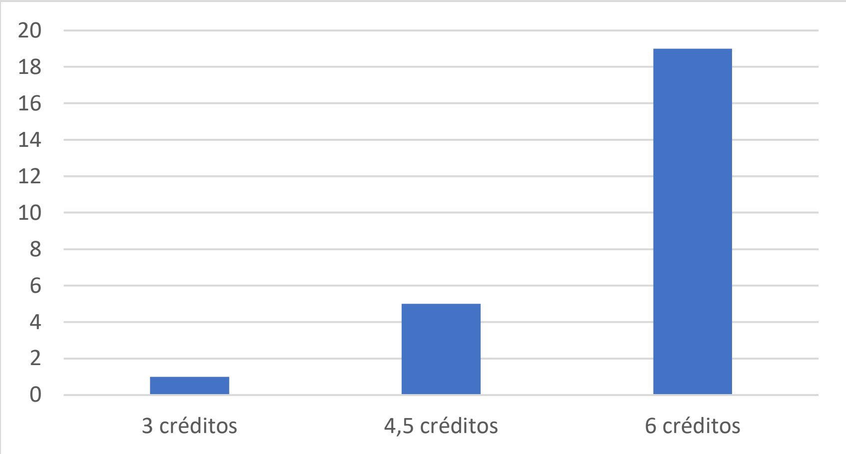

Figura 8 – Nº asignaturas de Grado con contenido exclusivo de Ingeniería Ferroviaria

En cuanto a los contenidos de las 25 asignaturas existe, con carácter general, una gran uniformidad de los mismos; es verdad que los tratan con diferentes estructuras de temarios, sin un orden preestablecido, dando en unos casos más profundidad a unos aspectos que a otros, pero a la postre van pasando con más profundidad o más de "puntillas" a los siguientes temas: el material móvil; al diseño de vía, tanto en los relativo a la superestructura como a la infraestructura; a la geometría de vía; a operaciones sobre la vía como la construcción, renovación, auscultación o conservación; a la tracción; la señalización, explotación, etc.; o a las terminales ferroviarias. De todos ellos, quizás los temas ligados al material móvil -el 40% de las asignaturas no entran en él- o el de las terminales ferroviarias -algo más del 50% no lo tratan- sean la excepción a esa homogeneidad de temarios.

Pero además de estas 25 asignaturas tratadas existen otras 11 asignaturas con contenidos parciales de esta disciplina. La inmensa mayoría, en número de 9, como ya se relató en el apartado anterior dedicado a la Ingeniería de Carreteras, son asignaturas mixtas de Carreteras y Ferrocarriles, todas ellas troncales -6- u obligatorias -3- de las especialidades de Construcciones Civiles o Transportes y SS.UU., que comparten -salvo en un par de casos- el 50% el temario de las asignaturas. Los contenidos que abordan de esta disciplina, son mucho más reducidos por tener que compartir "espacio" con la Ingeniería de Carreteras y se centran principalmente todas las asignaturas en el diseño de la vía y la geometría de la vía. El resto de temas que normalmente se tratan en las asignaturas de ferrocarriles no tienen asegurada su presencia en esas 9 asignaturas y pueden aparecer o no en las mismas.

Finalmente, en lo relativo al Grado, existen otras 2 asignaturas que entremezclan contenidos habituales de la Ingeniería Ferroviaria con los de Carreteras y los de Ingeniería del Transporte. Ambas son troncales, de 6 créditos y con muy escasa presencia de contenidos ferroviarios, pero que les sirve para “cubrir” con las exigencias en lo que a competencias se refiere.

5.2 La Ingeniería Ferroviaria en los estudios de Máster

Ya se vio al comentar la tabla 5 que, al igual que con la Carreteras, es casi inexistente la troncalidad -2 asignaturas- de esta disciplina en los 13 másteres impartidos en España. En total son 8 las asignaturas con contenidos íntegramente ferroviarios: además de las 2 troncales mencionadas (Cádiz y UPM) hay 3 asignaturas obligatorias de la especialidad de Transportes y otras 3 asignaturas optativas.

Ninguna de las 8 asignaturas tiene contenidos básicos de la disciplina (salvo una de la Universidad de Sevilla que ejerce de “nivelación” de conocimientos para los alumnos que no la cursaron en el Grado) optando la mitad de ellas por el desarrollo de sistemas ferroviarios específicos (alta velocidad, sistemas urbanos…) y el resto por la planificación, construcción y mantenimiento.

Como ya se hizo en el apartado dedicado a la Ingeniería de Carreteras, también aquí se presenta en la figura 9 la evolución de la carga docente troncal en los planes de estudio que conducen a formar ingenieros de caminos, canales y puertos. Se siguen los mismos criterios de cómputo de créditos mencionados en aquel momento y volviendo a aclarar que los datos referentes a los actuales planes de estudio (EEES) son la suma de la troncalidad del Grado (y/u obligatoriedad en la mención de Construcciones Civiles) y del Máster en la disciplina de Ingeniería Ferroviaria.

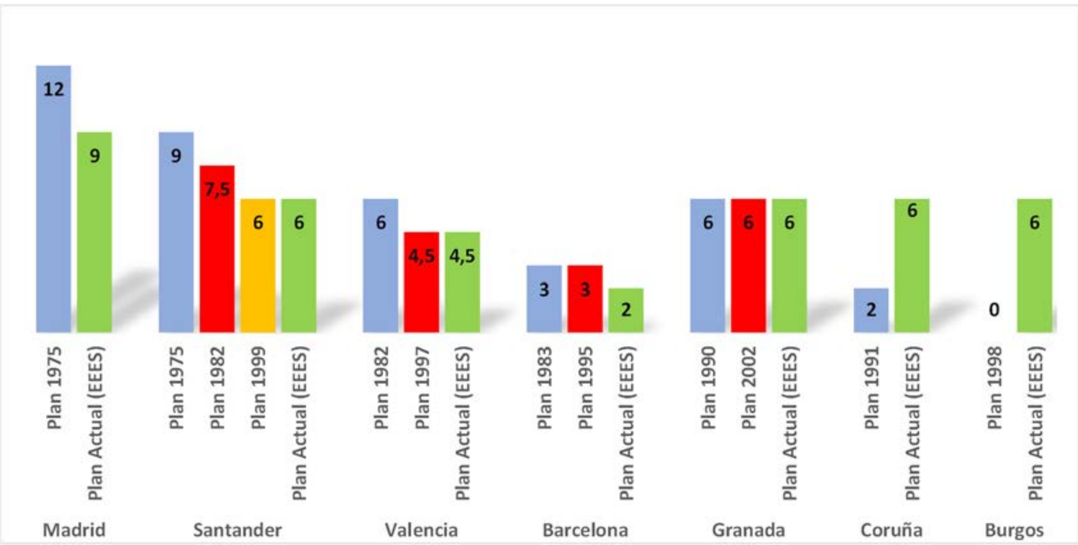

Figura 9 – Evolución del número de créditos de asignaturas troncales de Ingeniería Ferroviaria en diversas Escuelas

La figura 9 habla por sí sola de la pérdida de relevancia de esta disciplina con el paso de los años en las Escuelas con más tradición en España, llegando a ser en alguna de ellas casi intrascendente en el conjunto del plan de estudios. Y ello a pesar de los años "dorados" de inversión en alta velocidad o la reaparición en escena de los sistemas de transporte urbano ligero; y sin olvidarnos que con el actual marco de la EEES se ha incrementado la duración total de los estudios de 5 a 6 cursos, contabilizando el Grado y el Máster.

6. LA INGENIERÍA DEL TRANSPORTE

Ya se explicitó al comienzo de este trabajo que la disciplina tratada bajo la denominación "Ingeniería del Transporte" acogía las materias tradicionales de Economía, Planificación y Explotación del Transporte más otras que se han ido incorporando como son la Logística y la Intermodalidad o la Movilidad y el Transporte Urbano.

Si en el análisis realizado a las disciplinas de Ingeniería de Carreteras e Ingeniería Ferroviaria se detectaba una presencia mayoritaria de sus asignaturas en los Grados y muy escasa en los planes de estudios de los Másteres, no se puede decir lo mismo cuando se habla de la Ingeniería del Transporte, con una presencia más "equilibrada" en ambos tipos de estudios. De hecho, ya se recogía en la tabla 2 la presencia total de 71 asignaturas con contenidos exclusivos de esta disciplina en las titulaciones vinculadas a la ingeniería civil de las universidades públicas españolas, 41 de las cuales pertenecían a estudios de Grado y 30 a estudios de Máster. Y es que mientras en los estudios de Grado que habilitan para ejercer la profesión de Ingeniero Técnico de Obras Públicas, contenidos de esta disciplina solo son exigidos en la especialidad o mención de Transportes y Servicios Urbanos, en los estudios de Máster que habilitan para la profesión de Ingeniero de Caminos, Canales y Puertos, han de recogerse obligatoriamente requisitos formativos que permitan la adquisición de competencias ligadas a esta disciplina, lo que conlleva, a la postre, su presencia en la troncalidad de dichos estudios de Máster.

6.1 La Ingeniería del Transporte en los estudios de Grado

Como ya se hizo en los dos apartados anteriores, se comenzará este análisis con los estudios de Grado. Se decía un poco más arriba que son 41 las asignaturas con contenidos exclusivos de esta disciplina, que en función de su "carácter" se reparten de la siguiente forma:

- 2 asignaturas troncales en planes de estudio que incorporan las 3 menciones (los Grados en Ingeniería Civil de la UPC y de la Universidad de Santiago).
- 9 asignaturas troncales en un total de 7 Grados que incorporan en sus planes de estudio 1 o 2 menciones (solo en 3 de estos Grados está presente la Mención de Transportes y SS.UU.; y en 5 la de Construcciones Civiles).
- 19 asignaturas obligatorias en la especialidad de Transportes y Servicios Urbanos en 11 Grados (salvo 2 de estos Grados, en el resto se ofertan las 3 especialidades).
- 3 asignaturas obligatorias que se imparten tanto en la especialidad de Construcciones Civiles como en la de Transportes y SS.UU. de 3 Grados con las 3 especialidades.

- 6 asignaturas optativas en la especialidad de Transportes y SS.UU. de 5 Grados distintos.
- 2 asignaturas optativas no ligadas a especialidad alguna de 2 Grados distintos.

La información anterior vuelve a dejar patente que esta disciplina, al igual que las ya estudiadas, tiene cabida principalmente en las especialidades de los Grados y más específicamente en este caso en la de Transportes y SS.UU. La troncalidad se encuentra muy limitada y tan solo aparece en 2 de los Grados que imparten las 3 especialidades o menciones.

En la figura 10 que se muestra a continuación puede observarse cómo es el reparto de las 41 asignaturas impartidas con contenido exclusivo de esta disciplina en lo referente al “tamaño” de las mismas. Mayoritariamente son las de 6 créditos las que se encuentran en los planes de estudio y es cercano a ese valor -5,74 créditos- su dimensión promedio. Por lo general, las asignaturas optativas -su tamaño promedio es de 5,25 créditos- tienen menos envergadura que las troncales y obligatorias -5,86 créditos-.

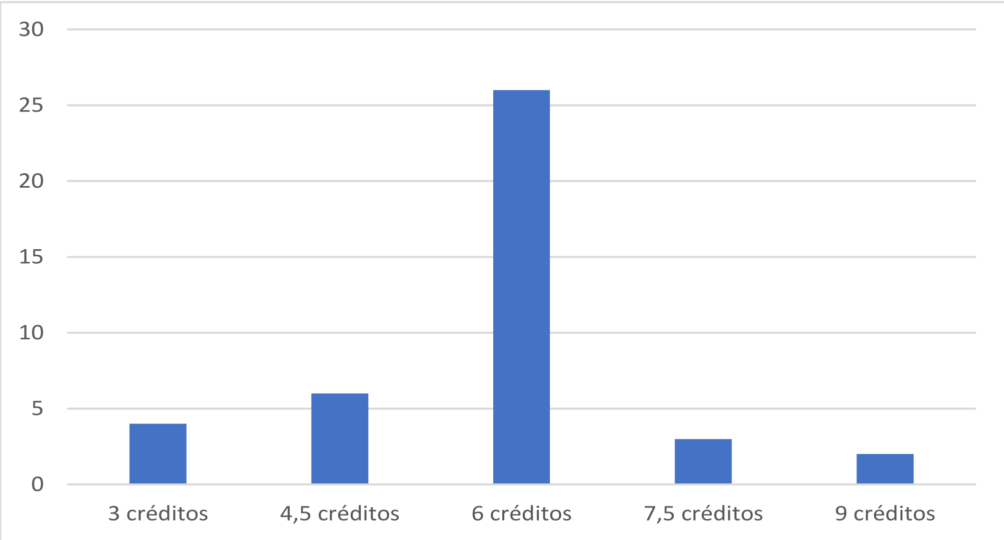

Figura 10 – Nº asignaturas de Grado con contenido exclusivo de Ingeniería del Transporte

Por lo que respecta a los contenidos de las asignaturas, la situación de esta disciplina difiere de las ya estudiadas con anterioridad, la Ingeniería de Carreteras y la Ferroviaria. Y difiere principalmente porque estas últimas han de tener contenidos obligatoriamente en las especialidades o menciones de Construcciones Civiles y de Transportes y Servicios Urbanos para satisfacer las competencias exigidas para las mismas, mientras que las de “Ingeniería del Transporte” solo son exigidas en la de Transportes y Servicios Urbanos. Y en concreto, según la Orden CIN/307/2009 de 9 de febrero, las competencias que deben adquirirse son el “*Conocimiento de la influencia de las infraestructuras en la ordenación del territorio y para participar en la urbanización del espacio público urbano, tales como distribución de agua, saneamiento, gestión de residuos, sistema se transporte, tráfico, iluminación, etc.*”; y el “*Conocimiento del diseño y funcionamiento de las infraestructuras para el intercambio* *modal, tales como puertos, aeropuertos, estaciones ferroviarias y centros logísticos de transporte*".

Son tan específicas las competencias y de alguna forma un tanto alejadas de las bases tradicionales de la Ingeniería del Transporte, que los contenidos que "cubren" dichas competencias no están, en casi ningún caso, en la troncalidad de las titulaciones y sí entre las asignaturas obligatorias de la especialidad de Transportes y Servicios Urbanos.

Debido a lo anterior, la mayoría de las asignaturas troncales ofertadas en el conjunto de los 30 Grados no están pensadas inicialmente para formar ingenieros de obras públicas especializados en Transportes y Servicios Urbanos, sino para ofrecer unos mínimos conocimientos de la disciplina a cualquiera de ellos, al margen de la especialidad; o como base sobre la que sustentar las asignaturas obligatorias de esta disciplina que aparecerán posteriormente en el Máster en Ingeniería de Caminos, Canales y Puertos. Es por todo ello que, en la mayoría de estas asignaturas troncales -8 de un total de 11- los contenidos están orientados a dar una visión general de esta disciplina; y solo 3 de las 11 asignaturas troncales son específicamente relativas a la formación de ingenieros en la especialidad de Transportes y Servicios Urbanos pues pertenecen a títulos (Extremadura y País Vasco) con plan de estudios "cerrados" conducentes a formar ingenieros en esta especialidad.

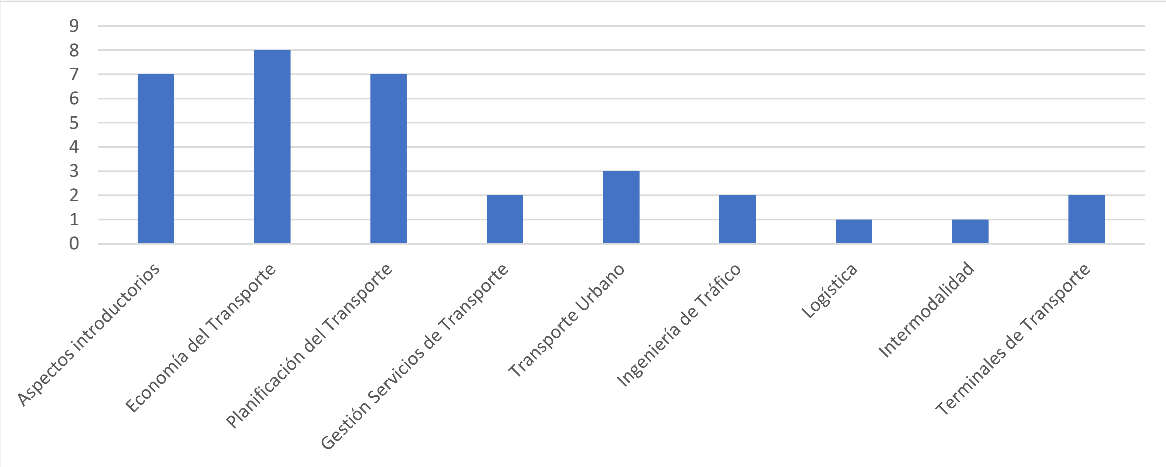

Figura 11 – Nº de asignaturas troncales en la que están presentes contenidos de diversas áreas temáticas en Ingeniería del Transporte

Y eso es lo que queda reflejado en la figura 11, en la que se representan cuáles son los contenidos principales en las 11 asignaturas troncales con contenidos exclusivos de esta disciplina en los 30 Grados estudiados en este trabajo. Salvando las 3 asignaturas mencionadas en el apartado anterior, las restantes se construyen principalmente entorno a aspectos introductorios del transporte (historia, características de los modos de transporte, datos para posicionar la materia...) y unas bases generales de Economía y Planificación del Transporte, a las que se complementa con pequeñas aportaciones de otras áreas temáticas.

Además de estas 11 asignaturas troncales con contenidos exclusivos en Ingeniería del Transporte, existen otras 4 asignaturas (3 en la Universidad de Extremadura y 1 en la UPV) en las que comparten "espacio" con otras disciplinas como la Ingeniería de Carreteras, la Ferroviaria o la Ordenación del Territorio.

Muy distinta es la configuración de las asignaturas "obligatorias" en la especialidad o mención de Transportes y Servicios Urbanos (ya se adelantó anteriormente que no existen asignaturas obligatorias de esta disciplina en la mención de Hidrología de ningún título y tan solo 3 en la de Construcciones Civiles, que a su vez se imparten también en la de Transportes y SS.UU.). Aquí se dan cita mayoritariamente los contenidos que sustentan las competencias de esa especialidad y así queda patente en la figura 12 donde se pone de manifiesto el número de asignaturas que acogen contenidos de Intermodalidad o Transporte Urbano.

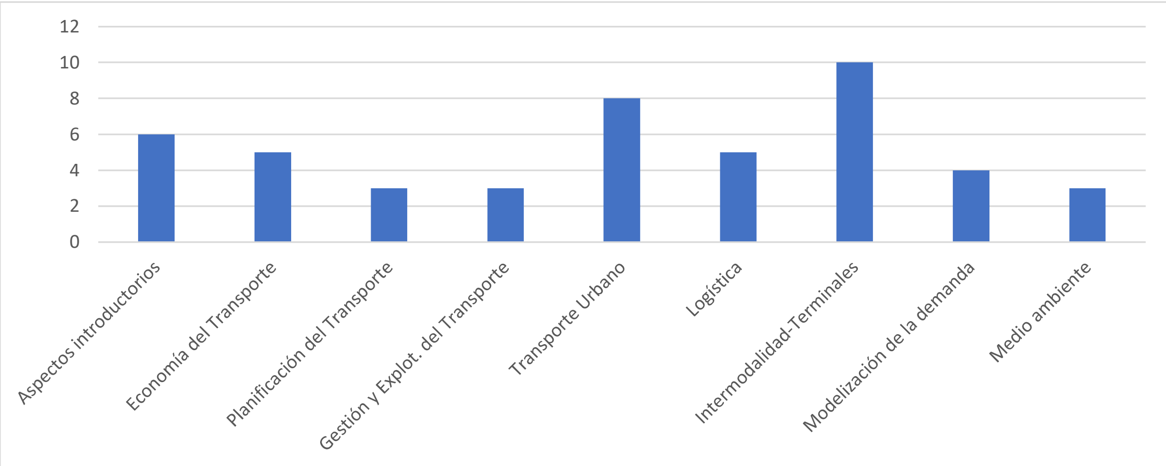

Figura 12 – Nº de asignaturas obligatorias de especialidad "Transportes y SS.UU." que incluyen contenidos de diversas áreas temáticas en Ingeniería del Transporte

Una última aportación en torno a la "Ingeniería del Transporte" en lo que a los Grados se refiere, es la relativa al número de asignaturas obligatorias con contenidos exclusivos de dicha disciplina y el número de créditos empleados en los currículos que dan opción a obtener la especialidad de Transportes y Servicios Urbanos en los 16 títulos que incluyen esta mención.

Como se constata en la figura 13, los planes de estudio afrontan de forma muy diversa los contenidos de esta disciplina para con ellos adquirir las competencias requeridas, oscilando entre una asignatura -en 5 títulos- y el número de 3, siendo los títulos con 2 asignaturas la mitad del total. Ello quiere decir que en el 30% de los títulos se introduce en una única asignatura toda la materia, por diversa que ella sea, para obtener las competencias. Ello conduce en algunos casos a observar temarios que son un verdadero "popurrí" de contenidos que, en algunos casos, por su exigua presencia, es complicado percibir los que dan cauce a la adquisición de las competencias exigidas.

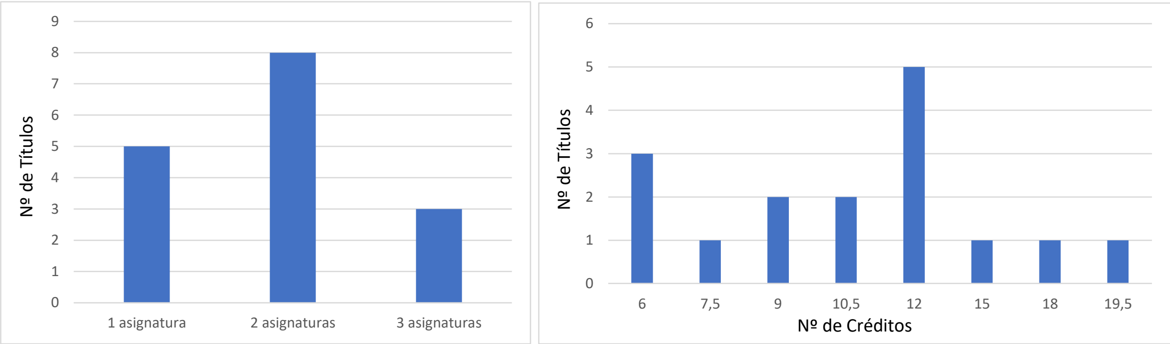

Figura 13 – Asignaturas obligatorias de la disciplina "Ingeniería del Transporte" y créditos empleados para obtener la especialidad "Transportes y SS.UU."

Algo semejante, en cuanto a la diversidad, puede decirse del número de créditos que han de cursarse obligatoriamente para obtener la especialidad. En esa misma figura 13 se constata cómo en algunos títulos se emplean hasta más del triple que en otros en impartir la docencia de esta disciplina. El valor promedio es de 11,06 créditos por titulación.

Solo una mención, antes de terminar con este apartado dedicado a los títulos de Grado, a las asignaturas optativas, de las que se relató al comienzo del mismo que eran un total de 8, de las que 6 estaban incardinadas en las menciones de Transportes y SS.UU. y 2 eran de carácter general no ligadas a especialidad alguna. Salvo un par de excepciones, los contenidos de las mismas se reparten equitativamente entre los ámbitos del Transporte Urbano y la Logística.

6.2 La Ingeniería del Transporte en los estudios de Máster

Como ya quedó reflejado al comienzo del apartado dedicado a esta disciplina, la presencia de la misma en los Másteres que conducen a la obtención del título de Ingeniero de Caminos, Canales y Puertos es mucho más elevada que en los casos de Ingeniería de Carreteras e Ingeniería Ferroviaria y ello venía dado porque en los estudios de Máster que habilitan para esa profesión deben acoger requisitos formativos para adquirir competencias relativas a esta disciplina, lo que hace obligada su presencia en la troncalidad de dichos estudios de Máster.

Como puede verse en la tabla 5 ya mencionada en varias ocasiones, son un total de 30 asignaturas las desplegadas en los 13 másteres estudiados, que según su "carácter" se reparten de la siguiente forma:

- 15 asignaturas troncales en el total de 13 másteres.
- 4 asignaturas obligatorias en especialidades de Transportes encuadradas en 3 másteres.
- 6 asignaturas optativas en especialidad de Transportes correspondientes a 3 másteres.
- 5 asignaturas optativas, pertenecientes a 4 másteres, que no están ligadas a especialidad alguna.

Todos los másteres tienen una asignatura troncal salvo los que se imparten en la Universidad de Oviedo y en la Politécnica de Cartagena. En estas 2 universidades no existen asignaturas de Ingeniería del Transporte en los Grados que también imparten, mientras que las 11 titulaciones restantes o tienen un Grado con la especialidad de Transportes y SS.UU. o tienen asignaturas troncales en Grados sin esa especialidad.

En lo relativo al "tamaño" de las asignaturas, las troncales -salvo una de ellas que alcanza 7,5 créditos- son abordadas con 4,5 créditos en 5 asignaturas y con 6 créditos las 9 restantes; las obligatorias de especialidad son más reducidas -entre 3 y 5 créditos- y las optativas de especialidad son todas de 4,5 créditos.

Entrando en el apartado de contenidos de las asignaturas, las troncales han de dar satisfacción a las competencias recogidas en la Orden CIN/309/2009 de 9 de febrero por la que se regulan los estudios de Máster que habilitan para ejercer la profesión de Ingeniero de Caminos, Canales y Puertos, y que textualmente dice: "*Conocimientos de la ingeniería y planificación del transporte, funciones y modos de transporte, el transporte urbano, la gestión de los servicios públicos de transporte, la demanda, los costes, la logística y la financiación de las infraestructuras y servicios de transporte*"; y "*Capacidad de planificación, gestión y explotación de infraestructuras relacionadas con la ingeniería civil*".

La diversidad de contenidos recogidos en la Orden Ministerial obliga en muchos casos a que la conformación de los temarios de las asignaturas troncales sea un reflejo de aquella en aras de cumplir las exigencias y vadear los procesos de acreditación. Bien puede decirse que al menos 8 de los 13 másteres impartidos son bastante fieles a ese perfil trazado por las competencias requeridas y además de forma relativamente equilibrada. El resto, aun "cumpliendo" las exigencias -en algunas ocasiones no es fácil percibirlo en los temarios-, no mantienen ese equilibrio y enfatizan el núcleo principal de la asignatura en aspectos muy concretos (Economía del Transporte en un caso; otra en Planificación del Transporte; Gestión y Explotación de los Servicios de Transporte; y en dos de ellas con una presencia principal de la modelización).

En lo relativo a las asignaturas obligatorias en especialidades de Transportes y a las optativas, tanto de especialidad como al margen de ellas, destaca ampliamente la oferta de las que centran sus contenidos en la Logística seguidas por las de Movilidad Urbana.

Para finalizar este apartado dedicado a la Ingeniería del Transporte en el ámbito de los Másteres, y al igual que se hizo anteriormente con otras disciplinas, se presenta en la figura 14 la evolución de la carga docente troncal en los planes de estudio que conducen a formar ingenieros de caminos, canales y puertos. Como ya se aclaró anteriormente, los datos referentes a los actuales planes de estudio (EEES) son la suma de la troncalidad del Grado (y/u obligatoriedad en la mención de Construcciones Civiles) y del Máster en la disciplina de Ingeniería del Transporte.

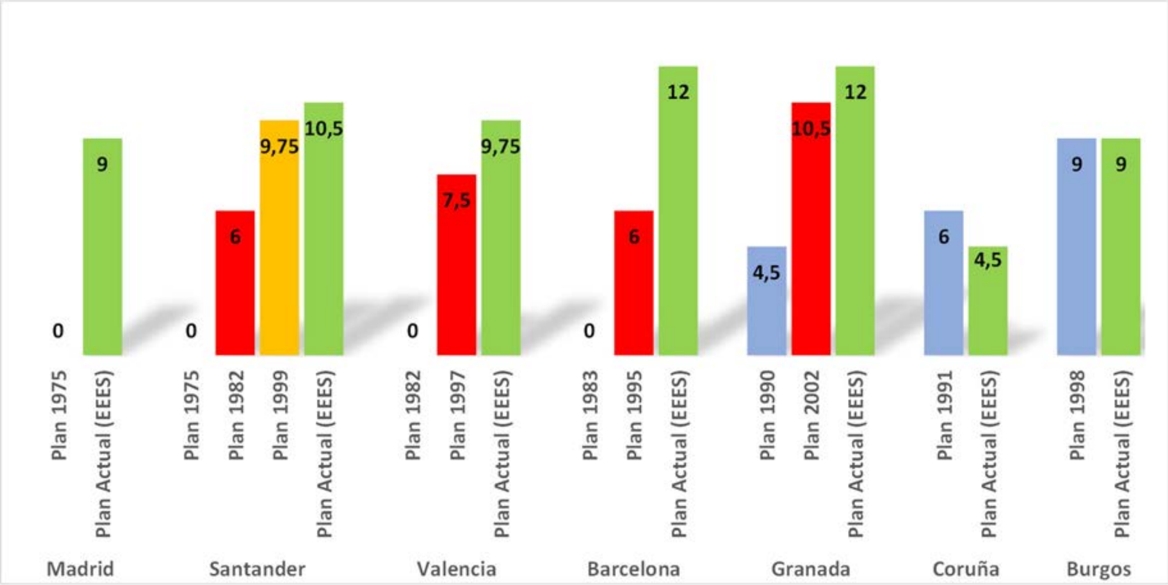

Figura 14 – Evolución del número de créditos de asignaturas troncales de Ingeniería del Transporte en diversas Escuelas

A la vista de la figura es más que evidente el crecimiento que esta disciplina está viviendo en los sucesivos planes de estudio de los últimos 25 años, más si cabe en las escuelas “tradicionales” que en sus primeros planes dejaban los contenidos de la “Ingeniería del Transporte” al ámbito de las especialidades. La tendencia contrasta mucho con las estudiadas anteriormente de la Ingeniería de Carreteras y la Ferroviaria.

7. LA PLANIFICACIÓN Y EXPLOTACIÓN PORTUARIA

Será muy breve la exposición en lo que respecta a esta disciplina, en otro tiempo siempre presente en los planes de estudios de la Ingeniería de Caminos, Canales y Puertos, aunque fuera en las vías de especialización de los últimos cursos. Y es que en la actualidad esa presencia ha pasado a ser testimonial pues apenas son 16 asignaturas las que se están impartiendo (8 en títulos de Grado y 8 en los de Máster) en las 43 titulaciones que se están analizando en este trabajo (30 de Grado y 13 de Máster). Y si además se tiene en cuenta que la mitad de ellas se imparten en 3 Escuelas (Ingenieros de Caminos de Madrid, y las Escuelas Politécnicas Superiores de la Universidad de Alicante y de Algeciras, perteneciente esta última a la Universidad de Cádiz) pues la sensación de exclusión de esta disciplina de los planes de estudio actuales es más que manifiesta.

Por lo que se refiere a los estudios de Grado, se decía más arriba que son 8 las asignaturas con contenidos de esta disciplina. Su reparto es el siguiente:

- 6 asignaturas obligatorias en la especialidad de Transportes y Servicios Urbanos en 5 Grados con las 3 especialidades (una de ellas se imparte también en la especialidad de Construcciones Civiles. Corresponden a los Grados en Ingeniería Civil de Alicante,

Cádiz, UPM y Sevilla; y al Grado en Ingeniería Civil y Territorial de la UPM (2 asignaturas).
- 1 asignatura optativa en la especialidad de Transportes y SS.UU. (Universidad de Santiago).
- 1 asignatura optativa no ligada a especialidad alguna (Universidad de Burgos).

En cuanto a los estudios de Máster en Ingeniería de Caminos, Canales y Puertos, el reparto de las 8 asignaturas, según su carácter, es el siguiente:
- 2 asignaturas obligatorias en la especialidad de Transportes (Alicante y Cantabria).
- 1 asignatura obligatoria en la especialidad de Hidráulica (Oviedo).
- 3 asignaturas optativas en la especialidad de Transportes (2 en la UPM y una en la UPV).
- 1 asignatura optativa en la especialidad de Hidráulica (Coruña).
- 1 asignatura optativa no ligada a especialidad alguna (Cádiz).

Salvo alguna excepción en la que la asignatura se encuentra ligada a la especialidad de Hidráulica, o alguna optativa de acceso general, por lo general se encuadran en las especialidades de Transportes, tanto en los grados como en los másteres. Y salvo una asignatura de Grado en la Universidad de Alicante que tiene 6 créditos, todas las demás se imparten en formato de 3 o de 4,5 créditos (7 y 8 respectivamente).

En cuanto a los contenidos de las asignaturas, salvo una muy orientada a la logística portuaria, las demás abordan con más o menos profundización los temas relativos al transporte marítimo y el comercio internacional, el espacio portuario y las infraestructuras al servicio de la planificación portuaria, y la gestión y explotación portuaria. Es obvio que aquellos centros universitarios que imparten 2 asignaturas (una de Grado y otra de Máster) como es el caso de las mencionadas EPS de Alicante y Algeciras, o el caso de la E.T.S.I.C.C.P. de Madrid, que llega a impartir 4 asignaturas (2 de Grado y 2 de Máster) llegan a abarcar cualitativa y cuantitativamente aspectos de la disciplina que las demás perfilan o abordan más sucintamente.

8. ALGUNAS CONCLUSIONES

El presente trabajo ha pretendido ofrecer una “fotografía” actual y un análisis de cómo las Escuelas que ofertan títulos en el ámbito de la “Ingeniería Civil” han integrado en sus planes de estudio los contenidos ligados a la Ingeniería e Infraestructura de los Transportes, tanto de los Grados como de los Másteres que habilitan para el ejercicio de las profesiones de Ingeniero Técnico de Obras Públicas y de Ingeniero de Caminos, Canales y Puertos, respectivamente. Para ello se han analizado los contenidos de un total de 209 asignaturas (68 de Máster y 141 de Grado) incardinadas en 13 títulos oficiales de Máster y 30 de Grado impartidos en las universidades públicas españolas.

Las disciplinas tratadas, en este orden, han sido las de Ingeniería de Carreteras (incluyendo la Ingeniería de Tráfico o la Seguridad Vial); la Ingeniería Ferroviaria y la Explotación Ferroviaria; la Ingeniería del Transporte (incluye las tradicionales de Economía, Planificación y Explotación del Transporte más otras que se han ido incorporando en las últimas décadas como la Logística y la Intermodalidad o la Movilidad y el Transporte Urbano; y la Planificación y Explotación Portuaria.

Con carácter general puede afirmarse que las materias cuyos contenidos pertenecen a la Ingeniería e Infraestructura de los Transportes no forman parte de la formación generalista de un futuro ingeniero técnico de obras públicas y tan solo de la formación de su itinerario de especialidad. Y salvo materias ligadas a la "Ingeniería del Transporte", tampoco forman parte de la troncalidad de los másteres. Por ello, existe un problema de carencias formativas al que se pueden enfrentar los alumnos que cursen la mención de Hidrología cuando en los planes de estudios de sus grados no exista troncalidad de disciplinas como la Ingeniería de Carreteras o la Ferroviaria y accedan a un máster sin troncalidad de estas mismas disciplinas.

Tanto la Ingeniería de Carreteras como la Ferroviaria (la 1ª tiene aproximadamente el doble de asignaturas que la 2ª) tiene su principal encaje en las especialidades de los Grados o en la troncalidad de Grados con una única mención, generalmente la de Construcciones Civiles. Con carácter general, los contenidos de ambas disciplinas en los Grados abordan en todos los títulos los aspectos esenciales de las mismas. Los niveles de profundización dependerán del "tamaño" de las asignaturas y del número de ellas, ya que en bastantes casos se da la circunstancia de asignaturas únicas que acogen los contenidos de ambas disciplinas.

Los contenidos de la disciplina Ingeniería del Transporte tienen una presencia más "equilibrada" en los estudios de Grado y de Máster. En los primeros muy ligada a la especialidad o mención de Transportes y Servicios Urbanos y en los estudios de Máster con una carga importante de troncalidad derivada de las exigencias de competencias que han de recogerse en los títulos que habilitan para la profesión de Ingeniero de Caminos, Canales y Puertos. La conformación de "temarios" de las asignaturas de Grado se inclinan por cuestiones básicas de la disciplina en los casos de asignaturas troncales; y por áreas como el transporte urbano o la intermodalidad en las de especialidad o mención, para dar cumplimiento a las competencias. En el caso de los másteres, los "temarios", salvo excepciones, son "popurrís" que procuran ser reflejo de la diversidad de contenidos recogidos en la Orden Ministerial que ordena sus enseñanzas y que hay que cumplir para vadear los procesos de acreditación.

Finalmente dejar patente la más que evidente pérdida de peso que la Ingeniería de Carreteras y la Ferroviaria están viviendo en los sucesivos planes de estudio de los últimos 25 años. Incluso con el incremento de duración total de los estudios, que ha pasado de 5 a 6 cursos, contabilizando Grado y Máster, la tendencia decreciente es acentuada en la mayor parte de las Escuelas, y en especial en las de más "solera". Muy al contrario ocurre con los contenidos de Ingeniería del Transporte, que en estos mismos años ha visto un indudable crecimiento de su presencia troncal cuando antaño estaba reducida al ámbito de las especialidades.

ABSTRACT

The purpose of this research was to study the feasibility of incorporating steel slags into coarse bituminous mixtures. The objective was twofold: to reduce dependence on natural aggregates, and to provide a use for industrial by-products. The slags studied come from the manufacture of carbon steel in electric furnaces and are divided into two types: Electric Arc Furnace (EAF) slag and Ladle Furnace (LF) slag. The mixture designed is coarse bituminous concrete (AC22G), for base courses in flexible pavements.

In a first phase, the physical characterization of the materials was carried out to check their suitability. In a second phase, three types of mixes were designed: a control mix (made with natural limestone aggregates), a mix where LF slag was introduced to replace the filler and the fine fraction (sand) of the mix; and finally, the feasibility of manufacturing a totally sustainable mix was analyzed, which would fully incorporate EAF slag as coarse aggregate and LF slag as fine aggregate and filler. In a third and final phase, the designed mixes were subjected to different mechanical, water sensitivity, and durability tests.

The research demonstrated that the incorporation of EAF and LF steel slag as a substitute for natural aggregate in coarse bituminous mixtures is feasible, meeting regulatory requirements, improving sustainability in the construction industry, as well as reducing emissions, and contributing to climate change mitigation.

1. INTRODUCTION

Since the end of the 20th century, social pressure to protect the environment has forced the scientific community to study different ways of recycling the by-products generated in industrial processes (Revilla-Cuesta et al., 2020; Rodríguez-Fernández et al., 2019). This recycling would reduce the amount of waste generated and convert the residues into valuable and sustainable resources (Gonzalo-Orden et al., 2019; Martinho et al., 2018).

One of the most studied industrial by-products is iron and steelmaking slags (Teo et al., 2020). These materials were first considered as waste and they were mainly dumped in landfills, producing important landscape impacts and posing a pollution risk to runoff waters that came into contact with them (Riboldi et al., 2020).

The growth of the world steel industry, which from 1950 to the present has increased from 189 to 1,600 million tons of steel produced annually, has led to an equally significant increase in the production of slag (Branca et al., 2020). Today, a wide variety of applications for steel slags have been developed (Gökalp et al., 2018), but slag consumption is far from reaching its production, resulting in a surplus of this waste that continues to be stored in landfills.

Among the multiple uses of steel slag, the most widespread are: its reincorporation into the steel production process (Li et al., 2020; Varanasi et al., 2019) and its use in the construction sector, mainly as a substitute for natural aggregates and binders in the manufacture of concrete and cementitious composites (Brand and Fanijo, 2020; Piemonti et al., 2021) or bituminous mixtures (Li et al., 2018; Pasetto et al., 2017). One of the applications with the greatest potential is the incorporation of these materials in road pavements, replacing natural aggregates (Dondi et al., 2021; Maharaj et al., 2017).

A bituminous mixture is a combination of coarse aggregates (>2 mm), fine aggregates (0.063-2 mm), mineral powder or filler (<0.063 mm) and a hydrocarbon binder, so that all the particles are covered by a homogeneous film of binder. On the other hand, road pavements can be defined as a set of overlapping layers, relatively horizontal and several centimeters thick, composed of different materials, suitably compacted and supported on the natural ground. Bituminous mixtures can be used in the surface layer of the pavement (wearing course) or the inner layers (base course and binder course).

The purpose of this research was to study the feasibility of incorporating two types of steel slag in coarse bituminous mixtures that are used for the base layer of a road pavement. The objective of this research was twofold: to reduce the dependence on natural aggregates, whose extraction is harmful to the environment, and to give a use to industrial by-products, which reduces the volume of stockpiles and improves sustainability both in the construction and steel industries.

2. MATERIALS

The two types of slags studied in this research proceed from the manufacture of carbon steel:

- **Electric Arc Furnace (EAF) slag**: it originates during the melting process of the scrap in the primary metallurgy. It is a coarse material, with a rough texture and blackish gray color. It is mainly composed of calcium silicates and metallic oxides, the latter being responsible for its dark color and high density and hardness. Its good mechanical characteristics (hardness, absorption, roughness and angularity) and its particle size allow it to be used as coarse aggregate in concrete and bituminous mixtures (Skaf et al., 2017).
- **Ladle Furnace (LF) slag**: it is obtained during steel refining in ladles. It is a fine material, whitish in color and powdery in texture. It is mainly composed of calcium and magnesium silicates and aluminates, which provides it with soft hydraulic properties (Parron-Rubio et al., 2019). Due to its size, which is usually under 2 mm, it can be used as fine aggregate in construction, while its hydraulic properties mean that it can be used as a mineral powder to replace lime or cement traditionally used in bituminous mixtures (Terrones-Saeta et al., 2021b).

Fig. 1 – Ladle Furnace (LF) slag (left) and Electric Arc Furnace (EAF) slag (right) used in this research.

3. MIX DESIGN

For the investigation, an AC22G mix was adopted, which according to the Spanish standard PG-3 (2015) is defined as a coarse bituminous concrete with a maximum size of 22 millimeters. This type is one of the most commonly used in base layers of flexible and semi-rigid pavements.

The slags were introduced into the bituminous mix in two phases:

- The first type was a mix consisting partly of steel aggregate, with LF slag as fine aggregate and mineral powder, and traditional limestone aggregate as coarse aggregate. This mix was labeled CBB

- The second type was a 100% sustainable mix, composed entirely of slags, with EAF slag as coarse aggregate and LF slag as fine aggregate and filler (labeled as NBB).

Finally, it was necessary to manufacture a third traditional mix, composed entirely of limestone aggregate, to serve as a reference, to assess the effect of the slag incorporation. This standard mix was labeled CCC.

Fig. 2 – Specimens of CBB (left) and NBB (right) mixtures

4. PERFORMANCE OF THE MIXTURES

4.1 Volumetric properties

The incorporation of the slags generated a greater void content in the mix, which increased the optimum binder content to achieve the target air voids. The mixtures studied, CBB and NBB, required a 15% and 35% higher volume of bitumen, respectively.

This greater void content was attributed to the fact that the bituminous mastic (filler+binder) formed by the LF slag is more rigid than that formed by the limestone mineral powder, and therefore has a lower capacity to penetrate the voids in the aggregate (Pasetto et al., 2020). On the other hand, the greater roughness of the EAF slag reduces its compactability and results in a higher porosity within the mineral skeleton. These adverse effects could be partly compensated by increasing the binder temperature (Pasquini et al., 2020).

4.2 Stability

Stability was measured by the Marshall test (EN 12697-34) and is defined as the ability of a mixture to withstand traffic loads and resist the resulting stresses with tolerable deformations. This feature is of the most important in base layers.

The results of this test showed that the introduction of LF slag as fine aggregate and mineral powder improved the stability of the mix by 12% with respect to the standard mix, while its joint incorporation with EAF slag as coarse aggregate greatly improved stability (around 40%), as some other researchers have found (Terrones-Saeta et al., 2021a).

The increase in stability was attributed to the higher stiffness of the siderurgic mastic mentioned above and the high roughness of the EAF slag, which increases the internal friction in the mineral skeleton. The above combined effect managed to overcome the effect of the higher binder content, an unfavorable circumstance for the stability of the mix as it implies higher flexibility/lower stiffness of the pavement.

4.3 Indirect tensile strength

The Brazilian test (EN 12697-23), which analyzes the indirect tensile strength (ITS) of a bituminous mix, showed that the mix with LF slag as fine aggregate and filler had a slightly better tensile performance (6%) than the standard mix. This proves a good adhesion of the mastic to the

On the other hand, the introduction of EAF slag as coarse aggregate was unfavorable for the tensile behavior of the mix. The NBB mix had a 25% lower ITS than the standard mix. This circumstance is attributable to the greater discontinuity of the mix due to its higher porosity, which is highly adverse under tensile stress.

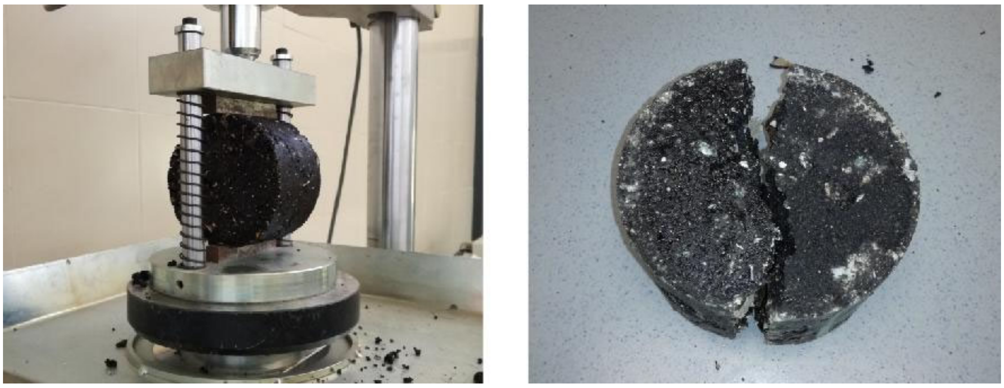

Fig. 3 – CBB mix during and after the ITS test

4.4 Abrasion resistance

Abrasion resistance was determined by the Cantabro test (EN 12697-17). The results of the mixtures studied were all excellent, with particle losses (PL) below 10% in both cases. In addition, both mixes gave results similar to those of the standard mix, so the incorporation of both the LF slag and the EAF slag did not have a detrimental effect on the wear resistance of the resultant mixes. The resistance to abrasion in slag mixtures has also proved to be excellent in other researches, and this feature is particularly relevant in open-graded and porous mixtures (Skaf et al., 2019).

4.5 Durability

The durability test results showed that the mechanical properties of the mixtures studied were hardly affected by the ageing process. For both mixtures, the loss of abrasion resistance after aging was below 3%.

These excellent results are in part due to the higher binder content of the slag mixes, but they also prove a good affinity of the LF slag to the binder, a quality mastic that provides good adhesion to the aggregates and improves the cohesion of the mixes and their resistance to ageing.

Fig. 4 – Specimens of the standard mix prior to testing, after the abrasion test and after the durability test (from left to right)

4.6 Water Sensitivity

Water damage is one of the primary causes of distress in flexible pavements, reducing their durability (Soenen et al., 2020). The moisture susceptibility test (EN 12697-12) showed that the incorporation of slag reduced the water sensitivity of the mix. This reduction was especially noticeable in the mix composed entirely of slag (NBB mix), whose mechanical properties were hardly affected by the action of water. This is due to the good affinity between the EAF slag and the binder, and also attributable to the higher binder content of these mixes (Pathak et al., 2020).

5. CONCLUSIONS

The main results of the investigation can be summarized as follows:

- The incorporation of LF slag as fine aggregate in coarse bituminous mixes is feasible, since it produces similar o superior results to those of the conventional mixes in most of the properties studied.
- The integral replacement of the traditional limestone aggregate with slags (EAF and LF) in base layers fulfilled all regulatory requirements in volumetric terms, stability, abrasion resistance and durability. However, the tensile strength performance was significantly worse than the conventional mix.
- The commercial use of the slags studied in this research should be subject to a prior study of the economic viability of two aspects: the higher cost of transporting EAF slag, due to its higher density, and the higher binder content that these mixtures require.

RESUMEN

Las glorietas son un tipo de nudo que canaliza los flujos procedentes de tres o más accesos mediante una calzada anular. De la experiencia acumulada en países de todo el mundo se deduce que, en muchos casos, este tipo de nudo tiene numerosas ventajas frente a una intersección convencional. Por este motivo, se ha extendido su aplicación como solución alternativa a las intersecciones convencionales tanto en zonas urbanas como interurbanas.

En general, las glorietas en servicio ofrecen unas buenas condiciones de circulación y un elevado nivel de seguridad. Sin embargo, existen casos en los que una inadecuada definición de su diseño en el proceso de proyecto da lugar posteriormente a problemas de funcionamiento o, incluso, de seguridad vial, que pueden corregirse si se identifican las deficiencias de diseño que los originan.

En este trabajo se presentan dos casos de estudio de mejoras del diseño de glorietas en servicio con medidas de bajo coste. El primer caso se refiere a una glorieta multicarril implantada en un entorno urbano con problemas de capacidad. El conocimiento de los parámetros con mayor influencia en la operación de los tráficos ha permitido proponer una serie de ajustes en el diseño geométrico. El segundo caso corresponde a una glorieta multicarril situada en entorno interurbano con problemas de seguridad derivados de las altas velocidades de entrada en los accesos del eje principal. La actuación propuesta se basa en la modificación del trazado y de la señalización.

1. INTRODUCCIÓN

Las glorietas son un tipo de nudo que canaliza los flujos procedentes de tres o más accesos mediante una calzada anular. De la experiencia acumulada en países de todo el mundo se deduce que, en muchos casos, este tipo de nudo tiene numerosas ventajas frente a una intersección convencional. Por este motivo, se ha extendido su aplicación como solución alternativa a las intersecciones convencionales tanto en zonas urbanas como interurbanas.

En el caso de España, la primera glorieta con preferencia para el tráfico en la calzada anular fue construida en 1976. Desde entonces, se ha producido una masiva extensión superando en la actualidad, en valor aproximado, las 35.000 unidades. A nivel internacional, esta cifra sitúa a España como uno de los países con mayor número de glorietas.

A pesar de contar con esta importante experiencia, en la actualidad se pueden encontrar en las carreteras españolas una serie de glorietas cuyos problemas de funcionamiento y seguridad tienen su origen en la propia concepción del proyecto y en su desarrollo posterior y que son susceptibles de mejora si se identifican y se corrigen las deficiencias de diseño.

El diseño de una glorieta es una tarea compleja y que requiere del trabajo de un especialista que lleve a cabo múltiples iteraciones hasta satisfacer una serie de objetivos. Las normas de diseño son un excelente recurso, pero no garantizan el éxito ya que la mayor parte de las glorietas presentan unas condiciones únicas que no se pueden ajustar a ningún estándar.

Las carencias en la aplicación de los principios de diseño a las condiciones específicas de cada proyecto pueden terminar manifestándose en la fase de explotación con pérdidas de funcionalidad y problemas de seguridad vial. Por este motivo, resulta de interés analizar las posibilidades de mejora del diseño en estos casos y su efecto en las condiciones de operación y seguridad.

En esta línea, la presente investigación propone la aplicación de una serie de ajustes de menor entidad en el diseño de glorietas en servicio y que, por este motivo, se han denominado de bajo coste. Estas se fundamentan en el conocimiento de los principios generales de diseño que gobiernan el proyecto de las glorietas.

El objetivo del presente trabajo es evaluar el efecto en la circulación y la seguridad de la aplicación de medidas de menor entidad en el trazado y señalización de glorietas con un funcionamiento deficiente.

Para ello se ha seleccionado dos casos típicos en la red de España:

- Glorieta multicarril urbana con problemas de capacidad.
- Glorieta multicarril interurbana con problemas de elevadas velocidades.

2. GLORIETA URBANA CON PROBLEMAS DE CAPACIDAD

El primer caso que se analiza es una glorieta de gran diámetro que resuelve la conexión de una vía de gran capacidad con el entramado urbano de un municipio (Fig. 1). Presenta las siguientes características:

- Elevado número de accesos distribuidos de manera no uniforme en los cuadrantes este y oeste de la intersección.
- Presencia de edificaciones y multitud de servicios en el entorno.
- Altas intensidades de tráfico en la glorieta (IMD = 38.232 veh/día).
- Presenta iluminación.

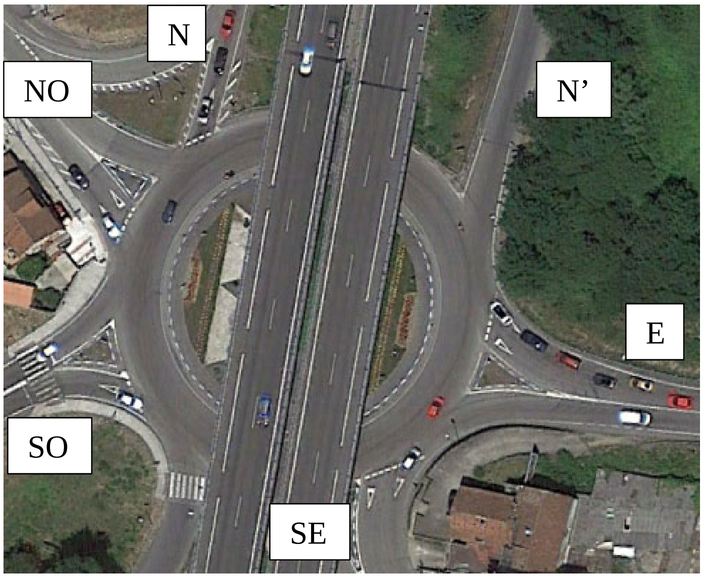

Fig. 1 Caso de estudio: glorieta multicarril con problemas de capacidad. Fuente: Google Earth.

La glorieta presenta problemas de capacidad, principalmente en las patas N y E (aspecto que se aprecie en la imagen satélite). Se plantea mejorar las condiciones de operación y el nivel de servicio a través modificaciones menores del diseño actual.

2.1 Datos de partida

2.1.1 Geometría

Se ha parametrizado la glorieta obteniendo todos los datos necesarios para la evaluación de la capacidad siguiendo el método clásico de Kimber (1980). Los valores se resumen en la siguiente tabla:

Entrada	v (m)	e (m)	l (m)	fi (g)	r (m)	D (m)
SE	6.43	6.93	0.00	21.0	18.9	64.0
E	4.08	7.29	5.70	36.0	17.7	64.0
N	4.15	4.15	0.00	31.0	12.0	64.0
NO	3.78	6.80	3.75	15.0	32.0	64.0
SO	3.78	4.86	4.56	19.0	20.0	64.0

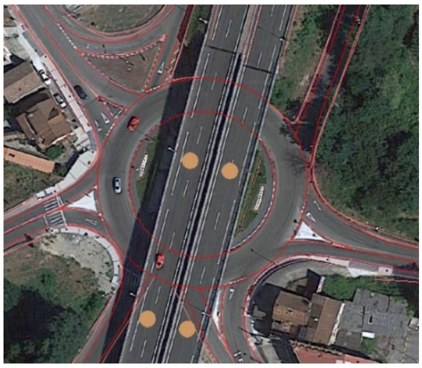

Tabla 1. Parámetros geométricos utilizados en el cálculo de capacidad.

Siendo:
v = la mitad de la anchura de aproximación.
e = anchura de la entrada.
l = longitud media efectiva del abocinamiento de la entrada.
fi = ángulo de entrada.
r = radio del borde exterior de la entrada.
D = diámetro del círculo inscrito.

Los círculos sombreados representan los apoyos de la estructura superior.

2.1.2 Tráfico

Se parte de un aforo de 16 h (entre las 6 h y las 22 h) realizado mediante cámaras de visión artificial en un día laborable de noviembre de 2018. No se pudieron obtener datos de accidentalidad.

2.2 Análisis de la situación actual

A partir de los datos registrados, y con la referencia de una estación permanente situada en las proximidades, se han obtenido las intensidades horarias IH-100 de vehículos totales en todos los movimientos:

	SE	E	N	NO	SO	
SE	46	170	16	149	326	706
E	74	0	562	282	152	1,070
N	120	169	26	59	302	676
NO	70	154	198	0	66	487
SO	232	273	192	0	0	696
	542	765	993	490	846	**3,636**

Tabla 2. Matriz origen – destino de intensidades IH-100.

Se consideró de acuerdo al aforo realizado un porcentaje de pesado del 6,5 %.

De los resultados del cálculo se concluye un funcionamiento deficiente, principalmente en dos entradas. Este aspecto se ha podido comprobar también en las visitas de campo.

	Ie (veh/h)	**Is (veh/h)**	**Qe (veh/h)**	**Qc (veh/h)**	**isat = Ie / Qe**	**NS**	
SE	707	542	1,424	1,012	0.50	A	Adecuado
E	1,070	766	1,072	953	1.00	F	Congestión
N	676	994	795	1,029	0.85	E	Saturado
NO	488	490	883	1,215	0.55	C	Adecuado
SO	697	846	976	857	0.71	B	Adecuado

Tabla 3. Resultados del cálculo de capacidad.

Donde:
Ie = intensidad de entrada.
Is = intensidad de salida.
Qe = capacidad en la entrada.
Qc = intensidad anular que corta dicha entrada.

Nivel de servicio global F. El trazado en planta es compatible con el paso de los vehículos más largos.

2.3 Propuesta de mejora

Debido a la configuración y el número de accesos lo ideal en estos casos es plantear dos glorietas, siempre que se garantice que las colas en la vía que conecta las glorietas no bloqueen las mismas. En el caso particular, dada su implantación en un medio urbano, no resulta factible debido al impacto en el entorno.

Por este motivo se plantea la mejora del diseño con medidas de menor entidad de manera similar a como lo han propuesto otros investigadores. McCulloch (2011) propone la mejora de la capacidad y de las condiciones de la canalización de los vehículos mediante la modificación de la señalización horizontal aprovechando el espacio generado en el diseño existente. Pochowski (2017) presenta la corrección de una glorieta multicarril en servicio con exceso de capacidad mediante la reducción del número de carriles. Para ello utiliza señalización horizontal. El efecto directo es la reducción del número de puntos de conflicto (aspecto muy favorable para la seguridad). En el trabajo de Gallelli y Vaiana (2019) se evaluó la transformación de la tipología de glorieta (de multicarril convencional a una turboglorieta) aprovechando el mismo espacio que la actual. La simulación resultó favorable en términos de capacidad y seguridad.

De manera particular para el caso de estudio, las correcciones de diseño que se proponen consisten en la mejora de las condiciones de las entradas con peor funcionamiento, las patas E y N, en base a la modificación de la geometría de los parámetros con mayor influencia: la anchura de entrada y la longitud media del abocinamiento. Además, se ha intentado facilitar la operación en el resto de accesos con una mejora de la canalización. Esto permite mejorar las condiciones de seguridad.

La estrategia, dadas las limitaciones de espacio, ha sido reducir la anchura de la calzada anular y el diámetro exterior, y aprovechar algún espacio adicional en las zonas sin servicios y edificaciones (espacio interior en las patas N y N'). La propuesta se puede observar en la siguiente imagen y se ha apoyado principalmente en las normas de diseño MF(2012), MF(2014) y MF(2016):

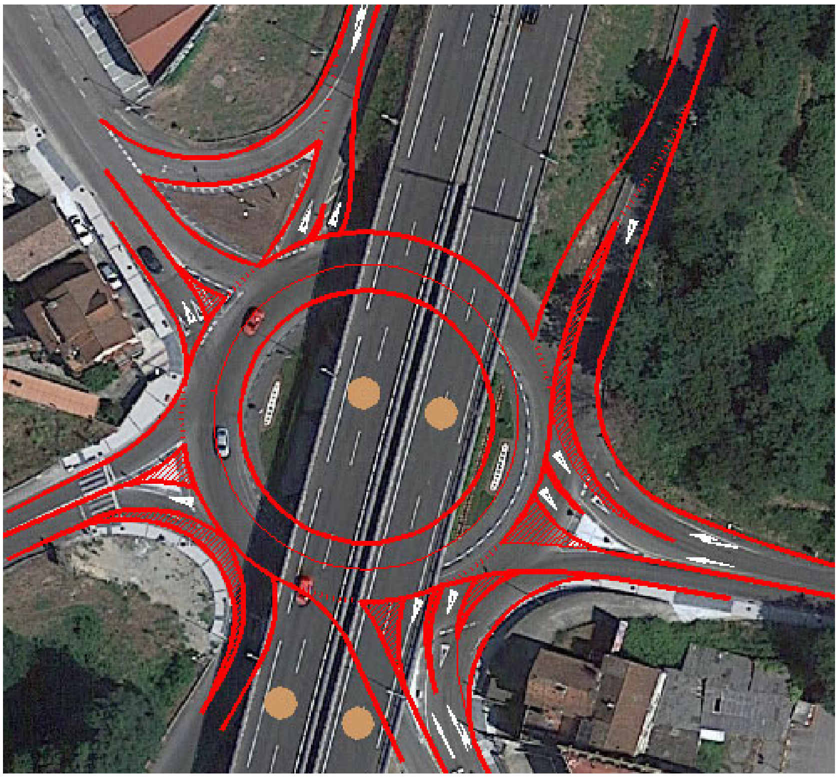

Fig. 2 Geometría de la propuesta de mejora.

Entrada	v (m)	e (m)	l (m)	fi (g)	r (m)	D (m)
SE	6.43	8.00	17.00	30.0	30.0	57.0
E	4.08	7.50	10.00	25.0	25.0	57.0
N	4.15	6.00	6.00	36.0	25.0	57.0
NO	3.78	4.50	4.00	27.0	17.5	57.0
SO	3.78	4.60	6.00	30.0	17.5	57.0

Tabla 4. Parámetros geométricos utilizados en el cálculo de capacidad.

El trazado propuesto no interfiere con ningún servicio y requiere adoptar nueva señalización en los accesos, principalmente en aquéllos que se han dotado con carriles segregados. Como se observa en la imagen el diseño es compatible con el paso de un vehículo articulado y, en la calzada giratoria, de manera simultánea con un turismo.

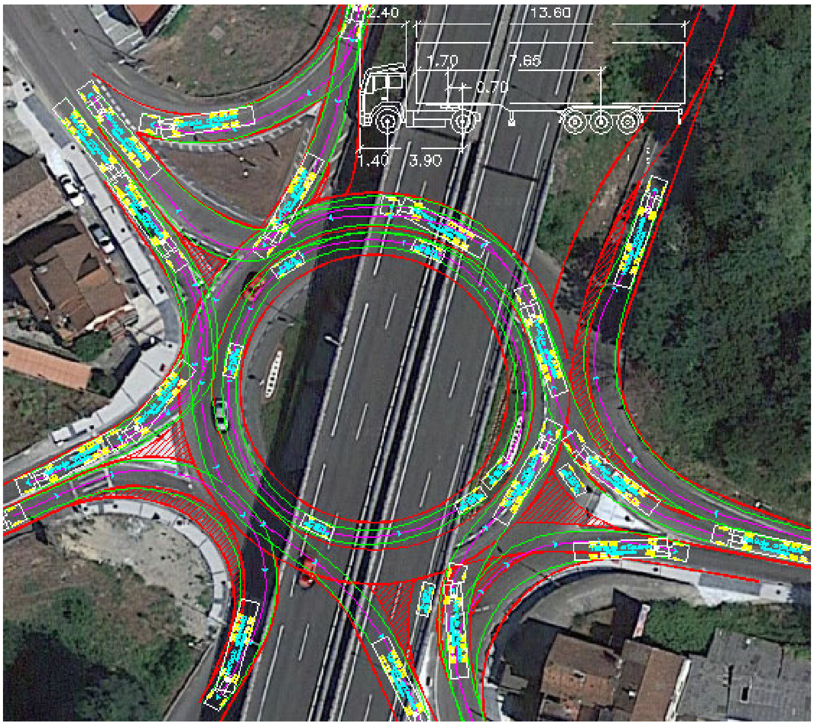

Fig. 3 Caso de estudio: comprobación de áreas barridas en la propuesta.

En cuanto a la capacidad, y como se observa en la tabla, el resultado es satisfactorio ya que los niveles de servicio se han mejorado notablemente. Un estudio de la evolución de la demanda de tráfico puede concluir hasta qué año el diseño podría mantenerse con unos niveles adecuados.

	Qe (veh/h)	**Qc (veh/h)**	**isat = Ie / Qe**	**NS**	**NS acceso**	
SE	1.510	1,012	0.35	A	A	Adecuado
SE (Bypass)	561	1,012	0.31	A		Adecuado
E	927	953	0.55	C	B	Adecuado

NO	822	1.215	0.6	B	B	Adecuado
SO	972	857	0.71	C	C	Adecuado

Tabla 5. Cálculo de capacidad en la propuesta de mejora.

Nivel de servicio global B.

3.GLORIETA INTERURBANA CON PROBLEMAS DE VELOCIDADES

3.1 Datos de partida

En el segundo caso se analiza una glorieta interurbana que resuelve la intersección entre una vía principal de doble calzada (carretera multicarril) y una secundaria (Fig. 4). Presenta las siguientes características:

- Elevadas intensidades de tráfico en la vía principal. Según los datos de aforos de una estación muy próxima, en el año 2018, se registró una IMD de 26.663 veh/d.

- La velocidad media en la vía principal de acuerdo a los datos publicadas por la Administración que gestiona la vía es de 79 km/h. Presenta una velocidad máxima señalizada de 80 km/h.

- A unos 300m, y en el movimiento norte – sur, se localiza un radar fijo de control de la velocidad.

- En los accesos de la vía principal se disponen bandas transversales de alerta (tipo resaltadas).

- Existe iluminación.

Fig. 4 Caso de estudio: glorieta multicarril con problemas de altas velocidades. Fuente: Google Earth.

3.2 Análisis de la situación actual

La problemática de esta glorieta se puede resumir en los siguientes puntos:

- No existe deflexión en el perfil de velocidades en los movimientos de paso por la vía principal (se puede cruzar mediante una trayectoria casi rectilínea). Esto genera altas velocidades en las entradas a la glorieta desde la vía principal (se recurre a un radar fijo) y, en consecuencia, un aumento de la probabilidad de accidente, tanto por pérdida del control del vehículo como por colisión con vehículos que circulan por la calzada anular durante la propia maniobra de entrada. Adicionalmente esta configuración puede provocar una pérdida de capacidad.

- No hay equilibrio en el número de carriles: accesos de uno y dos carriles y calzada anular de tres.

- La canalización de las trayectorias es inadecuada. Los movimientos de entrada y salida desde la vía secundaria se producen, observando las rodadas, hacia y desde el carril más interior (la salida desde el anillo debe hacerse desde el carril más exterior).

- La dimensión de los elementos no se ajusta a los movimientos reales de los vehículos. Como en el punto anterior, observando las rodadas de los vehículos, se pueden diferenciar amplias zonas de la glorieta que no son necesarias.

3.3 Propuesta de mejora

De forma general, en aquellos casos en los que se ha identificado una problemática similar a la del caso de estudio presentado, los investigadores han propuesto y analizado diferentes medidas con correcciones menores en el trazado y la señalización.

Price (2011) presenta varios casos en los que mediante ligeras correcciones de trazado se mejoran las condiciones frente al control de las velocidades y el guiado de los vehículos. Según la autora se deben evitar puntos angulosos en la delimitación de los bordes de calzada. A nivel normativo, cabe destacar la propuesta de la guía de diseño del estado de Queensland (Australia) (QDMR, 2006) para la mejora de la deflexión: ajuste de las dimensiones en las entradas de forma que se limiten las trayectorias de los vehículos más rápidos e imposición de curvas sucesivas de sentido contrario en las aproximaciones para favorecer una deceleración uniforme. Hu (2011) expone que, de acuerdo a las observaciones de campo, el 70% de los accidentes se producen en las entradas por lo que propone una serie de medidas para reducir la velocidad en las aproximaciones y mejorar la percepción de los carriles y la calzada giratoria. Estas se basan en la mejora de la señalización horizontal con marcas viales de selección de carriles, la señalización vertical y la implantación de reductores de velocidad y bandas transversales de alerta.

De manera particular para el caso de estudio, se realiza una corrección de la geometría de la aproximación en las dos entradas con problemas de velocidad. Además, se propone el ajuste de las dimensiones de la calzada anular y las patas para mejorar la canalización y el equilibrio de carriles. Se reforma la señalización horizontal y se aplican medidas complementarias de mejora de la señalización y el balizamiento como pueden ser bandas transversales de alerta, si se evalúa que no suponen afecciones sonoras a las viviendas del entorno. Para la definición de las marcas viales se sigue el criterio de la Guía de Nudos (MF, 2012) aunqueno es coherente con el actual Reglamento de Circulación.

En la siguiente imagen se muestra la geometría y las trayectorias más rápidas (en verde) en los accesos principales que puede establecerse siguiendo la metodología recogida en Rubio et. al 2019 y en Rubio (2017).

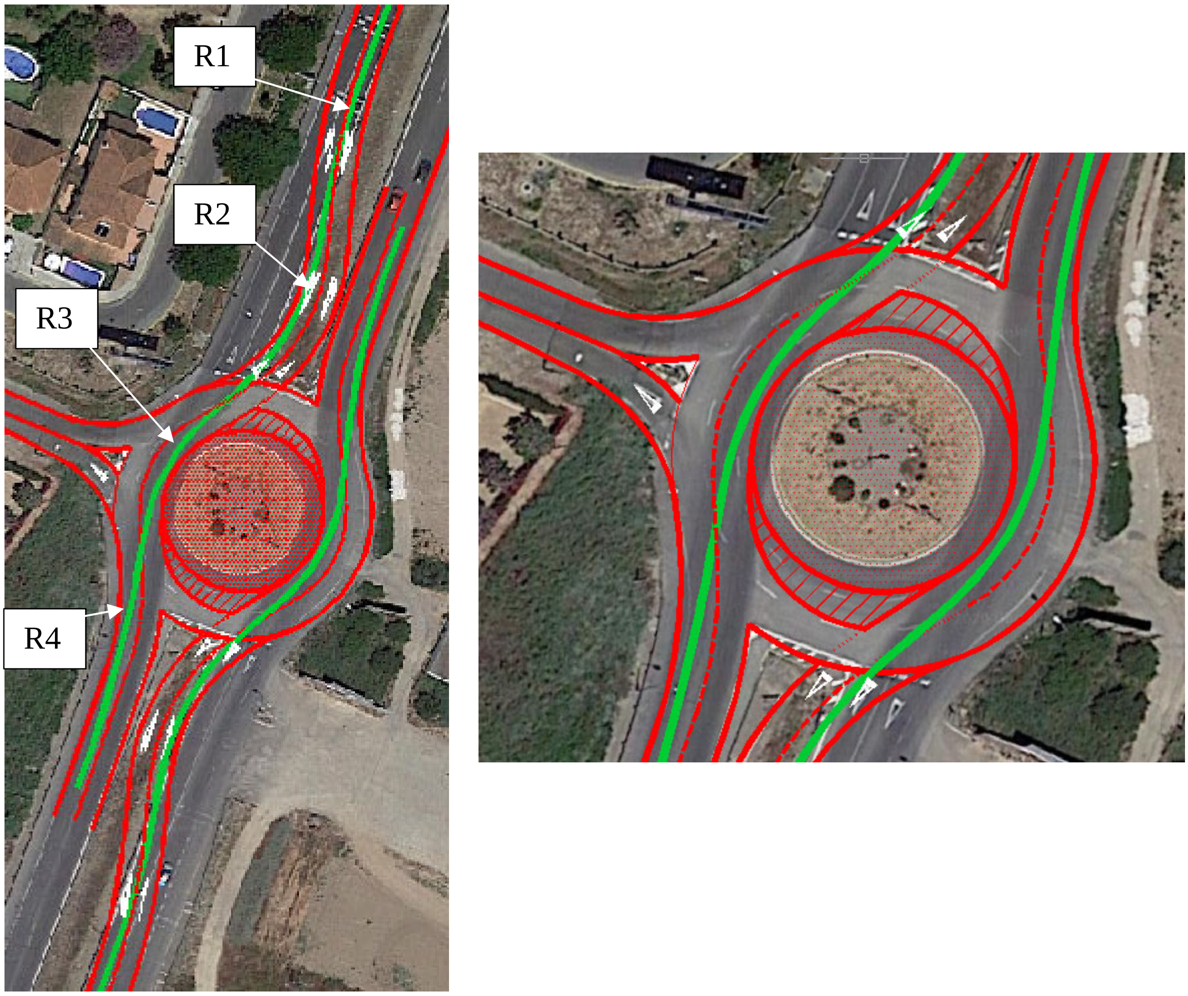

Fig. 5 Caso de estudio: glorieta multicarril con problemas de altas velocidades. Fuente: Google Earth.

Como se observa, la mejora del trazado en las aproximaciones permite el curvado de las trayectorias más rápidas y el descenso de las velocidades lo cual favorece la consistencia y, en definitiva, la seguridad viaria. El criterio que se ha seguido supone realizar una reducción gradual de la velocidad en la aproximación y hasta el paso por la calzada anular donde posteriormente se inicia la maniobra de aceleración hacia la salida. El resultado se considera satisfactorio como se puede concluir de los valores obtenidos, similares en ambas patas, y que se presentan a continuación:

- El primer radio de la trayectoria (R1) está en el orden de los 140m, luego se puede asumir una V_{85} de 55 km/h.

- El segundo radio de la trayectoria (R2) está en el orden de los 55m, luego se puede asumir una V_{85} de 35 km/h.

- El tercer radio (R3), en la calzada anular, está en el orden de los 35m, luego se puede asumir una V_{85} de 30 km/h.

- El radio de salida (R4) está en el orden de los 180m, y las velocidades dependen de la capacidad de aceleración de los vehículos.

Por tanto, con esta configuración se favorece la moderación de las velocidades y su consistencia.

4.CONCLUSIONES

En este trabajo se ha analizado el efecto sobre la circulación y la seguridad de la aplicación de mejoras de menor entidad en glorietas en servicio que presentan problemas de funcionamiento. Estas se han basado en el conocimiento y aplicación de los principios de diseño de glorietas y consisten fundamentalmente en la mejora del trazado y de la señalización y el balizamiento, de manera similar a como lo han propuesto otros investigadores.

El primer caso analizado se refiere a una glorieta multicarril implantada en medio urbano con problemas de capacidad. El conocimiento de los parámetros con mayor influencia en la operación de los tráficos ha permitido proponer una serie de ajustes en el diseño geométrico. Estos se han compatibilizado con el medio en el que se inserta la glorieta aprovechando los espacios anexos e interiores libres y minimizando de esta forma las afecciones. Los resultados del cálculo muestran una mejora significativa de los niveles de servicio y la sensibilidad del diseño al valor de la anchura de entrada, la longitud de abocinamiento y los carriles segregados de giro directo. Es conveniente en este caso y, en general, contrastar estos resultados con otros deducidos de un método de cálculo de capacidad diferente.

Por otra parte, los ajustes en la geometría permiten mejorar el guiado efectivo en las trayectorias naturales. La actuación se complementa con la mejora de la señalización y el balizamiento en coherencia con la nueva configuración que, en conjunto, proporcionan una mejor respuesta frente al condicionante de seguridad vial.

En el segundo caso se presentó una problemática diferente. La intersección de estudio es una glorieta multicarril situada en entorno interurbano con problemas de seguridad derivados de las altas velocidades de entrada en los accesos del eje principal. Como en el caso anterior, el conocimiento de los principios de diseño permitió enfocar la actuación que, en este caso, se basó en la modificación del trazado (curvado de las trayectorias) y la señalización (selección del carril en las entradas y la calzada anular). De manera adicional se modificó la sección transversal de la calzada giratoria proporcionando continuidad a los flujos y evitando afecciones en el exterior de la misma. Los resultados muestran que, en ambos accesos, se obtiene un perfil de velocidades similar en el que se observa una deceleración gradual hasta la llegada a la calzada anular. Así, el primer radio definido sitúa la velocidad para la trayectoria más rápida por debajo de 60 km/h y, para el segundo localizado de manera previa a la entrada a la calzada anular, por debajo de 40 km/h. En el perfil de velocidades original no existían restricciones (trayectoria más rápida casi rectilínea) más allá de la que prescribe la señalización vertical. El complemento mediante señalización y balizamiento permiten asimismo mejorar la percepción de la intersección y el guiado.

En definitiva, la aplicación de correcciones menores en el trazado y la señalización en glorietas con un impacto reducido en el entorno y en los costes se demuestra como una alternativa viable para la solución de determinadas problemáticas de funcionalidad y seguridad viaria.

RESUMEN

En la presente investigación se detallan los resultados de la investigación preliminar llevada a cabo en el marco del proyecto EMULCELL. Este proyecto nace con el objetivo de desarrollar nuevos tipos de emulsiones bituminosas mediante el empleo de nanocelulosas como agentes emulgentes. La finalidad de la presente investigación es la de minimizar los impactos ambientales asociados a la producción de este tipo de materiales de construcción y fomentar el uso de mezclas en frío, que presentan menores emisiones de gases de efecto invernadero y son de puesta en obra más sencilla y segura para los operarios.

Para llevan a cabo la presente investigación se ha utilizado un molino coloidal con el fin de fabricar diferentes emulsiones bituminosas, de tipo C60B5, pero sustituyendo parte del agente emulgente comercial por nanocelulosa. Con las emulsiones así fabricadas, se han llevado a cabo ensayos de envuelta con el fin de determinar la cantidad más adecuada de agua de envuelta y de comprobar la mayor o menor facilidad de estas emulsiones para recubrir toda la superficie del árido durante el proceso de fabricación de mezclas bituminosas en frío. Los resultados se han comparado con los obtenidos para una emulsión de control de tipo C60B5 comercial.

En general, cabe destacar la dificultad encontrada para obtener una emulsión catiónica. Finalmente, puede decirse que, en cuanto a envuelta, los resultados obtenidos son, en buena parte de los casos, similares a los obtenidos con la emulsión convencional. Sin embargo, se aprecia a simple viste una mayor cantidad de sedimento en las emulsiones fabricadas con nanocelulosa.

Por tanto, para obtener resultados concluyentes, se requiere profundizar en la investigación. En fases posteriores se realizará un detallado análisis de la sensibilidad al agua de las mezclas fabricadas con estas emulsiones, así como un análisis de su rigidez, deformación permanente y susceptibilidad térmica.

1. INTRODUCCIÓN

En 1997 se crea en Europa el Foro Alemán del betún, cuyos objetivos fundamentales eran aclarar los posibles peligros del betún y resolver problemas específicos de salud y seguridad de los trabajadores (Rühl y Musanke, 2006). También en 1997, se adoptó el Protocolo de Kyoto, cuyo objetivo fundamental era el de reducir las emisiones de gases de efecto invernadero (GEI) hasta los niveles de 1990 (Croteau y Tessier, 2008). La utilización de mezclas en frío claramente se encuentra alineada tanto con los objetivos del Foro Alemán del betún como con los del Protocolo de Kyoto.

El proyecto EMULCELL nace, por tanto, con esta doble motivación: reducir gases de efecto invernadero y favorecer la seguridad y salud de los trabajadores. Para ello, en el marco de este proyecto, se estudia la posibilidad de utilizar nanocelulosa como agente emulgente de emulsiones bituminosas para la fabricación de mezclas en frío mejoradas y más sostenibles. Esto permitiría sustituir agentes químicos comerciales por productos elaborados a partir de residuos de, por ejemplo, la industria papelera.

El mercado potencial de uso de estas nuevas emulsiones solo en España es enorme. Así, según datos del Ministerio de Transporte, Movilidad y Agenda Urbana (2018), solo la red de carreteras interurbanas de titularidad de los ayuntamientos tenía a finales de 2018 una longitud de 361.517 km. Son precisamente este tipo de vías secundarias, en las cuales las mezclas en frío presentan su mayor potencial de aplicación.

A nivel comercial, existe un derivado de la celulosa que se puede utilizar como agente emulgente de emulsiones bituminosas. Se trata de la carboximetilcelulosa de sodio (CMC) (Hou et al., 2019). Pero hasta la fecha no se han encontrado investigaciones relativas al empleo de nanocelulosa en emulsiones de este tipo.

2. MATERIALES Y MÉTODOS

2.1 Áridos

Como árido natural se ha utilizado una corneana, obtenida de la cantera de Astariz (Ourense), en la Comunidad Autónoma de Galicia. Sus principales propiedades pueden verse en la tabla 1.

Propiedad	Corneana
Índice de lajas (FI) según la norma UNE-EN 933-3	24 %
Partículas trituradas según la norma UNE-EN 933-5	100 %
Equivalente de arena (SE) según la norma UNE-EN 933-8 (0/2 mm)	61 %
Coeficiente de Los Ángeles (LA) según la norma UNE-EN 1097-2	14,2 %

Tabla 1 – Propiedades de los áridos

2.2 Nanocelulosa

En la presente investigación se han utilizado dos tipos diferentes de nanocelulosa: nanofibras de celulosa (NFC) y nanocristales de celulosa (CNC). Las propiedades de ambos tipos de nanocelulosa se incluyen en la tabla 2.

Propiedad	NFC	CNC
Densidad aparente	-	0,7 g/cm^3
Área superficial específica	-	400 m^2/g
Gramo de peso molecular	-	14.700 - 27.850
Tamaño de partícula	-	1-50 µm
Contenido de humedad	-	4 - 6 %
Densidad de cristalito	-	1,5 g/cm^3
pH(dispersión en agua)	-	6 - 7
Fuerza iónica	-	230 - 270 mol/kg
Viscosidad en agua (2%)	>20.000 mPas	-
Conductividad (2%)	<500 µS/cm	-
pH (2% en agua)	5 - 7	-
Capacidad de retención de agua	≥ 70 gH_2O/g	-

Tabla 2 – Propiedades de la nanocelulosa facilitadas por el suministrador

2.3 Agente emulgente comercial

Se han utilizado tres emulgentes comerciales de referencia: el Polybit QP-30 (de rotura lenta), el Polybit QPE-L (de rotura lenta) y el Prebit 100L (de rotura rápida). El primero está constituido por un polímero orgánico con grupos amino y propiedades tensoactivas con una dosificación recomendada entre el 2,5% y el 4,0%. El segundo está constituido por un copolímero orgánico con grupos amino y propiedades tensoactivas, con una dosificación recomendada de entre 0,8% y 1,2%. El tercero es un emulgente catiónico, líquido a 25ºC.

2.4 Betún

Para la fabricación de las emulsiones con nanocelulosa se ha utilizado un betún B160/220.

2.5 Emulsión bituminosa de control

Como emulsión de control se ha seleccionado una emulsión comercial C60B5 GE. Presenta un 59,8% de betún obtenido por destilación según la norma UNE-EN 1431. Su índice de rotura obtenido siguiendo la norma UNE-EN 13075-1 fue de 214, por lo que se trata de una emulsión de rotura lenta.

2.6 Fabricación de emulsiones bituminosas mediante molino coloidal

Con el fin de fabricar las emulsiones con sustitución parcial del agente emulgente químico comercial por nanocelulosa, se ha utilizado un molino coloidal emulsionador (Figura 1).

Fig. 1 – Molino coloidal utilizado

El procedimiento de fabricación utilizado se resume a continuación:

- Se calienta el B160/220 a 120ºC y se pesa la cantidad requerida.
- Se procede a constituir la fase dispersante: se pesa la cantidad de agua y emulgente requeridos y se mezclan a 60ºC con un agitador magnético. Finalmente, se ajusta su pH mediante la adición de HCl, hasta obtener un pH inferior a 7.
- Se acondiciona el molino coloidal a 80ºC.
- Una vez se tiene todo aclimatado a la temperatura de trabajo se introduce la fase dispersante en el molino coloidal, que trabaja a 3.000 rpm. Posteriormente se añade el betún paulatinamente de manera que el grosor del flujo no supere los 6 mm.
- Se abre la válvula de salida del molino para que fluya la emulsión bituminosa por el molino coloidal.

2.5.1 Ensayos de envuelta

El agua de envuelta es necesaria para la correcta dispersión de la emulsión durante la fase de mezclado de la mezclas bituminosa. Para determinar el contenido de agua de envuelta, se siguió la norma NLT-145. Se llevaron a cabo tanteos con diferentes contenidos de agua de envuelta. En concreto se probó con un 0%, 1%, 2% y 3% de agua de envuelta sobre el peso del árido seco. Además, para la totalidad de los contenidos de agua se analizaron dos contenidos de ligante residual: un 2,5% y un 3%. Para todos los casos se utilizó una mezcladora mecánica y una cantidad de árido de unos 500 gramos. El tiempo total de mezclado fue de 2 minutos: 1 minuto mezclando el agua de envuelta con el árido y, a continuación, 1 minuto mezclando la emulsión. Visualmente se determinó el contenido de agua más adecuado, como aquel que permite alcanzar un mejor recubrimiento de los áridos para ambos contenidos de ligante residual.

3. RESULTADOS Y DISCUSIÓN

3.1 Emulsión bituminosa de control

Como se aprecia en la figura 2, el agua de envuelta necesaria para la emulsión de control C60B5, se estimó en un 3%.

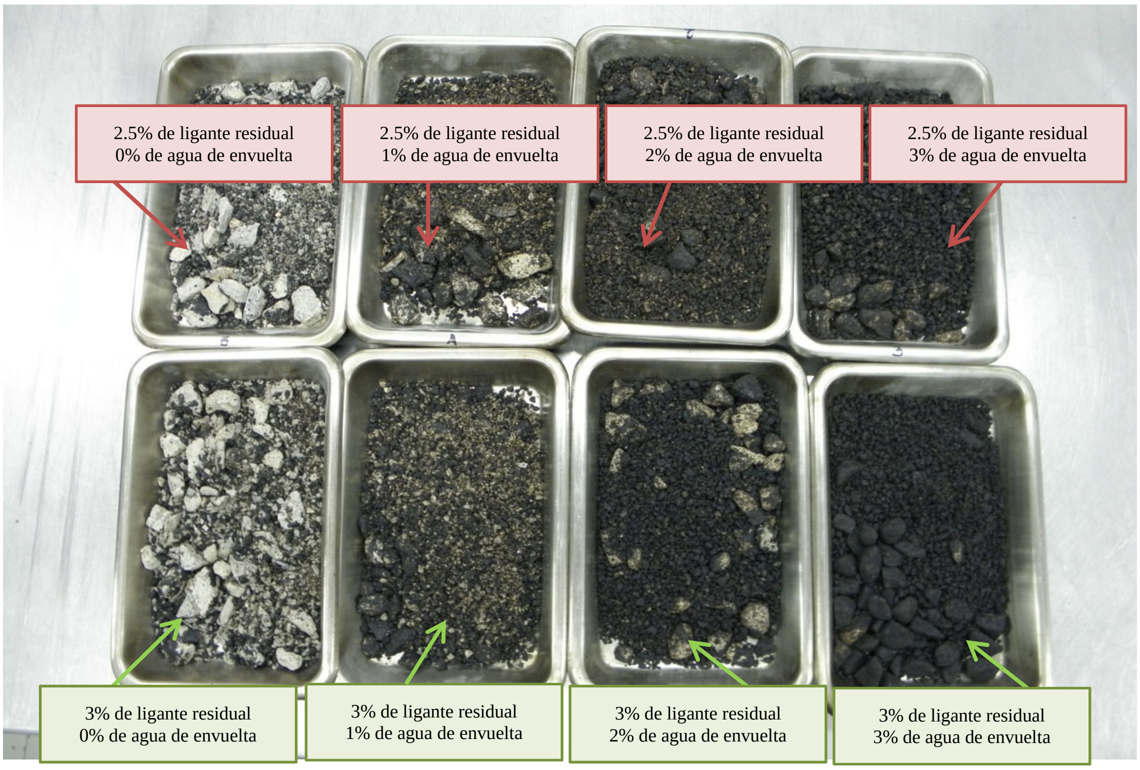

Fig. 2 – Análisis del agua de envuelta de la emulsión de control C60B5.

3.2 Emulsión con nanocelulosa

En laboratorio se hicieron diversas pruebas de fabricación con el molino coloidal de emulsiones tipo C60B5 utilizando los dos tipos de nanocelulosa (NFC y CNC) como sustitutos parciales del agente emulgente comercial. Durante la fabricación de las mismas se obtuvieron diferentes complicaciones. La primera de ellas es que, inicialmente, la emulsión obtenida al utilizar CNC como agente emulgente, resulta de naturaleza aniónica, cuando el producto buscado era una emulsión catiónica, más versátil para todo tipo de áridos y climatologías. Ese problema se intentó solucionar mediante la utilización de CNF y de otras nanocelulosas cationizadas. El segundo problema encontrado fue que realizar una sustitución total y elevada de emulgente comercial por nanocelulosa daba lugar a emulsiones con elevadas viscosidades, que llegaban a atascar el molino coloidal, lo cual hacía inviable su fabricación a escala de laboratorio. Para solventar este inconveniente se redujo el porcentaje de sustitución del emulgente comercial. Con todo ello, de entre todas las emulsiones fabricadas, finalmente llegó a analizarse la envuelta de un total de 8 emulsiones bituminosas con nanocelulosa:

- eNanocel-01: 0,4 % de CNC
- eNanocel-02: 1,2 % de CNC
- eNanocel-03: 0,8 % de CNC cationizada con Glycidyltrimethylammonium choride (GTMAC)
- eNanocel-04: 1 % de CNC cationizada con Glycidyltrimethylammonium choride (GTMAC)
- eNanocel-05: 0,4 % cationizada en origen.
- eNanocel-06: 0,4 % de CNC y 2 % de Polybit QP-30
- eNanocel-07: 0,6 % de CNC y 1 % de Polybit QP-30
- eNanocel-08: 0,6 % de CNC y 0,35% de Prebit 100L

En la figura 3 se incluyen los resultados de la emulsión bituminosa con nanocelulosa que aportó mejores resultados de envuelta: eNanocel-07. Como puede apreciarse, el 3% sigue siendo el contenido de agua de envuelta más adecuado. Además, los resultados arrojados por esta emulsión, son similares a los obtenidos para la emulsión de control.

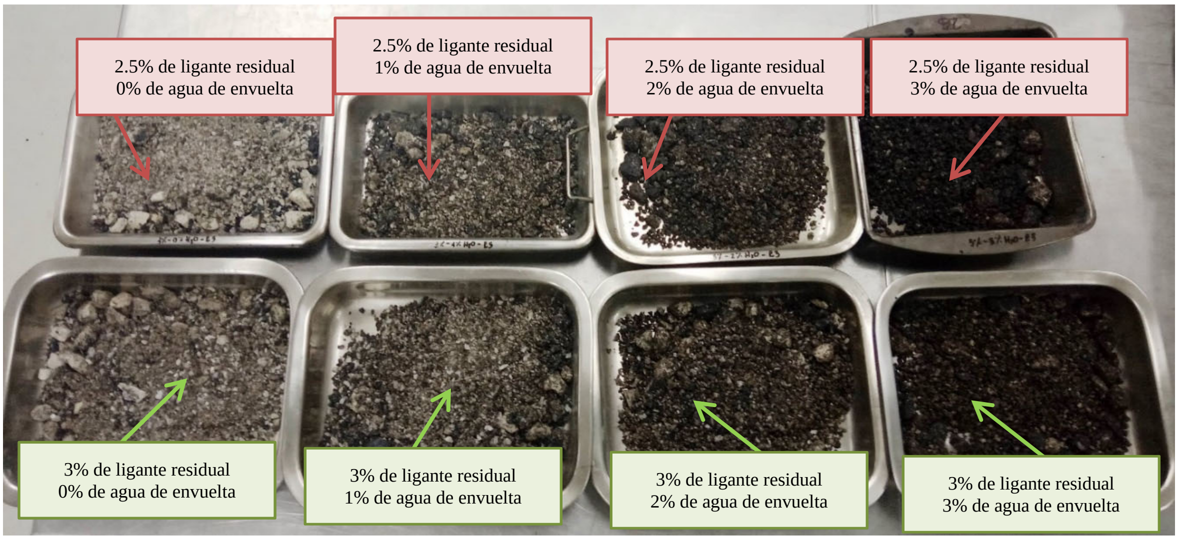

Fig. 3 – Análisis del agua de envuelta de la emulsión eNanocel-07.

Sin embargo, es preciso destacar que, como puede apreciarse en la figura 4, en la emulsión con nanocelulosa se obtuvo una gran cantidad de sedimento. Por ello, aunque los resultados obtenidos son alentadores, se hace preciso profundizar aún más en el análisis de esta nueva emulsión bituminosa. Particularmente mediante el análisis de sensibilidad al agua de mezclas en frío fabricadas con la nueva emulsión con nanocelulosa, así como el estudio de su rigidez y deformación permanente.

Fig. 4 – Sedimentos dejados por la emulsión eNanocel-07.

4. CONCLUSIONES

La dificultad de fabricar emulsiones bituminosas catiónicas de tipo C60B5 utilizando nanocelulosa como agente emulgente, ha quedado claramente patente con el análisis preliminar de laboratorio realizado para la presente investigación.
Sin embargo, tras una compleja investigación de laboratorio, se ha conseguido obtener hasta un total de 8 emulsiones con nanocelulosa como sustituto parcial del agente emulgente.

La que mejores resultados obtuvo en el presente análisis preliminar se dosificó con un 0,6 % de CNC y un 1 % de Polybit QP-30. Esta nueva emulsión arrojó resultados similares a la emulsión C60B5 de control en cuanto a agua de envuelta. Así, se estimó que un 3% de agua de envuelta es el contenido más adecuado.

La presencia de sedimentos apreciables a simple vista en la emulsión con nanocelulosa hace que sea necesario profundizar en el estudio de la misma antes de poder obtener una conclusión clara sobre su funcionamiento. En este sentido, se hace especialmente necesario analizar la sensibilidad al agua, rigidez y resistencia a la deformación permanente, de mezclas en frío fabricadas con esta nueva emulsión y comparar los resultados con los obtenidos para la emulsión de control.

AGRADECIMIENTOS

Junto con la constructora ourensana Misturas, S.A. participan en el proyecto el Centro Tecnológico de Investigación Multisectorial (CETIM) y el Grupo de Carreteras, Geotecnia y Materiales de la Universidade da Coruña (GCGM-UDC), con el apoyo de la consultora Eurofunding International.

El proyecto EMULCELL está co-financiado por el Centro para el Desarrollo Tecnológico Industrial (CDTI), Ministerio de Economía y Competitividad-Gobierno de España, y el Fondo Europeo de Desarrollo Regional (FEDER) (Ref. IDI-20171097)

Los autores quieren además agradecer a Repsol, Química de los Pavimentos y Áridos de Astariz que hayan facilitado parte de los materiales necesarios para poder llevar a cabo la investigación.

REVISION OF THE SPANISH QUALITY CONTROL PROCEDURE FOR ROFILLS AND RANDOM FILLINGS

Evelio Teijón-López-Zuazo
Professor of Construction Engineering, University of Salamanca, Spain
Ángel Vega-Zamanillo
Professor of Roads and Traffic, University of Cantabria, Spain
Miguel Ángel Calzada-Pérez
Professor of Roads, University of Cantabria, Spain

ABSTRACT

Infrastructure quality control must be done through an adequate control process, which must be well planned, programmed and executed. It implies the revision of the specific control procedures as part of the general objective of continuous improvement. It must be applied to the construction of quarries with stone materials, called rockfills for large sizes or random fillings for intermediate products. There continues to be a problem in terms of compacting control methods in the execution of these diggings, with little practical development of new techniques when the spread is of good – quality material an aspect that must be revised in order to ensure the quality of the final result extended and compacted. The current procedures for Quality Control in rock compaction have limited operability. For example, the granulometric analysis with macro-pits ($4m^3$) it is have done with heavy fractions, being a destructive testing. The average density control by nuclear methods has high heterogeneity, low performance and low thickness tested. The topographic measurement settlement is the most accurate, but it is a poorly referenced method. For the wheel impression test, the required values do not impose any limitation.

This research studies the application use to granites, slates and granitic alteration soils stabilized using cement. The necessary field and laboratory works were developed in order to elaborate new test procedures for a proposed compaction control in rocks. The compaction control procedures revised were wheel impression test, topographic settlement and plate load test (PLT). Doing simple regression on SPSS, in which any predictor outcome variable (dependent) should be placed (independent). An analysis of variance ANOVA shows the sums of squares and the degrees of freedom associated with each: is significant at $p < 0,05$. There is less than 0,5% chance that an F Levene – ratio this large would happen if the null hypothesis were true.

1. INTRODUCTION

Infrastructure quality control must be done through an adequate control process, which must be well planned, programmed and executed. It implies the revision of the specific control procedures as part of the general objective of continuous improvement.

The classical sense of road geotechnics implies that stone materials, with a high maximum size, were rejected. This meant that high quality materials were underused. Today, there is a less restrictive trend towards the use of materials to achieve the highest environmental efficiency. There is a need to review the quality control compaction at rockfills and random fills. Optimization of the compaction control means a reduction of the inspection times, adapting the quality to the high construction performance shown in figure 1.

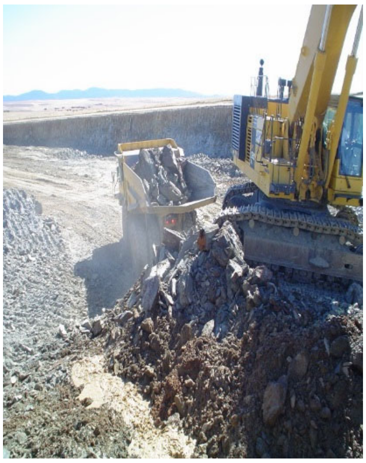

Figure 1. Rock diggings with high construction performance

This research is applied to the construction of quarries with stone materials, called rockfills for large sizes or random fills for intermediate products. With a high variety of rocks, this study has been particularized to granites rockfills, figure 2, and slates in random fillings.

Figure 2. Granitic rock excavation associated to rockfill

2. STATE OF THE ART

For Teijón-López-Zuazo et al. (2020), grading with pits, weighing different rock fractions presents a limited operability. The control of topographic settlements defined in the General Specifications for Roads and Bridges Works, PG-3 (2002), presents reference values and thresholds that are not very practical. The wheel impression test, UNE 103 407 (2005), usually complies. The plate load test, UNE 103 808 (2006), is only representative for plate load sizes five times the maximum of the aggregate.

There are limitations in the nuclear density methods UNE 103 900 (2013) due to the high particle sizes, the layer thicknesses to be tested, greater than 30cm, and the lack of reference in the Proctor test UNE 103 501 (1994). So, there continues to be a problem in terms of compacting control methods in the execution of rockfills and random fills, figure 3, with little practical development of new techniques when the spread is of good – quality material an aspect that must be revised in order to ensure the quality of the final result.

Figure 3. Execution of random fill

The French Standard includes in a more detailed way the use of rocky materials. Thus, the technical guide "Construction of embankments and esplanades" GTR (2003), published by the LPC (Laboratoire Central des Ponts et Chaussées), classifies within the group R_6 magmatic and metamorphic rocks (granites, andesites, gneisses, metamorphic schists and slates, etc.). The classification is made conforming to the values of resistance to fragmentation UNE-EN 1097-2 (2010), resistance to wear (micro-Deval) UNE-EN 1097-1 (2011) and dynamic fragmentation test, XP P 18-574 (1990). Sopeña (2007), with experimental sections, considers that the topographic settlement is the most important test in stone materials. It obtains graphically the number of passes from which the deformation ends, that is, the pass with which the stabilization of the settlements is reached, figure 4.

Figure 4. Topographic settlement control after roller pass

An example of other control techniques is the compactometer, Rahman et al (2012), which is used on the vibration equipment itself. These are the rollers with intelligent compaction (IC rollers). They have an accelerometer in the transducer and a measurer in the dashboard.

As a curiosity, as an example of the great possibilities of developing other techniques, space exploration has developed procedures to estimate soil density by remotely controlled drone raking from Earth. Gertsch et al. (2013) have deduced the density of the lunar soil raked with the raking force.

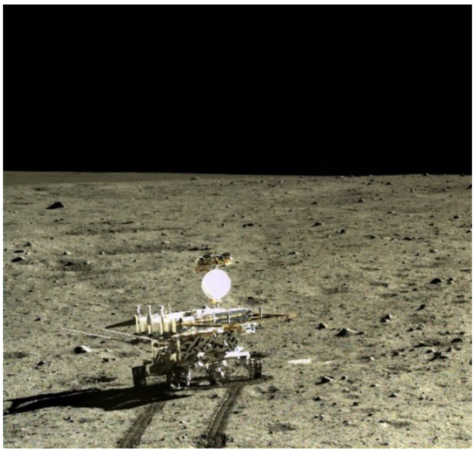

Figure 5. Lunar exploration (NASA)

Scale models with JSC-1a (artificial lunar regolite), have provided relationships between the density of the soil or regolite rock, the shale and the scarifiers of the ship.

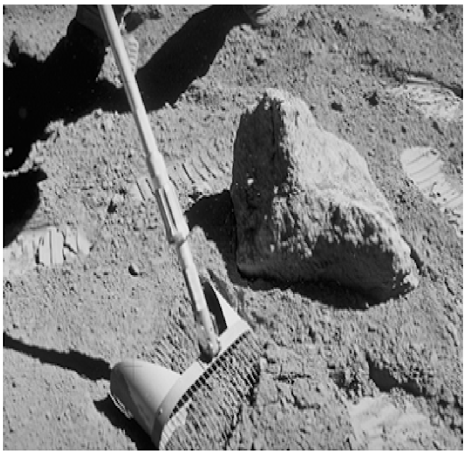

Figure 6. Apollo 16 photograph (NASA)

3. MATERIALS

The tests were carried out as part of the Quality Assurance Plan for the A-66 motorway on the Cáceres (N) - Aldea Cano section attached to the Ministry of Public Works, where were used granites, slates and slate alluvial materials. Table 2 provides a summary, including examples of the tests that were conducted on the slate alluvial material. The last row showing average values.

Table 1. Examples of physical parameters for slate alluvial material identification

4. METHODOLOGY

Thus, the necessary field and laboratory works are developed in order to elaborate new test procedures for a proposed compaction control in rocks. Compaction control procedures revised: wheel impression test (figure 7), topographic settlement, plate load test.

Figure 7. Wheel impression test: passing over the alignment pegs

The revision to the wheel impression test (UNE 103 407) implies modifying several aspects, such as the marking with plaster by levelling picks, figure 8, going from 10 points aligned at 1 meter to 2 rows of 5 points spaced 10 meters. This means an increase in the test length from 9 to 40 meters. It also moves from initial leveling over land to over pikes. Instead of taking readings on a wheelbase, the two truck tracks are measured, figure 9.

Figure 8. Wheel impression test: leveling over pikes

Figure 9. Schematic diagram of wheel impression test

Another revised test is the topographic settlement control, as shown figure 10. A measuring reference has been changed from the first roller pass to the penultimate one.

According to results in experimental sections, the criterion of settlement between the first and last pass of less than 1% has not been accepted (for a thickness of 1m, admissible settlement 10 mm). It has been proposed as a measurement criterion the settlement between the penultimate and last pass of the compacting roller, which in case of rockfills, should be less than 5mm. The measuring system has been changed from being undefined to having levelling picks distributed in 2 rows of 5 points spaced 10 m.

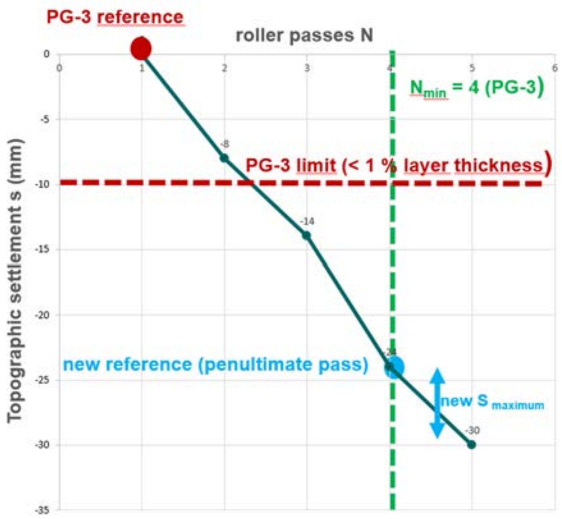

Figure 10. Revised topographic settlement test

According to the PG-3, the PLT test is representative when the plate diameter is at least 5 times the maximum size. This would result plates of 4300 and 2000 mm when the biggest standard size is 762 mm, figure 11. Traditionally the 300mm plate has been used, which gives positive results independently of the compaction conditions. It is more correct to use the 762 mm, which corresponds to the limit of manageability. It is proposed to review by size, using the Ø 762 mm plate in stone fillings and the Ø 600 mm plate in random fillings.

Figure 11. standard load plates (300, 600 and 762mm)

The PG-3 recommends not to use nuclear tests except when correlated with the sand method, although this test is also not representative for stone materials, figure 12. The determination "in situ" of density of soil by the sand method (UNE 103 503) is performed on soils with a maximum size of less than 5 cm and in a 15 x 20 cm sand hole when the maximum size is bigger than 30 cm. The Proctor test rejects the 20.0 UNE sizes, substituting them with fine particles: therefore, it is not representative for stone materials.

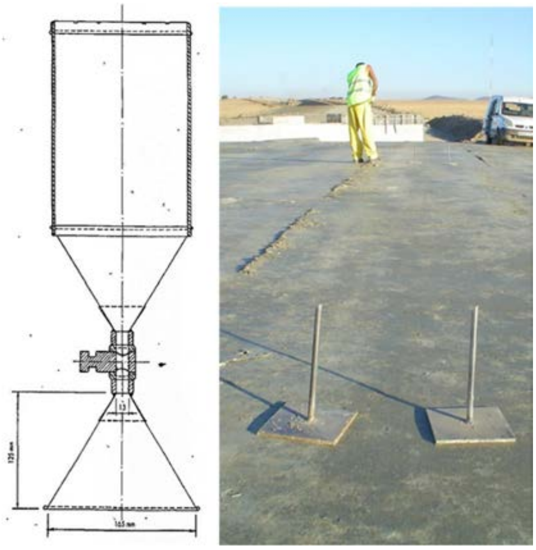

Figure 12. Sand method (UNE 103 503) and nuclear method for low depths

In PG-3, grain sizes are determined by pits, in the case of rockfills with a minimum volume of 4 m3 and a minimum surface area of 4 m2. In random fills, a minimum volume of 1 m3 and a minimum surface area of 1 m2 are required. These inspections are considered without practical use. Thus, the weighing of different fractions of rocks presents limited operativity. In addition, they are destructive tests, with minimum surfaces of 4 or 1 m2 of great difficulty of repair like located fillings. They also pose problems of safety at work, due to instability within the tasting walls.

This complex characterization is required on three processes: bench, spread and fill. PG-3 proposes to carry out a test section on stone materials and to establish a procedural control.

The revised procedure consists of fixing, from the test section results, the control parameters of the compacted layer.

5. RESULTS

The big number of compaction lots processed (450) made it necessary to classify them by material types: granites in rockfills and slates in random fillings. Finally, they have been subdivided by their use in core or crown. The general quality control specifications, that have been satisfactorily applied to the quality control, are shown in the table 2.

material	zone	N	GC (%)	h (mm)	s (mm)	PLT Ø (mm)	Ev_1 (MPa)	Ev_2 (MPa)	k
granite	core	5	---	≤ 4	≤ 5	762	≥ 50	---	< 3.2
	crown	5	98	≤ 3	≤ 5	762	---	≥ 120	< 3.6
slate	core	4	95	≤ 4	≤ 4	600	≥ 30	---	< 3.0
	crown	4	98	≤ 3	≤ 4	600	---	≥ 120	< 3.6

--- not applied

Table 2. General specifications

The variables have been entered into the IBM SPSS Statistics calculation program. An analysis of variance ANOVA shows the sums of squares and the degrees of freedom associated with each: is significant at p < 0,05. There is less than 0,5% chance that an F Levene – ratio this large would happen if the null hypothesis were true. A multitude of non-linear models have been analysed, although finally all the adjustments have been linear because no curve has been found that has significantly improved the adjustments.

As shown in table 3, an optimisation of the compaction control system has been achieved in rockfills and in random fillings, obtaining a reduction in the control time and a higher production rate.

material	zone	nuclear methods	wheel impression test	topographic settlement	PLT Ø(600mm)	PLT Ø(762mm)
granite	core			■		■
	crown	■		■		■
slate	core	■			■	
	crown	■			■	

■ significative test

ABSTRACT

The main objective of road conservation is to maintain the characteristics of the platform elements to ensure that vehicle mobility is carried out comfortably and safely. The orographic conditions of Spain, with a large length of high mountain roads and others at sea level; and winter weather events, with low temperatures, wind, water, ice, snow,…, which cause deposits of particles, filler, soils, small metals, or sea salt on the pavement surface, can be dangerous in the circulation of vehicles.

One of the traditional methods for maintaining wheel-pavement adhesion is to apply flux products, mainly salt (sodium chloride, NaCl) and calcium chloride (Cl_2Ca), solidly or humidified (salt brine). This chemical fluxes have the property of preventing the formation of ice as antifreeze, or facilitating their melting if it has already formed.

This research studies the influence of salt in the surface layer of pavement made of hot mix asphalt with conventional binder. The effect of the salt is analyzed under three different conditions: immerse the specimens in salt water; add salt as aggregate in the manufacture of the mix; and submerging the natural aggregate in water with several amounts of salt, dry it and then manufactured the mixture with it. The mechanical parameters of the mixture have been analyzed in the laboratory: density, air voids, adhesion, indirect tensile strength and plastic deformation. To do this, Marshall test, Water Sensitivity Test (ITSR) and Wheel Tracking Test have been performed.

The properties of hot mix asphalt do not decrease significantly when it is manufactured of salt added as aggregate, neither when it is submerged in salt water. The bituminous mixture offers negative results when it is manufactured with natural aggregate submerged in water with salt previously, because the adhesion between the aggregate and the binder is low.

1. INTRODUCTION

The conservation of roads is defined by actions aiming at restoring the initial properties of the road, homogenizing the quality of the pavements, correcting construction mistakes and adapting pavements to new traffic loads, getting a comfortable and safe circulation.

Some conservation activities are intended for the maintenance of the road in the winter season, avoiding or eliminating the presence of snow or ice on the road surface, because they have direct influence on the circulation of vehicles. In other places, such as roads in port and coastal areas, actions are performed that protect or reduce the damage of the pavement by aggressive elements (seawater, soils, chemical elements, wastes, oils,..).

However, the construction and conservation of highways implies an environmental impact, mainly with the consumption of natural materials, or the modification of others, to improve the mechanic properties and durability of the pavements (Organisation for Economic Co-operation and Development 1997). This implies in a large investment in winter road viability. For example, in the winter road viability campaign 2015-2016, Spain's Ministry had 1334 snowplow machines, 240,877 tons of fluxes, mainly salt, and 36 emergency car parks on the State Road Network, which cost more than 65 million of euros (ACEX 2017).

Fluxes are products, natural or not, that have the property of preventing the formation of ice, lowering the freezing point of the water to temperatures below 0ºC, or melting it in case it is already formed. The most commonly used materials in road winter viability are sodium chloride (NaCl) and calcium chloride ($CaCl_2$), in solid form or in brine form (water with a dissolved salt concentration greater than 5 %). Magnesium chloride ($MgCl_2$) is also used, but less than the previous ones. In other infrastructures, such as ports and airports it is common to use acetates (calcium acetate – magnesium and potassium acetate) and urea, less aggressive with this type of roads, but its cost is higher.

When salt is spread over the surface of the icy or snowy pavement, the salt dissolves in the layer of water that covers the icy surface, but without incorporating into the ice. The effect is that the freezing temperature of the solution decreases by increasing with the amount of salt. However, this decrease stops from a certain concentration. There is a concentration called “eutectic”, from which the addition of salt does not decrease any more the freezing temperature. If this amount of flux is exceeded, the freezing temperature of the solution starts to rise again until it reaches 0ºC. In conservation activities the salt extends as brine; with a sodium chloride (NaCa) concentration of approximately 23.1%, in order to achieve an eutectic concentration, so that the road surface will not freeze, or it may melt ice if it already exists, up to a temperature of -21.1ºC. Below this temperature, the effect of the de-ice will be lost. In theory, the de-ice effect occurs up to the eutectic temperature, but it really is before, because there is an increase in time for salt to act, even depending on humidity (García 2010).

The reaction with salt is endothermic, needing an external supply of heat to be able to dissolve the salt in water. This heat is generated from the elements in contact with flux, pavement and air. If the existing temperatures are -5ºC, it may be necessary to apply a ratio of calcium chloride (approximately one third), which functions as exothermic agent, generating heat to dissolve the salt better. If the temperature is below -15ºC, sodium chloride loses its fluxing effect. Salt acts as a flux because it is hygroscopic, and reacts with humidity and atmospheric temperature from relative humidity of 75%. When a film of water is formed on the surface of the ice or snow layer, there is a contact with the salt and a heat transfer to the outside, resulting in a cooling of salt and water, theoretically until the temperature of this solution reaches the corresponding value of the saturated solution (-21.1ºC). The initial heat that melts the snow, allows the absorption of the cold of the salt, generating a heat of the condensation that is released, generating the defrosting process (ACEX 2017). When salt dissolves in water the sodium (positive) and chlorine (negative) ions are floating, and one attracts hydrogen and the other to oxygen, breaking the hydrogen bonds of water. The problem is that the brine absorbs humidity, dissolving more and more, forming a saturated solution, and therefore decreases its antifreeze capacity, favoring new layers of ice. Therefore, it is often necessary to extend new layers of brine.

There are also studies on the behavior that bituminous mixtures have when they are in contact with de-icing salt. A direct effect of salt on the surface of the road, is that it stiffens the bituminous mixture, decreasing the penetration of bitumen. When salt ions dissolve in water, sodium ion (Na+) is poorly reactive in bitumen, while chlorine ion (Cl^-) reacts with sulfur ions (S^-) that bind the different carbon chains of binders , so that ion (Cl^-) is introduced into these carbon bonds, rigidizing them and weakening bitumen, decreasing adhesiveness between bitumen and aggregate. Hassan et al. (2012) studied the mechanical properties of the bituminous mixes affected by different types of de-icing agents and freeze-thaw cycles. For the specimens submerged in salt water, observed an increase in indirect tensile strength respect the specimens submerged in distilled water for 25 and 50 freeze-thaw cycles. Giuliani (2012) or Zheng et al. (2015) studied different types of additives added to the asphalt mixture as aggregate, to avoid the formation of ice in the roadways, composed basically of salt (NaCl and $CaCl_2$).

Others studies are not based on the deicing salt due to winter road processes. Seawater is a salt water with a salt concentration of approximately 3.5%. Seawater freezing temperatures are lower than distilled water, and in coastal areas, salt can modify the mechanical properties of the bituminous layers of roads near the coast. Feng et al. (2010) studied the effect of the salt in asphalt mixtures with some specimens submerged in seawater and have remained under freeze-thaw cycles. They simulated it by adding salt to the bitumen and subjecting the specimens to freeze-thaw cycles. They concluded, for all mixes studied (AM-16, OGFC-19 and AC-16), a decrease in the indirect tensile strength ratio, more evident in the AM mixture and less in the AC mixture.

The purpose of this study is to evaluate the mechanical properties of asphalt concrete mixtures that have been submerged in saltwater, manufactured with salt (salt added as aggregate or as anti-icing additive), and manufactured with aggregates that had been submerged in salt water. The tests carried out have been density, air voids, indirect tensile strength (ITS), water sensitivity test (ITSR) and wheel tracking test.

2. MATERIALS

2.1 Aggregate

The aggregate used is ophite. Some properties of aggregate are:

- Density = 2.92 gr/cm^3.
- Los Angeles Abrasion Test (UNE-EN 1097-2: 2010) = 16.0%.
- Water Absorption (UNE-EN 1097-6: 2014) = 1.0%.
- Flakiness Index (UNE-EN 933-3: 2012) = 9.0%.

2.1 Binder

For this study, a conventional B 50/70 bitumen has been used for the bituminous mixes. Some properties are:

- Penetration (25ºC; 100g, 5s) (UNE-EN 1426:2015) = 65.0 dmm.
- Softening Point (UNE-EN 1427:2015) = 47.2ºC.
- Frass Breaking Point (UNE-EN 12593:2015) = -9.0ºC.

2.3. Salt and seawater

The density of salt used is 2.165 g/cm^3. Its content of filler (under 0.063 mm) is 6.6%.

The seawater used comes from the Bay of Santander (Spain) near the Maritime Museum of the Cantabrian Sea. This was filtered by a 50 µm sieve. It has a salt concentration of 3.5%, completely dissolved.

2.4. Asphalt concrete

The bituminous mix analyzed is AC-16 Surf B 50/70 D. It is normally used in the surface layer of the pavements. The composition for the mix is in Table 1.

Passing rate (%)									Asphalt s/m (%)
Sieve size (mm)	22.00	16.00	8.00	4.00	2.00	0.50	0.25	0.063	
	100.0	95.0	71.5	51.5	38.5	21.5	15.5	6.0	5.0

Table 1 – Composition of asphalt concrete (AC-16 Surf B 50/70 D)

The manufacture of the asphalt concrete is done in a mixer with vertical shaft and planetary rotation. First, the aggregate is introduced in it and the bitumen are added. The binder content is 5.0% s/m, by weight of the mixture. They are mixed for one minute. After, the filler is added and mixing continues for 3 minutes more.

Marshall samples were used to calculate the air voids of the mix (UNE-EN 12697-34:2013) and the water sensitivity test (UNE-EN 12697-12:2009), while for the wheel tracking test (UNE-EN 12697-22:2008) slabs of 50 mm were manufactured.

3. METHODOLOGY

3.1 Salt treatments

The effect of the salt in the asphalt concrete is studied in three different ways.

3.1.1. Specimens submerged in salt water

In this case, specimens of asphalt concrete are submerged in water with different concentrations of salt. The salt is completely dissolved.

The amount of salt by weight of water are based in the percentage of salt in seawater (3.5%), and two different contents (5.0% and 10.0%). The quantity, the temperature and time that the specimens are submerged in water varies according to the test conditions.

The series of specimens are:

- Series 0: Reference. They are submerged in distilled water and 0.0% of salt by weight of water.
- Series 11: They are submerged in seawater with 3.5% of salt by weight of water.
- Series 12: They are submerged in distilled water with 5.0% of salt added by weight of water.
- Series 13: They are submerged in distilled water with 10.0% of salt added by weight of water.

3.1.2. Salt added to the mixture as aggregate

In this case, salt is added into the mixer when aggregates and binder are being mixed. Salt is a new aggregate and it is not a substitute for any initial aggregate (Giuliani et al., 2012, or Zheng et al., 2015). When the mixture is being manufactured, salt does not dissolve in the binder.

The series of specimens are:

- Series 0: Reference. 0% of salt by weight of binder.
- Series 21: 5.0% of salt by weight of binder.

- Series 22: 10.0% of salt by weight of binder.
- Series 23: 38.0% of salt by weight of binder.
- Series 24: 95.0% of salt by weight of binder.

3.1.3. Aggregate saturated in salt water

The aggregate is submerged for 72 hours at 20 °C in water with different salt concentrations. It is enough time to saturate the aggregate. After, the aggregate is dried at 60°C for 24 hours. Then, the particles are heated to obtain the mixing temperature. The amount of salt by weight of water to saturate the surface of the particles are based in the concentration of salt in seawater (3.5%), and two different contents (2.0% and 5.0%).

The series of specimens are:

- Series 0: Reference. Aggregate is not submerged in water with salt.
- Series 31: Aggregate is submerged in water with 2.0% of salt by weight of water.
- Series 32: Aggregate is submerged in water with 3.5% of salt by weight of water.
- Series 33: Aggregate is submerged in water with 5.0% of salt by weight of water.

3.2 Laboratory tests

3.2.1. Density and air voids

Density and air voids percentage of the bituminous mix are obtained according to the Marshall Test (UNE-EN 12697-34, 2013).

Fig. 1 - Marshall Test

The specimens of asphalt concrete are compacted by 75 blows per side (Figure 1). The diameter of the specimens is 101.6 mm and the height is 63.5 mm height. The test is carried out with four specimens for each series.

3.2.2. Water Sensitivity Test (ITSR)

This test calculates the Indirect Tensile Strength Ratio (ITSR), to evaluate the adhesion between aggregate and binder, according to the procedure “Method A” of the UNE-EN 12697-12 standard (2009). The resistance to traction of the specimens kept dry (ITSd) and wet (ITSw) was obtained (Figure 2). The Indirect Tensile Strength Ratio (ITSR) was calculated by dividing (ITSw) between (ITSd). In Spain, the Spanish Standard requires an Indirect Tensile Strength Ratio of at least 85% for mixtures for the surface layer, tested at 15ºC (PG-3, 2008).

Fig. 2 - Indirect Tensile Strength Test

The dimensions of the specimens are the same than Marshall Test. They are compacted with 50 blows per side, as it is established by PG-3 (2008). Each group of samples was separated into two groups. One of the groups was kept for three days in a room at 20ºC and the other was submerged in water at 40ºC for three days after a vacuum treatment for 40 minutes. After three days, the mixes were put into a room at 15ºC for two hours prior to the test. Then, an indirect tensile strength test was performed on both groups of specimens, according to UNER-EN 12697-23 (2004), using a universal static machine.

3.2.3. Wheel tracking test

This test evaluates the plastic deformation of the mixture when a moving vertical load is applied on the surface of the specimens. This test was done for cases in which the ITSR result in the sensibility water test was closest to 85%, according to the Spanish Standard. The test is carried out in accordance with the standard UNE-EN 12697-22:2008, “Procedure B in air” and “Procedure B in water”, compacted by roller compactor (UNE-

EN 12697-33:2006+A1, 2007). The dimensions of the specimens are 410.0 mm length, by 260.0 mm width, by 50.0mm height (Figure 3). Two specimens of each series have been tested. In Spain, the Spanish Standard requires a Wheel Track Slope (WTS) in air, at 60ºC, between 0.07 - 0.10 mm/103 cycles depending on the heavy vehicles categories.

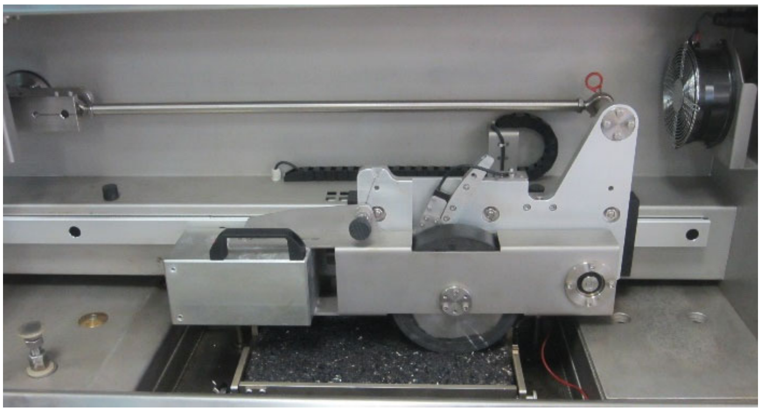

Fig. 3 - Wheel tracking Test

4. RESULTS

4.1. Density and air voids

The results of densities and air voids percentage obtained for AC-16 Surf B 50/70 D are shown in Table2.

Series		Air Voids (%)	Density (gr/cm^3)
Reference	A	6.1	2.51
Specimens submerged in salt water	11	6.1	2.51
	12	6.0	2.51
	13	6.4	2.50
Salt added as aggregate	21	6.0	2.51
	22	6.7	2.49
	23	6.6	2.49
	24	7.3	2.45
Aggregate saturated in salt water	31	6.5	2.50
	32	8.2	2.46
	33	6.4	2.50

Table 2 – Density and air voids content

The specimens submerged in seawater (series 11) or submerged in salt water with similar salt concentration than seawater obtained equals results than reference series A. Series 13, specimens submerged in salt water, with 10.0% of salt added by weight of distilled water, resulted with higher air voids content, and therefore, lower density.

For the second series, some differences appear when salt is added as aggregate to the bituminous mixture. When the salt particle content increases, the density of the mix decreases, and therefore, the air voids content increases. This happens when the salt modifies the particle size of all aggregates. Also, the density of the salt is lower than the density of the aggregate. The salt is added but it does not fill voids. Salt produces an increase in the total volume of the specimen and the air void volume increases.

For the third series, when only the aggregate has been saturated in salt water, small differences were observed. For a concentration of 3.5% of salt in water, the percentage of air voids is higher than the reference mixture; but the aggregate covered by salt does not modify the particle size of the mixture.

4.2. Indirect Tensile Strength and Water Sensitivity Test

The values of ITS and ITSR are in Table3.

Series		ITSd (kN)	ITSw (kN)	ITSR (%)
Reference	A	1687	1610	95
Specimens submerged in salt water	11	1687	1575	93
	12	1687	1636	97
	13	1687	1590	92
Salt added as aggregate	21	1595	1559	97
	22	1477	1493	101
	23	1625	1471	90
	24	1468	1432	98
Aggregate saturated in salt water	31	1595	1299	81
	32	1369	1040	76
	33	1544	1156	75

Table 3 – ITS and ITSR

For the first series, there is not significant variation between the specimens submerged in salt water and series A. The results of Indirect Tensile Strength Ratio fulfill the specifications of the Spanish standard, clearly above 85%.

For the second series, in which the salt is added as aggregate, the results of all ITS for dry and wet specimens are lower than ITS for the reference series. Anyway, the values of the all ITSR are very good and similar to the reference series, fulfilling the specifications of the Spanish standard. It could be caused by the fact that the asphalt concrete has more quantity of aggregates by the salt added to the mixer. The density of salt and its size are lower than the density and particle size of the ophitic aggregates, but filler/binder ratio of the bituminous mix is higher when salt is added. So, the Indirect Tensile Strength for wet specimens does not decrease as much as in dry specimens. In the case of a 10.0% of salt added by weight of binder the ITSR is greater than 100%.

The results for the specimens in which the aggregate is saturated in salt water are very low, and the ITSR values are below 85%. The Indirect Tensile Strength for wet specimens decreases significantly. In this case, the adhesiveness between aggregate and binder is affected by the salt that envelops the particles of the aggregate.

4.3. Wheel Tracking Test

For this test, one case of each salt treatment was selected in which the ITSR result in the sensibility water test was closest to 85%, according to the Spanish Standard. The test was carried out in air at 60ºC, and in wet.

The results of wheel track slope at 10000 cycles (WTS) and rut depth (RD) are presented in Table4.

Series		WTS (mm/10^3 cycles)		RD (mm)	
		In Air	In Water	In Air	In Water
Reference	A	0.08	0.07	3.2	4.0
Specimens submerged in salt water	13	0.08	0.05	3.2	2.3
Salt added as aggregate	23	0.07	0.07	3.2	3.7
Aggregate saturated in salt water	31	0.07	0.07	3.0	3.0

Table 4 – Wheel track slope and rut depth

All the values obtained are similar than series A, and wheel track slope comply the Spanish Standard for all heavy traffic categories. Salt does not affect the plastic deformation of the mixture.

5. CONCLUSIONS

The mechanical properties of a bituminous mixture AC-16 Surf B 50/70 D are not affected by salt dissolved in water with amounts similar to the concentration of salt in seawater, in high mountain and coastal roads.

When the asphalt concrete is submerged in salt water, density, percentage of air voids, adhesiveness between aggregate and binder, and plastic deformation resistance is maintained in the same conditions as the same mixture under non-aggressive environmental conditions.

The mechanical behavior of the bituminous mixture when the salt is added to the mix as aggregate is the best of all the treatments analyzed. The best results have been obtained with 10.0% of salt added by weight of binder. The density decreases by increasing the added salt, and filler/binder ratio is higher. Water does not worsen the characteristics of concrete asphalt when salt is added as aggregate.

The worst results have been obtained when the aggregate is previously saturated in salt water, especially for the water sensitivity. The salt creates a film around the surface of the aggregate particles, decreasing the adhesiveness.

No treatment affects the resistance to plastic deformations.

RESUMEN

Las técnicas de mantenimiento predictivo persiguen disminuir la aparición de fallos imprevistos, y la ejecución de las intervenciones correctivas necesarias que deben llevarse a cabo con anterioridad a la aparición de los fallos.

Esta comunicación presenta una metodología, que permite automatizar la predicción de alertas de mantenimiento en infraestructuras lineales de transporte, aplicada al caso de una red de carreteras. Combina información cuantitativa del estado del activo junto con datos de las intervenciones de mantenimiento operativos e históricos, haciendo uso de técnicas de analítica de datos y modelos de aprendizaje automático.

Una vez los modelos se encuentran entrenados, se infiere el estado del activo en el escenario futuro de interés, y las tareas de mantenimiento necesarias para evitar una degradación posterior o desajustes de las condiciones de seguridad y/o confortabilidad. La metodología genera una lista priorizada correspondiente a las alertas generadas por todos los activos de la infraestructura monitorizada.

La parte científica de esta comunicación presenta: i) el análisis de la información mínima necesaria para obtener predicciones de alertas, y de las intervenciones de mantenimiento más probables asociadas a ellas en redes de carreteras; ii) el diagrama de flujo esquemático del conjunto de herramientas desarrollado para predecir alertas de mantenimiento; iii) el procedimiento metodológico utilizado, para activar alertas y predecir las intervenciones más probables, necesario para resolver estas alertas; iv) la metodología para determinar la fiabilidad y el nivel de severidad de alertas frente a falsos positivos y negativos.

La parte empírica del artículo recoge la descripción y resultados de un caso piloto de red de carreteras.

Finalmente, se extraen conclusiones sobre el enfoque del procedimiento propuesto y la capacidad predictiva alcanzada.

1. INTRODUCCIÓN

El mantenimiento predictivo de las infraestructuras de transporte lineales ha despertado un interés considerable en las dos últimas décadas. La importancia de impulsar el desarrollo de herramientas de predicción fiables, a fin de maximizar la disponibilidad de las redes de carreteras y ferrocarriles, y optimizar los recursos dedicados a mantenerlas en servicio, es de suma importancia socioeconómica. Actualmente, desde la faceta gerencial, varios códigos profesionales de administración de activos lineales (e.g. Bentley Exor, Bentley Optram, HDM-4, INFOR EAM, PAVER, PMS Core) incluyen aplicaciones que brindan algún tipo de capacidades predictivas sobre alertas y operaciones de mantenimiento, que facilitan ciertos niveles de predicción; aunque se echa en falta mayores esfuerzos y avances hasta su completa automatización y universalización.

En el ámbito del desarrollo de las técnicas de predicción del estado de activos, se produjo un gran salto en los años 1940-60 con la introducción del concepto de fiabilidad y el uso de técnicas estadísticas y de optimización (Dekker, 1996), que dio lugar al cuerpo de conocimiento del *Mantenimiento Centrado en la Fiabilidad* (Moubray, 1998), una de las herramientas más utilizadas en la actualidad. Un segundo salto hacia delante aparece, en la década de los años 80, con la analítica de datos computacional, que permite inferir modelos de estimación de la evolución del estado de activos y componentes (e.g. inteligencia artificial, sistemas expertos). Esto da lugar a la estructuración en un novedoso corpus científico (e.g. aprendizaje automático: ML) entre los años 1980 y 2000 y su más reciente popularización (e.g. minería de datos) ha suscitado un gran interés por predecir el estado de las infraestructuras lineales de transporte con el fin de establecer programas de planificación de las intervenciones y tareas de mantenimiento, de acuerdo con los recursos disponibles y el mínimo impacto en el funcionamiento de la infraestructura.

La detección de alertas de mantenimiento se basa, por lo general, en la inspección del estado de los activos mediante la visualización/auscultación/medición de las características explicativas del activo involucrado. La evolución de estas características, estimadas de manera cuantitativa o cualitativa, utilizando técnicas de proyección (e.g. regresión) o cualitativas (e.g. experiencia), y la verificación cruzada con umbrales y límites (definidos por estándares técnicos prescritos por la administración/regulador de la infraestructura correspondiente), ha sido la principal herramienta para prever los posible fallos o deficiencias en el funcionamiento de los activos.

Estos umbrales se basan en el conocimiento acumulado adquirido durante un período prolongado de tiempo, en relación con la adecuación del estado de los activos analizados, y responden a una envolvente conservadora que garantiza la seguridad, integridad y correcto funcionamiento del activo como parte del sistema en el que se integra. Con el fin de mejorar la capacidad "predictiva" de este procedimiento, se han considerado nuevas y adicionales características explicativas, unitarias o combinadas, que se han ido progresivamente incorporando, durante el pasado, a la lista de índices a monitorizar y medir. Sin embargo, la gran diversidad de factores que afectan a un determinado activo, en relación con su estado, hace poco probable que se prevea el caso ideal en el que cualquier estado/condición pueda explicarse de manera integral utilizando un conjunto fijo de características medibles y, como consecuencia adicional, obtener una estimación fiable de la evolución de su integridad u operatividad. Esta falta de determinismo se solventa, parcialmente, con el conocimiento histórico recogido por el equipo de mantenimiento.

Durante décadas, la construcción de modelos deterministas o probabilísticos basados en características explicativas apriorísticas (i.e. modelos empíricos-mecanicistas) ha sido la tendencia más acusada (e.g. Lytton, 1987; NCHRP, 2004; AASHTO, 2008; Mubaraki, 2010). En la actualidad, los desarrollos se han enfocado en sustituir esa forma de proceder por el modelado basado en datos, haciendo uso de técnicas de minería de datos y aprendizaje automático (e.g. Quinlan 1986; Schwartz 1993; TRB 1999; Dick et al.2003; Podofillini et al.2006; Iqbal 2010; Podder 2010; Witten et al.2011; Karlaftis et al.2015; Plati et al.2015), y apoyándose en la creciente disponibilidad de datos capturados de las actividades y campañas de auscultación/monitorizado. Estas técnicas inteligentes (i.e. automáticas y de minería) han promovido el concepto de aprender de los datos, facilitando la extracción de patrones y tendencias al "dejar que los datos hablen por sí mismos". El uso de estas técnicas, complementadas con la información histórica contenida en el repositorio de órdenes de trabajo, permite una rápida mejora de las predicciones.

En el ámbito de las infraestructuras de carreteras, desde la década de los 90s, la tendencia se ha enfocado en la predicción de la evolución del estado de determinados componentes usando técnicas ML y analítica de datos; tal es el caso de la predicción de los índices asociados al pavimento, (Attoh-Okine, 1994; Bosurgi & Trifiro, 2005; Gong et al., 2018), o al estado global de éste (Eldin & Senouci, 1995; Salini et al., 2015; Sollazzo at al., 2017). En relación con la estimación de las intervenciones de mantenimiento ha habido importantes avances (Hanna et al., 1993; Taha & Hanna, 1995; Alsugair & Al-Qudrah, 1998; Domitrovic et al., 2018; Roberts et al., 2021); referenciadas por diversas publicaciones sobre el estado del arte en esta temática (TRB, 1999; Flintsch & Chen, 2004; Ismail et al., 2009; Ceylan et al., 2014; Abambres & Ferreira; 2020; Karimzadeh & Shoghli, 2020).

Esta comunicación presenta un enfoque metodológico para la estimación y activación de alertas asociadas a activos de infraestructuras lineales de carreteras relativas a intervenciones de mantenimiento, sean correctivas o predictivas. Su objetivo final es disponer de un sistema de información basado en un sistema experto que respalda y automatiza la gestión de la infraestructura desde la auscultación hasta el mantenimiento utilizando un enfoque modular. Se basa en: i) un sistema de gestión de los datos asociados a las variables explicativas de los activos implicados; ii) un conjunto de herramientas de analítica de datos (i.e. cuantificación del estado de los activos, gestión de alertas) y un sistema de apoyo a la toma de decisiones que recibe los resultados de estas herramientas y optimiza las intervenciones de mantenimiento. Esta comunicación presenta avances en el marco metodológico y analítico, y se avala con resultados obtenidos en un caso piloto (Infralert, 2016, 2017; Morales et al, 2017, 2018, 2020; Reyes, 2018). Las alertas estimadas se evalúan, de acuerdo con la información que brinda el sistema de toma de decisiones, en base a la evolución del estado de los activos de interés, reflejado por sus variables explicativas (e.g. características físicas endógenas, variables exógenas), y la base de datos de intervenciones históricas. Los resultados inferidos proporcionan las alertas etiquetadas con un determinado nivel de severidad y una clasificación de todas las alertas en una lista jerárquica de intervenciones junto con sus probabilidades de incidencia. El objetivo final es facilitar la gestión de todas las intervenciones activas y previstas, optimizando las operaciones de mantenimiento.

2. INFORMACION RELEVANTE PARA EL PROCESO DE PREDICCIÓN

En el enfoque propuesto, las alertas se infieren correlacionando los valores estimados (proyectados) de las características explicativas ($X_{i1},\dots,X_{in}$) del estado del activo (A_i), en un escenario futuro de interés para el mantenimiento, con la información almacenada en el repositorio histórico de mantenimiento (RHM). En este proceso están involucradas dos fuentes de datos principales diferentes: i) mediciones realizadas en la infraestructura en la que se incluyen los valores de las características relevantes; ii) datos de mantenimiento histórico que almacena, al menos: a) cada una de las intervenciones realizada (incluyendo información cronológica/tipológica); b) cuantificación/valoración de las variables de estado/explicativas previas a la intervención. Esto hace que la activación de alertas se base no solo en la comparativa de los valores estimados de las características explicativas con sus umbrales preestablecidos, sino también en el uso de la información no explícita oculta en estas fuentes de datos, lo que puede explicar la intervención necesaria realizada en casos pasados. Este repositorio también puede contener información registrada, con respecto a la evaluación subjetiva, del estado del activo inspeccionado por el equipo de mantenimiento previo a la intervención realizada (e.g. la evaluación subjetiva de cada característica explicativa individual del activo [$SX_{i1},\dots, SX_{in}$], una característica explicativa combinada [CX_i] y/o una valoración global del estado del activo [G_i]).

Además, existen otras características (variables endógenas y exógenas) que afectan a la evolución del estado del activo. Éstas completan el conjunto de características explicativas a tener en cuenta en el enfoque de intervención predictiva (e.g. flujo de tráfico, categoría de la infraestructura).

3. PROCESO METODOLÓGICO

El marco general propuesto se esboza en la Figura 1 donde se muestran diferentes módulos (que incorporan técnicas, metodologías, algoritmos y modelos) y sus interacciones, entradas y salidas. El enfoque tiene como objetivo estimar y priorizar las alertas de mantenimiento y predecir las intervenciones necesarias. En particular, se consideran dos tipos de alertas en la metodología propuesta: i) las desencadenadas por la desviación de los indicadores asociados a la calidad/estado de un activo establecido por la normativa vigente (e.g. europea, administración/gestor de la infraestructura), y ii) los índices cuantitativos que se infieren al correlacionar la información registrada de intervenciones históricas.

El Módulo AM1 (*Pre-alerts base on limits*) se encarga de generar pre-alertas basadas en límites, desde el punto de vista de aquellas características que superan sus umbrales asociados, utilizando como datos de entrada los valores pronosticados de las características explicativas del activo. El objetivo de este módulo es comparar el valor de cada característica prevista con el umbral correspondiente (según los parámetros de diseño/calidad/seguridad) para cuantificar el estado del activo. Como resultados, se proporcionan las siguientes salidas: i) Pre-alertas (*Warnings*) que indican que una característica específica excede su umbral prescrito, y ii) niveles de severidad técnica (*Technical Severity Level* TSL) de las pre-alertas estimadas. El TSL es un valor objetivo que se utiliza para priorizar las pre-alertas (e.g. en función de un criterio de distancia entre el valor de las características y los umbrales). El módulo AM2 se encarga de predecir alertas basadas en órdenes de trabajo (WO), desde el punto de vista de requerir una acción de mantenimiento (Sí/No); también estima las operaciones de mantenimiento necesarias más probables. Para lograr esto, el módulo incorpora dos submódulos funcionales diferentes. El primero (AM21) está específicamente dedicado a activar alertas atendiendo a la necesidad de mantenimiento (Sí/No) y su correspondiente nivel de severidad técnica global (*Global Technical Severity Level* GTSL) cuantificada en términos de todas las características previstas consideradas en su conjunto. El GTSL se infiere en función de todos los TSL de las características explicativas correspondientes $X = \{X_1, X_2, \ldots X_n\}$, previamente normalizadas (referidas a la misma escala) y ponderadas por valores preestablecidos α_i a cada característica individual X_i (sujeto a restricciones de ponderación unitaria $\alpha_1 + \alpha_2 + \ldots + \alpha_n = 1$). Aquí, las alertas son activadas por el estimador contenido en el primer bloque (*Alert Estimator*), que ha sido previamente entrenado con la información adecuada mediante un procesamiento de aprendizaje automático. El segundo submódulo (*Maintenance interventions* AM22) tiene como cometido la estimación de la tipología de intervenciones de mantenimiento más probables (ver Sección 3.2).

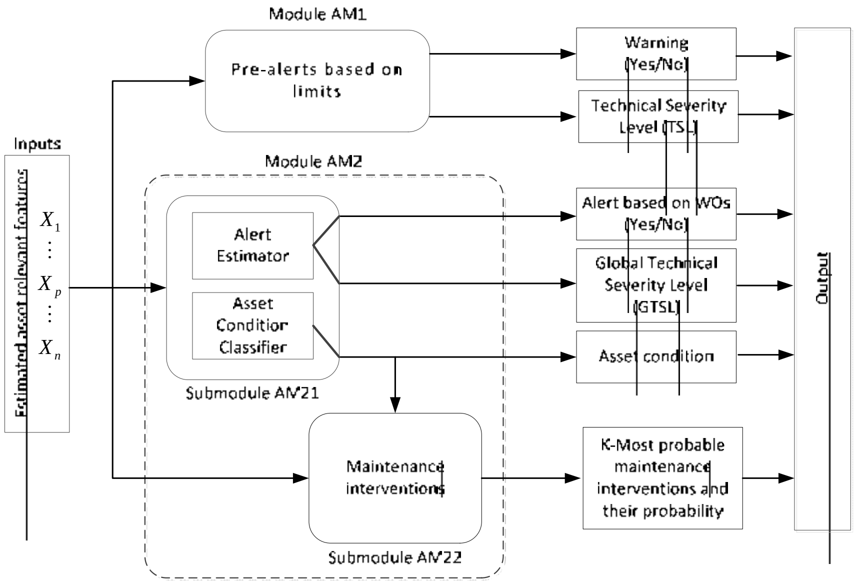

Figura 1. Marco metodológico

3.1 Proceso de aprendizaje y predicción de alertas

La metodología de aprendizaje, representado en la Figura 2, consiste en una clasificación automática basado en variables binarias (1-0: Sí/No). Se ha considerado un conjunto de cuatro modelos de clasificación binaria automática (i.e. árbol de decisión DT, red neuronal artificial ANN, vecinos más próximos KNN-K, máquina de vector soporte SVM).

De entre los cuatro modelos que se ensayan queda seleccionado el que proporciona las mejores capacidades predictivas. El submódulo AM21 también proporciona una salida opcional utilizando un segundo bloque (*Subjective asset condition* en la Figura 2), que "aprende" del conocimiento del RHM, con el propósito final de predecir una evaluación subjetiva del estado del activo (a partir del conjunto de características pronosticadas).

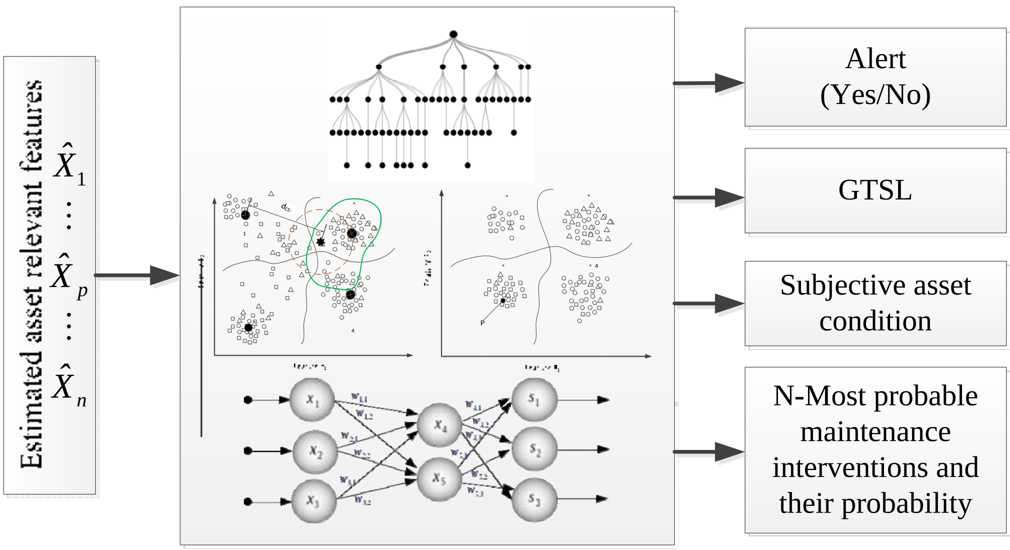

Figura 2. Esquema del proceso de aprendizaje y predicción

3.2 Proceso de predicción de tipo de intervenciones de mantenimiento

El segundo submódulo (AM22), Figura 1, tiene como objetivo determinar el conjunto de las k-intervenciones de mantenimiento más probables que deben realizarse, así como sus correspondientes probabilidades de incidencia, mediante un procedimiento de aprendizaje basado en datos de la base histórica de intervenciones. Para estimar el tipo de intervención más probable, en un activo específico, de acuerdo con el conocimiento contenido en la base histórica, se debe iniciar un proceso correlacionando los valores estimados de las características explicativas relevantes ($\hat{X}$) y el estado subjetivo pronosticado ($S\hat{X}, C\hat{X}, \hat{G}$) proporcionado por el submódulo AM21; este proceso hace uso de muestras de activos similares reportadas en el repositorio histórico; las predicciones del tipo de intervención se basan en un esquema de aprendizaje automático no supervisado que utiliza técnicas de agrupamiento y k-vecinos. Como resultado, el módulo AM2 proporciona: i) alertas activadas que identifican aquellos activos donde se requiere mantenimiento; ii) nivel de severidad técnica global (GTSL) de esos activos; iii) K-intervenciones previstas más probables asociadas a cada activo y alerta activada; y iv) probabilidades de incidencia de las intervenciones más probables.

4. REGLAS DE AUTOAPRENDIZAJE AUTOMÁTICO

Dado que el enfoque se basa en técnicas de aprendizaje automático, se encuentran definidas un conjunto de reglas de autoaprendizaje para mejorar las capacidades predictivas. Esta sección se centra en la metodología utilizada para discernir las predicciones de “falsos positivos” y “falsos negativos”, de acuerdo con las siguientes reglas:

- Un falso positivo surge cuando una estimación (derivada de los modelos) indica que se ha alcanzado un estado determinado, cuando no es así. Este caso se considera como una "falsa alarma", valorándose como caso positivo erróneo.
- Un falso negativo aparece cuando una estimación indica que no se ha detectado ninguna alerta (i.e. el estado previsto del activo es correcto), mientras que posteriormente tuvo que realizarse una intervención de mantenimiento correctivo; por lo que el pronóstico de fallos era erróneo.

La Figura 3 esboza una descripción del modo de proceder que debe seguir el equipo de mantenimiento cuando se comunica una alerta activada; incluyendo la información necesaria a registrar en la base de datos. Esto puede tener una causa "correctiva" o "predictiva". El caso de intervención preventiva no se tiene en cuenta en este documento, ya que sigue un plan predefinido y con reglas específicas. De acuerdo con esto, todos los datos registrados tienen asociado un campo de marca cronológica para identificar el instante en que se tomó cualquier decisión/acción (cuando la alerta se considera como “no atendida”, “atendida” o “intervenida”).

Los casos falsos pueden surgir cuando las estimaciones incorrectas se deben a: i) predicción incorrecta de una característica, ii) predicción incorrecta para solicitar mantenimiento (Sí/No), iii) predicción incorrecta del tipo de operación de mantenimiento requerido. En los siguientes párrafos se presenta una descripción gráfica de los casos.

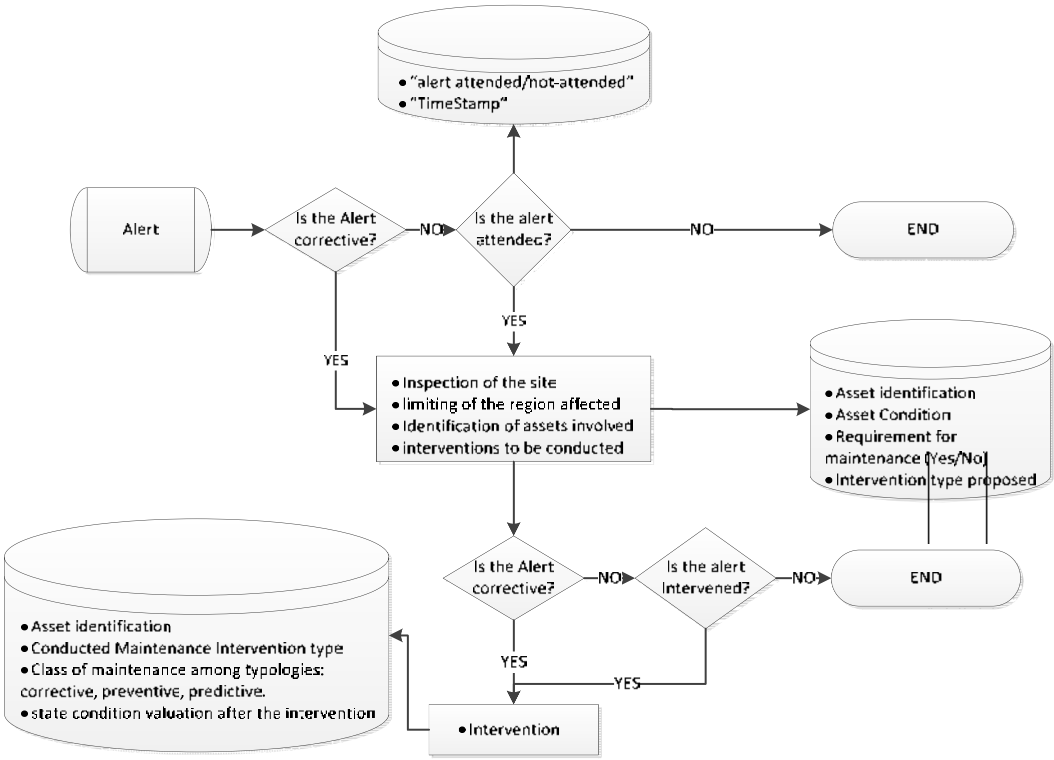

Figura 3. Diagrama de flujo del procedimiento de verificación y activación de alertas

4.1 Predicción incorrecta de una característica

Se analizan por separado dos posibles casos, falso positivo y falso negativo:

- i) Falso positivo. Tiene lugar cuando la alerta se activa por el valor esperado de una característica (individual, combinada, o multiplicidad de características), debido a la predicción incorrecta de los valores de las características. El procedimiento de alerta activada, puesto en marcha por el Equipo Gestor del Mantenimiento (EGM), finaliza con la evaluación de todos los activos implicados en la alerta y con el registro de información sobre el estado de dichos activos. La nueva información enriquecerá la base de datos (RHM) correspondiente al estado de los activos involucrados. El procedimiento de aprendizaje automático aprenderá de la información enriquecida de la base de datos, mejorando la tasa de éxito de acuerdo con la calidad de la información capturada en más ejecuciones de predicción.
- ii) Falso negativo. Surge cuando el valor esperado de las características (única, combinada o multiplicidad de características) está por debajo del valor que tendrán y también cae por debajo del umbral TSL. En este caso, el procedimiento de activación-de-alerta no se activa y no se predice ninguna alerta. Eventualmente, puede aparecer una advertencia correctiva y activarse el procedimiento de activación-de-alertas, que registrará la información identificada en la Figura 3.

4.2 Predicción incorrecta de incidencia de mantenimiento

Al igual que en el caso anterior, se analizan los casos de falso positivo y falso negativo:

- i) Falso positivo. Esto ocurre cuando el submódulo AM21 predice la necesidad de mantenimiento y se activa una alerta. Este caso sigue un patrón similar al caso (i) de la sección 4.1. El procedimiento de ML se mejorará de acuerdo con el enriquecimiento de la base de datos.
- ii) Falso negativo. Esto ocurre cuando el submódulo AM21 no detecta la necesidad de mantenimiento y no se activa ninguna alerta. Este caso sigue un patrón similar al caso (ii) de la sección 4.1.

4.3 Predicción incorrecta del tipo de mantenimiento

En este caso, se supone que la solicitud de mantenimiento se estima correctamente como positiva, de lo contrario el procedimiento vuelve a la sección 4.2. Solo es posible la predicción general de "tipo falso de mantenimiento ":

- Tipo falso. La alerta se ha activado debido a una solicitud de mantenimiento (submódulo AM21) y se proporciona un tipo de intervención de mantenimiento estimado. El EGM activa el procedimiento de *Alerta-activada* y el equipo de intervención de mantenimiento evalúa los activos implicados. El equipo detecta que el tipo de mantenimiento estimado no corresponde al tipo previsto, y que se ha realizado una predicción incorrecta del tipo de mantenimiento por parte del submódulo AM22. Se continúa el procedimiento de *Alerta-activada*, actuando de acuerdo con las acciones especificadas. La información capturada por este procedimiento (que refleja todos los presentados en la Figura 3) se registra en la base de datos RHM, lo que enriquece la información almacenada. Las estimaciones posteriores de los algoritmos ML se verán beneficiadas por la nueva base de datos enriquecida.

5. CASO PILOTO

Para el caso piloto se ha elegido una subred de carreteras de la zona centro de Portugal, con una extensión de 620 km, gestionada por *Infraestruturas de Portugal*. La información disponible consta de dos bases de datos: 1) la primera corresponde a los resultados de diferentes campañas de medición en las que se obtienen características representativas del estado de la vía; 2) la segunda recopila las intervenciones históricas de mantenimiento realizadas en la red en las últimas cuatro décadas. Al correlacionar ambas bases de datos se infieren las entradas y los objetivos para los modelos de aprendizaje automático. Sin embargo, los datos registrados se han filtrado previamente para extraer la información relevante que utiliza el sistema antes de activar toda la metodología predictiva de mantenimiento.

Con la información disponible para el caso piloto, los modelos se han implementado computacionalmente usando las técnicas de árboles de decisión (DT), k-vecinos más próximos (KNN), máquinas de vectores soporte (SVM) y redes neuronales artificiales

(ANN). Para comprobar la precisión de esos modelos, el conjunto de datos de los últimos años se ha dividido en tres subconjuntos: a) datos de entrenamiento y testeo, b) datos para predicción, c) datos de las operaciones de mantenimiento reales llevadas a cabo en los tramos usados para la predicción. El primer subconjunto se ha utilizado como base de datos para detectar la técnica de aprendizaje automática más adaptada a la naturaleza de los datos e información disponibles, manteniendo ésta fuera del conjunto de datos utilizados para predicción. El segundo subconjunto de información se ha focalizado en los datos existentes de las variables explicativas de los tramos (no incluidos en el conjunto de entrenamiento y testeo), para los que se conocía las operaciones de mantenimiento que se habían llevado a cabo (pero que no era información disponible utilizada para las predicciones) correspondiendo a un subconjunto de tramos de la red piloto. El tercer subconjunto corresponde a los datos de las operaciones de mantenimiento reales, entre los años 2012 a 2016, llevadas a cabo en los tramos del subconjunto anterior (b) con la finalidad de contrastación de la bondad/divergencia de las predicciones estimadas. La evaluación del rendimiento de los modelos se realizó mediante el uso de una matriz de confusión, basada en el recuento de los registros de prueba predichos correcta e incorrectamente. En esas matrices aparecen el tipo de mantenimiento real (M) y el predicho a tendiendo a los tipos de intervenciones, recogidos en la Tabla 1. La clase T0 está asociada a no-alerta, y el resto de las clases pertenecen a diferentes alertas de mantenimiento.

M	Alerta	Descripción
T0	No	No se requiere mantenimiento
T1	Si	No actuar
T2	Si	Microaglomerado, Recubrimiento-tratamiento de superficie
T3	Si	Capa fina mezcla caliente de asfalto (grosor ≤ 5 cm)
T3.1	Si	Fresado y extendido de capa fina de mezcla en caliente de asfalto (grosor ≥ 5 cm)
T4	Si	Capa gruesa de mezcla en caliente de asfalto (grosor > 5 cm) combinada con o sin fresado

Tabla 1- Descripción de los tipos de mantenimiento

Las curvas de aprendizaje de los modelos seleccionados se muestran en la Figura 4, donde se representan un total de cuatro gráficos; el eje horizontal (x) representa diferentes tamaños de conjuntos de entrenamiento, el eje vertical (y) el error obtenido. Las dos líneas gruesas representan el valor promedio de los conjuntos de entrenamiento y prueba; las líneas finas representan los percentiles 20 y 80 de los conjuntos de entrenamiento y prueba, proporcionado una cuantificación de la variación de las predicciones.

A medida que aumenta el tamaño del conjunto de entrenamiento, las líneas convergen hacia una asíntota que representa la cantidad de error irreducible en los datos. El error de la predicción del conjunto de entrenamiento en el modelo de k-vecinos más cercanos es siempre del 0%. Esto se debe al hecho de que la predicción de un registro se calcula a partir de una vecindad en la que se incluye el registro. El modelo DT presenta el error más bajo. Los modelos SVM, ANN y KNN arrojaron resultados similares; ninguno de ellos redujo el error promedio del conjunto de prueba por debajo del 5%. Solo el modelo DT alcanzó un error promedio por debajo del 5% utilizando un tamaño de conjunto de entrenamiento más elevado (375 registros).

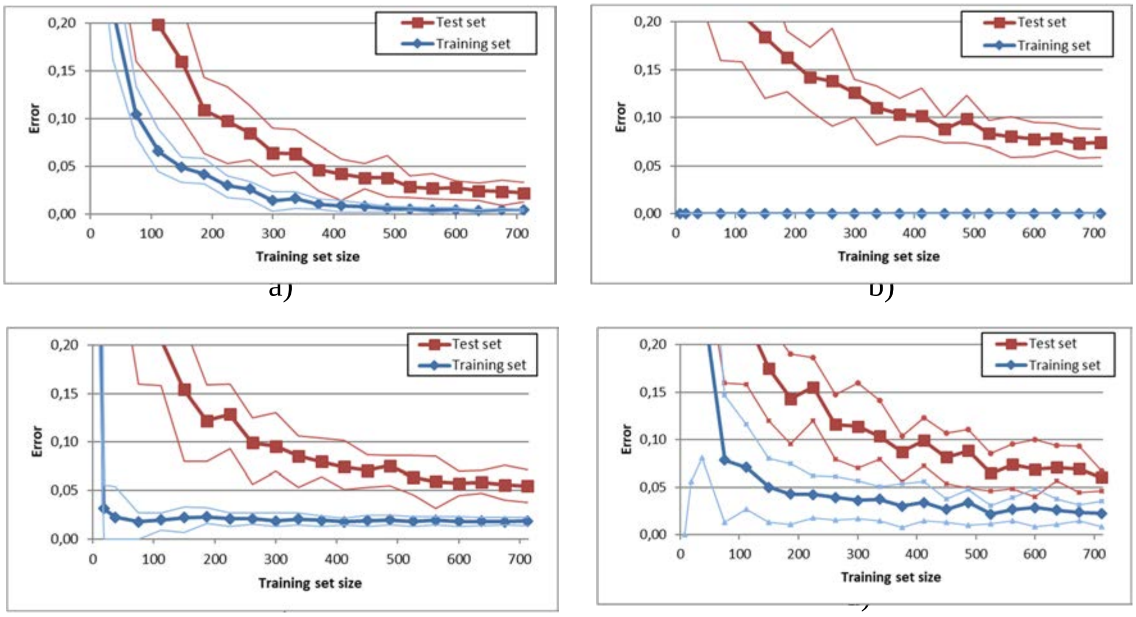

Figura 4. Curvas de aprendizaje: a) árbol de decisión, b) modelos de k-vecinos más cercanos, c) máquina de vectores soporte y d) modelos de redes neuronales artificiales.

Es importante subrayar que los resultados corresponden a un caso de datos numerosos. En la práctica real, la base de datos de mantenimiento histórico proporciona un conjunto de muestra válido limitado debido a múltiples causas: i) el número de intervenciones que se registran con descripción detallada no suele ser alto; ii) la información almacenada carece de coherencia cronológica (las intervenciones reales no se describan con el mismo rigor a lo largo del tiempo); iii) se cuantifican insuficientes características físicas explicativas. Por ello es importante que los modelos seleccionados logren un error de conjunto de prueba promedio bajo, con un número limitado de registros. En este caso, el modelo DT resulta ser la mejor opción.

La Figura 5 muestra la matriz de confusión para el modelo DT donde las columnas corresponden a la clase conocida (clase especificada por la orden de trabajo) y las filas a las predicciones inferidas por el modelo (clase de salida).

Los elementos diagonales muestran el número de clasificaciones correctas alcanzadas para cada clase; los elementos fuera de la diagonal muestran los errores cometidos por las predicciones del modelo. Cada celda contiene la misma información como porcentaje del tamaño total del conjunto de prueba. En la última fila y columna, estos gráficos presentan las medidas de rendimiento derivadas de la matriz de confusión: la precisión (ACC), recuperación o tasa de verdaderos positivos (TPR) y precisión o valor predictivo positivo (PPV), que se muestran en color verde; así como los respectivos índices complementarios: tasa de error (ERR), tasa de falsos negativos (FNR) y tasa de descubrimiento de falsos (FDR), mostrados en color rojo.

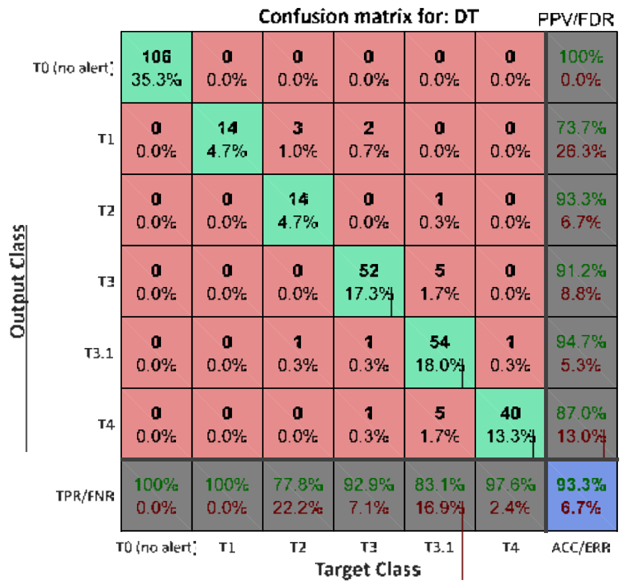

Figura 5. Matriz de Confusión (modelo DT).

5.1 Resultados

En la Figura 6 se extracta una selección de los resultados obtenidos tras aplicar las metodologías presentadas al conjunto de tramos de carreteras no incluidas en el proceso de elección y aprendizaje del modelo de predicción. La predicción del estado general de cada tramo se cuantifica numéricamente a través de la variable explicativa global (GTSL) y cualitativamente por el color de la celda. El penúltimo conjunto de columnas (*Estimated alert per year*) identifica los tramos en los que se predice (aconseja) la necesidad de realizar intervenciones de mantenimiento. El último conjunto de columnas (*Intervention by year*) señala los tramos en los que realmente se llevaron a cabo labores de mantenimiento. Los tipos de intervenciones de mantenimiento más recomendados, propuesto por el algoritmo de predicción, se identifican por el color asignado al tramo de carretera en el mapa de la Figura 7.

6. CONCLUSIONES

Se ha desarrollado una metodología, basada en un conjunto de varias técnicas, de aprendizaje automático supervisado y no supervisado para la predicción de alertas y de las operaciones de mantenimiento requeridas más probables. La aplicación práctica se ha llevado a cabo en una red de carreteras con una dilatada base de datos históricos. Los resultados obtenidos se fundamentan en la elección óptima de los mejores modelos predictivos basados en a) órdenes de trabajo de intervenciones contenidas en la base de datos histórica, b) características de los activos, c) y auscultaciones de medición.

Los principales resultados alcanzados son: i) el tipo de intervención estimado para cada tramo de carretera y la probabilidad de incidencia, ii) una lista ordenada de alertas estimadas según el nivel de gravedad técnica. Cada conjunto de predicciones se refiere a escenarios identificados por fecha. Los resultados evidencian que el marco metodológico proporciona buenas capacidades predictivas.

El trabajo presentado es parte de la generación de una herramienta inteligente de apoyo a la decisión con el objetivo de inferir planes de mantenimiento, basados en la generación de pronósticos de alerta y la selección óptima de operaciones en cuanto a las intervenciones más críticas a realizar. Estas últimas constituyen la información más relevante para avanzar en un sistema de ayuda a la planificación del mantenimiento de infraestructuras lineales de transporte a nivel operativo, táctico y estratégico, bajo un marco de sistema experto.

Las metodologías y resultados aquí presentados distan de ser exhaustivos y concluyentes, y se encuentran abiertos en varias líneas de investigación paralelas: a) sensibilidad a la calidad de la descripción de la intervención en el repositorio histórico con respecto a las fechas de las intervenciones, b) importancia de la descripción detallada/vaga del estado del activo previo a la intervención y, por último y de mayor relevancia a nivel de fiabilidad, c) el enriquecimiento de las bases de datos bajo el esquema procedural de verificación y activación de alertas.

AGRADECIMIENTOS

Esta investigación ha recibido financiación del Programa de Investigación e Innovación Horizonte 2020 de la Unión Europea (acuerdo de subvención n ° 636496). Algunos de los autores agradecen al Ministerio de Economía y Competitividad de España (MINECO) la subvención parcial concedida en el marco del programa nacional de I + D + i (TRA2015-65503) y del Programa Torres Quevedo (PTQ-13-06428). El contenido refleja únicamente la opinión de los autores y se declara que la UE y el MINECO no son responsables del uso que pueda hacerse de la información contenida en él.

Los desarrollos llevados a cabo en esta investigación no habrían sido posible sin la participación de la entidad *Infrastruturas de Portugal*, y la estrecha colaboración de sus técnicos João Morgado, Emanuel Duarte, y Teresa Martins.

RESUMEN

El creciente interés por acercar el patrimonio cultural a la sociedad ha impulsado la investigación en el ámbito del transporte durante la época romana. Su objetivo es conocer la organización territorial, las características del comercio y su influencia en la economía y la sociedad a través del tiempo y el impacto de las decisiones políticas en las infraestructuras y el desarrollo económico de los territorios.

Estos estudios se apoyan en los mapas confeccionados a partir de los emplazamientos de las ciudades y calzadas históricas. De tal modo que la precisión de sus resultados depende de la fiabilidad de tales cartografías históricas. Sin embargo, todavía persisten un notable número de ciudades y vías romanas sin localizar o cuyas identificaciones actuales no son seguras.

En el presente trabajo, se detallan las dificultades inherentes a la identificación de las calzadas romanas, así como las herramientas de las que se dispone para ello. Además, se describe uno de los métodos para localizar rutas antiguas conflictivas en su identificación junto con un caso de estudio. Como resultado, se puede observar la importancia de las estrategias para la reconstrucción de los trazados de las rutas antiguas y la identificación de las ciudades en los estudios de movilidad en el mundo antiguo.

1. INTRODUCCIÓN

El creciente interés por acercar el patrimonio cultural a la sociedad ha impulsado diferentes proyectos de investigación en el ámbito del transporte durante la época romana.

Un ejemplo es el proyecto ORBIS (2012) de la Universidad de Stanford que ha desarrollado un modelo que permite al usuario calcular los costes y tiempos asociados a las rutas durante la época imperial. Por su parte, el proyecto Mercator-e desarrollado por De Soto (2016) está enmarcado dentro de los siguientes objetivos del Programa Horizon 2020: rutas de movilidad transeuropeas y patrimonio cultural en Europa. En él se establecen estudios de conectividad y funcionalidad de la red de transporte romana en la península ibérica. De esta forma se pueden conocer la organización territorial, las características del comercio y su influencia en la economía y la sociedad a través del tiempo.

Estos estudios se basan en las fuentes de cartografía histórica. Sin embargo, todavía persisten un notable número de ciudades y vías romanas sin localizar. En algunas ocasiones existen diferentes propuestas de ubicación para un mismo itinerario o ciudad romana.

Las herramientas que se han utilizado para la determinación de los trazados han sido fundamentalmente fuentes geográficas antiguas, menciones de autores clásicos y medievales y las aportaciones de la arqueología y la epigrafía. Dentro de las primeras, las principales son: el Itinerario de Antonino, el Anónimo de Ravenna, la Cosmografía de Ptolomeo, la Tabla de Peutenger y los Vasos de Vicarello. En el caso de *Hispania*, últimamente han cobrado valor las Tablas de Barro de Astorga, desde que Fernández, Morillo y Gil (2012) demostraran su autenticidad por medio de pruebas de termoluminiscencia. En cuanto a las fuentes históricas, las menciones que los historiadores clásicos hacen sobre las ciudades, junto con la literatura medieval aportan una información cualitativa que puede servir para confirmar las localizaciones. Finalmente, los recursos arqueológicos y epigráficos, aunque escasos, suponen un elemento de comparación esencial para dar validez a las teorías propuestas. En la actualidad, el desarrollo de los Sistemas de Información Geográfica (GIS) está constituyendo un soporte para la arqueología. De este modo, Verbrugghe, De Clercq y Van Eetvelde (2017) mediante técnicas como el Light Detection and Ranging (LIDAR) y la de la Ruta del Menor Coste han realizado la reconstrucción de trazados de calzadas romanas en Bélgica.

Las dificultades para la identificación de las rutas están basadas en la imprecisión de algunos de los trazados citados en las fuentes junto con la carencia de evidencias epigráficas y arqueológicas suficientes de las ciudades y calzadas.

Uno de los precursores en el estudio del trazado de las calzadas romanas en *Hispania* fue Saavedra (1862), quien presentó un mapa en el que están la localizadas todas las *viae* de la Península Ibérica citadas en el Itinerario de Antonino. Blázquez (1892) propuso otros trazados para el mismo basándose en el análisis de las distancias del Itinerario y su adaptación al plano. Por su parte, Margary (1955) fue un pionero en el estudio de las vías romanas en *Britannia* con diferentes contribuciones como el descubrimiento de una nueva calzada y un sistema de numeración para las mismas.

Más recientemente y en el caso de *Hispania* resaltan los trabajos de Roldán (1966) y Moreno Gallo (2017). Éste último ha revolucionado el concepto que se tiene sobre la estructura y composición de las calzadas romanas interurbanas. Mediante un extenso estudio científico demuestra que aquellas están pavimentadas con material tipo zahorra, frente a la generalizada idea de pavimentos con grandes bloques de piedra. De tal manera que el uso de grandes bloques de piedra para el pavimento corresponde a calzadas urbanas.

Además ha realizado un estudio sobre las vías romanas en Castilla y León. En él se han complementado los recursos toponímicos, epigráficos e históricos con arqueología aérea y reconocimientos terrestres para confeccionar un mapa de calzadas romanas dentro de la citada Comunidad. Los trazados de algunas *viae* difieren sobre las propuestas de anteriores autores. Un nuevo trazado para una de estas vías, la Vía Aquitana, ha sido precisado por López-Zamanillo (2018) a su paso por la ciudad de Burgos mediante un estudio de la literatura medieval y trabajo de campo en la propia ciudad.

En casos especialmente conflictivos se debe recurrir a singulares metodologías como las propuestas por Verhaggen (2014) o Romera y Pérez-Acebo (2020). La segunda es interesante para el caso de trazados en valles con ríos sinuosos donde es difícil recurrir a alineaciones rectas entre estaciones. La última es adecuada en situaciones donde en el itinerario analizado existe un número consecutivo importante de estaciones o *mansiones* desconocidas.

En el presente trabajo se analiza un caso crítico de estudio mediante el método de Romera y Pérez-Acebo (2020). De esta forma se puede observar la importancia de las estrategias para la reconstrucción de los trazados de las infraestructuras de transporte terrestre romanas.

2. METODOLOGÍA

En este trabajo se va a hacer uso del método de Romera y Pérez-Acebo (2020) para la reconstrucción del trazado de las vías. El método consta de cuatro fases: determinación del dominio geográfico, correlación entre las coordenadas ptolemaicas y las de un sistema de referencia actual, obtención de la distribución de probabilidad espacial de las estaciones cuyo emplazamiento se desconoce y reconstrucción del trazado a partir de esas ubicaciones.

2.1 Definición del dominio geográfico

Como primer paso del método se deben definir los límites del dominio geográfico de la calzada objeto de estudio. Para ello, son de ayuda los trazados de vías paralelas a la calzada de estudio cuyo trazado sea conocido, además de límites geográficos como líneas de costa o divisiones territoriales si se sabe que la vía pertenece a una provincia romana en concreto.

2.2 Correlación entre las coordenadas del sistema de referencia WGS 84 y las coordenadas ptolemaicas

El planteamiento es localizar algunas de las *mansiones* por las que circula la ruta para reconstruir su trazado. Para ello, se deben obtener previamente unas regresiones lineales simples entre las coordenadas de Ptolomeo de localizaciones en la provincia romana por la que transcurre la vía y sus coordenadas correspondientes en el sistema de referencia actual WGS 84. Es determinante el hecho de que esos emplazamientos estén uniformemente repartidos geográficamente y que su ubicación en la actualidad no presente discusión.

2.3 Distribución de probabilidad espacial

Si los errores asociados a las regresiones lineales siguen una distribución normal, se puede utilizar la distribución normal bivariante como distribución de probabilidad de localización. Tras la citada comprobación, se establecen las distribuciones de probabilidad correspondientes a las localizaciones de las ciudades de emplazamiento desconocido por las que discurre la vía de estudio. A continuación, se utilizan esas distribuciones para valorar la viabilidad de cada una de las propuestas de localización para dichas ciudades. Si existen diferencias de probabilidad significantes entre las diferentes propuestas, se opta por aquella opción mejor localizada geográficamente.

2.4 Reconstrucción del trazado

Se hace pasar el trazado por las ciudades cuyo emplazamiento se ha estimado en base a su mayor probabilidad.

3.APLICACIÓN A LA VIA AB ASTURICA PER CANTABRIAM CAESARAUGUSTAM

Se ha optado por este caso de estudio por ser la vía más conflictiva del Itinerario de Antonino, debido a un gran número de estaciones consecutivas sin localizar en su tramo inicial. Existen propuestas diferentes para el trazado de la misma establecidas por distintos autores. En la Tabla 1 se detalla el itinerario correspondiente al primer tramo de la *via ab Asturica per Cantabriam Caesaraugustam*. Junto al nombre original de la vía se ha añadido entre paréntesis la numeración de Blázquez. Para simplificar la denominación de las *viae*, en lo sucesivo se va a utilizar dicha numeración. Para las mansiones identificadas se ha indicado entre paréntesis el nombre de la localización actual. A continuación del nombre de cada mansión, salvo en el caso de la primera de cada tramo, se muestran las distancias medidas en *milia passuum* (1.480 m), con respecto a la mansión anterior. Cuando figura más de un valor es porque los valores de los diferentes códices de los que se han obtenido esas distancias no coinciden.

***Ab Asturica per Cantabriam Caesaraugustam* (Camino 27)**
Asturica (Astorga)
Brigeco: 40
Intercatia: 20
Tela: 22
Pintiam: 24
Raudam (Roa): 11
Cluniam (Peñalba del Castro): 26, 16

Tabla 1 –*Ab Asturica per Cantabriam Caesaraugustam* según el Itinerario de Antonino

Se opta por proceder a la localización de la estación intermedia de *Intercatia* para la reconstrucción del trazado, por ser la *mansio* de la que más información se dispone y que condiciona claramente la trayectoria de la calzada. En efecto, tenemos sus coordenadas ptolemaicas, inscripciones epigráficas con su gentilicio y es citada por Apiano y Polibio. Para establecer las distribuciones de probabilidad correspondiente a la localización de *Intercatia*, se han obtenido previamente unas regresiones lineales simples entre las coordenadas de Ptolomeo de localizaciones en la Península Ibérica y sus coordenadas WGS 84. Dado que se busca una ubicación en *Hispania*, se decidió restringir las localizaciones únicamente a la Península Ibérica, seleccionándose 48 localizaciones incluidas en la *Cosmographia* de Ptolomeo.

Puesto que los errores asociados a las regresiones lineales siguen una distribución normal, se puede utilizar la distribución normal bivariante como distribución de probabilidad.

Entonces, se establecen las distribuciones de probabilidad correspondientes a la localización de la ciudad de emplazamiento desconocido, con objeto de valorar la viabilidad de cada una de las propuestas de localización para dicha ciudad. En la Figura 1 aparece representada dentro de los límites administrativos de las provincias que pertenecen al área de estudio la elipse correspondiente al error standard correspondiente a la localización de *Intercatia*. Los límites superior e inferior del dominio de localización de la vía 27 y de *Intercatia* están definidos por las vías 32 y 24, respectivamente, por ser dos calzadas adyacentes de trazado paralelo a la considerada y cuya trayectoria no es tan confusa. En dicha figura se representan mediante círculos las propuestas de emplazamiento para la ciudad considerada realizadas por diferentes autores. Como se puede ver en la Figura 1, la única posibilidad que entra dentro de la región correspondiente al error standard es Paredes de Nava. Por lo tanto, se opta por esta opción por ser la mejor localizada geográficamente.

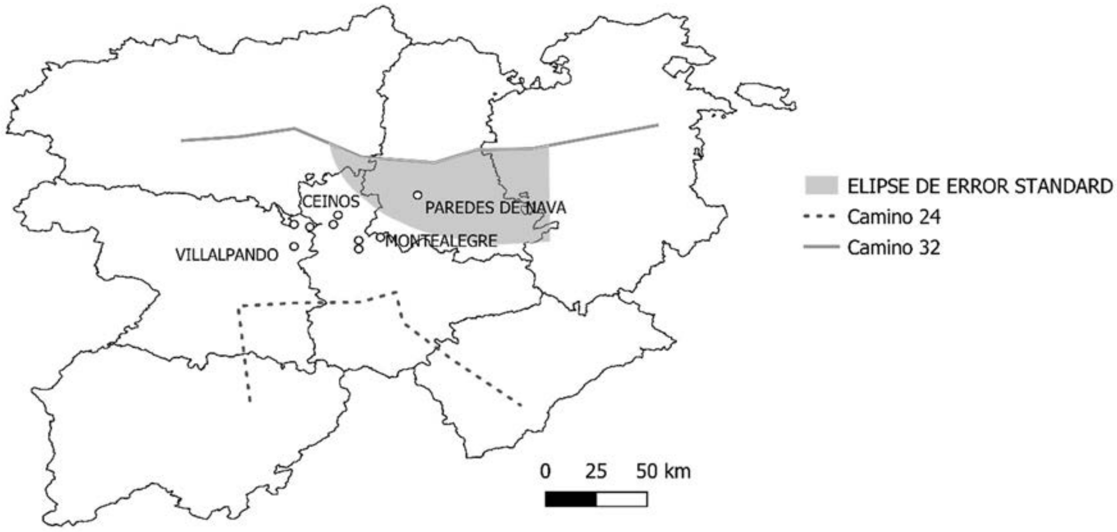

Fig. 1 – Elipse de error standard y localizaciones propuestas para *Intercatia*

En la Figura 2 se hace pasar el trazado de la vía estudiada por Paredes de Nava flanqueando el antiguo Mar de Campos por el norte antes de vadear el Carrión por Palencia. En realidad, no es necesaria una gran modificación del trazado propuesto por Saavedra para hacerlo pasar por esta ciudad. Se representan además las soluciones propuestas por Blázquez (1892) y Wattenberg.

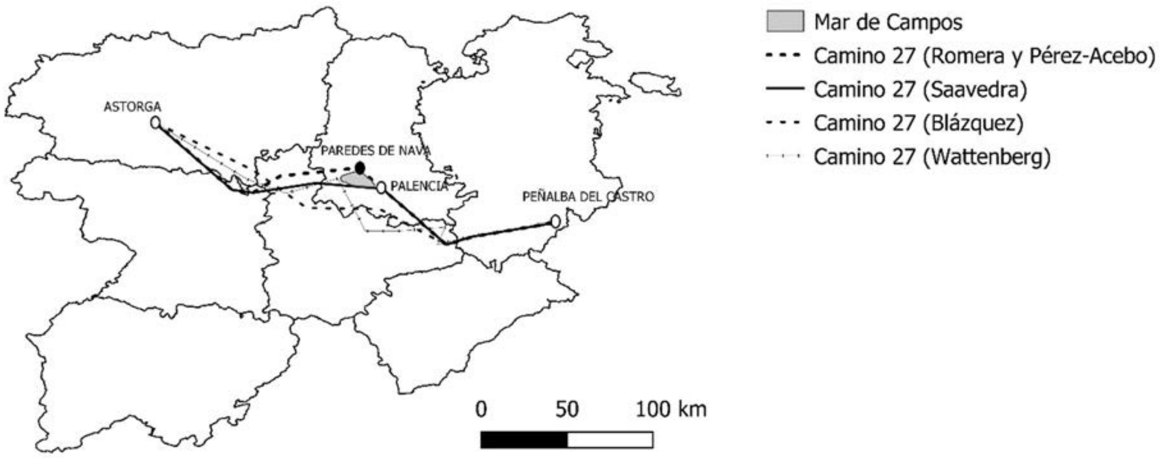

Fig. 2 – Trazados sugeridos para la vía 27 entre *Asturica* y *Clunia*

4. CONCLUSIONES

Los estudios sobre movilidad y transporte del mundo antiguo se apoyan en los mapas confeccionados a partir de los emplazamientos de las ciudades y calzadas históricas. De tal modo que la precisión de sus resultados depende de la fiabilidad de tales cartografías históricas. Sin embargo, todavía persisten un notable número de ciudades y vías romanas sin localizar.

En ocasiones, además existen propuestas geográficas muy dispersas para un mismo emplazamiento.

Teniendo en cuenta las dificultades inherentes a la identificación de las calzadas romanas, se describe uno de los métodos para localizar rutas antiguas especialmente conflictivas en su identificación junto con un caso de estudio.

Para el uso del planteamiento realizado en este trabajo es necesario que las opciones propuestas estén dispersas geográficamente, de lo contrario los valores de probabilidad serían similares debido a la dispersión de las coordenadas de la *Cosmographia*.

Como resultado, se puede observar la importancia de las estrategias para la reconstrucción de los trazados de las rutas antiguas y la identificación de las ciudades en los estudios de movilidad en el mundo antiguo y en el conocimiento sobre los elementos del patrimonio.

AGRADECIMIENTOS

Este trabajo ha sido posible gracias al apoyo de la Universidad del País Vasco UPV/EHU (PPGA20/26). Del mismo modo, queremos agradecer la ayuda al Grupo de Investigación del Gobierno Vasco IT1314-19.

Responsable área mezclas bituminosas, CTCON, España

ABSTRACT

In the framework of road infrastructures, CHM has led a study that investigates construction products in order to combat the heat that is accumulated and released by urban surfaces, such as asphalt, especially in summer, seeking to minimize the "island of urban heat".

This project is the result of having developed reflective pavements (cool pavements) than have passed through the first phase at the laboratory level, manufacturing on an industrial scale and their small-scale testing to ensure proper implementation, as well as their implementation by means of a large-scale demonstrator, operating on 24.000 m^2 of pavement in the city of Murcia (LIFE HEATLAND).

This mixture has a series of benefits with respect to conventional mixtures, leading to an improvement in the urban environment and quality of life of the citizens of the implantation environment and which are mainly:

- Saving energy in air conditioning and in the consumption of public lighting.
- Saving energy consumption and raw materials.
- Improves air quality.
- Improves noise pollution.
- Improves comfort and health of pedestrians.
- Economic and environmental benefits.

To date, the demonstrator has been monitored and the following conclusions have been obtained, validating this type of pavement as a mechanism to reduce the urban heat island effect:

- Initial luminance of reflective pavement 2.5 cd / m^2 under the lamppost, 150% higher than in the conventional asphalt street.
- Solar reflectance is almost four times higher than conventional asphalt.

- Average surface temperature for reflective pavement of 7-11 ºC lower than conventional.
- Asphalted areas where tire rubber has been deposited as a result of the rolling of vehicles are heated 1-3 ºC more than clean areas.
- Environmental noise level of the area: 3 dB (A) lower.

1. MAIN INFORMATION

1.1 Introduction

Research project developed by CHM Obras e Infraestructuras, S.A., with the collaboration of CTCON, within in framework of the REPARA 2.0 project, supported by co-financed by Centre for the development of Industrial Technology (CDTI) and European Regional Development Fund (ERDF).

At first, we are going to explain what the cool pavements are and how they help to reduce the climate change. So now we are going to define key concepts which are the following.

The development of the innovative asphalt pavement with high solar reflectance arises in order to mitigate the effects of climate change and, specifically, due to the global warming that is taking place on our planet according to the latest anomaly data determined by NASA, with annual anomalous average temperature variations of between 1-2 ºC, while in summer periods this range of temperature variation is between 1-4 ºC at the national level.

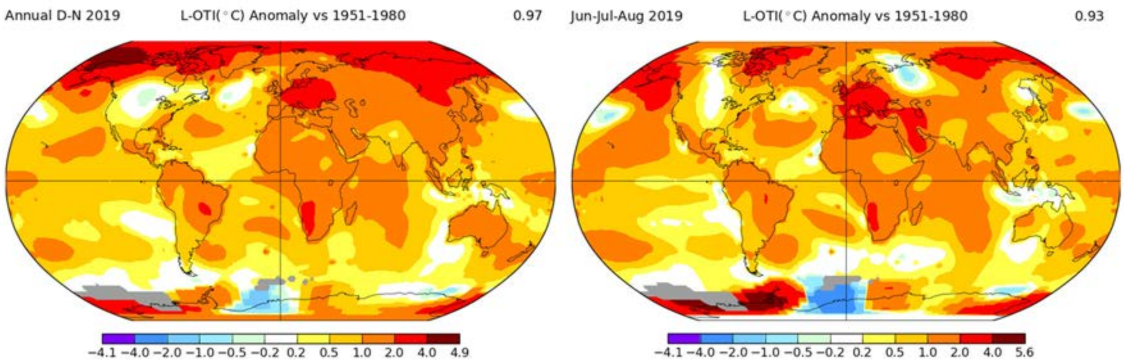

Fig. 1 – Average variation climate (2019), about Surface temperature, and variation of June-August 2019. NASA, Goddard Institute for Studies

The actions which have contributed to this climate change it is found in the last 50 years the population has start to live in urban areas instead of rural areas. See Fig. 2.

This fact has caused the proliferation of big urban zones where it is produce the phenomenon known as “Urban heat island”.

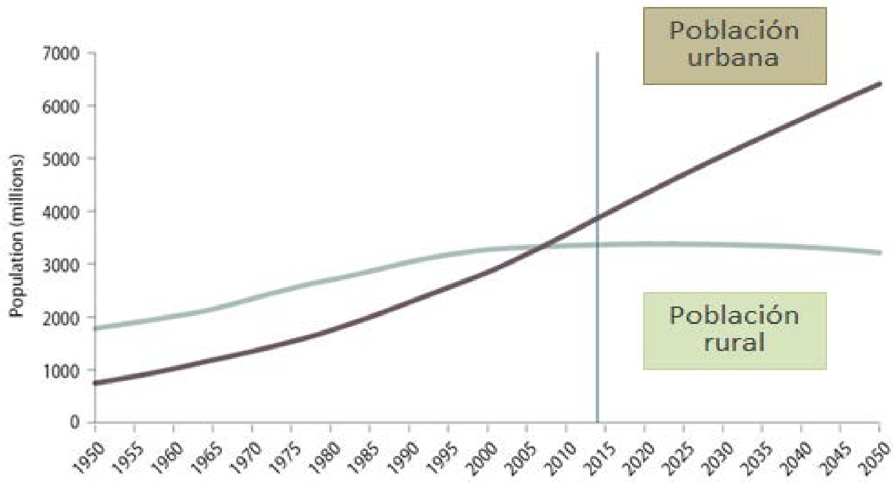

Fig. 2 – Source: data from World Bank about the basis of the Urban Perspective of the United Nations

1.2 Urban heat island (UHI)

It is the effect when an area, which has been created by the human, get a temperature hotter than the around area without modify.

This temperature difference can be seen in the following graph "referential temperature urban profile compared to rural areas", where it can be seen between urban centers and surrounding areas such as the countryside, without modifications by humans, it is got temperatures differences between 3ºC and 4ºC. See Fig. 3.

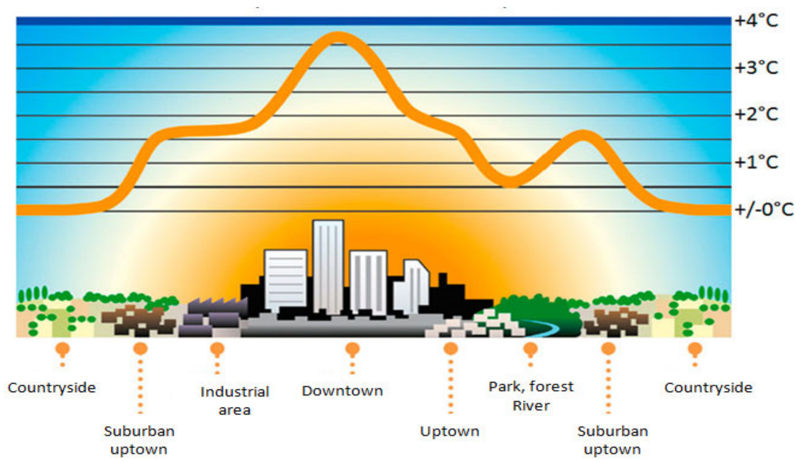

Fig. 3 – Referential temperature urban profile compared rural areas. Source: Saint-Gobain PPC. Translate, own development

Therefore, it is obtained one of the actions which cause the urban heat island effect is to change areas with vegetables materials by other materials, such as concrete or asphalt, among others.

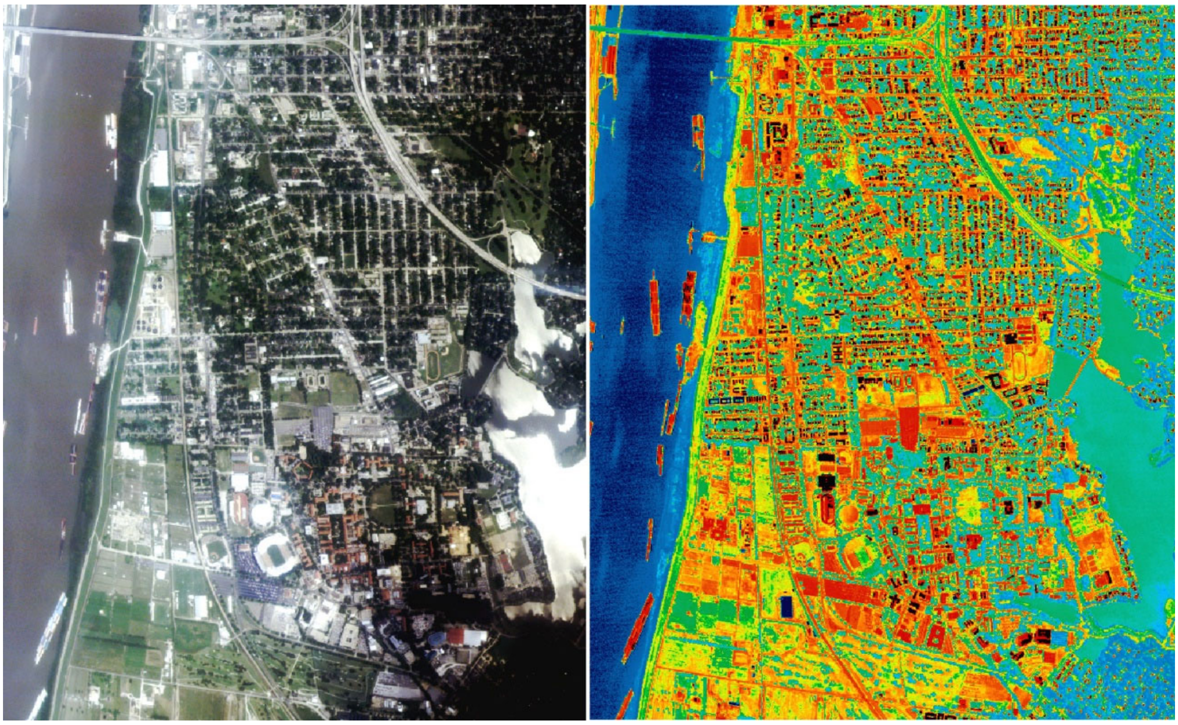

Fig. 4 – Thermography, Baton Rouge city, USA. NASA

From this and after the consulted bibliography, it has been estimated the general distribution of surfaces is identified with the distribution of the following diagram, in which the majority areas modified in the cities are constituted by pavements in general. It is had the pavements constituted around 39% of the modified surfaces in a city and these are capable of absorbing and storing energy in the form of heat, which is notoriously contributing to the aforementioned urban heat island effect. See Fig. 5.

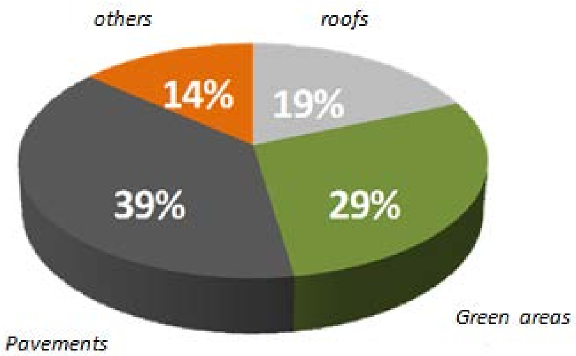

Fig. 5 – Surface distribution in urban areas.

Conventional pavements are able of absorbing up of the 90% of the incident solar energy that means they have a low solar reflectance.

1.3 Solar reflectance

It is the relation between reflected solar energy and incident solar energy. See Fig. 6.

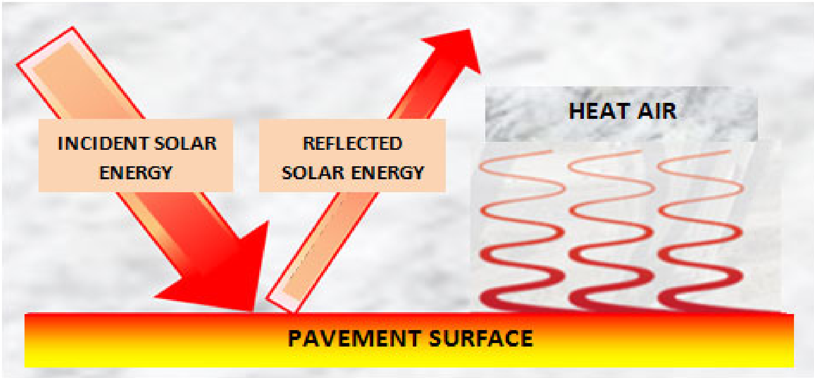

Fig. 6 – Solar reflectance. Source: own development

That the reason why, conventional pavements contribute to urban heat island effect by the following mechanism:

- Solar energy hits the pavements surface.
- Part of that energy is reflected, approximately 10%.
- The rest of the energy is absorbed as heat by the pavement, around 90%, which causes the surface to heat up, reaching surface temperature of up to 70ºC. This means, especially at night, there is a flow of hot air (convection) which increases the ambient temperature and increase the urban heat effect.

This effect gives a great Energy demand and due to the poor ventilation in the cities with respect to the existing one in the field, it is produce an overheating of urban areas.

On the other hand, solar radiation which is a thermal radiation defined as a set of electromagnetic radiation emitted by the sun which in form of waves propagates in the form of waves with lengths between 150 and 400 nanometers (nm). The radiation which reaches the Earth oscillated between 300 and 2500 nm, the rest is rejected by the atmosphere. This wavelength range it divided in three electromagnetic spectra: UV spectrum: wavelength range between 280 – 400 nm; VIS spectrum: wavelength range between 400 – 700nm; IR spectrum: wavelength range between 700 – 2500nm.

The magnitude which measures the solar radiation is called irradiance and its units are W/m2, each wavelength will have a determinate irradiance. The standard distribution of the irradiance is definite by the ASTM standard G173-03-AM 1.5G, where it is quantified the energy power which affects the Earth layer in each one of the three spectrums (UV, VIS and IR).

These values are measure at sea level, 20ºC temperature and with a determined inclination of the sun (37ºC) to the terrestrial surface. If all irradiances values of all wavelength are added, the total radiation which arrive to the Earth will be 963,8 W/m². With these incident solar results and measuring the reflected energy, one can know the reflectance percentage of a surface. See Fig. 7.

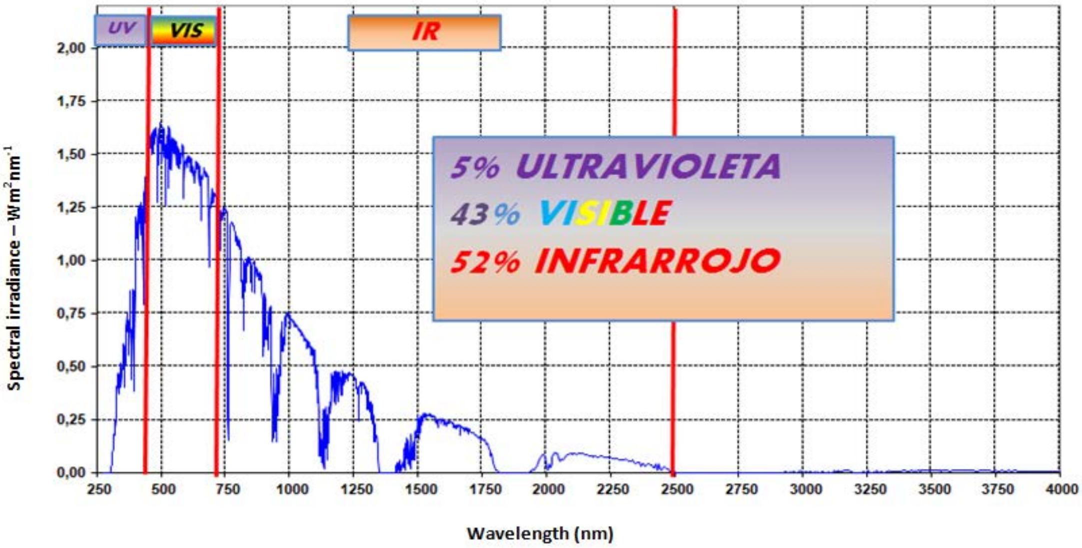

Fig. 7 – Graphic representation of solar spectrum AM 1,5 G-ASTM G173-03.

It can see, approximately the 5% of the energy which affects the Earth's surface corresponds to the ultraviolet spectrum (UV), the 43% to the visible spectrum and 52% to the infrared (IR).

The reflectance value range to zero (for surface without reflectance) from one (for surface with total reflectance). The result may give as a percentage. The absorbance is an inverse concept of reflectance. See Fig. 8.

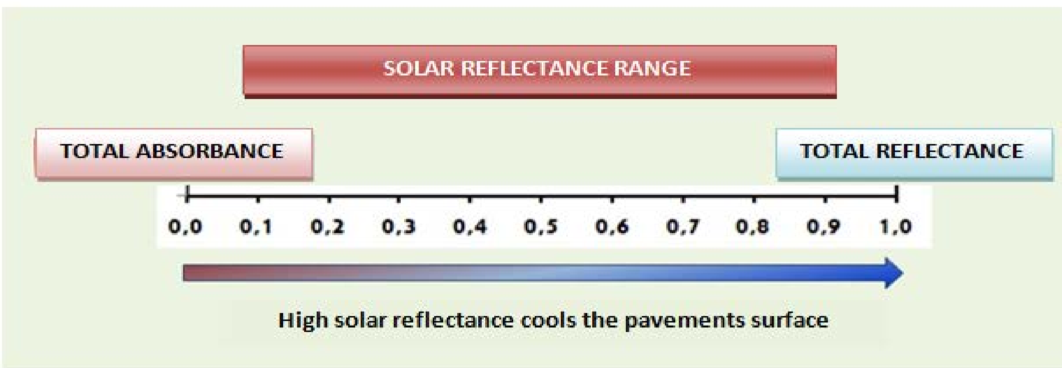

Fig. 8 – Solar reflectance range. Source: own development.

The solar spectrum is composed of UV, VIS and IR, it can determine within the total solar reflectance, the reflected part in the ultraviolet spectrum (UVR), the visible- VISR spectrum and the infrared-IR.

2. MATERIALS AND METHODS

These reflected pavements are able to reduce the surface heating, especially in cities, as a consequence the ambient temperature, so this gets a great importance in summer periods. See Fig. 9.

Fig. 9 – Cool Pavement. Source: own development

According to the LEED v4-ND Certification system sponsored by the US Green Building Council for the Development of Residential Areas, in the chapter GIB CREDIT: HEAT ISLAND REDUCTION, it is selected the measures which the horizontal surfaces of the pavements have to adopt to minimize the heat island effect in the cities.

In particular, pavements are considered reflective when the initial reflectance index is equal or greater than 33% and the reflectance index at three years is equal or greater than 28%. Therefore, based on the definition of the reflectance index, the higher the solar energy reflected, the higher the reflectance index and the lower the solar energy or the heat absorbed by the pavement surface, resulting in less heating of the ambient air, so a lower ambient temperature.

2.1 Measurement methods of solar – SR reflectance on opaque surfaces

In the process of designing the reflective pavements, two test methods have been used to measure the reflectances of the entire solar spectrum in the materials and mixtures developed. One uses a UV-VIS-IR spectrophotometer that measures reflectances in laboratory samples and in the other a pyranometer is used to measure the solar reflectances on surfaces of already constructed pavements.

2.1.1 Spectrophotometer UV-VIS-IR:

To measure the solar reflectance from flat surface it is used a UV-VIS-IR spectrophotometer with integration sphere according to ASTM E 903-12 standard. It is the ideal method for small laboratory samples, 5 x 5 cm in size. It does not serve to measure reflectances on field surfaces. The measurement range is between 300 and 2500 nm of wavelength.

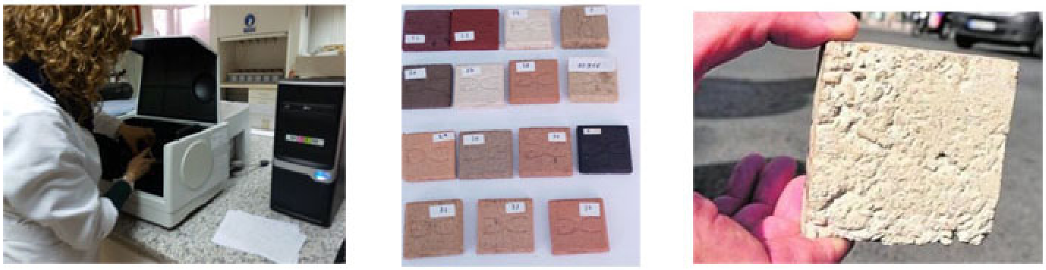

Fig. 10 – Spectrophotometer and simples used

This method of measurement allowed the characterization of the raw materials to use for establish the composition and final dosage of the asphalt pavements developed, according to the criteria of the LEED certification system mentioned above.

2.1.2 Pyranometer:

The solar reflectance is calculated from the measurement of the intensity of the solar radiation, incident and reflected by a surface, with the ASTM E1918 standard (ASTM 2006). Large areas are needed, such as circles with at least four meters in diameter and squares with four lateral meters and a low slope. It measures both the incident energy and the reflected energy in W / m².

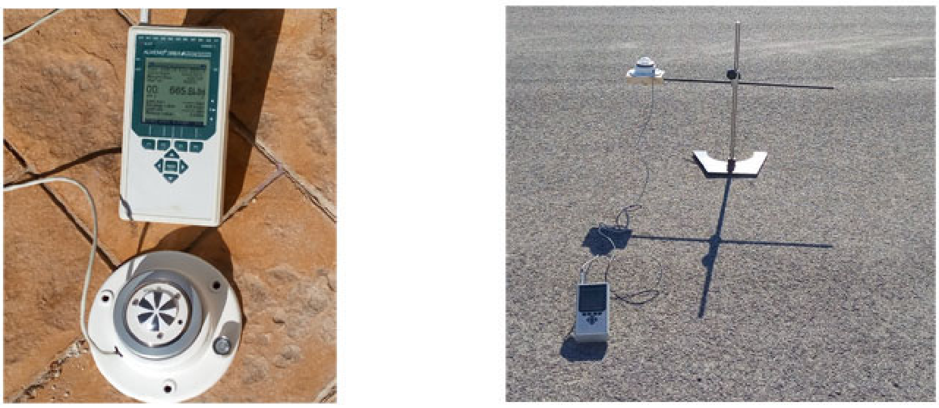

Fig. 11 – Pyranometer and field measurement

According to the defined reflective mixture, tests have been made with their corresponding measurement, which it has been obtained that initially the reflectance index is 40% compared to 7% of a conventional mixture.

Therefore, based on the initial value obtained, initially this mixture is considered reflective and it is expected that it can contribute to mitigate the urban heat island effect.

2.2 Behavior

Regarding, the variation of temperature itself, both superficial and internal, the following figure shows a reference sample of conventional mixture and another of reflective mixture, which the temperature inside of both with respect to the surface temperature varies around 3-4ºC, of which the behavior of both is similar and the data obtained are comparable.

The surface and interior temperature of the reflective mixture differs 8-10°C with respect to the conventional mixture. This temperature difference does not depend on the ambient temperature but depends on the radiation which reaches the exposed surface.

With this, the reflective mixture, when subjected to a lower temperature, will have a longer life than the conventional mixture.

In addition, the reflective mixture has been subjected to the regulatory tests in Spanish regulations (granulometry, density, hollow%, water sensitivity, Marshall deformation, rolling resistance - track test, etc.) and it is concluded that it meets the regulatory requirements, like conventional asphalt pavements.

2.3 Benefits

According to North American studies, in particular, the one realized by the investigating group Heat Island Group of the National Laboratory of Energy Lawrence Berkeley (LBNL), for pavements with reflectance index superior to 40%, the benefits are the following:

- Energy savings: in lighting system -Public light- and air conditioning system -air conditioner-.
- Natural improvement: air quality.
- Improvement quality of life: comfort and pedestrian.

It is expected a temperature reduction on surface between 10-12ºC respect to conventional mixture, probably it will be a temperature reduction of 1-2ºC so it will save 0.5KW/m2 in air conditioner, as a consequence a reduction in energy demand.

In addition, the decrease in ambient temperature causes the slowdown of photochemical reactions and, consequently, the formation of "smog" by the 5% decrease in tropospheric ozone due to tropospheric ozone in abundant quantities is considered a pollutant of the atmosphere.

Respect to change of the hue of the reflective mixtures with respect to the conventional ones, it would suppose a saving of 30% in public lighting due to the need of less power in the luminaries, which translates in a saving of energy consumption, together with the above, leads to lower levels of CO2, NOx and VOCs to cover the energy demand.

On the other hand, with the solar reflectance measurement methodology, the total solar reflectance value is obtained in %. You can also obtain the % of the reflectance of the three spectra (UV-VIS-IR) separately, this possibility of calculation is very important for the design criteria of the reflective asphalt mixtures. We look for pavements with high reflectance in the visible and infrared, and low reflectance in the UV (this will avoid any inconvenience to the users of the pavements), for this we will take into account the color and physical-chemical characteristics of the components of the mixtures.

From this, it wanted to check if the clear tone of the reflective pavement could be harmful to health due to the level of reflectance. To do this, a comparison was made of the reflectance values for the wavelengths of each spectrum in other surfaces which are harmful to health such as snow, and another with conventional pavements which are not.

It is known the ultraviolet-UV electromagnetic spectrum is harmful to health; the following figure determines the solar reflectance values and shows that the UV wavelength behavior of the reflective asphalt pavement is more similar to conventional asphalt pavement, far from the reflectance of a surface harmful to health such as snow. See Fig. 12.

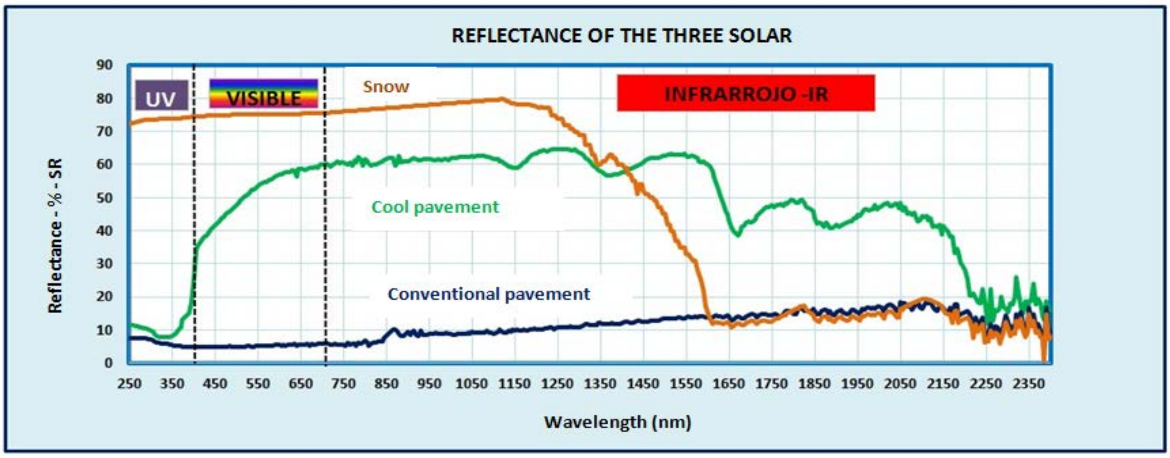

Fig. 12 – Graphic representation of the reflectance of the three solar spectra on snow surfaces, reflective and conventional asphalt pavements.

Therefore, from the design system of obtaining reflectance of the pavements separately, low reflectance of the ultraviolet-UV spectrum can be achieved, which will allow to circulate through the reflective pavements reducing the need to use sunglasses or sunscreen, in contrast to what occurs in other surfaces such as snow, due to its high reflectance of the ultraviolet-UV spectrum and that the mixture developed so far meets the expectations of being a reflective asphalt pavement that may contribute to the mitigation of change climate.

3. RESULTS

The developed technology has been studying by CHM, with CTCON collaboration, with REPARA 2.0 project. Also, a prototype LIFE HEATLAND project with the European support of the LIFE program whose general objective until 2020 is to group forces to contribute to sustainable development achieve the objectives and goals of the European 2020 Strategy and the strategies and plans of the European Union on the environment and climate. The following results are:

- 24.000 m2 of the cool pavement installed. The pavement albedo is expected to be increase from the 0.05 for conventional asphalts to 0.46 for the new technology.
- Four metering towers built-up and data acquisition system correctly working.
- Quantitative and qualitative demonstration of the effectiveness of the innovative pavement to mitigate the UHI effect. Throughout the test program, about 1.5 million data will be obtained: metering towers will register, every 30 minutes, 24 hours/day and during 2 years, the following parameters: pavement surface temperature, air temperature (at 0.5, 1.5 and 4 m height), moisture, wind speed, solar irradiance, air ozone, illumination level and noise; together with thermography, existing and new pavement samples analysis and other related information.
- To actually mitigate the UHI effect in the implementation area. It is expected to reach an air temperature decrease of 1.5ºC and a surface pavement temperature decrease of 10ºC. Energy savings of 7% for refrigeration devices and 5% for street lighting are expected.
- A mathematical model to predict the effect of the innovative pavement implementation in other urban areas.
- Quantitative demonstration of the economical balance of the new technology and its feasibility.

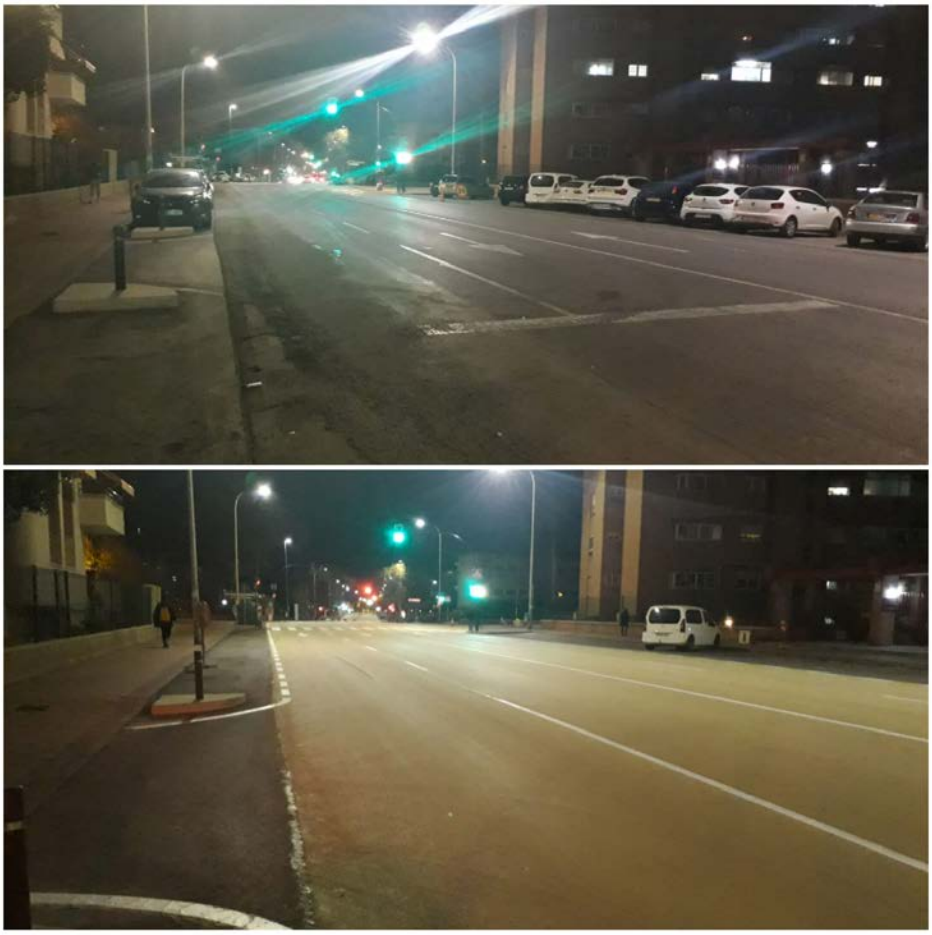

Fig. 19 – Night results, before and after cool pavement.

4. CONCLUSIONS

Until today, the demonstrator has been monitored and the following conclusions have been obtained, validating this type of pavement as a mechanism to reducing the urban heat island effect:

- Initial luminance of reflective pavement 2.5cd / m2 under the lamppost, 150% higher than the conventional asphalt street.
- Solar reflectance of 30%, almost four times higher than that of conventional asphalt.
- Average surface temperature with reflective pavement 7-11ºC lower than that of the conventional pavement surface
- Areas of the asphalt where rubber has been deposited from the tires as a result of the rolling of vehicles are heated 1-3ºC more than the clean areas.
- Lower environmental lower noise level of the area: 3 dB (A).

ABSTRACT

In the construction of land transport infrastructures such as roads, highways, or railways, one of the factors that determine their design most is the characteristics of the terrain through which they run. Additionally, tunnels have become one of the most adopted solutions to reduce environmental impact. The characteristics of the rock mass are a key point to decide the layout of the tunnel and its construction method. However, the rock masses are discontinuous, anisotropic, and heterogeneous media, so their classification and knowledge are needed for a safer design of these infrastructures.

The rock mass is not an industrial material with “pre-established” properties and behaviours, but rather a natural material that needs to be analyzed, understood, and standardized. The need to understand the behaviour of the rock mass has led throughout modern history to the use of different standards, which lead to the development of geomechanical classifications, with the aim of establishing a common language that translates the very advanced geological language in the macro and microgeological behaviour, which is needed for applications in civil engineering. In the last decades of the 20th century, and in the present 21st, the efforts in the process of understanding the intact rock and the rock mass has been constantly increasing because a better understanding of the rock mass behaviour implies a better result in reached in projects involving affection to rock masses. This paper briefly reviews the history of rock mass classifications, their implications in rock mechanics and their applicability in the definition of behaviours as a function of natural conditions and human action, as well as their direct implication in some fields of the transport infrastructures management with regard to hazard and risk assessment.

1. INTRODUCTION

The construction of infrastructures generates physical and geometrical changes of the ground in which they are integrated. It is necessary to have an explicit knowledge of the behaviour of the ground, as it will usually modify the natural equilibrium of the ground, which is constantly changing due to physical and geological processes.

The understanding of the micro and macro geological context is needed for its consideration in design processes. Therefore, the relationship between geological and engineering disciplines is required for proper design, construction and use. This article highlights the importance of the interpretation of the rock masses in which infrastructures are developed, from the point of view of design, construction and operation management.

The implication of Rock Mass Classifications (RMC) in the assessment of the safety and durability of infrastructures is addressed in this article through different risk and hazard indices, together with cases of infrastructure application and management.

2. GEOLOGY AND ROCK ENGINEERING

The geological model on which an infrastructure is built must encompass both the microscopic scale of the materials and their macroscopic scale and their geological evolution. Civil, mining and rock engineering intensively analyse the behaviour of industrial materials, and this same understanding should be transferred to natural materials such as soils and rocks, since, due to natural or anthropic processes, changes in their behaviour and, consequently, their action on infrastructures are imposed to them. For this reason, the relationship between engineering projects must be complemented with precise geological models. Civil and mining engineering have been designing structures on rock masses for centuries, using the principles of rock mechanics and engineering (Hoek, 2007).

The rock mass encompasses both the scale effect of the material that make it up, as well as its intrinsic characteristics as an isotropic material, and the singularities that make it anisotropic.

2.1 Geology in the engineering context

An understanding of the geological environment is required for proper design of excavations and foundations in infrastructures, whether tunnels, slopes or structures. Often, misconceptions are made in order to save costs and time in the development of projects, starting from extensive borehole investigation in the area under study, without taking into account the geological environment and its evolution in which the small-scale investigations are integrated (Hoek and Bray, 1977; 1989).

The geological setting, its configuration and state, has direct implications on the rock mechanics design with aspects such as: tectonic stresses, metamorphic processes, history of overburden and erosion discharges, as well as the modelling of the terrain by them, cooling processes of igneous material, sediment desiccation, etc (Palmstrom and Stille, 2015).

The influence of geological factors on rock mechanics, starting from the problem of mechanics of materials, has to do with the material sensu stricto and the forces that are imposed to it (Hudson and Harrison, 2000). From these basic principles of mechanics, basic forces and stresses are imposed to the rock mass, to which are added the physical actions of exogenous agents such as water and air and the action of these over time. It is well known that all the natural actions to which the rock mass has been exposed (rock intact + discontinuities) are processes of geological origin.

2.2 Rock mass units

The rock mass conceptually consists of two elementary units (Figure 1). Based on the geological conditions of the environment, the so-called intact rock and discontinuities are the main units defining the rock mass. In addition to these fundamental units, there are singularities of geological and hydrological origin, such as faults, karst, saturation, etc.

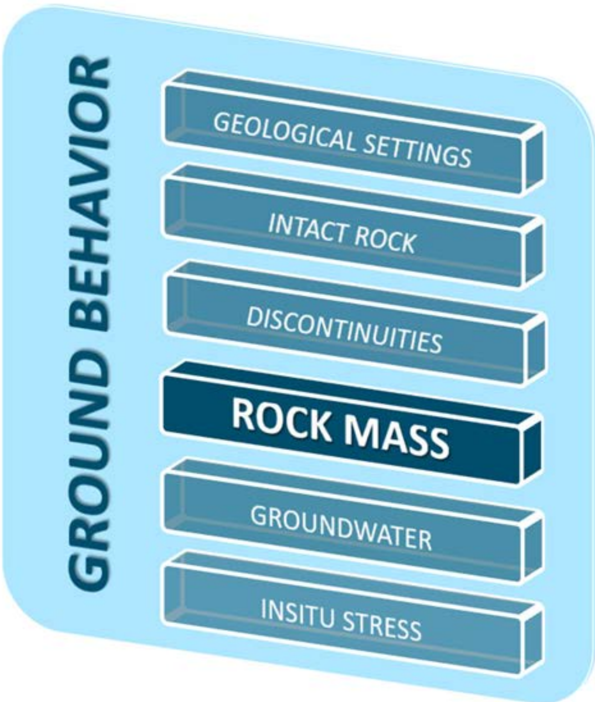

Fig. 1 - Ground behaviour and fundamental units

Homogeneous, isotropic material consisting of mineral aggregates, which can be crystals with or without preferred orientation or ammorphic masses, is called intact rock (Wittke, 2014). The aggregate of crystals and the matrix in which they are embedded, i.e. the mineral skeleton, exhibit mechanical properties that are used in rock engineering.

In various scientific publications, the rock mass is defined as a heterogeneous material consisting of fragments and blocks of rock of different sizes, intact or altered, with their defects, separated by a series of discontinuities, such as joints, faults, bedding planes, etc., which also vary in composition in space and time (Bieniawski, 1989; Potvin et al. 2012; Palmström 1996; Hoek and Brown 1980).

From the point of view of the fundamental units of the rock mass, intact rock and discontinuities, geological compression is essential, since the genesis of the material, its composition and physical-chemical properties, and consequently its mechanical properties, depend on the geological processes that the material has undergone throughout its geological history.

Likewise, within the geological history, the succession of tectonic processes generates stresses in the materials creating folding, compressional/distensive structures (faults). The physical/chemical changes (geomorphological/metamorphism) determine the structure and behaviour of the materials, as well as the topography modelled by the geological history. The evolution of the rock mass and its spatial distribution, episodes of kinematic instability and dissolution processes occur. These processes generate the natural conditions for the evolution of the relief, to which anthropic modelling must be added.

The singularities that characterize the rock mass, defined as the set of planes of weakness that interrupt the cohesion of the intact rock, are named with terms such as discontinuity, fracture, joint, lithoclase, with a common meaning in the specific literature.

2.3 Rock mechanics and Civil Engineering Project

Rock mechanics plays a fundamental role on the feasibility of a civil engineering project developed in a rocky environment. The principles and applications of rock mechanics are nowadays encompassed in what is known as Rock Engineering (Hoek, 2007). As mentioned above, Rock Engineering is closely related to the geological context, its interpretation and adaptation to engineering needs.

Mainly, but not only, solutions for infrastructure projects based on tunnels have been the ones that impose a lesser impact on the environment. At the same time, tunnel design for civil engineering projects has increased continuously during the last 70 years. Rock engineering requires well-structured development processes (Figure 2), always starting from a geological basis and how it conditions the success of the project.

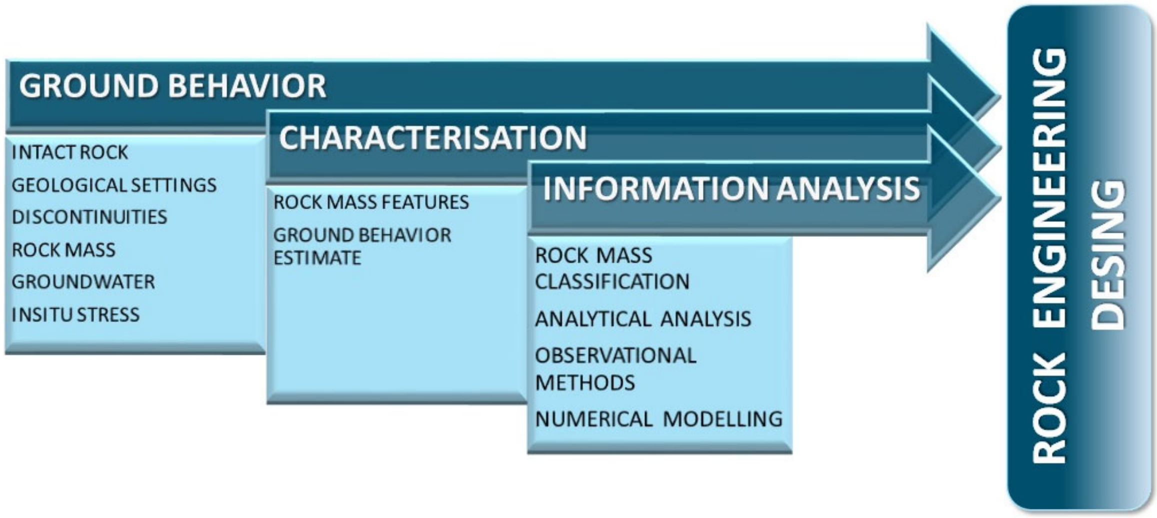

Fig. 2 - Rock mass units and Rock engineering relationship (based on Palmstrom, 2015)

With the structure of the basic processes required in a Rock and Civil Engineering project, the appropriate tools must be used to evaluate and develop the final design approach with the following items:

- Rock engineering processes (Figure 2)
- Feasibility
- Risk Management
- Estimation of time and cost of the project

From the Rock Engineering point of view, the geological context, its application to the design principles and the use of the needed tools for it, aims at achieving a design with the safety factors imposed by the standards, as well as the evaluation of the risks and costs necessary to carry out the design.

In both slope stability and foundations the processes have to be governed by the principles of Rock Engineering, but the design and construction of tunnels involves constant verification of the initial conditions during construction, as the uncertainty of material changes and investigation intensity may not be appropriate. Both geological and investigation uncertainty have a direct implication on the risk and costs of tunnel construction.

3. ROCK MASS CLASSIFICATIONS

3.1 Philosophy

Taxonomy is the science that deals with classifications, starting from theoretical aspects that involve foundations, principles, procedures and rules (Singh and Goel, 1999).

Throughout modern history, the rock mass has been the target of analysis, understanding and generation of indexes or languages to describe its quality or performance from an engineering point of view, but above all its stability and safety under modifications of its natural original state.

The rigour of the studies that lead to each RMC, as well as the simplification in the description of their nature and state summarised in different categories and/or parameters, make Rock Mass Classifications (RMC) a powerful tool that is easy to understand as well as widely used in different fields and stages of an engineering project. However, the application of RMC has to be exhaustive in its determination so that it can be assumed with guarantees as the basis of empirical design.

3.2 State of art

The development of geomechanical classifications began mainly to provide a tool for the construction of tunnels and mines. Later evolution led to their use also in the design of slope stability and bearing capacity of foundations.
Since first rock mass classifications appeared, the basic idea has been to reflect both aspects: the intact rock and the conditions and characteristics of the discontinuities that separate the rock into blocks, fragments or masses, thus making up the rock mass. Therefore, historically, an attempt has been made to categorize the basic aspects of an isotropic and homogeneous material from the matrix scale to the anisotropy and discontinuities that form the rock mass, depending on the scale assessed.

Thus, it is verified that the rock mass must be described as a discontinuous, anisotropic and heterogeneous material. Table 1 details the most common geomechanical classifications, with some others of minor relevance or use in rock mechanics projects (Cosar, 2004; Fernandez-Gutierrez, et al. 2017).

Rock Mass Classification	**Author**	**Application Areas**
Protodyakonov	Protodyakonov (1907)	Tunneling
Rock Load	Terzaghi (1946)	Tunneling and steel support
Stand-up time	Lauffer (1958)	Tunneling

Rock Mass Quality Index	Aydan et al. (2014)	Rock mass properties
Rock Mass Quality Slope (Q Slope)	Barton and Bar (2017)	Slopes, cliffs

Table 1 – Compilation of Geomechanical Classifications

Most of geomechanical classifications, as shown in Table 1, were proposed to help engineers during design of tunneling and mining supports. Taking advantage of the development of these indices, the fields of applicability of RMCs, such as slope and foundation stability and the estimation of rock mass properties, have been extended.

Talking about the origin of the classifications, the one that has gained more relevance throughout history has been RQD (Deere and Patton, 1971) due to its integration in other indexes and its applicability in tunnels, slopes. It also allows the possibility of its estimation in any rock outcrop.

Historically, the most widely used classifications, mainly for the design of tunnels, are: RMR, Q index, GSI, and RMi. These RMCs have been listed in order of relevance in terms of their use in projects.

3.3 Description and relationships

The relationships between the most relevant geomechanical classifications will be shown below, based on the parameters that are considered or evaluated in each one of them. The formulations of each classification are also summarised.

3.3.1 Rock Mass Rating (RMR)

The Rock Mass Rating, RMR, was initially proposed by Bieniawski (1974; 1975; 1976; 1979; 1989). It is an index that evaluates the competence of the rock mass based on 6 parameters:

- R_1: Intact rock strength.
- R_2: Rock quality designation (RQD).
- R_3: Joins Spacing (J_s).
- R_4: Joints conditions (J_c).
  - $R_{4.1}$: Persistence
  - $R_{4.2}$: Aperture
  - $R_{4.3}$: Roughness
  - $R_{4.4}$: Joint weathering
- R_5: Groundwater Condition
- R_6: Discontinuities orientation correction.

Equation (1), established by Bieniawski (1974; 1989; 2000), is based on the arithmetic sum of the parameters participating on the classification. Since 2000, there are trends involving the parameters R_2 and R_3 (R_{2-3}) (Bieniawski, 2011) in order to determine the joint/meter scores from 40 to 0 for jointless masses (0 joints/meter) to extremely jointed rock masses or sugar cubes (50 joints/meter), shown in Equation (2).

$$RMR_{c(73-89)} = R_1 + R_2 + R_3 + R_4 + R_5 + R_6 \quad (1)$$

$$RMR_{c(89)} = R_1 + R_{2-3} + R_4 + R_5 + R_6 \quad (2)$$

The characterization without the water effect (R_5) and the correction for the orientation of the discontinuities with respect to the construction element (tunnel, slope, and foundation) is called RMR_b (basic), shown in Equation (3).

$$RMR_b = R_1 + R_2 + R_3 + R_4 \quad (3)$$

In 2014, the relation of the original 6 parameters is updated to Equation (4) and renamed RMR_{14} (Celada et al. 2014) using 3 factors, named F_0 (which is approximately R_6, according to 1974-1989's classification), F_e (excavation method adjustment) and F_s (stress-strain associated with tunnel face behaviour).

$$RMR_{14} = (RMR_b + F_0) \times F_s \times F_e \quad (4)$$

The rock mass is classified into 5 classes according to standardised methodology scores.

3.3.2 Rock Mass Quality (Q index)

The Quality Index, developed by Barton and co-workers in 1974 (Barton et al. 1974) and in later years (Barton et al. 1976;, 1977; 1980), also uses 6 parameters to estimate rock mass behaviour:

- Rock Quality Design (RQD).
- Joint set number (*J_n*).
- Joint roughness (*J_r*).
- Joint alteration number (*J_a*).
- Joint reduction number (*J_w*)
- Stress Reduction Factor (*SRF*).

Equation (5) defined by the author, is divided into 3 ratios, each one being indicative of three very important concepts in Rock Mechanics.

$$Q = \frac{RQD}{J_n} \times \frac{J_r}{J_a} \times \frac{J_w}{SRF} \quad (5)$$

Where some parameters are grouped:

- Block Volume = *RQD*/*J_n*
- Shear strength = *J_r*/*J_a*
- Active Stress = *J_w*/*SRF*

In 2002, in order to establish correlations with other ground parameters the original author (Barton, 2002) presented the modified index, *Q_c*, which relates the simple compressive strength of intact rock (σ_c) to the Q index, reducing the quality of the rock mass for values of Q < 100, Equation (6).

$$Q_c = \sigma_c \times \left(\frac{Q}{100}\right) \quad (6)$$

The rock mass is classified into 9 classes or categories, which according to Grimstad et al. (2004) are recommended for tunnel support technologies.

3.3.3 Geological Strength Index (GSI)

Geological Strength Index (GSI), was developed in 1995 by Hoek et al. (1995). This qualitative observational index originally related the structure of the rock mass according to the degree of fracturing and its volumetric arrangement, together with the state of the rock mass itself in its surface (Sanchez et al. 2017).

This index is constantly being reviewed and updated by different authors. An example of this, is the calibration of Cai and Kaiser (Cai et al. 2004) shown in Figure 3 which includes the relation to the joints condition. Russo (2007) also includes to this the *jC* parameter of RMi, which is based on quantitative parameters. Both are included in classification abacuses.

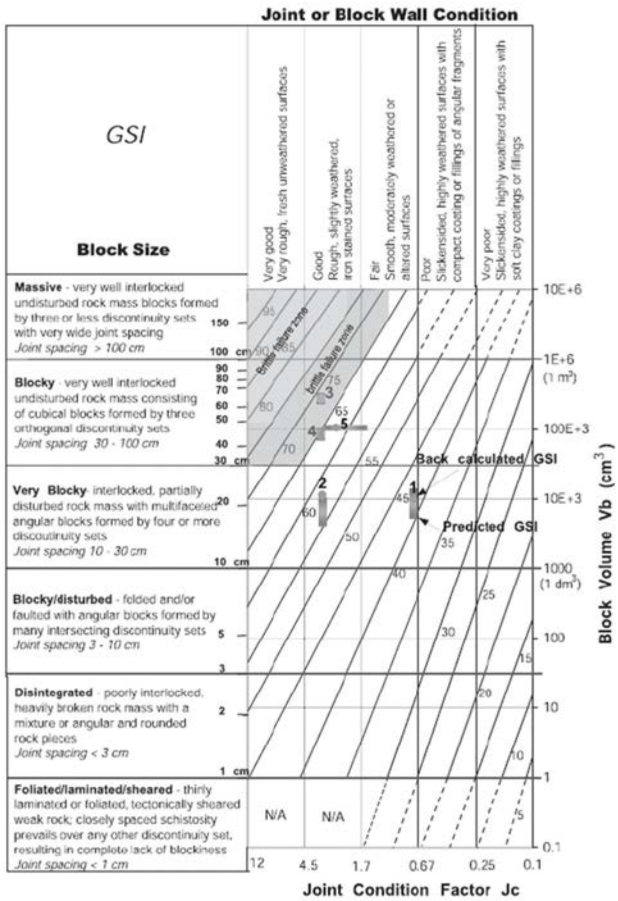

Fig. 3 - Hoek's chart for the determination of the GSI modified by Cai, Kaiser et al. (2004)

Hoek et al. (2013) related the joint condition ($JCond_{RMR89}$) of RMR_{89} (3), Equation (7) and the parameters defining the shear strength of the joints (J_r and J_a), according to Q system, Equation (8), so that the GSI value and its classification can be obtained based on the most common geomechanical characterisations.

$$GSI = \left(1{,}5 * JCond_{RMR_{89}}\right) + \frac{RQD}{2} \tag{7}$$

$$GSI = \frac{52\frac{Jr}{Ja}}{\left(1+\frac{Jr}{Ja}\right)} + \frac{RQD}{2} \tag{8}$$

Based on the graph, the rock mass is classified into 6 block size ranges and 5 rock mass states, related to each other by the score obtained.

3.3.4 Rock Mass Index (RMi)

Rock Mass Index (RMi) was developed by Pälmstrom in Oslo (Norway) in 1995 (Palmström, 1995) taking into account the main parameters of the rock mass and intact rock. This classification relates the uniaxial compressive strength of intact rock to the shear strength properties of the joints that divide the rock into blocks.

Relationships are differentiated for jointed rocks, Equation (9), and massive rocks, Equation (10).

$$RMi = \sigma_c * JP = \sigma_c * \sqrt{jC} \times {V_b}^D \quad (9)$$

$$RMi = \sigma_c * f_\sigma = \sigma_c * \left(\frac{0{,}05}{Db}\right)^{0{,}2} \quad (10)$$

Where σ_c is the uniaxial simple compressive strength of the intact rock, *JP* is the joint index that defines the conditions of persistence, aperture and roughness of the joints, V_b and D_b are the parameters defining the volumetric and surface geometry respectively. *D* is a correction parameter for the joint condition *jC*. f_σ is the massivity factor of the rock mass.

3.3.5 Relationships and Correlations

As has been briefly described, each RMC considers a different relationship between the fundamental units of the rock mass, such as the intact rock and the discontinuities that divide it, being these two main concepts the ones that are common to all classifications.

In Figure 4, it is schematically shown which parameters of the geomechanical characterisation of the rock mass are evaluated by each RMC, as well as the relationship with the geological and geomechanical models that have to integrate the rock mechanics designs and their relationship with civil engineering projects. Some classifications developed for tunnel support, such as RMi, include factors such as the number of joint families and the orientation in relation to underground excavation, water affection or stress state, for the estimation of the recommended support, but not in the geomechanical classification sensu stricto.

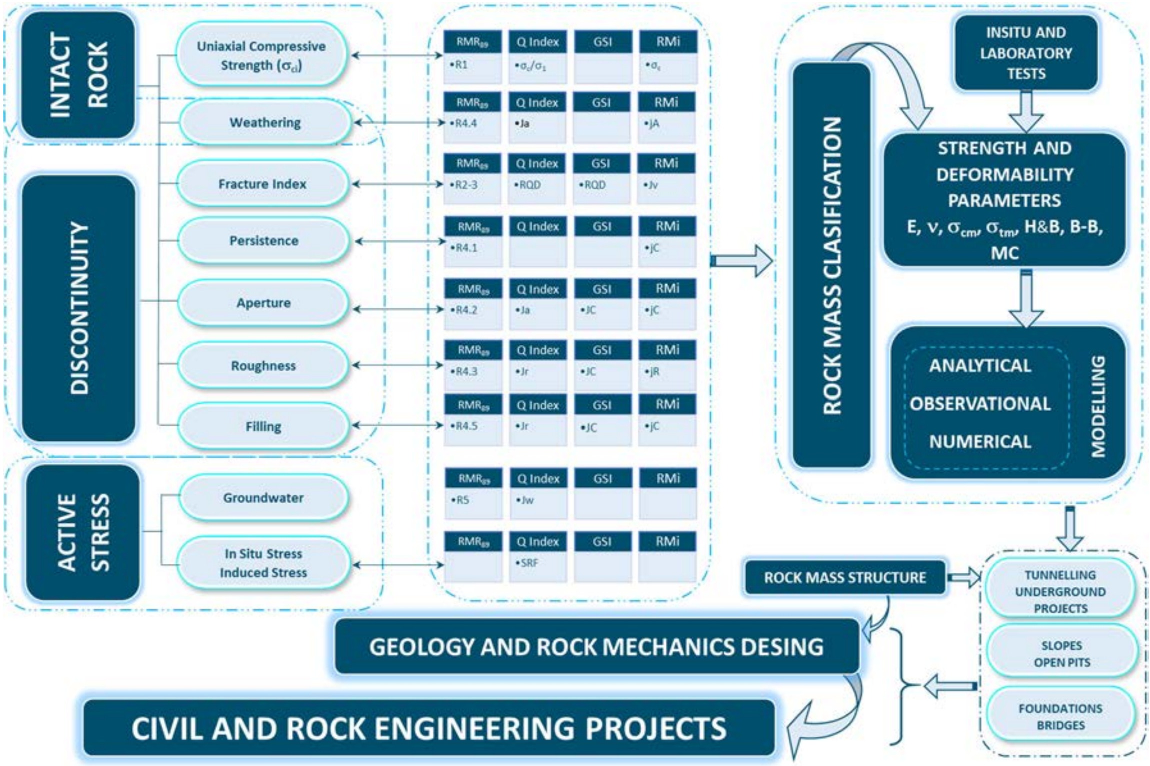

Fig. 4 - Rock Mass Classifications and Civil Engineering Projects

On the other hand, RMCs have been studied to propose a great number of correlations, mainly between RMR and Q and between RMR and GSI. There is a large number of authors and correlations between various geomechanical systems or indices in the specific literature. In this article we show graphically some correlations, obtained for specific lithologies, since it is considered by the authors, that in the field of correlations, lithologies of similar sedimentary and tectonic environments, show better fitting than general correlations for any type of lithology (Sánchez et al. 2016; Fernandez-Gutierrez et al. 2017). Figure 5 shows the correlations between RMR and Q, both generally, as well as the one developed by Fernandez-Gutierrez et al. (2017), which analyzes the relationship for fine-grained sedimentary rock formations.

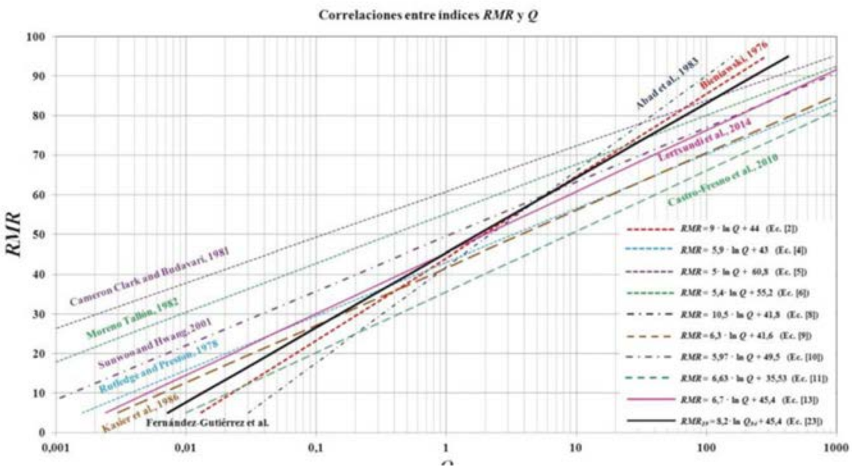

Fig. 5 - RMR-Q correlations (Fernández-Gutiérrez et al. 2017)

Figure 6 shows the comparison of correlations between RMR and GSI for different lithologies in Andean environments (Sánchez et al. 2016) compared to the original one proposed by Hoek (Hoek 1995).

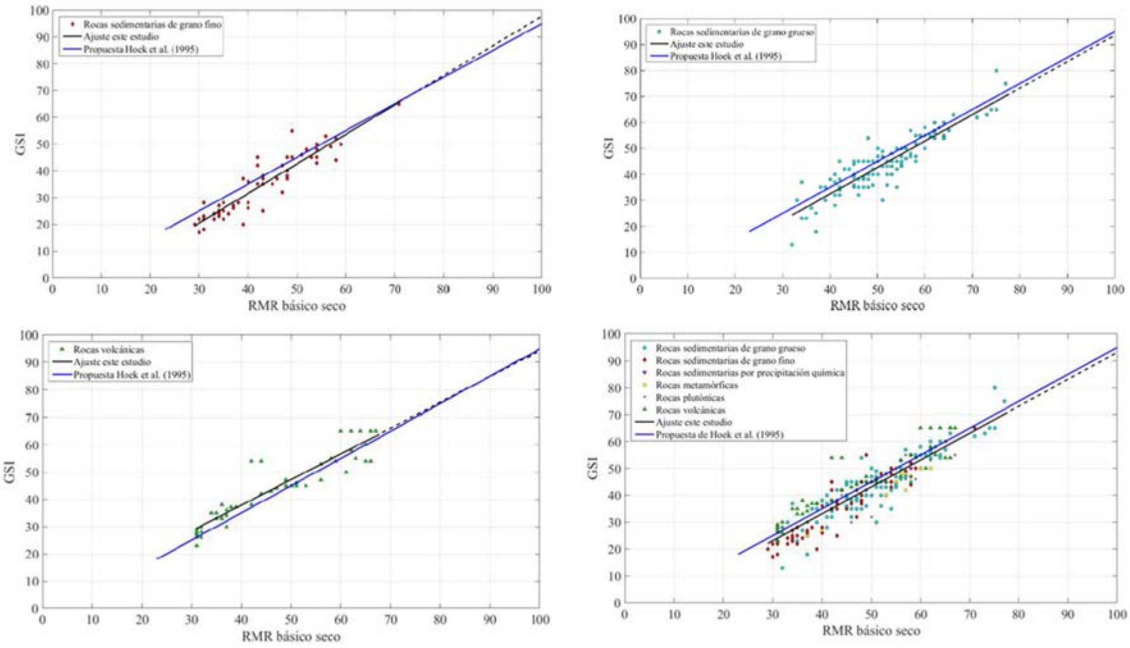

Fig. 6 - RMR-GSI correlations in Andean environments (Sanchez et al. 2016)

4. ROCK MASS CLASSIFICATIONS FOR SAFER INFRAESTRUCTURES

As shown so far, the relationship of geology with geomechanical characterization and design plays a very important role in the final designs of a civil engineering project. Therefore, a bad design, either due to the lack of budget, lack of importance given to the role of rock mechanics, or lack of expert judgement, has serious implications in relation to the safety, risks, durability and final costs of an infrastructure.

In the specific literature, there are numerous cases of the relationship between design costs and construction costs due to causes usually referred to as geological. Some of these causes may be difficult to detect, but many others are due to a lack of rigour in the design.

Figure 7 (Palmstron et al. 2015) shows the sequence of an underground excavation project and the influence of a good design (rock mechanics and engineering) over the final costs, compared with a bad design where the final cost is increased. It can be seen how the costs and time during the construction and operation phases can be very high when proper management of design fails.

Generally, an infrastructure project is designed under the regulations of each country, the Eurocode 7 and the specifications of each infrastructure owner.

A rigorous approach should impose that each design of slopes, walls, foundations, embankments and tunnels had to be verified during construction according a Factor of Safety requirement, comparing this with the design.

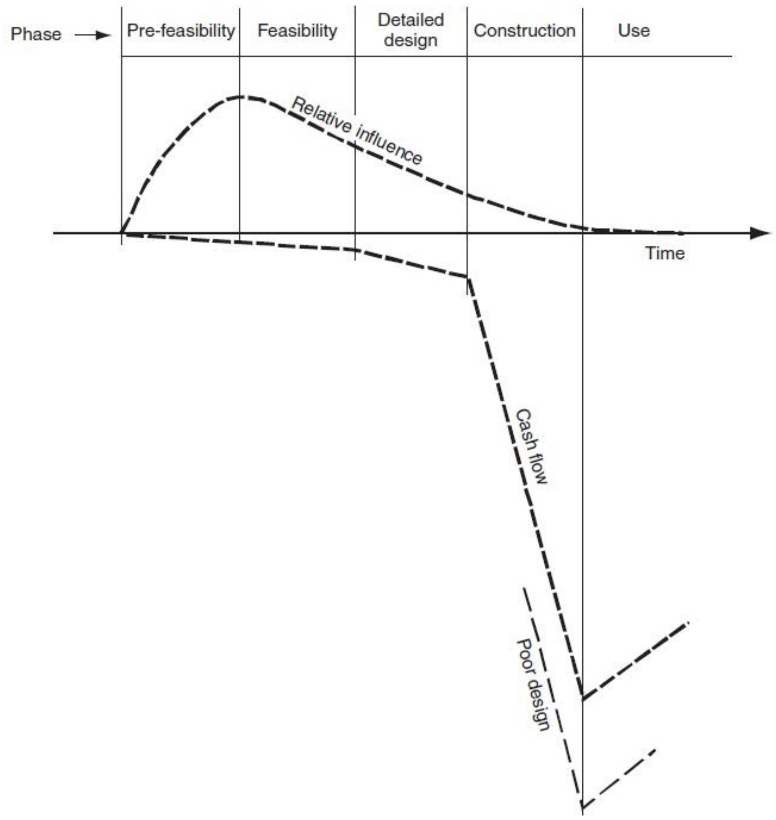

Fig. 7 - Relationship between costs and project stages (Palmström, 2015).

The analysis and implications of the factors of safety requirements by any Rock and Civil Engineering projects is not the subject of this paper.

4.1 Infrastructure risk management

Once the construction phase of the infrastructure has been completed, it should be mandatory to verify the available Factor of Safety (FoS) compared with respect to that proposed or deduced during design phase. This one should be the starting point for verifying the evolution of the finished works during its operation life. In most cases, this post-construction condition is not correctly assessed, which generates increased maintenance and risk remediation costs. These costs are often higher than those during the construction phase and also involve the users.

The relationship of the probability of failure to the safety factor (Figure 8) is related to the quality in engineering studies, (Silva et al. 2008). In this study, based on the analysis of real cases in dams, it is stated that for the cases of high FoS (Factor of Safety), high failure probabilities can be associated with the quality of the engineering projects.

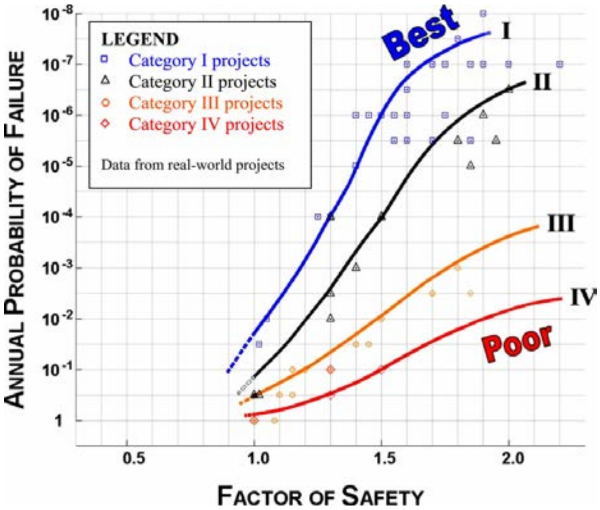

Fig. 8 - Factor of safety versus annual probability of failure (Silva et al. 2008).

Figure 9 adapts the flow chart defined by Fell (Fell et al. 2008), defining risk assessment and risk management analysis process, which can be generally applied to infrastructures with risks due to ground instabilities (slopes, foundations or tunnels), taking as final target risk mitigation and management strategies. The hazard of a phenomenon has a fundamental weight on the degree of risk, which is ultimately defined by exposure and vulnerability (UNISDIR 2009).

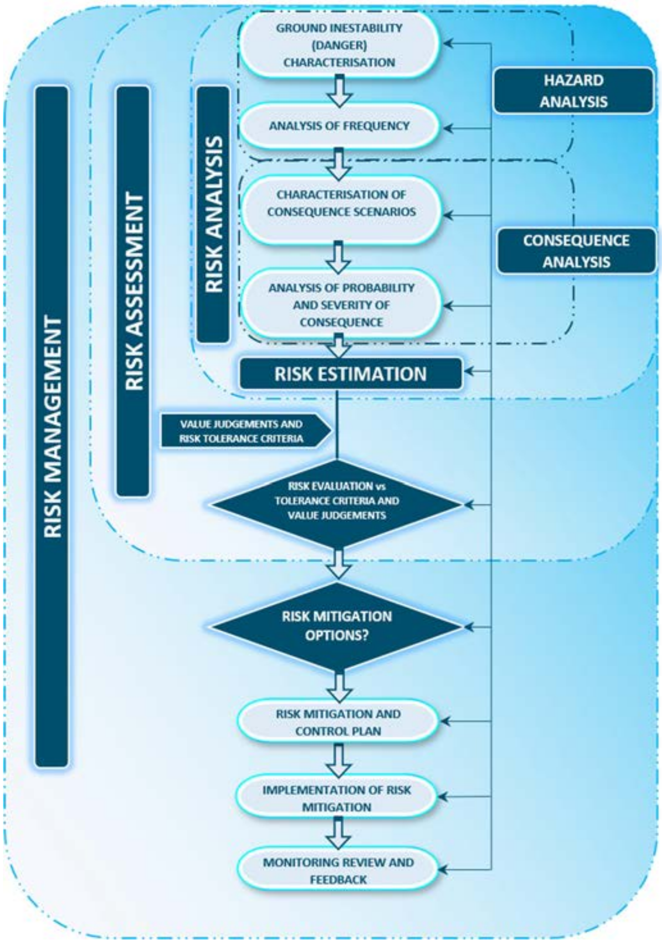

Fig. 9 - Framework of geotechnical risk network (based on Fell et al. 2008)

4.2 Risk management in tunnels

In this section, only the geotechnical risks which can occur in a tunnel are considered. The involvement of the rock mass in the construction of tunnels results in a series of geological and geotechnical risks which have to be assessed in the design and construction of tunnels. (E Matos et al. 2006).

Figure 10 shows the relationships between the technical expert involved in tunnel design, associated with geology and rock engineering, including technical and economic feasibility.

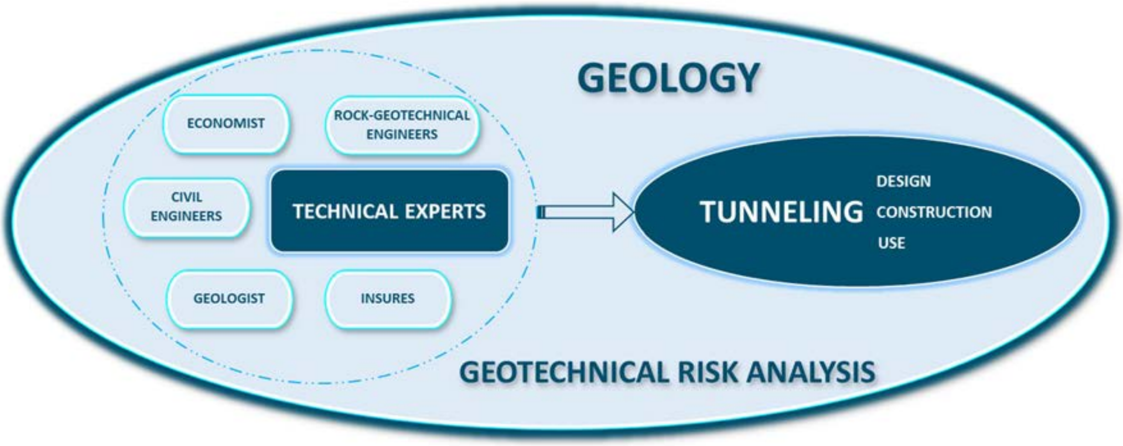

Fig. 10 - Elements involved on risk analysis in tunnels (based on Matos et al. 2006).

Some typical geotechnical risks might be:

- Unstable slopes or rock falls at road o rail infrastructures or tunnel portals.
- Problems with construction through fault zones, low strength of the rock mass, lack of stability and squeezing conditions
- Potential effects of the project to the environment, such as settlements or vibrations.
- Changes of the natural water regime, water inrush in tunnels
- Karst conducts and cavities
- Earthquake loads

As an example of the treatment of geotechnical risks in tunnels, the study of the underground museum in Salzburg (Schubert, 2006) is presented. In the analysis, which started in 1990, the geotechnical hazards were classified into risk factors and solutions were found to mitigate them, thus reducing the costs which were initially assessed.

Table 2, relates the geological risk factors and their probability of occurrence in Monte Carlo analysis, obtaining the volume of ground affected. In addition, the risk factors with the associated potential costs (horizontal axe) are schematically shown in Figure 11.

Geotechnical risk factors	Probability of occurrence		Quantity	Unit
	From	To		
R1 loose, un—cemented conglomerate	1%	3%	96.000	m^3
R2 need of grounting to strengthen of rock mass	5%	10%	12.000	m^3
R3 need of surface treatment of conglomerate	30%	70%	3.000	m^3
R4 extensive water seepage	0%	2%	96.000	m^3
R5 major unfavorable joint, need of pre-stressed anchors	50%	150%	10	Stk
R6 treatment of caves	110%	130%	1.000	m^3

Table 2 - Geotechnical risk factors quantity and probability of occurrence.

4.3 Risk management of slopes

Road and railway infrastructures, with linear designs, usually in some of their sections are located in areas that require excavation for geometric fitting, generating slopes.

In the case of rock slopes, in addition to characterization, analytical, observational and numerical studies, geological and geotechnical risk assessments should be carried out during design and construction. Geological risk assessments, in this case of slope instabilities in transport infrastructures, should be confronted by infrastructure managers using specific tools such as hazard and risk indices.

In this section, mention is made of the implications of geomechanical classifications and rock mass characterisation applied to hazard and risk indices in various studies.

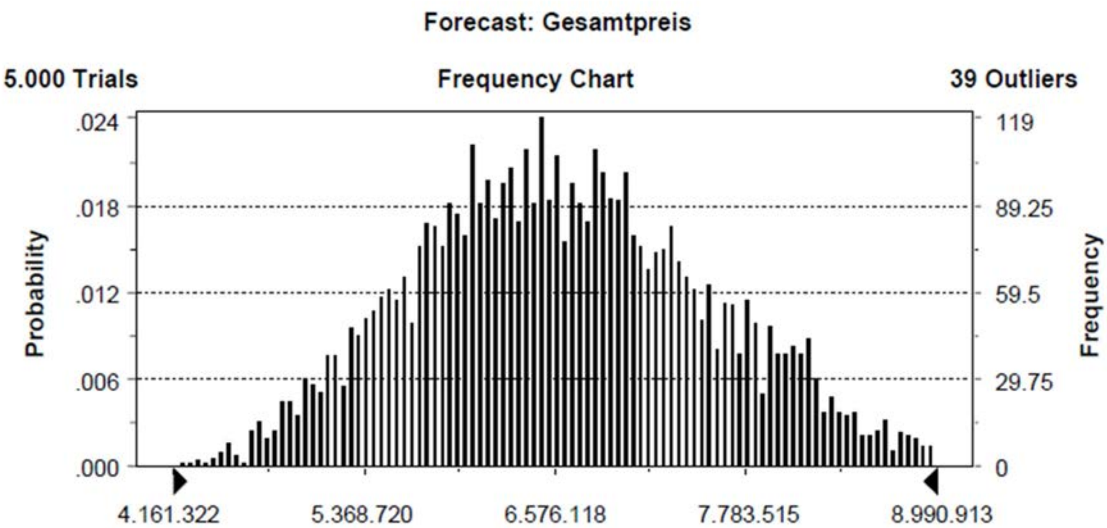

Fig 11 - Geological geotechnical risk factors and their expected cost variation (Schubert, 2006)

The *Rockfall Hazard Rating System (RHRS)* developed by Pierson, 1990 in Oregon for FHWA, considers qualitative rock mass criteria, modified by Budetta (2004) using the SMR (Romana, 1995) geomechanical slope index. This index has 9 exponential scoring categories. The methodology bases its classification on 9 factors grouped into geometry, infrastructure characteristics, geology and geomechanics, climatology and frequency of rockfall instabilities (Geoconsult, 2019). The purpose of the methodology is the evaluation of the characteristics of the infrastructure to allow rockfall conditions according to the original methodology (Pierson, 1990), but adapted to any kinematic instability of the rock mass, planar, wedge, toppling failure (Budetta, 2004). Depending on the danger posed by the hazard, the magnitude and frequency are evaluated, as well as the road platform, in relation to the visibility and distance of reaction of the drivers in case of falling of any object on the road. The volume of this object as well as the slope of the route are also considered.

Geoconsult in 2018 adapted methodology proposed by Budetta (2004) according to Spanish road standards, analysing 27 km of road to categorise the existing risks on the A-136 road in Huesca (Figure 12).

In this case, the infrastructure owner is provided with a tool for monitoring the risks present on the road, as well as with a strategic plan with mitigation measures and criteria for maintenance investment prioritization.

Figure 13 shows the dispersion in the estimation of geomechanical quality in rock slopes defined with RMRb and SMR.

Logically, the rock mechanics and geology component in the risk assessment of this methodology is a key issue, as it is a geological hazard process.

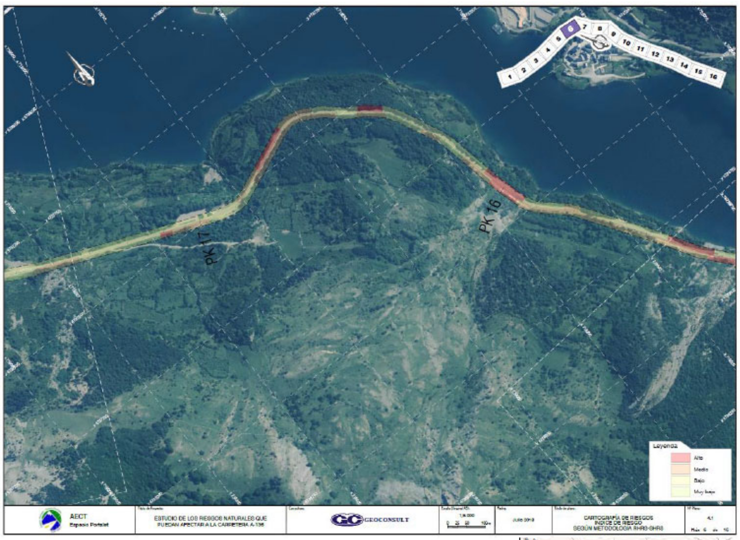

Fig. 12 - Map of a sector of the A-136 road classified with RHRS (Geoconsult, 2018).

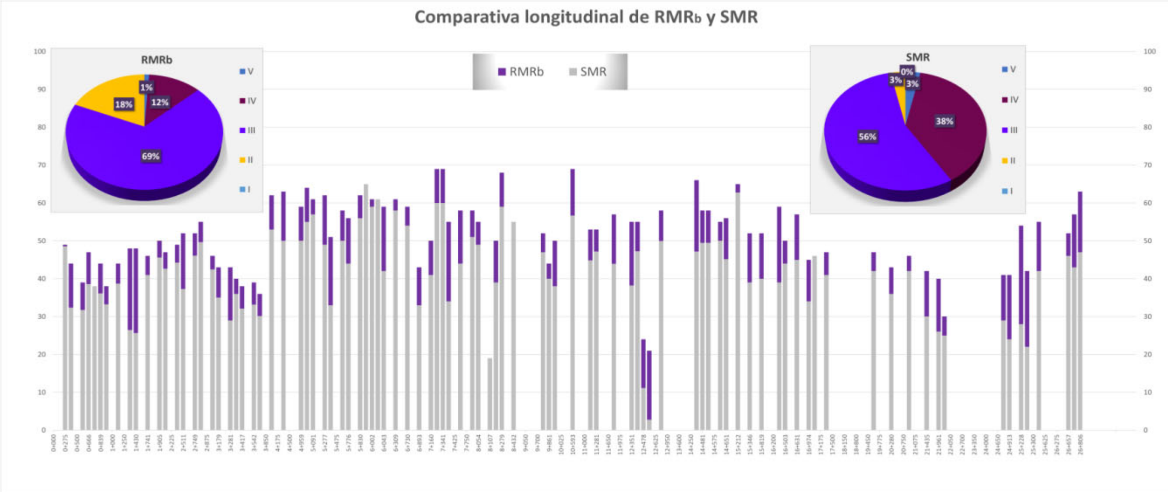

Fig. 13 - Comparison of the geomechanical quality according to RMR_b and SMR in the rock slopes of the A-136 road.

On the other hand, Corominas et al. (2017) used a single quantitative risk assessment criterion (QRA, ECR Spanish acronym) for road infrastructures in Gipuzkoa. This methodology was introduced by Fell et al. (2008).

Quantitative Risk Assessment, QRA, (Fell et al. 2008; Corominas et al. 2017) consists on the quantitative determination of risk based on the probability of failure/breakage and its consequences (Fell et al. 2005), in Risk Points (PoR Spanish acronym) located along the infrastructure analysed in the study.

Parameters are defined as Cost Units (CU) for all situations, considering direct and indirect costs, based on affection and closure conditions of infrastructure due to incidents (mainly of geological hazard such as slopes failures in rock mass). Phenomena related to the rock masses which usually can cause fail in the operation and whose common descriptor is the amount of damage to the infrastructure have been included in Table 3.

Notation	***Mechanism***	***Discipline***	***Cost Unit evaluation***
DR	Rockfall	Rock Mechanics	CU / m^3
CD	Debris Flow	Geotechnical Engineering	
EC	Support Failure	Rock and Civil Engineering	
RL	Brittle failure (lanslide)	Geotechnical and Rock Engineering	CU / m^3 and length

Table 3 – Failure Mechanism, Discipline and Cost Units (based on Corominas et al. 2017).

5. CONCLUSIONS

Geological models and their relationship with the characterization of the rock mass have a fundamental role in rock mass classifications (RMC) for the adequate development of Rock and Civil Engineering projects.

The construction of tunnels, slopes and foundations in transport infrastructures must be undertaken through a well-structured process of analysis and design of the stability of the rock mass in which they are located. The quality of the engineering studies and their control during construction have a direct relationship with the costs of the infrastructure, implying that a low-quality project may involve more failures per year, even with an adequate safety factor, as the uncertainty of the process and investigation intensity followed during the design and construction phases are possibly higher than high quality projects.

Risk assessments of transport infrastructure against geological hazards associated with rock mass stability have a direct relationship with infrastructure operation and costs for the owner and users.

ABSTRACT

Ride-hailing is an emerging service that is transforming door to door mobility in urban areas. Users can easily request a ride through a smartphone app that informs them of the pickup time, the location of the vehicle, and the fare that they will pay in advance. Even though it is well know that Uber implements a dynamic pricing approach depending mostly on supply, demand and competition with other services, there is still little empirical evidence on the main drivers explaining the fare strategy of the company. Using 10-month data from the Uber's Application Programming Interface (API) in the city of Madrid, this research studies the evolution and trends experienced by Uber fares in terms of several explanatory variables. It also explores the main differences between Uber and taxi fares.

The results indicate that trip distance, day of the week, origin and destination of the trip, and rain precipitation have a statistically significant impact on Uber fares. The findings also show that on average, Uber fares are lower than taxi fares, with the exception of particular hours of the day. The analysis also demonstrates that Uber fares slightly decreased during taxi strikes.

1. INTRODUCTION

Information and Communication Technologies (ICT) are radically changing mobility habits as they help connect customers to services through smartphone applications. These apps have important advantages to riders in terms of information, availability, and payment systems. Taking advantage of ICT, ride-hailing is one of the emerging mobility options that is revolutionizing door to door mobility services.

Users can easily request a ride through a smartphone app that informs them of the pickup time, the location of the vehicle, and the fare that they will pay in advance. The app also facilitates the payment to the user.

Uber, Lyft, Cabify, and Didi Chuxing are examples of ride-hailing companies offering their services through smartphone apps. The popularity of these companies is rising due to their availability, convenience, and quality of service compared to traditional taxi systems (Rayle et al., 2016; Shokoohyar et al., 2020). As a consequence of that, traditional cabs, threatened by ride-hailing apps, have set strikes and demonstrations all around the globe to protest for what they consider unfair competition.

One of the main differences between ride-hailing and taxi services is that ride-hailing platforms freely adjust their fares using real-time dynamic algorithms (K. Chen & Sheldon, 2015), while taxi fares are fixed and generally regulated. That means that ride-hailing fares automatically increase when demand is higher than the supply of drivers within a specific area. Dynamic pricing is also called “surge pricing”, and it is an automated system based on the simple principles of demand and supply conditions. Thus, passengers pay a higher fare for rides during times of high demand. When fares applied sharply increase due to high demand conditions, users are generally informed prior to requesting a ride.

The aim of this study is to explain and understand fare patterns by ride-hailing operators. To that end, we collected data from one of the most popular ride-hailing companies worldwide, Uber, so as to conduct an econometric model to explain Uber fares as a function of several exogenous variables. The research exploits supply data from Uber rides collected in the city of Madrid from September 2018 to June 2019, which were obtained by the Uber’s Application Programming Interface (API).

This paper contributes to the state of the art on transportation networking companies (TNCs) in three main aspects. First, we analyse the fares applied by a ride-hailing operator over a long period of time (ten months), to explore the evolution of Uber fares according to several variables. Some previous studies are based on simple simulation approaches (Pepić, 2018), or online surveys to riders (Smart et al., 2015), but did not examined prices actually offered to ride-hailing customers. Other contributions have focused on fare supply during short periods (days or weeks), or special events (L. Chen, n.d.; Hall et al., n.d.; Jiao, 2018; Shokoohyar et al., 2020), but they lack insight from longer timespans, which is important to obtain robust conclusions on the patterns followed by ride-hailing fares. Second, we compare Uber and taxi fares using real data about prices. And third, due to some particular characteristics of the case study, we study to what extent taxi strikes impact on Uber fares.

The paper is structured as follows. After this introductory part, the state of the art and practice concerning ride-hailing services is provided.

A description of the main characteristics of Uber and taxi services in the city of Madrid (Spain) is then presented. This is followed by the description of the data set, their descriptive statistics and the model specification used for this research. The main findings on the evolution of Uber fares and the comparison between Uber and taxi prices are presented. The last section draws the main conclusions and new research avenues.

2. RIDE-HAILING DEMAND AND SUPPLY: SCIENTIFIC BACKGROUND

The scientific literature devoted to ride-hailing has increased in the past few years in parallel with the increasing adoption of these services worldwide. Despite the limited amount of empirical data available up to date, many contributions have been conducted in different research areas regarding ride-hailing, namely: individuals' adoption and frequency of use of these services, estimates of ride-hailing effects, and knowledge of ride-hailing supply. It is worth noticing that nowadays, the majority of research pieces are focused on specific countries, such as the US and China (see comments by e.g. (Mohamed et al., 2019)), with only a few analyses conducted in other geographical areas.

The first group of contributions has modelled individuals' adoption and frequency of use of ride-hailing, both at the individual and trip level as noted by (Lavieri & Bhat, 2019). These papers conduct econometric models to identify the explanatory factors determining the use of these services . For instance, many research works have concluded that ride-hailing users tend to be young people, are familiar with new technologies, and have a higher level of education (see e.g. (Alemi et al., 2018; Rayle et al., 2016; Wang & Mu, 2018)). Furthermore, it has been found that wealthy individuals and residents of urban areas are more likely to adopt ride-hailing services (Alemi et al., 2018; Goodspeed et al., 2019; Lavieri & Bhat, 2019; Tirachini & del Río, 2019; Yu & Peng, 2019). These papers are typically based on the information collected through questionnaires or geo-located trips provided by ride-hailing operators.

The second group of contributions is aimed at approaching the effects of ride-hailing services on the performance of urban sustainability indicators. For instance, there is evidence that the irruption of ride-hailing services has resulted in an increase of road congestion (see, e.g., (Clewlow & Mishra, 2017; Erhardt et al., 2019; Gehrke et al., 2018; Wenzel et al., 2019)). Regarding the impact on other transport modes, many authors such as (Nie, 2017), (Shaheen et al., 2016), or (Henao, 2017) have found out that transport demand of ride-hailing has been mainly captured from taxi services and, to a lesser extent, public transport. Among the positive effects of ride-hailing, we can mention the improvement of road safety (Peck, 2017) and the encouragement of car-free styles (Jin et al., 2018).

Other aspects such as the real impact of ride-hailing on car ownership decisions remain unanswered, with contributions concluding positive (see e.g. (Gong & Song, 2017)), negative (e.g., (Gehrke et al., 2018)) or even neutral effects (e.g. (Rayle et al., 2016)).

Again, these research works generally use information from surveys or geo-located trips.

Finally, the third group of contributions focuses on the supply side of ride-hailing. Given the scarcity of empirical data and the unfeasibility to get large amounts of information from e.g. questionnaires, these papers have often obtained data through Application Programming Interfaces (APIs) provided by operators. For instance, (Cramer & Krueger, 2016) analysed the utilization rate for Uber drivers versus taxi drivers in five major US cities. They concluded that ride-hailing drivers present a significantly higher fraction of their time and share of miles driven with a passenger in their car. (Berger et al., 2018) examined how the irruption of ride-hailing impacted the taxi supply and found a noticeable decline in taxi drivers' earnings, but not in their level of labour supply. Similarly, for the case of Spain, (Akimova et al., 2020) found that the irruption of ride-hailing companies in this country had a significant negative impact on the profitability of the traditional taxi companies in Madrid and Barcelona. Additionally, (Brodeur & Nield, 2018) studied the influence of weather conditions on ride-hailing demand in NYC, concluding that ride-hailing trips increase by 19% when it rains.

Price is a key factor generally considered when analysing ride-hailing supply. For instance, (Shokoohyar et al., 2020) studied a 13-day database collected from the Uber and Lyft APIs to determine to what extent weather conditions influence ride fares, trip duration, and pick-up waiting time in the city of Philadelphia. They found a statistically significant positive effect of extreme weather conditions on ride-hailing fares during weekdays, and a negative impact during weekends due to the lower demand experienced those days compared to normal weather conditions. By exploiting a randomly-drawn Uber dataset from several US cities, (K. Chen & Sheldon, 2016) studied how driver-partners on the ride-hailing platform respond to the dynamic pricing of trips and concluded that drivers tend to drive longer and provide more trips at times with high surge prices.

Despite the increasing attention devoted to the study of ride-hailing services, the current literature has some gaps that have motivated this research. As can be observed, there is a need in the current literature to analyse the evolution of ride-hailing fares during longer periods of time to capture for instance monthly variations. While previous contributions have focused on short timespans, longer periods may allow e.g. exploring potential seasonal effects on ride-hailing fares and obtaining more robust conclusions on their change over time. Additionally, competition between ride-hailing companies and taxis should be explore more in depth.

While previous contributions such as (Akimova et al., 2020) have focused on the impact on earnings, from the supply side, it should be interesting to compare the evolution of fares in ride-hailing services versus the prices applied by taxis, their direct competitors. In this respect, (Smart et al., 2015) found that, for the case of Los Angeles, Uber rides were cheaper by a considerable measure compared to taxis. While this result is based on an online survey to riders, comparing ride-hailing and taxi fares through more massive datasets would provide additional and useful insight.

Finally, given the direct competition between taxi cabs and ride-hailing services, there is a lack of evidence on how an event concerning the taxi supply (e.g. strikes in the taxi sector) impacts on ride-hailing services.

3. THE CASE STUDY OF MADRID CITY

This section provides a brief description of the case study selected to analyse the trends and evolution followed by ride-hailing fares, and their comparison with prices in the taxi sector. Madrid is the capital of Spain and its most populated city, with a total of 3.3 million inhabitants and a metropolitan area comprising 6.5 million inhabitants. The city has two main ring highways (M-30 and M-40), which absorb a significant share of intra-city trips made by private vehicles. In recent decades, Madrid has experienced rapid growth, and a suburbanization process, so many residents and jobs are moving from the city center (districts inside the M-30 ring) to outer neighbourhoods or municipalities within the Madrid metropolitan area.

Mobility in Madrid is characterized by a strong presence of public transport modes. According to the last Metropolitan Mobility Survey (Consorcio Regional de Transportes de Madrid, 2019), there are 7.9 million trips on average in a working day in the city: 36.1% of trips are made on foot, while private transport and private vehicle trips account for, respectively, 33.8% and 26.3% of the trips. Minority options (taxi, ride-hailing companies, bicycle, motorcycle, etc.) represent 3.4% of urban trips.

Ride-hailing services started to operate in Spain in the city of Madrid in September 2014, with the irruption of Uber. At that time, Uber drivers did not have any license, which was against Spain’s transport legislation, so the service was forced to stop offering rides in the country, therebay ceasing all its activities in December 2014. In order to fulfil with all legal requirements, Uber drivers got VTC licenses and the company’s activities resumed in Madrid in March 2016. It was followed shortly after by the Spanish company Cabify, also offering ride-hailing services. Demand for Uber and Cabify rides sharply increased and extended to other Spanish cities, which caused severe opposition from the taxi sector throughout the country.

The taxi sector reacted with hostility to this new competitor due to a negative impact on their economic profitability. Taxi drivers complained that ride-hailing companies did not pay taxes in Spain, did not comply with labour legislation in the country, and benefited from being allowed to change their fares freely. As a consequence of that, demonstrations and strikes from the taxi sector have been common in recent years in Spain, particularly in Madrid. In February 2016, there was the first march of taxi drivers against ride-hailing services. In January 2019, taxi drivers blocked access to the main road in the city for days and even caused violent incidents (Akimova et al., 2020).

Some particular characteristics can be pointed out in the ride-hailing and taxi sectors in Spain. For instance, unlike other countries such as the United Kingdom or the US, where ride haling services are almost fully liberalised, the number of VTC licenses in Spain is currently limited by the government. Furthermore, since 2018 VTC licences are regulated at the regional level, but ride-hailing drivers can occasionally offer their services in any city of the country, depending on the specific demand needs. By contrast, taxi licences in Spain are limited and regulated at the municipal level, and taxi drivers can only offer their services in the specific city where the licence is awarded. It is also worth noticing that most local governments in Spain have suspended the launch of new taxi licenses for decades. As a result, the number of taxi licences in many cities (and particularly in Madrid) have remained almost constant for more than 20 years (Vassallo et al., 2018), mainly due to the pressure of taxi drivers to keep or increase the prices of their licences in the secondary market. According to the Ministry of Transportation (Ministerio de Fomento, 2020), as of March 2020, there were 63,917 taxi licenses and 16.450 VTC licenses in Spain. In the case of Madrid, there were 15,665 taxi licenses and 8,375 VTC licenses, what makes Madrid one of the Spanish cities with the highest ratio of VTC licenses per taxi licenses.

As noted above, Uber and Cabify are the two most widespread ride-hailing services in Spain. Nevertheless, this paper only focuses on Uber services, data due to the lack of data available for the case of its competitor Cabify.. In Spain, Uber provides three different services, namely UberX, UberBlack, and UberVan. UberX is by far the most popular and demanded Uber product, UberBlack is the premium service (Hughes & MacKenzie, 2016; Jiao, 2018) and UberVan is a service for groups of up to 6 people. Uber fares are determined by multiple factors, namely the base fare, the price per kilometre, the price per minute, and the "surge pricing" factor, which is the output of the dynamic algorithm (Ngo, 2015).

Taxi fares in the city of Madrid are set by the City Council, and are determined according to trip distance, trip duration, day of the week, and time of the day (BOAM Boletín Oficial Del Ayuntamiento de Madrid - Núm. 8546, 2018). It should be noted that trips departing or arriving at the airport have a special fare scheme when the origin or destination is located within the inner districts (inside the M30 ring road). In those cases, a fixed fare of €30 is applied regardless of any other trip characteristics.

There are four components which determine Uber and taxi fares in Madrid in 2019 (BOAM Boletín Oficial Del Ayuntamiento de Madrid - Núm. 8546, 2018; Jimenez, 2019): i) a starting fee, which is fixed no matter the duration or length of the ride; ii) fare per minute; iii) fare per kilometre; and iv) minimum fare, which is a minimum fare for each service to reimburse drivers for short rides. This fare, only applied in the case of Uber rides, is charged when the cost of the ride is below €3.50. Taxi services do not include the "minimum fare" component, but the starting fee applied is significantly higher when compared to Uber rides (the starting fee of Uber X is 0.40€ and the starting fee of the taxi is 2.50€ or 3.10€ depending if it is working day or not and depending on the hour of the day in which the ride was requested). In addition to these four components, Uber applies dynamic pricing in its rides when the demand is particularly higher than the supply of drivers.

4. DATA DESCRIPTION

This section presents the data used to explore the trends and evolution followed by ride-hailing fares, and their comparison with prices in the taxi sector. Multiple sources and type of information were employed . Regarding the prices offered by ride-hailing, we collected the information through Uber's Application Programming Interface (API). This tool allows collecting real-time information of requested rides by controlling the latitude and longitude coordinates (origin and destination point) sent by the script developed by the authors of this paper. As noted above, prices applied by Cabify, the other ride-hailing company operating in Spain, were not available and consequently it was not possible to include this company in the analysis.

For the purpose of collecting information on ride-hailing prices, the authors defined 10 locations throughout the city, which were used as origins and destinations of the requested rides. These locations were selected with the aim to homogeneously cover the whole city (see Figure 1), including both inner and outer neighbourhoods (inside and outside the M-30 ring, respectively). We also included special locations such as Madrid-Barajas airport and Atocha train station, with a high demand for ride-hailing and taxi trips in the city. These locations defined a network with 90 potential origins-destinations in Madrid, but we had to subsequently reduce the combinations in a noticeable way (see comments below). The data were requested to the API and stored at 1-hour intervals from September 1st 2018 to June 9th 2019. Figure 1 shows all routes considered in the analysis.

From the service models offered by Uber in Madrid, we focus on UberX rides because it is the most popular Uber service (Hughes & MacKenzie, 2016; Jiao, 2018). The following information was collected from each ride requested in the Uber API: fare, trip distance, trip duration, and the time the ride was requested (year, month, day, and hour). Uber fare indicates the cost of the ride shown by the app. Trip distance and trip duration indicate the trip distance and duration for a given origin and destination, respectively.

It is worth noticing that trip duration reported by the Uber API is based on real traffic conditions, therefore It can be considered a proxy of road congestion in the city.

In order to capture changes in ride fares over time, we included categorical variables controlling for time-related variables for requested rides, namely month, day of the week and hour (time of day). The analysis also controls for potential differences in ride fares depending on the origin and destination of the requested trip. Consequently, we may expect that rides within the city center would be cheaper, given that ride-hailing supply is generally higher in this area of the city.

Therefore, a categorical variable was created to control for the location of the origin and destination of each, particularly whether they are inside or outside of M30, Madrid's inner ring highway.

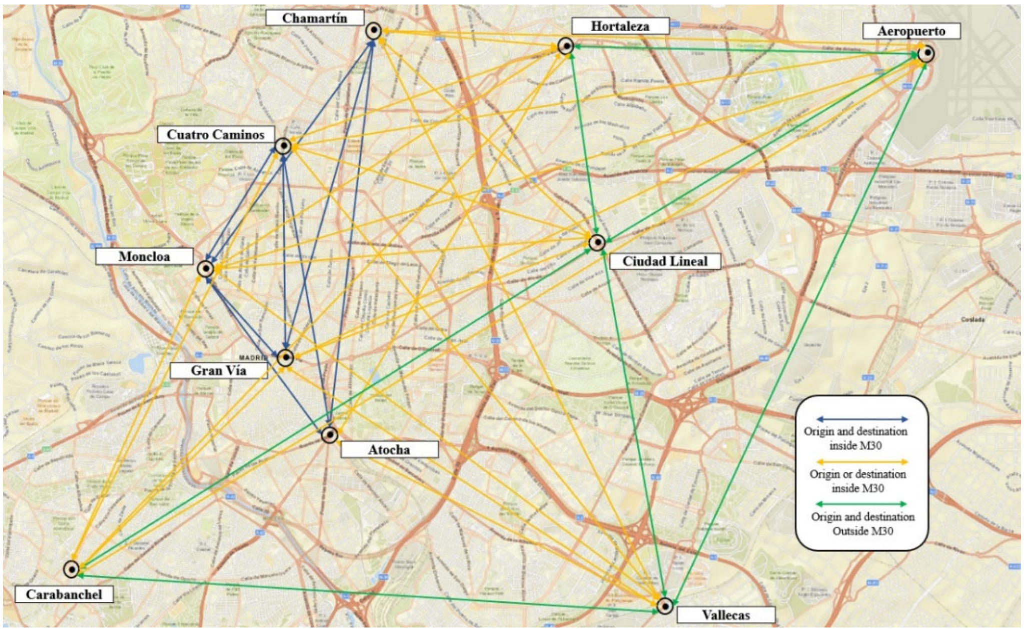

Fig. 1 – Routes selected

In addition to these variables, we also included further information regarding the taxi sector. Firstly, taxi fares were calculated for each ride, following the regulation of the Madrid City Council (BOAM Boletín Oficial Del Ayuntamiento de Madrid - Núm. 8546, 2018) and based on the information collected through the Uber API regarding trip distance, trip duration, type of day, and time of day hour of each trip. This step allowed us to estimate taxi fares and calculate the difference between the prices applied by UberX and taxi services for each specific ride.

The analysis also considers taxi strikes that happened during the period of analysis, in order to control for special events affecting the transport supply of its main competitor. We included a categorical variable capturing the days of strike in Madrid between September 1st 2018 and June 9th 2019.

During the period analysed in this research, there have been taxi strikes for 20 days. Nevertheless, it should be pointed out that a few additional strikes happened in the taxi sector in Madrid in 2018, before the time period covered by the research.

The analysis incorporates weather conditions since they could influence the Uber dynamic pricing and affect ride fares, as found by (Shokoohyar et al., 2020). We collected data on rain precipitation (measured in millimetre) on a 1-hour interval. This variable was obtained from the State Meteorological Agency (AEMET), Ministry of Agriculture, Food, and Environment.

Once the information needed for the research has been collected, a first exploratory analysis of the sample was conducted. It revealed that ride prices for many OD pairs keep constant over time and equals the minimum fare, as explained before. Therefore, these OD combinations were not valid for the purpose of the research so the sample was reduced to 40 OD pairs. A total of 277,840 valid requested rides were finally included in the analysis. Descriptive statistics of the final data sample can be observed in Table 1.

Variables	**Typology**	**Summary statistics**		**Units**
Uber fare (FARE)	*Continuous*	*Mean*	*20.6*	*€*

Table 1 – Summary statistics of explanatory variables

As exploratory analysis, Figure 2 shows Uber fare behaviour per day, hour, and strike event. Uber fares vary around the day and hour.

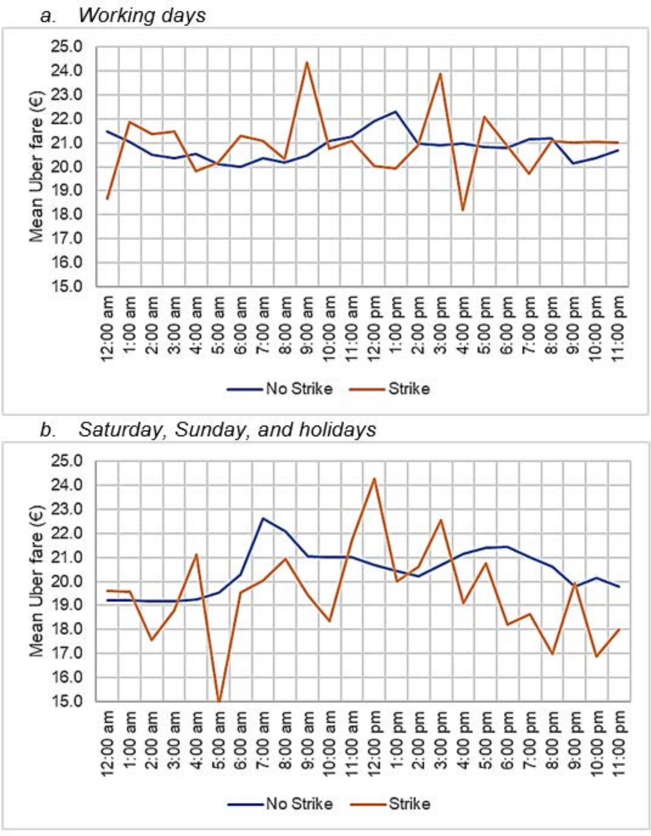

Fig. 2 – Mean Uber fare behavior

5. METHODOLOGY

In order to explore the evolution and trends followed by fares applied in the ride-hailing sector, we adopted a generalized linear model (GLM) framework. The dependent variable to be modelled is the fare applied by Uber services. Nevertheless, the paper also provides some insight regarding differences in terms of prices offered by Uber and taxi services.

GLM is a widely statistical technique used when the response distribution of the dependent variable is non-normal (Oliveira et al., 2018). It is made up of three components: random component, a linear predictor, and a link function. The random component consists of a response variable with independent observations that can be defined by a probability density function of the exponential family (Agresti, 2015). In this case, the Uber fare showed to follow a gamma distribution (k=7.145, θ=0.345) and therefore we used the natural log function, g(μ_i)=ln(μ_i) as a link function. Additionally, a linear predictor relates parameters with the explanatory variables using a linear combination defined as:

$$\ln(Y) = \beta_0 + \Sigma_j \beta_j X_j + \varepsilon \quad (1)$$

In our case, the set of explanatory variables Xj includes: trip distance, trip duration, month of the year in which the ride was requested, day of the week, hour of the day, taxi strike, origin/destination of the ride and rain precipitation, as can be seen in Equation 2:

$$\ln(FARE) = \beta_0 + \beta_1 DIST + \beta_2 TTIME + \beta_3 STRIKE + \beta_4 PREC + \beta_5 DAY + \beta_6 SPAT + \Sigma_i \beta_i MONTH_i + \Sigma_j \beta_j HOUR_j + \Sigma_{k,j} \beta_k DAYxHOUR_j \quad (2)$$

where:

- FARE is the dependent variable to be modelled, Uber fare.
- DIST is the trip distance of the requested ride.
- TTIME is the trip duration of the requested ride.
- STRIKE is a dummy variable that equals 1 when there is taxi strike and 0 otherwise.
- PREC is the rain precipitation, measured in mm.
- DAY is a dummy variable that indicates the day of the week. It equals 1 for non-weekdays (Saturday, Sunday, or holidays), and 0 otherwise (weekdays).
- SPAT is a categorical variable that controls for the location of the origin and destination of each particular ride, as detailed in Table 1.
- $MONTH_i$ is a set of dummy variables reporting the month (i) in which the ride is requested.
- $HOUR_j$ is a set of dummy variables reporting the hour of the day (j) in which the ride was requested.
- $DAYxHOUR_j$ indicates the interaction between DAY and $HOUR_j$ variables.

- B_k is a vector of coefficients to be estimated. The coefficient of variables indicates that when a specific explanatory variable X_i increases by one unit, holding all other predictors constant, the rate ratio (RR) increases by $e^{\beta i}$.

As can be observed, five explanatory variables used in the model are categorical (STRIKE, DAY, SPAT, MONTH, HOUR), so choosing a base reference is needed to explain the modelling results properly. This enables us to determine whether Uber fares are statistically significant when compared to the base reference. For instance, the base reference of STRIKE is when there is taxi strike. The base reference of DAY is working days. Regarding the SPAT variable, the base reference is the ride whose origin and destination is inside the M-30 highway. June 2019 is taken as the base reference of MONTH. Finally, 11:00 p.m. to 12:00 a.m. is considered as the base reference of HOUR. Base references chosen in each case can be observed in Table 1.

6. RESULTS

This section summarizes the main findings of the analyses conducted in this study. Prior to conducting the analyses, we studied potential multicollinearity problems in the sample.

Trip distance and trip duration variables were highly correlated with each other according to multicollinearity tests (Gujarati & Porter, 2009). Therefore, we decided to include only trip distance.

6.1 Uber fares

The results of the model explaining Uber fares are presented in Table 2. The signs of the modelling coefficients and their statistical significance are in line with the expected results.

All explanatory variables are statistically significant and, therefore, the p-value is accepted.

The model confirms the significant impact (with a level of 99% confidence from a statistical point of view) of the variables: trip distance, day of the week, location of the origin/ destination of the ride, and rain precipitation level. The taxi strike variable was significant with a level of 90% confidence.

The trip distance variable is positive and statistically significant, thus indicating that longer distances are associated to higher Uber fares as seems reasonable. According to the modelling results, Uber prices increase by €1.07 for each additional kilometre. Additionally, the variable controlling for the location of the origin and destination of the rides has positive and statistically significant coefficients. This means that coeteris paribus Uber fares decrease when both the trip origin and destination are inside the M-30 ring road.

This result seems reasonable due to the greatest supply density of Uber drivers in the city centre. Some detailed results are provided by the model. When the trip origin takes place inside the M-30 ring and the destination is located outside the M-30, Uber fares increase by 31.6% compared to the base reference. Price rises are lower when the trip origin is outside the M30 and the destination is inside it (+24.2%), and when both the origin and destination of the trip are outside M-30 (+23.2%), compared to the base case.

Wald test: 0.0288

Table 2 – Modelling results

Day of the week also evidences to have a significant influence on prices offered by Uber services. The coefficient sign for this variable is also positive and statistically significant (see Table 2). According to the modelling results, coeteris paribus, Uber fares increase by 4.8% on Saturdays, Sundays, and holidays, compared to weekdays.

The influence of the time of day on Uber fares is also analysed (see Figure 3a). The model estimates conclude that, on average, Uber fares decrease by 2.3% from 12:00 p.m. to 5:00 a.m., compared to the base reference (from 11:00 p.m. to 12:00 a.m.). As expected, Uber fares increase on average by 9.5% from 6:00 to 9:00 a.m., coinciding with the morning peak hour. This result may be related to the higher demand and traffic congestion typically observed in this period (Gramaglia et al., 2016; Vassallo et al., 2012). The model also shows that, on average, Uber fares increase by 3.2% from 3:00 p.m. to 9:00 p.m. The afternoon peak hour, which in Madrid happens from 5 p.m. to 7 p.m., is included within that time frame. Fare rises in the afternoon peak hour are significantly lower than in the morning peak hour. Periods not mentioned above were not found statistically significant in the model.

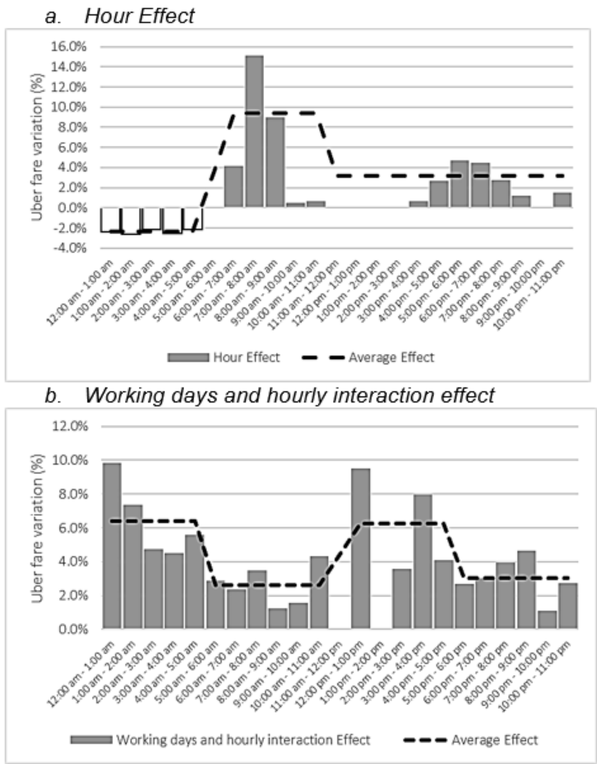

Fig. 3 – Effect generated by the hour to Uber fare

Furthermore, we analysed the day of the week and the hour interaction. This is motivated by the fact that the change in Uber prices at e.g. late hours may be significantly different during weekdays and non-weekdays. As previously mentioned, Uber fares are higher on Saturday, Sunday, and holidays compared to working days. However, the modelling results make it clear that this effect changes quite a lot throughout the day (see Figure 3b). We can identify two time periods when the fare rise is significantly noticeable: from midnight to 4.00 a.m., due to the high demand of people getting back home from night leisure activities (dinner, party, etc.); and from noon to 4.00 p.m., coinciding with the weekend dinner time in Spain. In these two periods, Uber fares increase around 6% according to the modelling results.

Concerning the Taxi strike variable, we obtain a negative statistically significant coefficient with 90% confidence. This result indicates that Uber fare decreases during taxi strikes. According to the modelling results, Uber fares drops by 0.94% compared to the base scenario (no taxi strike). This result appears to be surprising since we may expect that Uber had taken advantage of the taxi strike situation to rise the fares. The explanation we found to this empirical result is that Uber decided to use taxi strikes to capture new clients by maintaining, or even reducing, their usual fares rather than by rising prices. This fact was possible from the supply perspective since, as mentioned above, VTC licences can easily move across different cities of Spain during special occasions or events.

Finally, we found that weather conditions may influence the Uber dynamic pricing and affect the ride fare, which is in line with (Shokoohyar et al., 2020). The coefficient obtained for the rain precipitation variable is positive and statistically significant, and sates that Uber fare increases by 0.3% when rain per hour increases by 1 mm. This is likely due to the higher traffic congestion generally observed during rainy times and, therefore, longer trip duration.

6.2 Comparison of prices offered by Uber and Taxi Services

Furthermore, Uber and taxi fares are also compared. In this analysis we excluded airport trips departing/arriving within the M30 ring because taxi fares for these routes are fixed irrespective of the destination. The difference between the two fares is around €4.5 on average. In general, our findings suggest that taxi fares are higher than Uber ones in all types of day: working days, Saturday, Sunday, and holidays. This result confirms the hypothesis proposed by (Pepić, 2018), who obtained similar results regarding taxi and ride-hailing prices on the basis of a simulation approach.

We found that fare differences are higher in working days, from 10:00 p.m. to 6:00 a.m., compared to the rest of the day (see Figure 4a). This is mainly due to the fact that Uber reduces its fares in this period of time. In leisure days (Saturday, Sunday, and holidays), the trend is similar throughout the whole day (see Figure 4b) with the exception of the midnight period. A t-test was conducted to check whether there is a statistically significant difference between the means of Uber and taxi fares. We found evidence to believe that the difference is lower than 0. This result implies that, for the case of Madrid, Uber prices are lower, in a statistically significant way, than taxi prices.

Finally, we also analyse whether there is a significant fare difference depending on the hour of the day and day of the week. We found that in working days, there is statistical evidence that their means are significantly different except from mid overnight (1:00 a.m. to 4:00 a.m.), late morning (10:00 a.m. to noon), and early evening (from 6:00 p.m. to 7:00 p.m.). Therefore, the analysis suggests that Uber and taxi fares are similar only during these periods. Regarding leisure days (Saturday, Sunday and holidays), there is statistical evidence that Uber prices are significantly lower than taxi fares except from mid-late (9:00 a.m. to 11:00 a.m.) and mid-afternoon (2:00 p.m. to 4:00 p.m.). These findings mean that Uber and taxi fares are only similar during leisure days in these specific periods.

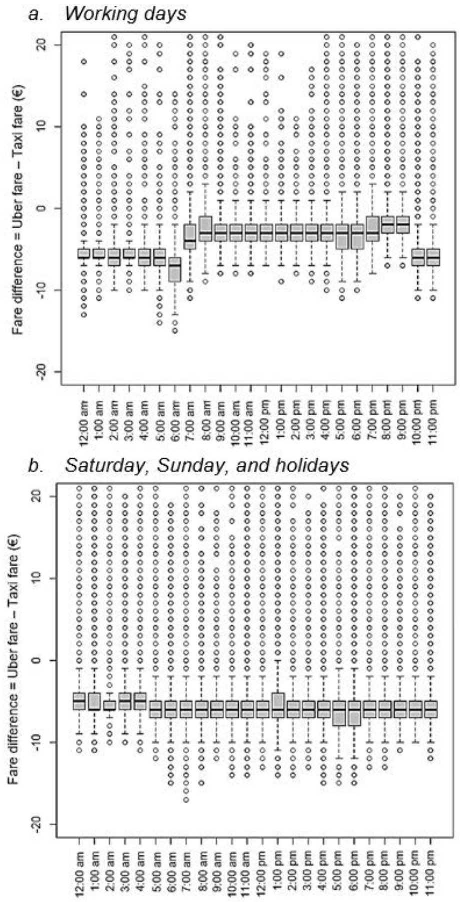

Fig. 4 – Uber and taxi fare difference behaviour

7. CONCLUSIONS

This study explores the evolution and trends experienced by ride-hailing prices, according to different explanatory variables: trip distance, the time the ride was requested (year, month, day and hour), origin/destination of the ride, weather conditions and taxi strikes. To that end, we applied an econometric specification using 10-month data (from September 2018 to June 2019) for Madrid obtained from the Uber's API. In addition, the paper explores the differences between Uber and taxi fares.

The results indicate that trip distance, the time the ride is requested, the origin/destination of the ride and rain precipitation significantly increase the fares offered by Uber. Particularly, Uber prices tend to increase during rainy conditions, but decrease in areas with higher service supply, such as the city centre. The modelling results show significant differences in Uber prices throughout the day. Uber fares increase significantly during the weekday morning peak hour (+9.5%) and, to a lower extent, during mid-afternoon and mid-evening (+3.2%) coinciding with the afternoon peak hour. By contrast, Uber prices significantly drop overnight (-2.3%). In addition to this, it is worth noticing that Uber fares are significantly higher during leisure days, likely due to the higher demand of leisure trips observed in this type of days.

Additionally, the results from this research show that Uber may have taken advantage of taxi strikes to capture new clients through fare reductions since, according to the model results, violent strikes conducted by the taxi sector coincided with a small decrease in Uber prices. This was possible from the supply side because the Spanish legislation makes possible to transfer ride-hailing supply licences across cities for high demand periods.

This research also found that, at least for the case of Madrid, Uber prices are on average significantly lower than taxi fares, with the exception of particular times of day within off-peak hours. The results suggest that taxi fares are around €4.5 higher than Uber in any type of day: working days, Saturday, Sunday, and holidays.

Some aspects can be pointed out for further research. Extending the analysis conducted in Madrid to other geographical areas (e.g. American cities) would provide broader insight. While the ride-hailing sector is regulated and the number of ride-hailing licenses are limited in Spain, this is not the case in many other cities. Additionally, studying the reasons motivating individuals' choices towards ride hailing and taxi adoption would be of the greatest interest to understand users' behaviour.

RESUMEN

Más allá de las aplicaciones para mejorar la fluidez y seguridad del tráfico, los sistemas cooperativos se están planteando como herramientas catalizadoras para lograr mayores niveles de automatización de los vehículos. El objetivo consiste en que los vehículos puedan disponer de información con un horizonte de percepción superior al que les proporcionan sus sensores embarcados y que, en la actualidad, están limitando sus prestaciones de funcionamiento autónomo y los escenarios en los que se pueden desenvolver como tales.

En este sentido, se han desplegado 2 corredores cooperativos interconectados en vías periurbanas de Madrid, concretamente, en la entrada por la autovía A6 y un tramo de la vía de circunvalación M30 totalizando más de 20 km. Estos corredores cooperativos están formados por un conjunto de RSUs (RoadSide Units) que se comunican con los centros de control C-ITS y que proporcionan una cobertura continua y con muy bajos tiempos de latencia a lo largo de todo el recorrido.

De esta forma, los vehículos dotados de OBUs (Onboard Units) podrán recibir esta información en tiempo real y, en caso de ser conducidos de forma autónoma, podrán realizar ciertas maniobras como la adaptación de la velocidad o maniobras de cambio de carril sin intervención del usuario.

En este artículo se trata la arquitectura desplegada y se presentan los resultados de los ensayos que se han realizado, tanto de la eficiencia en la transmisión de la información desde el centro C-ITS a las RSUs y su difusión a las OBUs de los vehículos, como la respuesta de los vehículos con conducción autónoma ante las indicaciones recibidas.

1. INTRODUCCIÓN

Los sistemas cooperativos se definen como aquellos sistemas de seguridad, eficiencia y confort en el entorno vial basados en el intercambio de información entre vehículos y/o infraestructuras, mediante comunicaciones inalámbricas (Cruz, 2019). Incluso se puede extender el intercambio de información a usuarios que no se encuentren en el interior de un vehículo en el instante de recibir el servicio mediante el uso de dispositivos móviles o tabletas. Al encontrarse el vehículo conectado en un entorno cooperativo posibilitará que además de poseer los datos propios y los percibidos por medio de los sensores embarcados, podrá disponer de la información transmitida por el resto de los vehículos, las infraestructuras a su alrededor y centrales de tráfico (Jiménez, 2012).

Car 2 Car – Communication Consortium (https://www.car-2-car.org/) busca el desarrollo, prueba y despliegue de sistemas cooperativos en Europa basados en la comunicación de corto alcance entre vehículos, entre vehículos e infraestructuras y entre vehículos y otros usuarios de la carretera para mejorar la seguridad y la eficiencia vial. Otras comunicaciones complementarias, como la telefonía, serán consideradas cuando sean requeridas. El principal objetivo del consorcio es garantizar la interoperabilidad de los sistemas cooperativos, abarcando todas las clases de vehículos a través de marcas y fronteras representando a empresas de vehículos o infraestructuras, autoridades y organizaciones relacionadas con los C-ITS e institutos de investigación.

En los últimos años, se han acometido diferentes proyectos en España para el despliegue de estos servicios en corredores de carreteras reales. En concreto, el proyecto Auto C-ITS (https://www.autocits.eu/) tiene por objetivo el contribuir al despliegue de los servicios cooperativos en Europa mejorando así la interoperabilidad de los mismos entre países, y promoviendo el papel de los servicios cooperativos (C-ITS) como catalizadores para la implementación de la conducción autónoma. Para ello se han desarrollado tres proyectos piloto en tres grandes ciudades europeas situadas en el corredor atlántico: Madrid, París y Lisboa (Figura 1).

Fig. 1 - Proyectos piloto del proyecto Auto C-ITS

El piloto español formado por INSIA-UPM, INDRA y la DGT ha desplegado en el carril de vehículos de alta ocupación (VAO) situado en la A-6 desde el km 7 al km 17 entre las carreteras M-30 y M-40 (Figura 2). El piloto ha desplegado tres servicios C-ITS Day 1, en los que los vehículos autónomos y conectados realizan las maniobras de seguridad basándose en la información recibida de la autoridad de carreteras a través de una infraestructura C-ITS. Se marca con indicadores en color rojo muestran las RSU que cuentan con conectividad 5G mediante la que se comunican con otras RSU y los vehículos de la carretera, además de conexión a internet para comunicarse con el centro de control.

En verde se muestran las RSU que solo cuentan con conectividad 5G sin salida a internet que hacen las funciones de repetidores de los mensajes obtenidos del centro de control a través de las RSU en rojo.

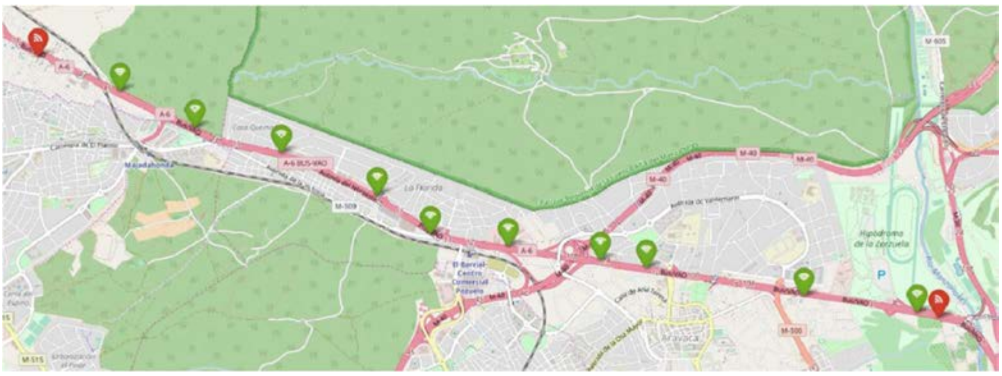

Fig. 2 - Ubicación de las RSUs C-ITS en la A-6 (km 7, km 17)

La plataforma europea C-ROADS (https://www.c-roads.eu/pilots/implemented-services.html) es una iniciativa de diferentes Estados miembros y operadores de carreteras que desean colaborar para lograr el despliegue de servicios C-ITS de forma armonizada e interoperable en toda Europa. La armonización es el activo principal de la cooperación C-ROADS, ya que garantiza un despliegue sostenible y eficiente de los C-ITS. En consecuencia, todos los participantes comparten la visión de los objetivos principales que son, además de la armonización, la implementación a través de pilotos de los servicios Day 1 y Day 1.5, las demostraciones de la implementación de C-ITS y el avance hacia una implementación a gran escala.

A nivel español, (C-ROADS Spain), pretende impulsar la participación de todas las entidades del sector, además de influir en las decisiones a tomar en Europa. Está compuesto por 5 pilotos (Madrid, SISCOGA en Galicia, Cantábrico, Mediterráneo y DGT 3.0), cada uno de ellos con su particular conjunto de tecnologías y servicios C-ITS. Esta heterogeneidad tiene como objetivo cubrir un amplio espectro de casos, con el fin de evaluar el impacto de la movilidad conectada en muchos escenarios representativos.

2. FUNCIONAMIENTO DE LAS COMUNICACIONES V2X

La comunicación V2X se refiere a la capacidad de un vehículo de poder comunicarse con cualquier otro receptor, ya sean infraestructuras (V2I), peatones (V2P), otros vehículos (V2V) o con redes (V2N) (Figura 3). Mediante la transmisión de mensajes, el vehículo puede conocer en tiempo real la situación de los demás vehículos próximos en la vía, enviando y recibiendo información sobre una retención del tráfico, una bajada de la velocidad, la necesidad de cambiar de carril por un obstáculo en la carretera o el peligro que puede haber más adelante debido a un accidente, entre muchos otros eventos posibles.

Gracias a los centros de control de tráfico, se puede controlar en tiempo real la situación en las vías y, si es necesario, mediante este sistema de comunicaciones, enviar información hacia los vehículos, utilizando mensajes que serán recibidos por las infraestructuras, que posteriormente los diseminarán a los vehículos en su rango de comunicaciones. Para ello, se emplean módulos de comunicación V2X. Estos módulos tienen la capacidad de enviar y recibir mensajes (ETSI-ITS, 2014), tengan el origen que tengan, siempre que esté verificada su autenticidad. En caso de estar instalados en la vía, se denominan Road Side Units (RSUs), situados en infraestructuras altas como pueden ser pórticos de información o farolas para, de esta forma, tener visión directa con los vehículos y así transmitir con mayor facilidad y rango los mensajes. Esta versión de módulos de comunicaciones está hermetizada para tener la capacidad de soportar las inclemencias del tiempo. Las unidades localizadas en los vehículos son On Board Units (OBUs), las cuales son en esencia iguales que las RSUs, con un tamaño más contenido para estar colocadas en el vehículo sin perder apenas capacidad de carga.

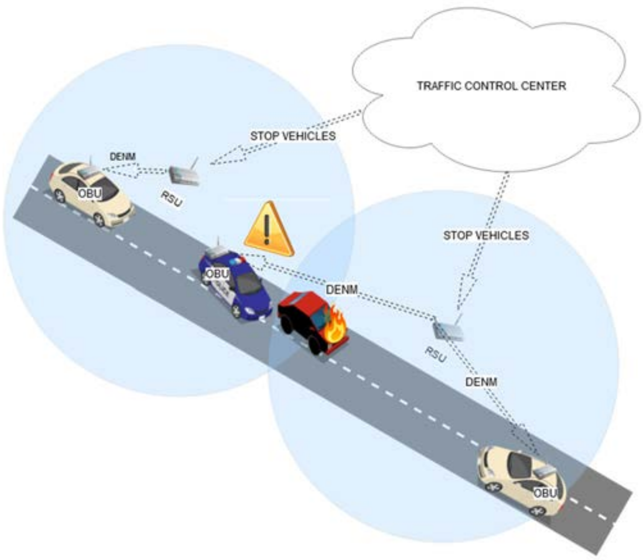

Fig. 3 - Diagrama de funcionamiento de las comunicaciones V2X

Un ejemplo típico de la comunicación V2X sería el control de un atasco. El centro de control de la autoridad encargada del tráfico, la Dirección General de Tráfico (DGT) en España, enviaría un mensaje a las RSUs de la carretera situadas en el rango cercano al atasco, indicando una ruta alternativa que permita la descongestión del tráfico. Al recibir este mensaje, se enviaría a continuación a las OBUs de los vehículos en el rango que indique el centro de control, avisando con antelación a los conductores del atasco.

La comunicación V2X tienen un gran potencial en el futuro de los vehículos conectados y autónomos, pudiendo en la actualidad avisar al conductor de posibles pasos a seguir mediante los ADAS (Advanced Driver Assistance Systems) en la conducción y, en el futuro, controlar totalmente las capacidades del vehículo y el recorrido a seguir mediante el envío de mensajes.

3. FUNCIONAMIENTO DEL VEHICULO

Con el fin de probar la capacidad de los corredores cooperativos para ser catalizadores de la conducción autónomo, se emplea un vehículo Mitsubishi i-MIEV (Figura 4), automatizado por el Instituto Universitario de Investigación del Automóvil (INSIA), perteneciente a la UPM.

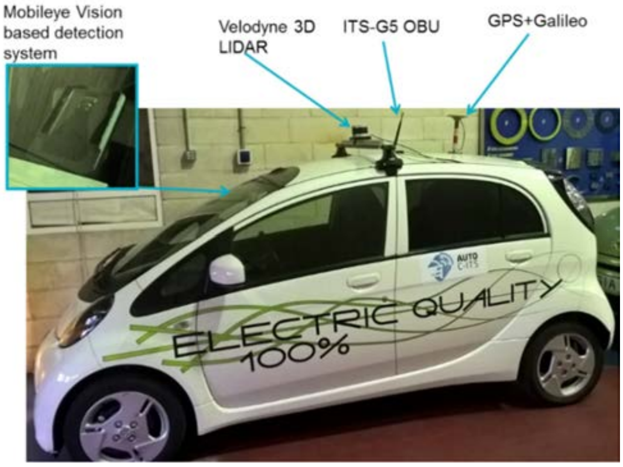

Fig. 4 – Detalle del vehículo autónomo del INSIA

Este vehículo ha sido automatizado siguiendo el esquema de automatización de la Figura 5. Este esquema sigue la misma distribución utilizada por el vehículo Stanley (Thrun et al, 2006) de "The Stanford Racing Team" en la competición "2005 DARPA Grand Challenge" (Buehler et al, 2007).

Se pueden encontrar en primer lugar los sensores con los que cuenta el vehículo en la actualidad que son un GPS con corrección inercial, una base de datos en la que se encuentra el mapa pregrabado mediante sus posiciones GPS, la lectura de la velocidad y el ángulo de volante que se recogen del CAN BUS del vehículo, el módulo de comunicaciones V2X, además de una cámara Mobileye y un LiDAR. Dentro del módulo de percepción debe destacarse para el objeto de los ensayos que se ha implementado un generador de waypoints a partir de los puntos GPS en bruto guardados en la base de datos.

En el bloque de planificación se encuentran los dos módulos de alto nivel principales en el vehículo; por un lado, el path tracking que realiza el cálculo de la velocidad y el ángulo de volante necesario para seguir la planificación del mapa y, por otro lado, el sistema decisiones que recoge la consigna calculada por el módulo de path tracking además de las consignas recibidas de los sensores Mobileye y LiDAR y la consigna dada por el módulo de comunicaciones. El módulo de toma de decisiones se encarga de centralizar la información recibida de cada uno de los módulos y enviar al control la consigna más adecuada en cada momento.

El último paso del ciclo de control corresponde a los módulos de control de velocidad y control de giro de volante los cuales reciben las consignas del módulo de toma de decisiones y las convierten en señales adecuadas para los actuadores del vehículo. Todas las funciones del vehículo controlan a través de una pantalla táctil que permite activar/desactivar el control autónomo además de seleccionar los sensores que se utilizan en cada momento y el mapa pregrabado a utilizar.

También cuenta con la posibilidad de realizar el control del vehículo de manera manual dentro de automatización a través de un teclado.

En el esquema se han señalado en rojo aquellos módulos que no se utilizan en las pruebas del presente estudio.

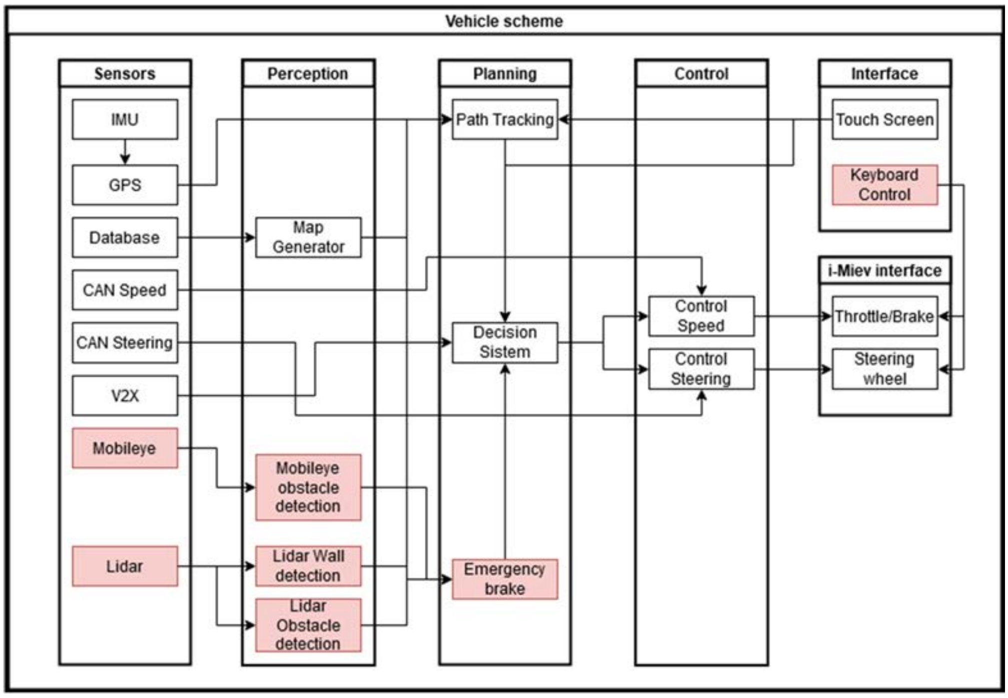

Fig. 5 – Esquema del Sistema de control del vehículo autónomo de INSIA-UPM

4. ENSAYOS EN CARRETERA

Se han realizado ensayos en carretera con tráfico a lo largo de los corredores cooperativos desplegados y que proporcionan cobertura continua. En concreto, en este artículo se muestra el caso de un ensayo en el carril bus-VAO de la autovía A6 en la salida de Madrid.

El ensayo con un recorrido de 7,8 kilómetros se ha realizado de manera completamente autónoma. El objetivo de este ensayo es mostrar el comportamiento del vehículo en una posible situación real, en la cual durante la conducción recibe la información de los eventos, emitidos por la DGT, debido a retenciones en la vía. Durante el recorrido se han simulado 3 eventos en la carretera cuyo radio de acción se puede ver en la Figura 6.

Fig. 6 - Representación de la ruta realizada en el ensayo

Para los eventos emitidos en el ensayo, se ha seguido el método de definición de eventos del “common data dictionary” del estándar de comunicaciones V2X el cual clasifica la naturaleza los eventos por causa (ETSI-ITS, 2019) y subcausa (ISO, 2019), asociándoles a cada uno de los mismos un protocolo de actuación definido por los centros de control de tráfico de cada Estado.

Para este ensayo se han utilizado tres eventos diferentes con dos tipos de consigna de actuación del vehículo. Por un lado, los eventos pueden indicar una consigna de velocidad máxima en el radio de relevancia del evento. El vehículo mantendrá la velocidad mínima entre la velocidad marcada por el mapa definido previamente y la consigna de velocidad de evento. Por otro lado, los eventos pueden indicar la necesidad de un cambio de carril, hacia el izquierdo (por defecto, el vehículo circula por el carril derecho) para lo cual el vehículo recalculará el trazado del mapa para situarse en el carril inmediatamente siguiente a la izquierda del actual.

Los eventos que se han emitido para este ensayo son los siguientes.

- El evento A consiste en una reducción de velocidad a 35 km/h debido a una retención. Este evento se encuentra situado en las coordenadas (40.474913, -3.833989) y tiene un radio de acción de 200 metros. Este evento ha sido definido con causa 6, subcausa 0 que indican que se encuentra una superficie deslizante.
- El evento B con causa 6, subcausa 0 que indican que se está realizando un trabajo en la carretera, consiste en un cambio de carril y posterior regreso. Este evento se encuentra situado en las coordenadas (40.465152, -3.797245) y tiene un radio de acción de 250 metros.
- El evento C definido con causa 26, subcausa 0 que indican que hay un vehículo lento en la carretera, consiste en una reducción de velocidad a 20 km/h debido a una retención. Este evento se encuentra situado en las coordenadas (40.464283, -3.789678) y tiene un radio de acción de 100 metros.

5. RESULTADOS

En este apartado se muestra el comportamiento del vehículo tanto durante los eventos descritos anteriormente cómo durante su conducción en modo autónomo. Para ello se van a revisar dos características principalmente que son el control de la velocidad y el control del ángulo de volante.

En la Figura 7 se muestra la gráfica de velocidad durante el ensayo. El vehículo comienza parado y acelera progresivamente hasta alcanzar su velocidad objetivo de 60 km/h. Se muestran algunas oscilaciones el control de velocidad de ±5 km/h debido a la orografía del terreno. En la sección indicada con el número 1 se encuentra el primer evento el cual consiste en una reducción de velocidad a 20 km/h, El vehículo realiza una reducción brusca de velocidad hasta situarse en la velocidad objetivo y la mantiene durante el radio de relevancia del evento. Al salir del radio de relevancia recupera progresivamente la velocidad hasta los 60 km/h fijados por el mapa. En la sección marcada con el número 2 se produce el siguiente evento que consiste en un cambio de carril, el cual no conlleva cambio en la velocidad. Al llegar a la sección marcada con el número 3 se observa una reducción de velocidad a 35 km/h como indica el evento C. Para concluir el ensayo el vehículo realiza automáticamente una frenada progresiva hasta detenerse.

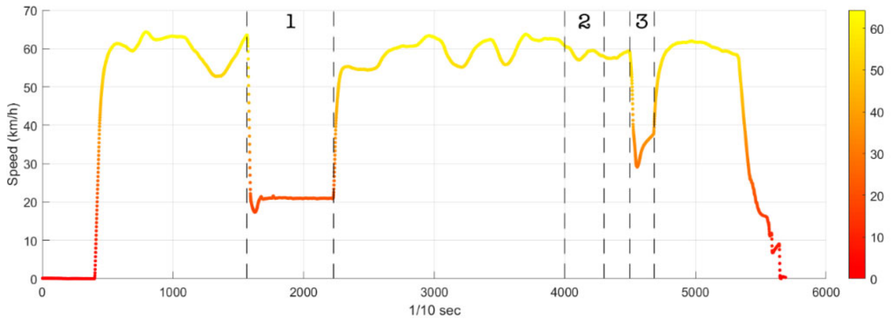

Fig. 7 - Perfil de velocidad

En la Figura 8 se observa en detalle el evento de cambio de carril. Como se puede observar, la actuación del evento se realiza con un pequeño desfase correspondiente al tiempo que tarda el vehículo en procesar los eventos y actuar en consecuencia. Este retardo, menor a un segundo, se observa tanto a la entrada como a la salida del evento.

Fig. 8 - Detalle de la maniobra de cambio de carril

La Figura 9 muestra la evolución del control del ángulo de volante durante el ensayo, este mantiene el vehículo centrado en el carril en todo momento excepto durante el evento B que, como se ha descrito anteriormente, conlleva un cambio de carril. En la ampliación de la gráfica se muestra el momento en el que el control realiza el cambio de carril ejecutando un giro a la izquierda que rectifica para alinearse con el carril izquierdo y posteriormente, al salir del radio de relevancia del evento, un giro a la derecha que lo devuelve al carril inicial. Durante el resto de la gráfica se perciben las correcciones para el mantenimiento en el carril.

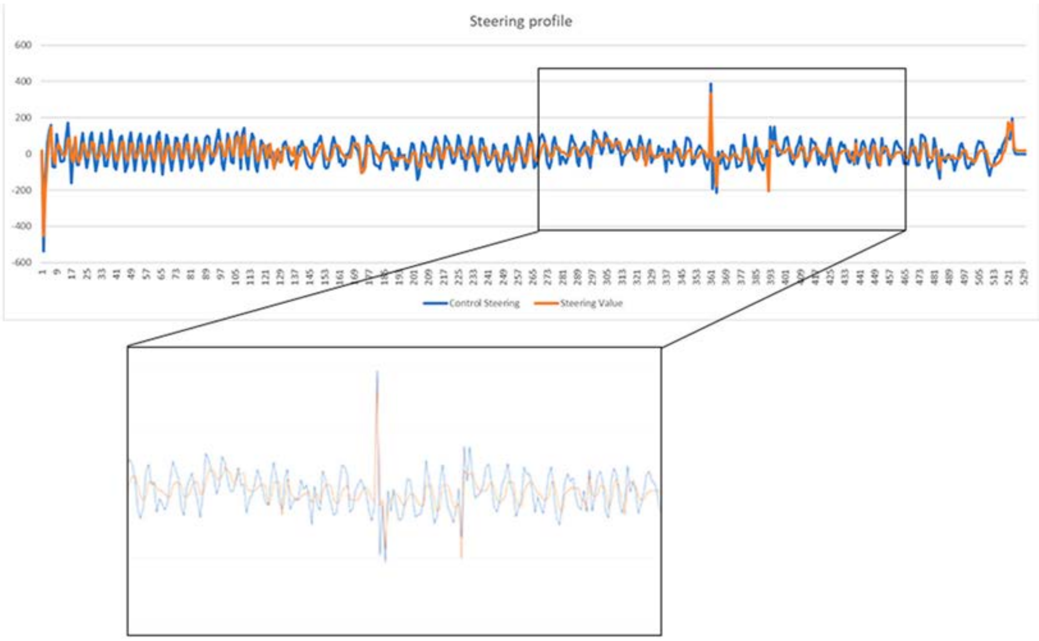

Fig. 9 - Detalle de control de ángulo de volante

6. CONCLUSIONES

En este artículo se ha mostrado cómo las indicaciones en el corredor cooperativo permiten la operación de un vehículo autónomo en función de consignas externas. El vehículo es capaz de conducir de manera completamente autónoma sobre un mapa pregrabado, manteniéndose en su carril y pudiendo ejecutar las acciones de reajuste de la velocidad junto con un cambio de trayectoria cuando ha resultado necesario, como respuesta a la información de los eventos emitidos por el centro de control de tráfico. De esta forma, parece afianzarse la afirmación de que los sistemas cooperativos tendrán un papel crucial en el ecosistema de la conducción autónoma, además de servir como catalizadores para los altos niveles de automatización en la conducción.

AGRADECIMIENTOS

Este trabajo ha sido parcialmente financiado por el Ministerio de Ciencia e Innovación a través del proyecto “Sistema de arbitraje distribuido para conducción cooperativa conectada y autónoma en entornos complejos. CCAD” (PID2019-104793RB-C33) y por la Comisión Europea a través de los proyectos CEF-Transport sector “AUTOCITS” (2015-EU-TM-0243-S) y “C-ROADS Spain” (2016-EU-TM-0272-S).

TINNGO: TRANSPORT INNOVATIVE GENDER OBSERVATORY.
SPANISH HUB. TAXI CASE STUDY.

Mireia Calvo Monteagudo
Project Manager, ITENE, Spain
Margherita P.M. Colleoni
Competitive Intelligence Specialist PhD, ITENE, Spain

ABSTRACT

It is well - known that women are generally under-represented in some technical fields, as it is the specific case of the transport sector. This lack of balance gender-wise is even more visible in the taxi industry, leading to a gender gap that should be filled in the next years.

Flexibility, loyal customer network and friendly environment are some of the opportunities highlighted in the study. Besides, entry barriers are also outlined, like the initial investment, misunderstandings between colleagues at the beginning and shortage of communication skills.

All the findings derive from real women who have been working in the industry for more than ten years, so that the evolution of the taxi sector from a gender point of view has been also considered and explained through real lived experiences.

In the present study, an exhaustive analysis of the situation of the Spanish taxi sector is presented and analyzed. Based on real interviews to female taxi drivers, the main opportunities, and entry barriers and obstacles of working in the taxi sector are collected and used to assess how the transport sector fits the key needs of the interviewees and favor the work-life balance.

All data regarding the city and participants to the case study are kept anonymous.

This analysis is done in the framework of the European project TInnGO which main objective is to create a framework and mechanisms for a sustainable game change in European transport through a transformative strategy of gender and diversity sensitive smart mobility.

1. INTRODUCTION

According to the Women in Transport ETP Platform for change, only the 22% of the employees in the European transport sector are women. Moreover, the principal users of the public transport for their daily movements are women too. In fact, usually the women's daily mobility is characterized by fragmented short travels, with several stops during the day, whereas men usually make direct travels form work to home mainly by private vehicle.

Considering these facts, the European project TInnGO proposes to investigate the reasons behind this situation. The TInnGO project: Transport Innovative Gender Observatory is funded by the European Union's Horizon 2020 research and innovation programme (Grant Agreement no. 824349)

The objective of TInnGO is to promote gender equality in all areas of transport at European level, applying strategic mechanisms to facilitate access and participation of the population both as users and workers and through the adaptation of infrastructures and services to the population and gender needs.

The main result of this initiative will be the development of a Gender Innovation Observatory in European Transport. To feed this platform, ten hubs across Europe are collecting data and address locally important issues in intelligent mobility with a gender perspective and mainstreaming analysis.

The main activity of these hubs is the analysis of the current situation at local level, the global understanding of problems and analysis of solutions, the generation of new knowledge and its exchange between the different hubs. As a result, gender equality guides will be developed to evaluate the activities developed in their environment.

All the information collected, and the smart mobility concepts developed are uploaded to a transport gender observatory and open innovation platform developed by TInnGO. (https://transportgenderobservatory.eu/)

Among the ten hubs, the Spanish hub focused onto two areas: one related to the transport safety and security from the perspective of users and vehicles; and the other one centered in the gender equality in employment, considering both passenger and freight transport.

The Spanish hub is involving companies in the sector to analyze the current situation in Spain and providing their point of view.

The aim of this hub and TInnGO project is to take a step forward in gender equality in transport by introducing new strategies in gender equality in an integrated way for the whole society. In this sense, focusing on the employment perspective, the Spanish hub developed an analysis on the taxi sector employment, highlighting the main challenges and needs of the women taxi drivers.

2. OVERVIEW: THE TAXI INDUSTRY

The transport sector is not gender – balance, according to Women in Transport EU platform for change only the 22% of transport workers are women. If we focused on the land transport the percentage is even smaller up to 14% according to the transport.

Focusing on the taxi sector the percentage in the greater cities is lower. For example, in London the percentage of female taxi drivers registered are around the 2% as defined in (http://femaletaxidrivers.co.uk/, s.f.)

2.1. Description of the national context in the transport sector

The transport sector in Spain is made up of many small companies. Following the data provided by the Spanish National Statistics Institute (INE) based on the national classification of economic activities (CNAE), 5.2% of working people are employed in the transport sector. 19.35% are female and 80.65% are men. The following graph elaborated by data from the National Statistics Institute, Employed by gender and branch of activity from 2009 to 2019, shows the evolution of the number of people working in the industry over the last 10 years and the differences between male and female employees (INE, Insituto Nacional de Estadística - , n.d.).

Fig. 1: Evolution of transport workers over the last 10 years by gender

The evolution of the transport sector has only undergone minor fluctuations over the last decade. 2019 was the year with the highest volume of workers, with 829,200 male employees and 198,900 female ones, whilst 2013 was the year with the smallest number of workers, with 690,300 male workers and 147,400 female ones.

The following table, elaborated by data from the National Statistics Institute and called Employed by gender and branch of activity, shows a breakdown by different transport areas, with women accounting for between 11% - 44% of the jobs, depending on the sector (INE, Insituto Nacional de Estadística - , n.d.):

2019	**Both**	**Men**	**Women**
Road and pipeline transport	599,700	531,300	68,400
Maritime and inland waterway transport	25,600	18,400	7,200
Air transport	56,500	31,600	24,900
Storage and related transport activities	227,800	168,500	59,300
Postal and courier activities	118,500	79,300	39,100
Total	1,028,100	829,200	198,900

Table 1: Employed by gender and branch of activity in transport and storage.

2.2. Description of the taxi sector in Spain

The case study performed in Spain has been focused on the road transport sector and has concentrated specifically on the taxi sector. There are a total of 69,792 taxis in Spain. The graph below (see Fig. 2) shows how many taxis there are in the different regions of Spain, with Madrid having the largest taxi fleet and La Rioja the smallest, the number of total number of taxi vehicles in each region is shown. The data is obtained from the National Statistics institute called public service cars by region, autonomous cities and provinces, territorial scope and availability of taximeter in 2018 (INE, Instituto Nacional de Estadística, 2018).

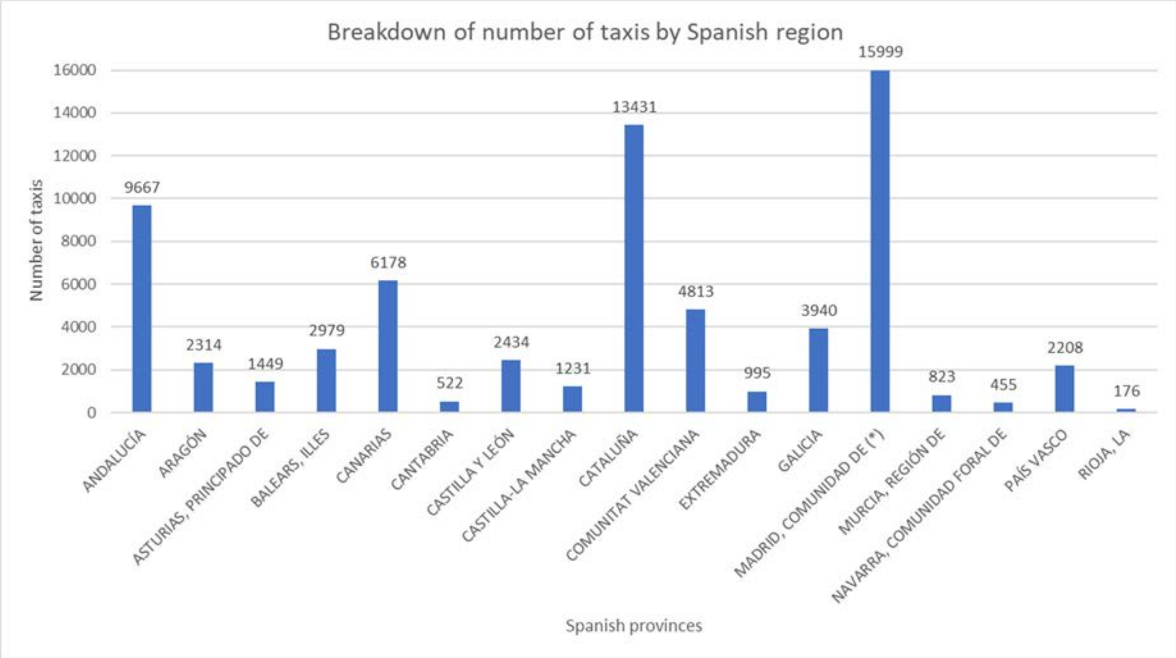

Fig. 2: Breakdown of number of taxis by Spanish region

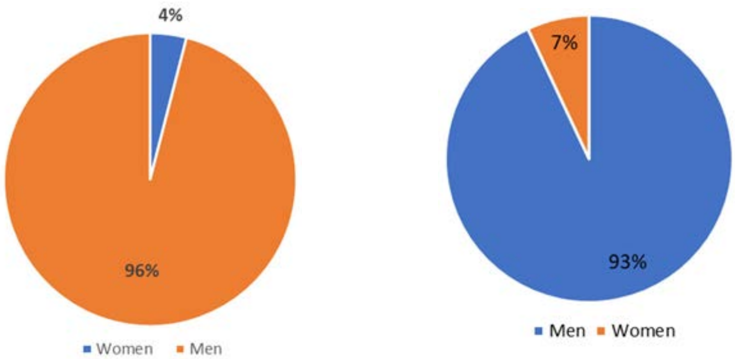
Following infotaxi.net, only 4% of taxi drivers in Spain are women (Haro, 2019). The taxi industry traditionally a male-dominated profession. Nevertheless, the number of women working in this sector has increased in a small but significant way over the years.

Nationality-wise, around 50% of taxi drivers are Spanish and the other 50% are foreigners, implying that multiculturality in the sector is very high (see Fig. 3).



a) b)

Fig. 3: a) Breakdown of taxi drivers by gender, most of the taxi drivers are men; b) Taxi licenses. Almost all of the taxi licenses belong to men in the Spanish city under analysis.

In the city where the interviews took place there are approximately 3,000 taxi licences, where less than 10% belongs to female taxi drivers. There are around 5,000 taxi drivers in total, because around 2,000 licences have two drivers (see Fig. 3b**)**.

Most of taxi drivers in Spain are self-employed people who work using their own vehicles.

However, there are also taxi drivers that are salaried employees and work for other self-employed taxi drivers sharing their employer's taxis. In these cases, both chauffeurs have a legal agreement in which the salaried employee gives their boss a fixed percentage of the money earned during their working day based on the number of rides they pick up.

Taxis are considered as a public service that is regulated by local councils. Therefore, each region has a different way of working, with a different regulatory framework, that regulates days of rest and working hours. No gender bias is explicitly applied and conditions for both male and female taxi drivers are the same.

Generally, Taxi drivers are members of taxi associations which support them in administrative tasks and by providing and managing platforms to optimize booking performances. In order to book a taxi, the clients (taxi users) can contact a taxi booking company which will look for the closest taxi driver available to assign the requested ride.

Taxi drivers must register with these booking companies first before they can be assigned rides and customers.

3. METHODOLOGY

The present case study has been carried out by ITENE consultants in the framework of Task 9.1 Identification of current and future issues in the employment of women in Smart Mobility (SM.). This task was led by University of Copenhagen (UCPH) (UCPH, 2019).

The interviews were based on a common questionnaire provided by the leader of the task with the aim of investigating career path of the interviewees, opportunities, and barriers for employment in the sector and work life balance activities. As the sector is masculinize, it is difficult to get the contact of the female taxi drivers. In this case, the contact with potential female taxi drivers was achieved by contacting a dedicated association known beforehand.

The first interviewee and the association encouraged the other taxi drivers to participate.
Seven interviews were performed by ITENE both face to face and by phone. In each case the questionnaire was filled with the required information and any additional detail was also considered. It is fairly to highlight that the on-site interviews provided more information that the interviewee made by phone. The face-to-face meeting and the direct contact made the interviewees feel more comfortable and share they own experiences and feelings with more details.

Before the interview, the interviewees read the participation sheet which informed about the purpose of the study, the main benefits and risks of participating, the participation was voluntary, what would happen with the results.

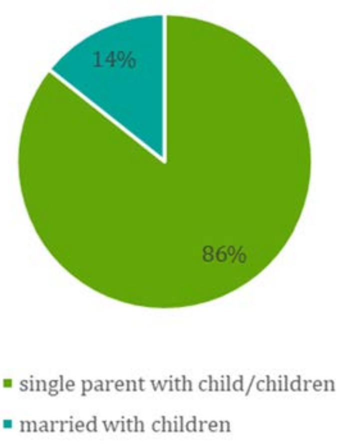
The participation sheet also informed about the data protection and confidentiality following the General Data Protection Regulation 2016 (GDPR) and the Data Protection Act 2018. Finally, they signed a consent form before starting their participation in the study.

4. CASE STUDY

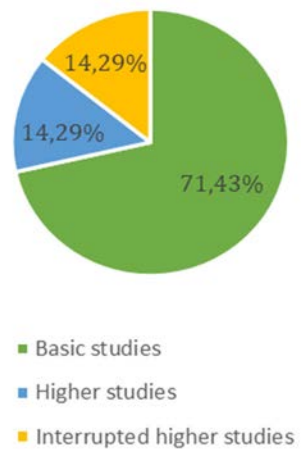
4.1 Overview of the family and working background of the participants

A total of seven female taxi drivers were interviewed. In the following, they are identified with the numbers Interviewee 1 to Interviewee 7.

All of them are self-employed workers in Spain, owning their taxi licences and vehicles. Six of the interviewees were Spanish and one was from another European country. Most of them have been working in the taxi sector for more than 10 years. They are experienced taxi drivers mainly working in the city centre and they have seen how the sector has changed over the years (see figures Fig.4 to Fig.6).

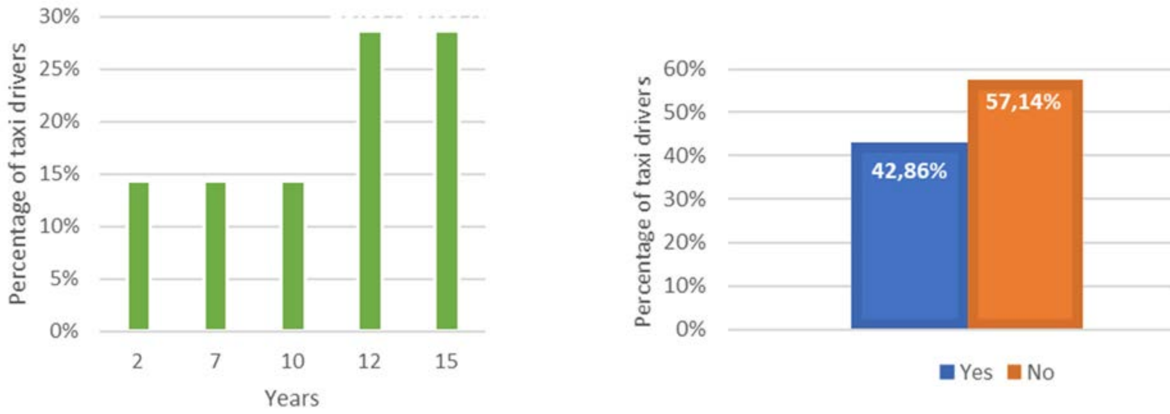


a)



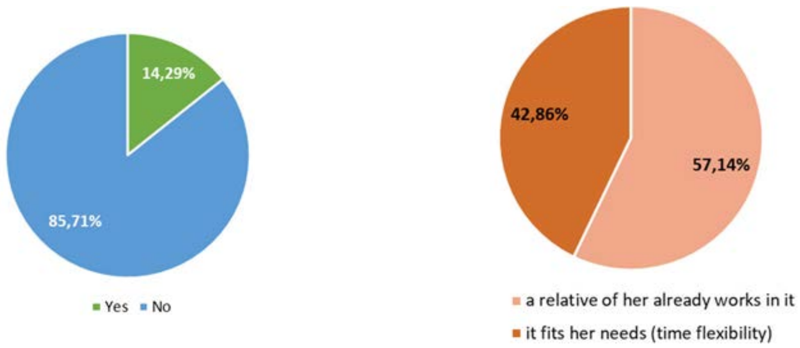
b)

Fig. 4: a) Family situation: most of the interviewed are currently single parents with child/children; b) Study qualifications of the female taxi drivers: most of the interviewed had accomplished basic studies, mostly related to administration fields.



a) b)

Fig. 5: a) Years working as a taxi driver. Most of the interviewees have been working as taxi drivers for more than 10 years. b) Do they employ an additional driver? Around the 40% of the interviewees employed a chauffeur.



a) b)

Fig. 6: a) Do they work at night? Most of the female taxi driver do not work at night shifts; b) They decided to become a taxi driver because… Main reasons for choosing to work in the taxi industry is a relative of the interviewee already works in the sector and the time flexibility.

4.2 Findings about opportunities in the sector

- Flexibility

Most of the interviewees chose to work in the taxi industry to accomplish with family commitments so they could organise their own working timetable (see **Fig. 6b**). Being self employed gives them flexibility and working as a taxi driver let them the chance to define its working schedule. Actually, Intesparviewee 7 remarked that she is able to take care of her children since during the week, from Monday to Friday, she is less busy than on weekends... All of them have been working mothers and keeping the work-life balance is crucial for all of them. As an example, one interviewee claimed that is key for her to be able to "*get out of the office because my kid has the flu*". In addition, another advantage of being a taxi driver for Interviewee 3 is the ability to quickly recover from a work accident because it is usually related to car damages that have a straight and easy solution.

- Family support

Four out of seven interviewees declared that have relatives working as taxi drivers, that is generally how they came in contact with the taxi sector (see **Fig. 6b***)*. For example, Interviewee 3 shares her licence with her husband, so two people operate under one licence, doubling income. In addition, Interviewee 7 thinks that sharing licenses in family is a good way to earn extra income in university terms. Interviewee 4's son already works as a taxi driver.

All the interviewees had previous experience in working in other sectors. Three out of seven interviewees like being a taxi driver and one of them admitted that *"being a taxi driver was her dream job"*. The other four interviewees still dreamed about their ideal job but due to their age and money needs, they decided to keep working as a taxi driver until retirement. Most of them plan to hire another chauffeur because it would allow them to have more time for themselves (four out of seven taxi drivers have one already).

- Friendly environment and support

The working environment in the taxi sector is pleasant, for women, men and multicultural drivers. They support themselves and endorse the taxi drivers that follow the rules, including in situations that the customers do not respect another colleague. Interviewee 7 described one specific case that happened to her: she was the first taxi in the queue and two women went straight forward to the taxi directly behind that of our respondent, because it was driven by a male taxi driver. The male colleague explained that they needed to take the first taxi in the queue (our respondent's taxi), but astonishingly the users refused to go with a female taxi driver. The male taxi driver calmly answered: *"If you don't want her as a taxi driver, I am not going to provide you with the service either"*. Our respondent only discovered this fact some time later, when her colleague told her what happened. She really appreciated his support.

In addition, all the interviewees belong to common groups in chat platforms in order to share between colleagues new potential races. Within this groups our interviewees feel more comfortable and supported in the sector. They can share their own experiences and make networking with the colleagues.

- Multiculturality

All of them agreed that they work in an international environment, in terms of customers and colleagues. The taxi sector comprises a range of different cultures and people, sharing the same difficulties and opportunities. Arabic cultural has a different approach to women, and sometimes it generates ambiguous situations due to different perception of the female role in society. Nevertheless, good work relationships have been built thanks to dialogue and understanding.

- Customer loyalty

All of them positively valued the daily contact clients and colleagues. Customer-wise, most users are glad to see a woman as a taxi driver. In fact, they remarked that "*foreigners are more surprised than Spaniards when they see a female taxi driver*". For example, Interviewee 3 stated that in *her country she would have not worked as a taxi driver because of the lack of safety on the road. On the other hand, many women there usually drive buses*".

Taxis belonging to women are considered cleaner and tidier than the men ones. Moreover, the interviewees stated that customers highly appreciate them as drivers, since they are considered to be safer and more cautious drivers than male drivers. As a consequence, they feel more comfortable, confident and secure when depending on women on the road. One of the respondents shared a customer sentence: "*My husband gets hysterical in the car and we get there later than when we go with you, as you always keep calm.*

All these features make female taxi drivers more appealing for the customers of all genders. In fact, one distinctive characteristic is that they usually have loyal customers. Interviewee 7 explained that she had faithful clients that called her monthly, and others once or twice a year for trips of different lengths. In addition, one of these loyal customers hired her to take their children alone to school in her taxi."

- Support gender initiatives

Being a taxi driver gives the opportunity to contribute to the welfare of the society. The interviewees joined a national initiative that aims at supporting women that are victims of gender crimes. Our interviewees explained that some taxis (all of the respondents included here) have a purple ribbon on their taxi aerial which means that if a woman feels unsafe or she has been victim of gender violence will make use of a free ride to get to a safer place.

Fortunately, only one of the interviewed taxi drivers has had to provide this type of service.

4.3 Findings about entry barriers in the industry

- Investment

The initial investment to entry in the taxi sector is very high. The first step is to obtain the taxi driver title. Once the title is obtained, there are two big investment. On the one side the acquisition of a taxi license and the purchase of a taxi vehicle. These two acquisitions are expensive and not everyone can afford them. Therefore, one of the main reasons to entre in the sector is because a relative already work on it (see **Fig.6**). The active taxi drivers know who will leave the sector, who will retire, and they get advantage of getting new licenses.

In addition, some of the taxi drivers share the licenses with their familiars.

- Initial Colleagues' mistrust

As the taxi sector is strongly male-dominated, at the beginning of working in the sector, more than ten years ago (see **Fig. 5**) many of the respondents had to put up with a range of comments about being a woman, defending her right and ability to work as men do.

Interviewee 3 admitted that when she started this job, she had several run-ins with colleagues. For example, during her first year, a colleague told her that she should not have been a taxi driver because she was a woman. She defended herself by replying "*I am just doing the job that your son doesn't want to.*" She has never had a problem with this colleague ever since. Interviewee 6 argued with another colleague, who claimed that *driving a taxi was not a job for women*. Despite of initial rushes, relationships among colleagues improved and currently, the respondents are well-considered and accepted in the taxi community.

The basic condition for acceptance is to abide by the rules of work: do not overtake a colleague on the inside, do not work on your rest days, respect the queue. Respect is gained by working according to the rules.

- Communication

The taxi sector daily deals with many different customers from different countries. Foreign languages usually represent an issue for the respondents, that would appreciate to receive English-speaking courses to improve their communication skills, better than the general basic courses they have received so far.

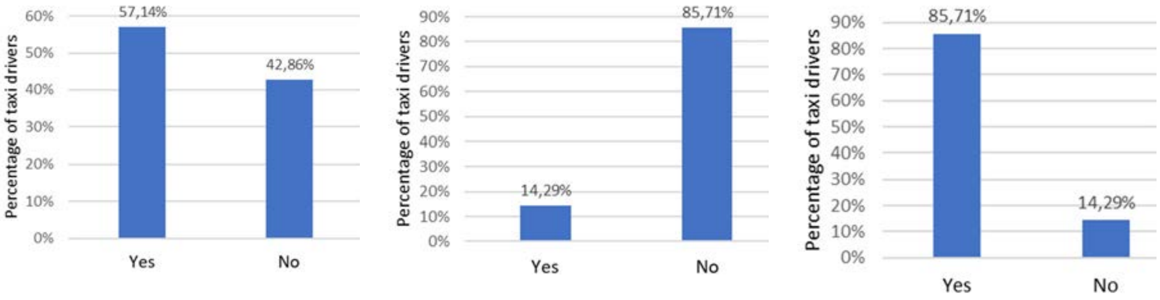
- Customer rejection

Although it is not common, surprisingly, some of the interviewees have experienced rejection by female customers. Interviewee 6 had a small misunderstanding with a customer that she had to pick up at a railway station. The customer had requested a taxi service, and when he saw that a female taxi driver was waiting for him, he claimed that the booking service should have notified him that the taxi driver was going to be a woman instead of a man.

- Hustle and bustle of the road

Enjoying driving is a mandatory requirement to join this profession together with the ability of keep calm in the traffic and the ability to manage tense situations. Interviewee 7 confessed that when she was younger, she hated driving because she got nervous, but that she had been able to overcome her fears and now she enjoys driving on a daily basis.

All the respondents have generally anecdotes along they careers but these female drivers do not have issues on a daily basis and most are very happy and glad to be taxi drivers (see Fig.7)



a) b) c)

Fig. 7: a) Do they dreamed about other jobs? Reviewing the dreamed jobs around the 57% dreamed with another job although the majority will keep as taxi driver. b) Do they plan to change job in the next 10 years? Only one respondent will change the job, all the other respondents will keep as taxi driver. c)Are they happy with their job? All of the interviewees, except one, are satisfied with their current job (taxi driver).

5. CONCLUSION

The Spanish taxi industry has been traditionally a masculinised transport sector and still only the 4% of the taxi drivers are women. Despite the high entry investment to purchase both taxi license and vehicle, the growing opportunities offered by this field make this job more and more appealing for women, mostly because it favours the work life balance and allows the employees to coordinate properly their daily duties. The family support, one of the key reasons to start working in this industry, also allows to take an advantage of one taxi license, increasing the family income. The friendly work environment makes female drivers feel supported, gender independent. The multicultural environment helps them to know and respect other cultures, adopting many different points of views of the situations they live on the road. Thanks to their patience and calm driving the interviewees have been able to build a loyal customers network that trust them and their way of driving. Moreover, the sector offers the opportunity to support gender initiatives in order to help citizens in difficult situations.

In conclusion, the interviewees are pleased to work as a taxi driver since this job gives them the chance to have regular incomes and run a family at the same time. Although the sector is still highly male - dominated, more women are expected to join the taxi industry in the next years, reducing the gender gap that is currently affecting the transport sector.

FUNDINGS

This study is part of the research performed in the framework of the European project TInnGO: Transport Innovative Gender Observatory funded by the European Commission through the European Union's Horizon 2020 research and innovation programme (Grant Agreement no. 824349). Specifically, the study is included in the Deliverable 9.1.

Identification of current and future issues in employment of women in SM lead by University of Copenhagen

ACKNOWLEDGEMENTS

We would like to thank the support and assistance provided by taxi drivers and Javier Moya.

ABSTRACT

A platoon can be defined as a group of consecutive vehicles that exchange information, so that they drive in a coordinated way, allowing very small spacings and still travelling at relatively high speeds. The concept of vehicle platooning is not new. In fact, scientific articles on platooning were published as early as the 1970s, and the first large-scale pilot test on platooning was carried out at the end of the 1990s. The main purpose of these early research works was to improve traffic efficiency and reduce consumptions, as well as to develop the existing technology.

These contributions were very valuable, although somehow limited by the relevant technology still being in its infancy. Precisely, the development of technology and communications in the last years has given new impetus to research on vehicle platooning on freeways as one of the possible forms of cooperation among connected automated vehicles (CAVs). The point of view of these recent studies has also been extended: in addition to traffic efficiency, the role of platooning is analyzed in terms of safety, sustainability, business productivity, etc.

In this context, there are today many scientific publications on vehicle platooning with different purposes, set in distinct scenarios and based on diverse vehicles and technologies (regular or segregated lanes, cars or trucks, vehicles with different SAE levels, etc.).

In order to organize and consolidate the existing knowledge, a comprehensive and systematic review must be performed.

This work represents a first approximation to this more ambitious objective. Firstly, platooning has been conceptualized in order to facilitate its analysis and comparisons among studies. Secondly, key publications on platooning have been analyzed to determine the most significant impacts expected from its implementation.

Finally, some important research gaps and disparate findings on the topic have been identified.

1. INTRODUCTION

Since the development of the first intelligent transport systems in the 1980s (Weiland and Purser, 2000), researchers, companies and administrations have been working to apply developments in technology and communications to combat the undesired externalities caused by transport, particularly by road transport. Especially during the present century, decisive advances in vehicle automation, monitoring and communication networks, both Wi-Fi and mobile, have allowed this struggle to be taken to a higher level and definitively visualizing future autonomous and connected mobility as feasible. Several cooperation strategies based on different communication schemes among mobility agents, namely vehicle-to-vehicle (V2V), vehicle-to-infrastructure (V2I) and vehicle-to-all (V2X) communications, are being developed with the aim of improving traffic flow and safety and reducing transportation environmental impacts (Fagnant and Kockelman, 2005; Maiti et al., 2017; Razmi et al., 2020).

One particular form of cooperation, the concept of vehicle platooning, started to attract interest as early as the 1970s. At that time, vehicles involved in platooning projects and research were passenger cars and, mostly, heavy vehicles, fitted with *ad hoc* designed sensors (Tsugawa, 2016). Additionally, the role of infrastructure was often decisive in those years, during which numerous studies on Automated Highway Systems (AHS) emerged. In this early research, the most attractive benefits expected from platooning were those economic ones linked to potentially lower fuel consumption (Browand, 2004; Lammert et al., 2014; Alam et al., 2015; Tsugawa, 2016). On the contrary, current studies mainly focus on light vehicles with a high degree of automation *per se* (Maiti et al., 2017; Bian et al., 2019; Sala and Soriguera, 2020). In addition, the importance of infrastructure is decreasing in relative terms, while that of communications is increasing (Bian et al., 2019; Jia et al, 2019; Li et al., 2020). Also, the expected benefits of platooning in terms of improved traffic flow and safety are tipping the balance towards research in these areas (Xu et al, 2013; Ye and Yamamoto, 2018; Jo et al., 2019; Calvert et al, 2019).

Nevertheless, the most addressed platooning-related topic is the so-called *string stability*. Researchers of different fields propose varied longitudinal and lateral control strategies to avoid that, due to the close vehicle formation within a platoon, state disturbances propagate and amplify along the string of vehicles.

These studies start by mathematically defining string stability, continue using particular analysis methods to derive conditions that ensure this stability and, finally, design controllers that satisfy them (Feng et al., 2019). Each of these steps can have many variants, depending not only on the approaches used, but also on the target platoon system characteristics (e.g. vehicle features, following policies, etc.). The great variety and complexity of string stability studies would require a particular comprehensive review. Therefore, this topic is out of the scope of this paper.

Instead, the present work is aimed at providing an overview on research and developments on platooning, particularly focusing on its expected impacts on areas such as traffic flow, road safety, human drivers' behavior, consumptions and emissions (Figure 1). An extensive literature review has allowed identifying and summarizing the most significant results on each topic, taking into account both the distinct contexts considered and the different analysis methodologies employed. Previously, a brief classification of platooning typologies is provided, in order to facilitate the understanding of their possible influence on the results. Finally, the paper highlights those issues with more uncertainty, either because they have hardly been addressed or because the results obtained have been disparate.

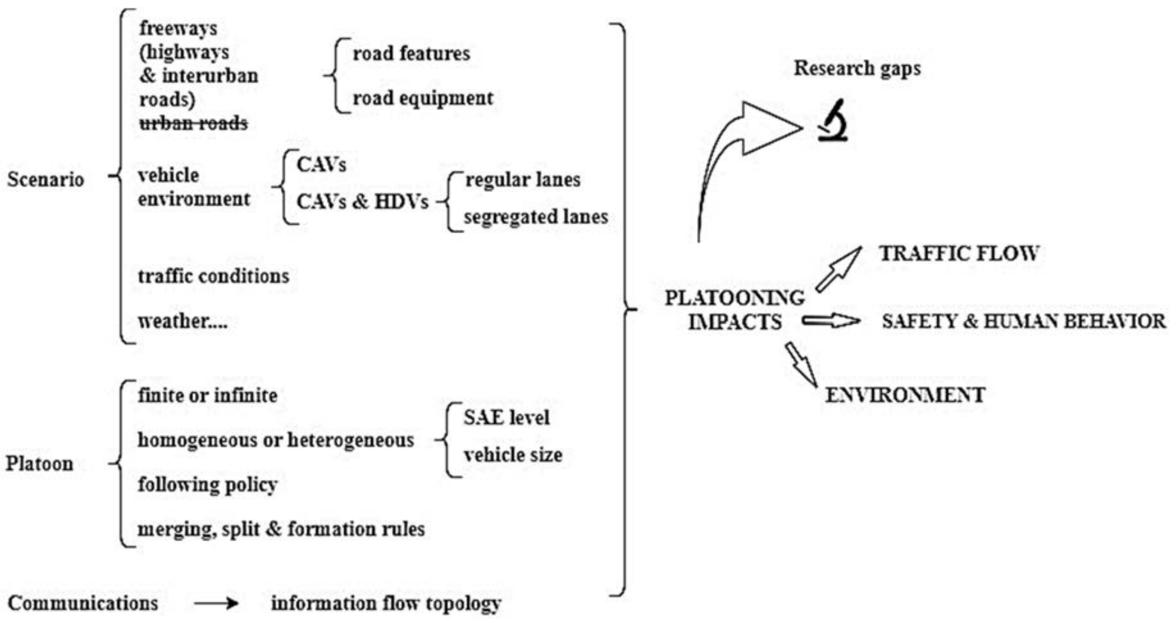

Figure 1. Graphical abstract of the article (own elaboration).

Authors have used a semi-structured approach to choose the papers that underpin this review. In the first stage, only those studies published in scientific journals indexed in the Journal Citation Reports platform were considered. From these studies, the ones containing the words *platoon*, *platooning* or *road train* in the title, abstract or keywords were searched in the Scopus database. A quick scan of the abstract allowed identifying those referring exclusively to traditional vehicles, urban environments or intersections (the word *platoon* is often used to identify a set of vehicles arriving at/leaving a signalized intersection during a particular cycle), which were disregarded.

Also those published in journals from fields other than transportation, vehicle or communications engineering, or associated areas (e.g. environment, psychology). Among the remaining papers, those with the highest number of citations were selected. Increasing minimum thresholds were established according to their year of publication. The final set of chosen references was supplemented with studies obtained from backward snowballing, being the acceptance criteria (e.g. indexing or number of citations) in this case looser than for the main papers.

The remainder of the paper is structured as follows: Section 2 classifies platooning according to three different criteria, which is important for the subsequent comparison of studies. Sections 3, 4 and 5 respectively summarize, as per the performed review, platooning impacts on traffic flow, safety and human behavior, and the environment. The most important conclusions of the analysis are extracted in Section 6, in which remaining research gaps are also highlighted.

2. PLATOONING TYPOLOGIES

It would be possible to differentiate numerous typologies of platooning based on diverse criteria. The following subsections attempt to perform this classification in a simple and concise way, according to the type and number of platooned vehicles, the information flow topology and the following policy within the platoon.

2.1 Classification according to the type and number of platooned vehicles

Usually, research on platoons focuses on vehicles of similar size, i.e., light (e.g. Gouy et al, 2014; Ye and Yamamoto, 2018) or heavy vehicles separately (e.g. Ramezani et al., 2018, Calvert et al., 2019). So far, only a small number of authors have tried to define strategies for the formation of platoons of vehicles with different sizes (e.g. Sun and Yin, 2019). The diverse mechanical features of these vehicles (acceleration and deceleration capacity, maximum speeds, speeds and gears on slopes, etc.) are obstacles to overcome. However, there are others such as the difficulty that large differences in size between consecutive vehicles may represent for sensors and communications, or the lack of comfort/the feeling of insecurity they may cause to drivers or passengers (think, for example, of a car placed between two large trucks) (Feng et al., 2019). These challenges are compounded by the fact that, unless a particular strategy is defined, the relative position within the platoon of these differently sized vehicles would vary in real time.

Another differentiating factor among vehicles is their degree of automation. In this regard, it should be noted that very few studies specify the SAE level (SAE, 2016) of the vehicles they are considering, and authors refer to them loosely as (cooperative) "autonomous vehicles", “automated vehicles”, “self-driving cars” or “human-driven vehicles”, among others. Therefore, the reader must suppose this automation level based on the capabilities vehicles are provided with throughout the text.

Some researchers argue that, as platooning involves driving at short intervehicle distances for an extended period, and eventually at high speeds, reactions to safety-critical events such as the sudden braking of vehicles ahead should not depend on the human factor.

Accordingly, SAE levels 4 and 5 are preferred, as human intervention is restricted to very limited occasions (Konstantinopoulou et al., 2019). Nevertheless, especially for the case of truck platooning, most current field operational tests and implementations feature heavy vehicles of SAE levels 1 and 2. Eminently video cameras, radars and vehicle-to-vehicle communications are used to keep close formations travelling at medium-low speeds, being drivers still quite actively involved (Kockelman et al., 2016; Kuhn et al., 2017; Knoop et al., 2019; Calvert et al., 2019). Although some improvements are achieved, the overall potential advantages of platooning cannot be maximized with these lower levels of automation. In this context, institutions like the European Road Transport Research

Advisory have assumed a simpler classification (when compared to the SAE one) for heavy vehicles that specifically limits the platooning possibilities they have (ERTRA, 2015). For the remainder of this paper, the term CAVs will refer to cooperative medium-high automated vehicles.

In this context, it is called *homogeneous platoon* that consisting of vehicles of the same (or similar) characteristics in terms of size and degree of automation. On the contrary, a platoon is *heterogeneous* if there are notable differences of any kind among its vehicles, either in size, degree of automation (including traditional human-driven vehicles – HDVs-) or both.

Regarding the number of vehicles in the platoon, it is possible to differentiate between *finite platoons*, for which a maximum number of vehicles is set, and *infinite platoons* (Feng et al., 2019; Zhou et al., 2021). Obviously, real platoons will always be finite, but the use of infinite platoons in research allows simplifying and generalizing the analysis of platoons with a high number of vehicles, seeking to maximize all potential benefits of this mode of cooperative driving. However, some authors question the interest of research on infinite or very long platoons. On the one hand, common challenges of cooperative driving, such as information flow and management, are accentuated. On the other hand, it seems unlikely that a large number of vehicles would decide to take at the same time a same route long enough so as to make a profit, unless it is a predetermined management decision. For example, a decision linked to logistics, i.e., an agreement among different companies whose goods must be transported from similar origins to similar destinations. In case this kind of platoons would be materialized, another aspect to take into account would be their interactions with other non-platooned vehicles. Although this aspect is important for any kind of platoon, some particular measures only advisable for medium-short platoons would have to be imposed for large platoons.

One example would be their driving restricted to the leftmost lane, so as not to prevent other vehicles, for instance, from entering or exiting a freeway or from making a lane change (Eckhardt et al., 2016). Note that, for the case of long truck platoons, this situation would be just the opposite of the current one, in which heavy vehicles usually drive in the rightmost lane. Additionally, very large truck platoons could lead to an accelerated deterioration of existing pavements and structures (Song et al., 2021).

2.2 Classification according to the information flow topology

Although platooning can benefit from V2X communications, the information exchanged among vehicles is key to achieve a good performance and, particularly, to ensure string stability. Not only information on other vehicles' speeds or positions, but even slight accelerations, decelerations or direction changes, among others, must reach each particular vehicle in time so that it can react accordingly. In this way, disturbances diminish and their propagation and amplification along the string of vehicles are avoided.

Logically, for a particular vehicle within the platoon, information coming from its nearest vehicles will be not only relevant, but also more feasibly obtainable from the point of view of sensors and communications. Therefore, information flow topologies (IFTs) such as *predecessor following* (PF), *two-predecessor following* (TPF) and *bidirectional* (BDL) are widely used in research. In parallel to the development of powerful communications, more generalized schemes such as *r-predecessor following* (rPLF) are being increasingly applied. For their part, other studies consider that some information about the leader, especially (but not only) its position, should reach the whole platoon. Taking into account that the leader will be relatively far away from some members of the platoon, the exchange of information among nearby vehicles is considered necessary anyway. In this context, *predecessor leader following* (PLF), *two-predecessor leader following* (TPLF) or the generalized *r-predecessor leader following* (rPLF), as well as *bidirectional leader* (BDL) IFTs are more and more commonly used in the studies (Zheng et al., 2016; Feng et al., 2019; Gong et al., 2019). Figure 2 represents the information flows of these configurations.

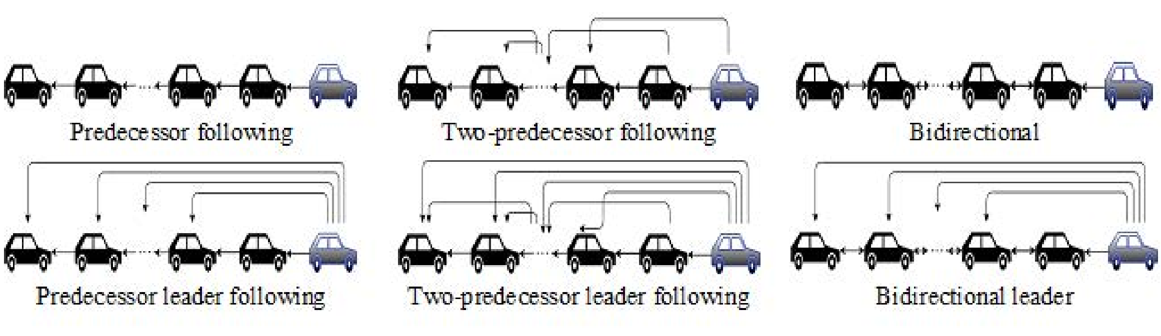

Figure 2. Most typical information flow topologies for platoons (the leader vehicle is highlighted. Own elaboration).

The possibility that an increasing number of vehicles can exchange information with each other despite being at considerable distances is the result of improvements in communications. However, the greater the amount of information transmitted, the greater the likelihood of communication delays, packet losses and other related issues, usually associated with the congestion of the communication channels (Xu et al., 2013; Zheng et al, 2018; Li et al., 2020). Therefore, the fact that more vehicles exchange information does not necessary imply either a higher degree of stability within the platoon or more benefits linked to a particular platooning behavior. Researchers try to find a tradeoff in this regard.

Another aspect that must be highlighted is that neither of the former information flow configurations is static, as both the vehicles and their positions within a platoon change over time. Accounting for these dynamic changes in real time is one of the main challenges for researchers on platooning (Feng et al., 2019).

2.3 Classification according to the formation, split or following policies

The first condition for the potential benefits of platooning to be exploited is that there is a sufficient penetration of vehicles with a level of automation that allows platooning (Bergenhem et al., 2012; Janssen et al., 2015). However, the strategies on the basis of which platoons are formed also play an important role. The *a priori* least favorable strategy in this respect would be the so-called *opportunistic platooning* (Liang et al., 2014; Sala and Soriguera, 2020*)*, also known as *on-the-fly platooning*, according to which only those CAVs that happen to drive consecutively in the same lane would form a platoon. More efficient would be the *cooperative platooning*, whereby all CAVs within a certain range would try to join in a platoon, respecting the maximum lengths established, if any (Sala and Soriguera, 2020). Even more optimal strategies have been designed in the field of logistics. One example is the *online, dynamic planning or real time platooning*, according to which, just before or during the journey, vehicles announce their destination and/or tentative routes so that other interested vehicles can platoon with them during part or the total of the journey. Another example is the *offline, static* or *scheduled platoon planning,* in which trips are announced in advance to facilitate the coordination among companies (Bhoopalam et al., 2018). Many side aspects complicate this coordination, as, for instance, the mandatory rest stops for drivers in the transportation sector (Goel, 2010; Goel, 2014).

Although the relevant legislation has yet to be updated, it is expected that a minimum number of rest stops will continue to be mandatory, except for SAE level 5 vehicles. With lower automation levels, the driver will have to be prepared to react to any emergency. The type of load carried could also be relevant for the suitability or not of forming/joining a platoon in some specific cases (e.g. living beings against dangerous products, etc.) (Meisen et al., 2008).

Other details concerning the formation and split of platoons at the individual vehicle level are also under study. The fact that a vehicle joins a platoon, as well as when it leaves it, is not trivial. Getting these operations right is essential not only to maximize the benefits of platooning, but also to avoid traffic flow disturbances. In terms of merging, some authors advocate that a platoon should maintain its speed and the joining vehicle should accelerate to catch it. This is the so-called *catch-up strategy* (e.g. Liang et al., 2013; Ko, 2019). Other authors are in favor of a *slow-down strategy*, that is, a slight deceleration of the platoon to facilitate the merging of the vehicle that has announced its willingness to join it (e.g. Meisen et al., 2008; Ko, 2019). There are also intermediate solutions (e.g. Saeednia and Menéndez, 2016; Saeednia and Menéndez, 2017; Farag et al., 2019). Additionally, some authors assume that vehicles should join existing platoons at the back, and others consider the merging in the middle or at the front (e.g. Farag et al., 2019; Paranjothi et al., 2020).

Fewer studies address vehicles' leaving of the platoon. These often stress the importance of this maneuver to be announced in advance, especially to the immediate follower, which, among other things, will have to close the gap left by the departing vehicle (e.g. Maiti et al., 2017; Duret at al., 2019; Paranjothi et al., 2020). Again, a single tail split will have different consequences for the platoon's stability and efficiency than a single front split or a split from the middle, and each of them must be separately and deeply analyzed yet (Maiti et al., 2017). In any case, both the merging and the diverging possibilities will also depend on the vehicles' characteristics, especially the size (Maiti et al., 2017, Farag at al., 2019).

Apart from these different building/splitting strategies, any vehicle in a platoon follows a pre-established following policy during its journey. The three main policies considered so far are the *constant distance policy*, the *constant time distance policy* and the *nonlinear distance policy*. In the two first, followers drive respectively maintaining a fixed distance in space, either in terms of gaps or spacings (e.g. Gong and Du, 2018; Jia et al., 2019; Li et al., 2020) or in time, usually in terms of time headways, but also of time gaps (e.g. Dolk et al., 2017; Bian et al., 2019; Wang et al., 2020). These distances vary across the different studies, depending, among others, on vehicles' size and level of automation. Constant time headways between 0.6 and 1 s are quite common in the literature, whereas the variability in space distances is much broader. For example, Zhou et al. (2017) considered a spacing of 7 m for truck platooning, while Zheng et al. (2018) worked with 25 m for generic platoons.

The *nonlinear distance strategy* (e.g. Orosz, 2016) is usually implemented with the aim of improving platooning string stability and overall benefits, as it better accounts for the influence of the road characteristics (mainly of slopes) on the mechanical capabilities of vehicles, especially if they are heavy. Other less used following policies can be found in the literature, some of them more complicated and difficult to implement in practice, and others that, on the contrary, only impose minimum (but not maximum) space or time distances for the sake of safety (e.g. Zhou et al., 2017).

A few authors (e.g. Vukadinovic et al., 2018) have also addressed the definition of following policies for the leader with respect to other platoons or individual vehicles travelling ahead in the same lane.

3. PLATOONING EFFECTS ON TRAFFIC FLOW

Platooning is expected to have a first positive impact on traffic flow directly linked to the fact that vehicles drive maintaining short distances between them, i.e., occupying less space. This allows for a better use of road capacity (van Arem et al., 2006; Shladover et al, 2015; Nowakowski et al.,2015; Lioris et al., 2017). Further research is needed to quantify this improvement, which will in any case depend on the scenarios (penetration rate of CAVs, platoons' frequency and length, following policies, road characteristics, etc.). If these would be really positive, capacity could be doubled or tripled at intersections (Kockelman et al., 2016; Lioris et al., 2017) and even quintupled on freeway stretches (Kockelman et al., 2016; Sala and Soriguera, 2020). Mainly for heavy vehicles, which are normally a minor share of the flow with particular features, coordinated driving within a platoon could lead to an additional improvement for traffic flow as a result of an increase in traffic homogeneity (Nieuwenhuijze et al., 2012; Ramezani et al., 2018). In this context, travel time savings are also expected (Jo et al., 2019).

However, it is also claimed that too long platoons would increase traffic congestion if the capacity of a certain segment would be surpassed (Bhoopalam et al., 2018). Especially for the case of platoon formation under scheduled planning, this could be a consequence of too many vehicles driving the same route if no restrictions are set. An appropriate traffic assignment model could avoid these issues (Angelelli et al., 2016; Bhoopalam et al., 2018).

Platoons' length, especially depending on the driving lane, could cause other undesirable disturbances such as hindering or impeding the maneuverability of other vehicles wishing, for example, to change lanes or enter or leave a freeway (Nowakowski et al., 2015; Calvert et al., 2019). This could cause sudden accelerations or decelerations on their part, resulting in shockwaves and even in dangerous situations. Precisely because of their greater disruption to other vehicles, Calvert et al. (2019) claim that truck platooning should not be allowed in saturated traffic flow to avoid higher delay times in the overall network.

The mixed scenarios with CAVs sharing roads with HDVs will be particularly complex. Indeed, the interactions among these different vehicles and their consequences for both traffic performance and traffic safety are unclear no matter the cooperative driving mode of CAVs, but also widely researched (Razmi et al, 2020). For the specific case of platooning, even with a high penetration rate of CAVs (i.e. a favorable scenario for platoon formation), HDVs could, intentionally or not, interrupt them if no proper strategies are defined.

This would prevent making the most of platooning potential benefits for traffic flow and, again, generate risky situations. In this context, dedicated lanes for CAVs could minimize these interactions and, additionally, favor platoon formation (Kockelman et al., 2016; Talebpour et al., 2017; Lee et al., 2018; Razmi et al, 2020).

Moreover, higher speed limits could be allowed in these lanes without compromising safety and increasing traffic flow benefits (Ye and Yamamoto, 2018). Tsugawa et al. (2016) particularly addressed the use of dedicated lanes for truck platooning, observing a doubling of capacity, albeit under ideal conditions. However, dedicated lanes would only be reasonable for appreciable penetration rates of CAVs, depending the minimum required rate, among others, on the total number of lanes on the target roads. Traffic conditions would also play a role in this regard. Minimum penetration rates of CAVs between 15% (Yang et al., 2019) and 50% (Xiao et al., 2019) so that dedicated lanes are profitable can be found in the literature, which indicates that more research is needed. In fact, some negative consequences linked to dedicated lanes have already been detected and must be further analyzed. For example, a possible congestion increase in the non-dedicated lanes because of the non-cooperating vehicles having less capacity available (i.e., less lanes) and/or the formation of shockwaves because of abrupt lane changes linked to this vehicle distribution (Talebpour et al., 2017; Zhong, 2018; Xiao et al., 2019). Even when no so determining, permanent dedicated lanes would prevent HDVs from taking advantage of the capabilities of CAVs to reduce traffic instabilities for the whole flow (Ntousakis et al., 2015; Gueriau, 2016; Xiao et al., 2019; Amirgholy et al., 2020). Therefore, some researchers opt for dynamically dedicate lanes to platoons (or to CAVs in general) when appropriate (e.g. Chen et al., 2016, Zhong, 2018; Razmi et al., 2020). Most of them agree that their use should be optional, i.a. to prevent abrupt maneuvers of lane changing vehicles that could lead to shockwaves (Talebpour et al., 2017). The possibility of CAVs sharing these lanes with high occupancy vehicles (HOV) of any SAE level or that of allowing general HDVs to use these lanes after paying a toll have also been considered (Xiao et al., 2019; Liu and Song, 2019). Especially this last policy should be carefully implemented so that dedicated lanes are still worth reserving.

A summary of the mentioned findings is included in Table 2. As already indicated, string stability of platoons is beyond the scope of this work. However, it must be noted that it is a prerequisite not only for platooning to contribute to improved traffic flow, but also to ensure that its effect is not exactly the opposite (Ploeg et al., 2011; Nieuwenhuijze et al., 2012; Calvert et al., 2019).

SCENARIO	IMPACT (EX. REFERENCES)
Mixed environments	✓ Capacity increase (Kockelman et al., 2016; Lioris et al., 2017) ✓ Traffic stabilization & homogenization (Ramezani et al., 2018; Amirgholy et al., 2020)
	× Capacity overrun (Angelelli et al., 2016; Bhoopalam et al., 2018) × Disruptions (Nowakowski et al.,2015; Calvert et al., 2019)
Segregated lanes	✓ Capacity increase (Tsugawa et al. 2016; Lee et al., 2018) ✓ Free flow & high speeds (Ye and Yamamoto, 2018; Razmi et al, 2020)
	× Congestion in regular lanes (Zhong, 2018; Xiao et al., 2019) × Shock waves due to abrupt lane changes (Talebpour et al., 2017; Razmi et al, 2020)

Table 2. Main impacts of platooning on traffic flow (✓positive; × negative)

4. PLATOONING EFFECTS ON SAFETY AND HUMAN BEHAVIOR

There are two main points of view when addressing the relationship between platooning and road safety: focusing on the vehicles that form one particular platoon, or in terms of each platoon's interactions with other single or platooned vehicles (Table 3). Some expected issues regarding the latter perspective have already been appointed, such as those linked to HDVs performing risky maneuvers to, for example, surpass a long platoon (Axelsson, 2017). However, there are more. In fact, driving simulator studies have shown that human drivers change their normal driving behavior when interacting with a platoon, even when this "interaction" is only its observation. The most common consequence is these drivers imitating the platoon intervehicle distances relative to other forward moving HDVs and/or accelerating to run parallel to platoons if their speeds are higher (Skottke et al., 2014; Razmi et al, 2020). Taking into account that humans have longer reaction times than CAVs and are more error-prone, dangerous situations and accidents related to this behavior are expected (Schakel, 2010; Yang et al., 2019). Nevertheless, their importance for the overall computation of the accident rate has yet to be quantified (Razmi et al, 2020).

The factors behind this behavioral change are not completely understood, but a few studies have shed some light on the topic. For example, trust in technology seems to play a role (Al Haddad, 2020; Zhao et al., 2020). In fact, the effect of trust has already been observed in studies addressing the acceptance and intention to use of different systems.

These studies also showed that trust is dynamic and evolves over time and with extended exposure to automation (Ghazizadeh et al., 2012). This may be the reason why previous experience with automated vehicle (AV)-like functions, such as adaptive cruise control (ACC) or cooperative adaptive cruise control (CAAC) systems, is often associated with greater relaxation/confidence and bolder behavior on the part of drivers interacting with platoons. Indeed, even in traditional environments, drivers tend to drive faster and in a more aggressive way (shorter gaps, more abrupt maneuvers, etc.) if their vehicles are equipped with these systems (Hoedemaeker and Brookhuis, 1998; Bianchi et al., 2014; Balk, 2016). Notwithstanding, CACC reduces drivers' stress and fatigue, which could mitigate the potential unfavorable consequences of this tendency (Stanton and Marsden, 1996). Going back to mixed environments, drivers of traditional vehicles are influenced differently depending on the period interacting with the platoon and on the platoon significance in terms of length or height. In this regard, the longer the time or the more significant the platoon (e.g. long truck platoons), the shorter their accepted distance to the vehicle ahead (Gouy et al., 2014; Yang et al., 2019). As mentioned, more research is needed to fully understand these interactions, both analyzing the aforementioned factors under different boundary conditions, and addressing other remaining questions such as the impact of drivers' gender, age, driving experience, physical and mental condition, etc.

CONTEXT	IMPACT (EX. REFERENCES)
Mixed environments	✓ More stability (Stanton and Marsden, 1996; Gueriau, 2016) ✓ Reduced human role (Nieuwenhuijze et al., 2012; Turri et al., 2017)
	× Risky interactions (Axelsson, 2017; Calvert et al., 2019) × Drivers' bolder behavior (Skottke et al., 2014; Razmi et al, 2020)
Safety within the platoon	✓ Coordination (Xu et al., 2013; Bhoopalam et al., 2018) ✓ Minimal human role (Axelsson, 2017; Rahman and Abdel-At 2018)
	× String instabilities (Axelsson, 2017; Feng et al., 2019) × Disengagement & takeover (Varotto et al., 2015; Favaro et al., 2019)

Table 3. Main impacts of platooning on safety (✓positive; × negative).

Within a platoon of CAVs, lower reaction times, vehicle coordination and an inferior role, if any, of the human factor are expected to reduce the number of rear-end collisions (Xu et al., 2013; Bhoopalam et al., 2018). This improvement has already been demonstrated by means of microscopic simulations.

For example, for a penetration rate of CAVs of 40%, Rahman and Abdel-At (2018) observed a significant reduction in the longitudinal crash risk along a dedicated lane for platoons (for CAVs in general), in which these followed a constant time headway policy of 0.6 s. However, side aspects such as those pointed out in section 3 (e.g. the effects of the disturbations caused by vehicles trying to change lanes) or the aforementioned possible changes in human drivers' behavior were neglected in the study. These authors also observed that safety conditions, albeit to a lesser extent, also improved with the presence of the same rate of CAVs with no vehicle segregation. Again, there is need for further studies considering, among others, different road geometries, different policies both for the platoon formation, split and driving and different overall traffic conditions. (Axelsson, 2017). Moreover, this must be done considering *homogeneous* and *heterogeneous* platoons separately, as specific formations accounting for vehicles' size, engine capabilities, etc. can also influence the consequences, for example, of an emergency braking (Bhoopalam et al., 2018). String instabilities, often linked to unsafe situations, must be specifically analyzed and addressed.

It must be borne in mind that the human factor cannot be disregarded within the CAV-platooning framework either. Unless platoons consist of SAE level 5 vehicles, drivers will continue to play a role, at least in emergency contexts. Depending on the vehicle level of automation, there will be certain situations that CAVs will not be able to handle. Thus, they will require drivers to resume the control of the driving task. Within a platoon, i.e., with short distances among vehicles and at relatively high driving speeds, both the drivers' reaction time and the quality of these reactions will be key to avoid multiple vehicle collisions. A study performed by Varotto et al., (2015) with ACC-equipped vehicles showed that drivers needed on average 3.85 s to resume control after sensor failure. Note that this could be a cause for disengagement of CAVs, also in platooning scenarios.

Eriksson and Stanton (2017) additionally observed that reaction times rose to 6.06 ± 2.39 s if drivers were performing a secondary task. Still not on platooning but with platooning-capable vehicles of SAE levels 2 or 3, studies analyzing real data collected in California found that their drivers' reaction times to take control of the vehicle after disengagement had a stable distribution at 0.83 s (Dixit et al., 2016). However, there were differences depending on the type of disengagement (the cause, if active or passive, etc.), the type of road and the previous number of miles travelled in these automated vehicles. Reaction times were found to increase with increased vehicle miles travelled, which was assumed to be related to a gradual increase in trust (Lv. at al., 2018). Simulation has also been used to assess disengagement and takeover in highly automated vehicles. Favaro et al. (2019) analyzed the reactions of 40 human drivers (50% male and 50% female) placed in 36 simulated autonomous technology disengagement scenarios. The study showed that vehicle speed significantly affected the takeover, much more than other factors as, for instance, the driver's age. A similar observation can be found in Zhang et al (2019).

In addition, they noticed that reactions were faster and more appropriate in very risky situations, if drivers had had previous similar takeover experiences and if they were not performing another visual task during the automated driving. Zeeb et al. (2016) also confirmed the role of distraction. For their part, Roche et al. (2020) found a link between drivers' stress level and takeover overreactions. If these same tendencies apply to the specific case of platooning and which their consequences would be taking into account platooning specific driving characteristics is still a research niche. As leaders play a special role in platoons, driver's reactions should be specifically analyzed for this position in the string.

5. ENVIRONMENTAL IMPACTS OF PLATOONING

Most authors agree that platooning will have positive effects from the environmental point of view. Indirectly, platooning is expected to contribute to the improvement of traffic flow and, therefore, to avoid the overconsumptions and harmful emission peaks linked to congestion. Directly, platooning lowers air drag (Wadud et al., 2016; Turri et al, 2017). As aerodynamic drag accounts, for example in highway driving, for 50%–75% of tractive energy requirements (Kasseris, 2016), platooning would allow reducing the average energy consumption and emissions when compared to those linked to single non-cooperative vehicles (Scora and Barth, 2006).

Focusing on platooning direct benefits, their relevance will depend on several factors.

Zabat et al. (1995) analyzed some of them using wind tunnel tests and numerical simulations to assess fuel savings for van platooning in different scenarios. These comprised, among other variables, different intervehicle distances and platoon lengths. The total savings range for all boundary conditions was between 10%-30%, but values between 20%–25% were the most frequent. Clearly, longer platoons achieve higher total savings (Zabat at al., 1995; Bhoopalam et al., 2018). Fuel economy also improves for smaller intervehicle spaces (Zabat at al., 1995; Zhang et al., 2020). Platooning speed, on the contrary, does not seem to play an important role in this regard (McAuliffe et al., 2018; Zhang et al., 2020).

For its part, the size of the platooned vehicles is determinant. Several studies have demonstrated that consumption-related benefits can be especially significant for truck platooning, particularly on highways (Patten et al., 2012; Silberg 2013; Nowakowski et al., 2015; Bhoopalam et al., 2018). As for lighter vehicles, intervehicle distances again have a strong influence. For example, Browand et al. (2004) observed in track tests with tandem trucks that fuel consumption savings reached 11% when these distances were of 3-4 m, but descended to 8% for distances between 8-10 m. Humphreys et al. (2016) perceived this tendency using simulation. Masses and loads limit savings, but their influence is weaker (Lammert et al., 2014, Zhang et al, 2020).

However, for any specific vehicle size, namely for heavy vehicles, individual reductions in energy consumption significantly differ depending on their position within the platoon, consistently with the physical concept of air drag. Indeed, after intervehicle spaces, position is the variable with the greater impact (Zhang et al, 2020). In track tests, leaders were found to save 2.7% to 5.3% of the average fuel needs, while followers increased these figures to 2.8-9.7% (Lammert et al, 2014). Although the exact percentages for savings/consumptions depend on many other boundary conditions, the role of position can be unambiguously observed. For instance, Lu and Shladover (2011) reported, for a test performed with a 3-truck platoon on a real road, reductions in fuel consumption of 18% and 23-24%, respectively for the leader and the followers. Computational fluid dynamics are also often used to assess air drag reduction and, subsequently, consumption savings.

Using this method, Davila et al. (2013) observed that benefits for the followers were double those for the leader. Taking into account the influence of position, some authors have proposed different strategies to proportionally divide the total savings achieved by the whole platoon during a common trip among all members of the string. This distribution is especially suitable for the case of truck platooning under scheduled planning (Bhoopalam et al., 2018). In fact, without a solution to balance out these unequal gains, effective platoon formation would probably be undermined, as no company would want their trucks to be leaders. On the contrary, a good coordination among companies could result in benefits for all and, thus, promote platooning (Zhang et al, 2020).

SCENARIO	IMPACT (EX. REFERENCES)
All (stronger impacts for automated heavy vehicles & uninterrupted traffic)	✓ Reduced energy/fuel consumptions linked to reduced air drag (Lu and Shladover, 2011; Turri et al., 2017) ✓ Reduced energy/fuel consumptions linked to traffic flow improvements (Alam et al., 2015; Bhoopalam et al., 2018) ✓ Lower emissions linked to lower consumptions (Scora and Barth, 2006; Wadud et al., 2016)
	× Improvements dependent on many variables (Zabat at al., 1995; Zhang et al., 2020) × Unequal distribution of savings in the platoon (Davila et al., 2013; Lammert et al, 2014)

Table 4. Main environmental impacts of platooning (✓positive; × negative).

Table 4 summarizes the preceding findings. It must be noted that most of the aforementioned studies have been performed using vehicles with a low-medium level of automation and petrol or diesel engines. Higher energy savings are expected when vehicles are fully automated and electric.

On the one hand, SAE level 5 vehicles will allow for smaller intervehicle spacings and squeeze eco-driving modes. Indeed, Stephens et al., (2016) predict consumption savings to reach, at least 25%, for highway car platooning during non-peak hours. Higher percentages would apply for truck platooning. On the other hand, Alam et al. (2015) have demonstrated that energy savings while platooning are higher than fuel consumption savings, and internal losses are expected to be negligible for electric engines. Other factors such as not needing to implement significant rest periods for drivers will also allow optimizing consumptions (Zhang et al, 2020). Nevertheless, additionally *ad hoc* strategies such as cooperative look-ahead control could help to achieve extra savings in fuel and energy consumption until highly automated vehicles hit the road (Alam et al., 2015).

6. CONCLUSIONS AND REMAINING CHALLENGES

The development of automated and connected transport will offer users new forms of mobility that are more pleasant and comfortable, in which travel times can be used to perform other activities. It will also allow for an increase in the competitiveness of companies associated with the expected reduction in transportation costs and route optimization, among others (Martínez-Díaz et al, 2018). However, the main objective of future mobility is to put an end to current transport problems, i.e. congestion, accidents and environmental damage. The performed analysis confirms that platooning is one of the forms of cooperative driving with the greatest potential in this respect.

First, the frequent formation of medium length platoons could lead to an increase in road capacity due to the small intervehicular distances maintained. In addition, string-stable platoons could accentuate the proven ability of cooperating vehicles to reduce traffic instabilities and, thus, to improve traffic flow. This latter improvement over traditional driving would be even more noticeable when heavy vehicles are involved. Second, coordination within vehicles and, thus, the avoidance of abrupt maneuvers carried out on an individual basis, would also lead to an enhanced safety. This improvement would become more noticeable as the penetration rate of vehicles with a high degree of automation increases, in parallel with the decrease in the weight of the human factor.

Third, platooning would involve a reduction in energy and fuel consumption while driving, which would also result in a drop of harmful emissions. These improvements are mainly linked to lower air drag for the followers and would be particularly advantageous in the case of truck platooning. In addition, there are also environmental benefits linked to the aforementioned improvement of traffic conditions.

Notwithstanding, in order to fully reap these benefits and to avoid potential unwanted effects of platooning, studies must consider increasingly realistic (and thus complex) contexts. Although more gaps exist, research on the following issues is especially required (Figure 3):

- *General IFT*. Most research on platooning (including research on string stability) assumes one or several specific IFTs. Therefore, their results are associated with these particular configurations. Such fixed schemes could be imposed in certain circumstances, e.g. scheduled platooning in logistics. However, it is expected (and desirable) that future platoon formation will be dynamic and highly volatile. I.e. vehicles may join or leave the platoon quite fluently. There is need for more general platooning strategies reliable for all possible IFTs.
- *Heterogeneous platoons*. As indicated, only a few studies consider the possibility of vehicles of different sizes and/or automation capabilities conforming a platoon. Indeed, their feasibility has yet to be determined. If suitable strategies could be derived, platoons would form more frequently and, consequently, their potential benefits could be better exploited.
- *Mixed environments*. Although already addressed, the large number of possible scenarios makes it necessary to dive deeper into this topic. The simultaneous presence of platoons and single vehicles on the same road should be analyzed comprising all vehicles' degree of automation, size and mechanical characteristics, road features (e.g. number of lanes, longitudinal profile), general traffic management strategies set (e.g. variable speed limits, lane change restrictions, dedicated lanes), weather conditions, etc. Platoons' actual impacts will ultimately depend on their interactions among them and with other vehicles.

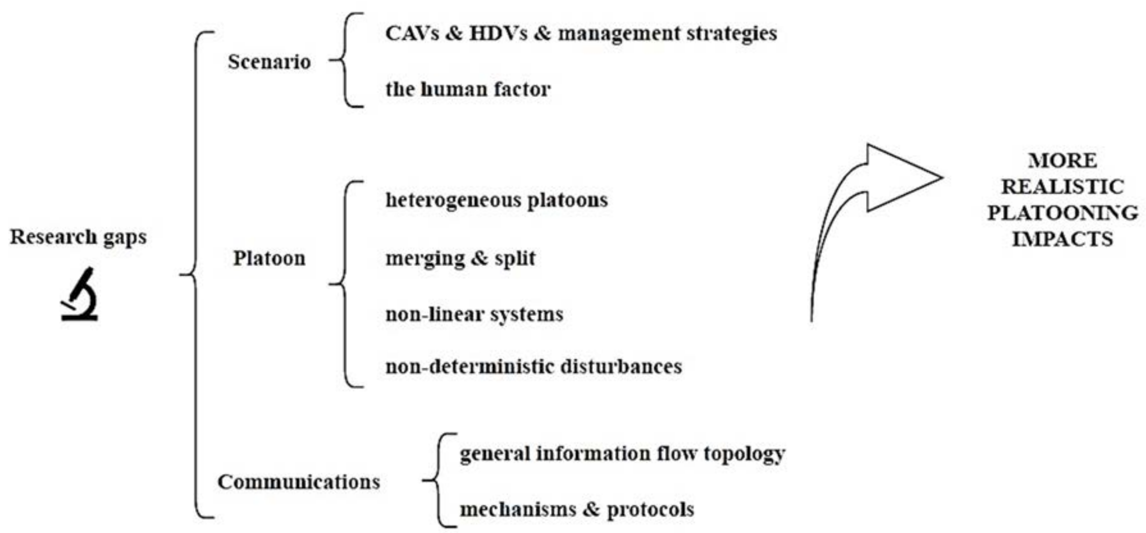

Figure 3. Key research gaps on platooning (own elaboration).

- *The human factor*. Especially for safety reasons, drivers /passengers' behavior in the aforementioned mixed environments, both within and out of platoons, must be further examined. This analysis should cover people's expected role, highly linked to vehicles' automation level, but also users' particular features, both identifying (e.g. age) and circumstantial (e.g. fatigue level).

- *Communication mechanisms and quality*. It is key to determine the information type (i.e. variables), quantity (i.e. how many agents it comes from, including infrastructure) and frequency (i.e. how often it is updated) that needs to be exchanged among vehicles in order for a platoon to circulate efficiently and safely. Given platoons' dynamic nature, this exchange is a challenge in itself. However, there are additional problems, such as the limited capacities of communication networks. Research must account for the possibility that these become congested, resulting in delays in the reception of information and/or in some data not reaching the intended recipients. In addition, a balance must be struck among interoperability, privacy protection and the prevention of cyber-attacks.
- *Non-linear platooning systems and non-deterministic system disturbances*. Most studies, also those focusing on string stability, consider vehicle dynamics within the platoon to be linear either *per se* or by the introduction of linearization techniques. In addition, stochastic external disturbances that can affect the platoon are usually disregarded. Both assumptions allow simplifying the analyses, but also affect any derived results, as none of them matches reality.

As mentioned, more questions remain in topics as diverse as platoons' string stability, above all the lateral, platooning planning and routing in logistics, or network design accounting for platooning, among others. The authors would like that this overview encourages new research contributions on this promising form of cooperative driving.

ABSTRACT

One of the main problems in urban areas is the steady growth in car ownership and traffic levels. Therefore, the main challenge to reach sustainable and liveable cities is focused on a shift of the demand for mobility from cars to collective means of transport. For this purpose, buses are a key element of the public transport system. This paper presents a cross-case analysis, from a diagnostic through big data management of the urban bus operation in Oviedo (Spain) and Tangier (Morocco). For this aim, several performance indicators (KPIs) were estimated for both networks and services. In the evaluation of the service the KPIs were grouped in five categories considering the consumption of resources (inputs) and the results or production obtained (outputs). Once the KPIs were estimated, they were compared to minimum requirements needed to satisfy demand depending on the cities characteristics (population, cover area, alternative transport systems). Finally, a qualitative comparison of the overall performance of the two networks was done. Results showed that even though at first sight, the service characteristics might seem different:

Tangier´s network is made up of 44 lines, with a length of 795 km and a fleet of 192 buses. While Oviedo´s network has 16 lines with an extension of 205.9 km and a fleet of 67 buses there are several common indicators like the monthly average of users in urban lines that rounds 125,000 passengers, a capture ratio of 40 persons per bus, and a similar bus availability every 1000 inhabitants (0.22 and 0.30). However, it was possible to observe some gaps in the system functioning, mainly in Tangier´s network which overall performance is worse than Oviedo´s in most of the analysed aspects.

1. INTRODUCTION

According to the World Economic Forum, by 2020, 56.2% of the world´s population lives in urban areas. Consequently, impacts related to mobility are growing; like traffic congestion, GHG emissions and pollutant, and traffic accidents.

The main problem is the excessive dependence on private vehicle, which without appropriate measures will derive in significant challenges to sustainability.

Among several factors, transport systems determine the form and socio-economic development of a city. Mobility and accessibility provided by the transport system play a major role in shaping cities, influencing the location of social and economic activities and the style and pace of life by facilitating trade, permitting access to people and resources (Zuidgeest, 2005).

Population growth produces urban expansion, which, together with dispersal of amenity and activity have increased the demand for and dependence on motorized transportation. To address these problems and their impact on the transport infrastructure, improvement in bus systems (and hence operations) in developed and developing countries can be considered a potential cost-effective approach to reach transport sustainability.

Regarding medium-size cities, bus is often the most common and, in most cases, the only public transport service available, as most of the cities have no metro o tram network. For example, in the European Union in 2014, 57.6 billion passenger journeys were made using public transport of which 55.8% used buses, with metro systems accounting for 16.1 %, tramways or light rail 14.5 %, and suburban railway 13.6% (UITP,2016).

In comparison to private vehicle dominated urban transport systems, those that are largely reliant on buses produce significantly less congestion, lower energy consumption and emissions. This is because buses are inherently efficient both in terms of road space and fuel consumption per passenger kilometre. Depending on the type of bus (standard, articulated, bus-train or double articulated), a fully load bus can replace between 5 and 40 cars with a corresponding fuel saving ranging from 40 to 97% (UITP, 2015). All the potential benefits mentioned, have produced a speedy evolution in bus and related technologies infrastructure, concepts of operation, business models and operations best practice or benchmarking, with increasing evidence that buses can be considered an appropriate alternative to meet sustainability requirements. This is in terms of efficiency, emissions, space occupancy as well as operational effectiveness as buses are more easily adapted to passenger requirements and do not require heavy infrastructure. Moreover, buses represent a safe transport mode registering low accident rates compared to other surface modes.

Public transport performance (in this case bus qualitative performance) can be understood in two dimensions. The first dimension relates to public values and users' expectations of the society (Jorgensen and Bozeman, 2007; Koppenjan et al.,2008). The second dimension of performance refers to ways of measuring broad goals into quantitative metrics.

These metrics are performance indicators (KPIs), such as emissions/passenger or average distance to public transport stops. Measuring the performance of bus systems service by different indicators can be influenced by different elements of the organisation of public transport systems, such as the ownership structure operator (public or private), contractual allocation of risks, or integration fares. (Hirschhorn et al., 2019). Therefore, when possible, the overall performance of the system should be estimated by composite indicators which can be useful due to their ability to integrate large amounts of information into easily understood formats.

The objective of this paper is to evaluate Oviedo´s and Tangier´s bus networks and services through the estimation of several KPIs based on the data provided by the operator (ALSA). The qualitative analysis of their overall performance, together with the cross-case analysis between their urban bus systems will allow designing policy-packages to improve sustainable operation according to each country´s reality.

This paper is structured as follows. Section 2 reviews the indicators to analyse a bus network performance. Section 3 sets territorial context and presents the indicators estimated for both study cases. The results of the cross-case analysis to evaluate the networks performance are presented in Section 4 and finally Section 5 provides some conclusions and propose future research.

2. REVIEW OF BUS PERFORMANCE INDICATORS

Efficiency and performance measures in public transport are necessary to monitor progress toward a planned target. Efficiency measures compare realized and optimal levels of outputs and inputs. They can also be used as means of evaluating recently realized or proposed extensive changes towards increased deregulation or reorganization.

The performance criteria´s should serve as an instrument to evaluate the system condition, level of service, and safety provided to costumers based on economic, environmental and community policy goals. Performance indicators should also evaluate day-to-day performance for strategic management, analysis of options and trade-offs. One of their main objectives is to give information for decision on how to allocate resources and help prioritize improvements to the neediest areas. In general performance measure indicators should be policy driven, which can be used in analysis of options and trade-offs, decision making on resource allocation, and monitoring to provide clear accountability and feedback. In addition, they can show trends, or warn of problems, influencing both immediate actions and long-term plans.

The efficiency of public transport system has been reported in terms of operational indicators, engineering indicators, labor indicators, social indicators, resource indicator and financial indicators on literature.

The NCHRP (2005) report categorizes performance measures for general transport assets under Preservation of assets, Mobility and accessibility. Operations and maintenance, and Safety. Public Transport Authority of Western Australia (2004) in their annual report used five categories of performance measure with indicators. This includes Use of public transport measured by passenger per service km and total passenger-kilometres, Service reliability, Level of overall customer satisfaction, Customer perception of safety and Level of notifiable safety incidents. In the context of developing countries Armstrong-Wrigth and Sebastian (1987) listed passenger volume, fleet utilization, vehicle-km, break-down in service, fuel consumption, staff ratio, accidents, and cost of bus services as operation performance indicators in addition to quality indicators. Additionally, Iles (2005) grouped efficiency indicators under labor, operational, engineering, personnel, and financial indicator. The relevance and appropriateness of each measure depends on the context of analysis and on data availability. For this research, data provided by ALSA which is the operator of bus services in both cases was used to estimate the indicators that will be presented in the following sections.

3.TERRITORIAL CONTEXT AND METHODOLOGY

3.1 Study cases and data sources

Despite their geographic proximity Spain and Morocco have considerable economical and cultural differences. A clear prove is their GDP, while Morocco´s GDP per capita is around 2.650 euros, Spanish GDP per capita is almost ten times higher reaching 24.500 euros.

This difference translated to transport is observed in their motorisation rates. By 2019 Spain had 513 vehicles each 1.000 inhabitants, while Morocco only 105.

For this research, Oviedo´s and Tangier´s bus networks were defined as case studies since both can be considered medium-size cities in their countries and have the same operator (ALSA) which ensures the availability of comparable data. The difference in context and countries reality of the two networks was considered of interest to be able to design policy-packages that include measures that can be transferable to other cities with similar characteristics but different contexts.

The municipality of Oviedo with a population of 220,000 inhabitants (INE 2019) is the capital of the region of Asturias, located in the north of Spain.

The Oviedo Metropolitan Area is composed of the core city and several parishes around, which are between 4 and 12 km away from the city.

The modal share is 66.4% for walking and biking, 24.1% for car and motorcycling and only 8.5% for public transport (Observatorio de la Movilidad Metropolitana, 2019).

Public Transport Authority of Asturias plans the urban bus network and Transportes Urbanos de Asturias (TUA) operates it under an administrative concession. In 2019 the total ridership was approximately 12.0 million.
The urban bus network of Oviedo has 15 daytime lines and 1 night-time line with a fleet of 67 buses to cover the service. Seven of the daytime lines run along the city and transport 90% of the users, while the other 8 lines connect the city with the parishes and carry the remaining 10% of demand.

Tangier, the capital of Tangier-Assilah Prefecture, has a population of 943,817 inhabitants (Haut-Commissariat au Plan, HCP). It is the most important prefecture in the Tangier-Tetouan-Al Hoceima region in Morocco. and is divided into three urban communes and nine rural communes.

Currently Tangier´s public transport network is covered by the urban and metropolitan bus network operated by ALSA. Tangier´s network is made up of 44 routes grouped in 27 urban and 17 rural lines. It had a total ridership of 40.3 million in 2019, from which 40 million of passengers used the urban lines. Although a feasibility study was carried out in 2015 for the construction of a tram network, following the examples of Rabat and Casablanca, no progress has yet been made on this issue.

To perform the performance analysis of this research, aggregated monthly data for all the lines in both networks have been gathered. Lines G, U and V from Oviedo, and 27 and 30 from Tangier were not considered due to unavailability of full data. Since they are recently incorporated lines, their performance does not affect the quality of this study.

Data has been obtained from different sources according to its nature:

- Urban area, route layouts and bus stops were downloaded from TUA and ALSA website.
- Monthly bus supply and demand variables were provided by ALSA, the operator of both networks.

Figure 1 presents the bus networks of Oviedo and Tangier which performance will be analysed in the following sections.

a) b)

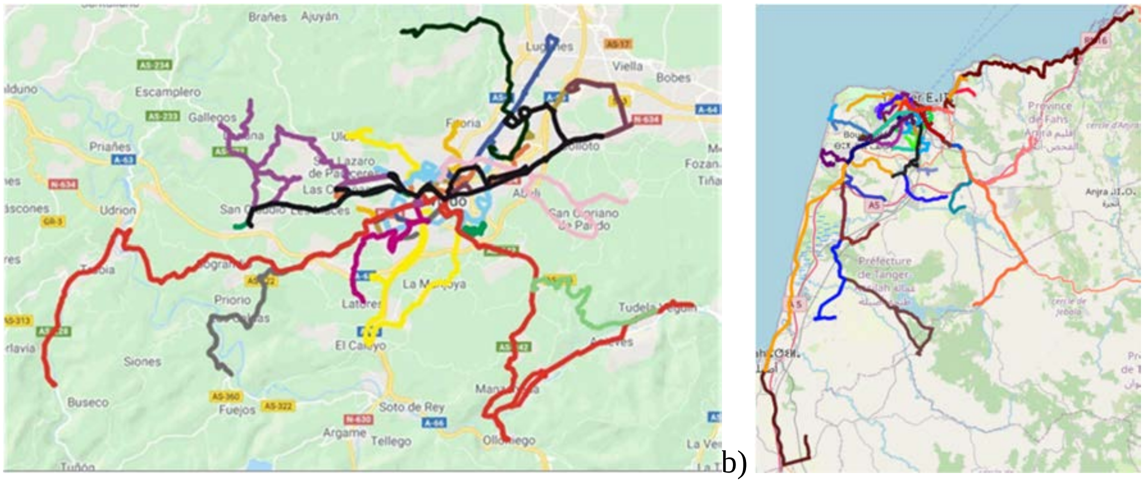

Figure 1 a) Oviedo's and b) Tangier´s bus network

3.2 Oviedo´s and Tangier´s network´s performance indicators

In order to evaluate the performance of the bus service of Oviedo and Tangier, and based on the data availability for each network, the service efficiency was estimated through the analysis of KPIs grouped in five categories. Fleet, supply, and accessibility (inputs) and quality and operational performance (outputs) presented in figure 2. These indicators take into account both users´ and operator´s perspective.

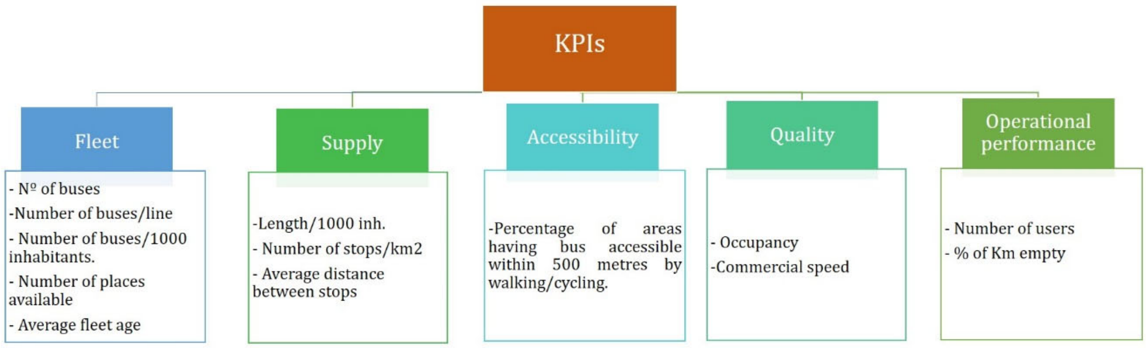

Figure 2 System efficiency indicators considered.

3.2.1 Fleet

One of the most important factors of quality and level of service of public transport is the availability of adequate infrastructure, including road and vehicle infrastructure. In both Oviedo and Tangier, road availability is not a key issue influencing the performance of the bus networks considered in the present research so no further analysis would be conducted.

On the other hand, vehicle infrastructure determines the capacity and speed of the bus. Number of spaces/vehicles offered on the line at a given time would influence on the comfort of the passengers specially on peak hours when the bus occupation is higher. Table 1 presents the details of bus infrastructure for both cases considered.

The most common bus configuration reflects the number of places available for people sitting, the number of places for people standing, and the number of places available for people with reduced mobility (RMP). It can be seen that Tangier´s most common bus configuration does not have places for people with reduced mobility. However, other bus configurations available on its fleet do.

Case	Most common bus configuration	Nº buses	Nº Buses/ line	Nº buses/1000 inhabitants	Nº places available/1000 inhabitants		
					Sitting	Standing	Reduced mobility
Oviedo	25+66vp+2rm+D	67	4.19	0.3	9.55	25.50	0.59
Tangier	33+62vp+D	190	4.32	0.2	6.70	11.08	0.10

Table 1 Vehicle data of both networks

The number of buses required per 1,000 population will depend on the public transport mode share, the presence or otherwise rail or other public transport modes, the capacity of the buses and the extent to which they may be utilized in terms of daily kilometres per bus.

With so many variables involved, the minimum requirement varies considerably from city to city, but typically lies between 0.5 and 1.2 buses per 1,000 population (Public-Private Infrastructure Advisory Facility- World Bank). Considering that in Oviedo and Tangier buses are the main public transport system, table 1 shows that both fleets have less buses than the required ones to fulfil the population needs properly. It can also be seen that, although the fleet sizes of the two cases are considerably different, they present a very similar number of buses available for each line. However, the number of places available each 1,000 inhabitants shows that Oviedo´s network has almost the doble of vehicle infrastructure for its population compared to Tangier.

3.2.1.1 Average fleet age

The average vehicle age is a useful indicator of the status of the fleet. If the fleet has an even age profile, the average age of the fleet will be approximately half the age of the oldest vehicle. An acceptable average age depends on factors such as the types of vehicles operated, levels of utilization and operating conditions, and is sometimes influenced by legislation, for example, in some countries the operation of the buses over a certain age is not permitted.

A high average age may be because high standards of maintenance enable vehicles to be successfully operated over a long life, but more often it is because there are not sufficient funds available for fleet replacement (more frequently in developing countries). For a reasonable well-maintained fleet of premium quality vehicles operating on urban services in developing countries, the average fleet age would typically be between five and eight years, being stricter in developed countries.

The average fleet age of Oviedo is 5.3 years with the newest bus having less than 1.5 years and the oldest one around 8.5 years. In the case of Tangier, the average age of the fleet is around 5.2 years with the newest having less than 2 years and the oldest around 6.5 years.

3.2.2 Supply

Supply refers to the presence of a public transport network or mode in an area/locality. There are several indicators that represent the supply of a transport system. The indicators considered for the present work are:

3.2.2.1 Length/1000 inhabitants

Network coverage measures use data that are generally already registered by the operator and thus are easier to calculate, however, they generally provide more macroscopic results that can be misleading at first glance.

Table 2 presents the length of the two networks, together with the network length every 1,000 inhabitants. The results show that despite the fact that Tangiers network is more than 4 times longer than Oviedo´s network, the length of network available every 1,000 inhabitants is 60% higher in Oviedo.

3.2.2.2Number of stops

Bus stops represent user´s access to the service. Table 2 shows that Oviedo´s network has a total of 273 stops while Tangier´s network has 386 stops over its entire length. Analysing the geographical distribution of the stops there is a similar number of stops every square kilometre in both networks (1.46 and 1.28 respectively). However, Oviedo´s network has triple the number of stops per 1,000 inhabitants than Tangier.

<table>
<tr><th rowspan="2">Case</th><th colspan="3">Network length (km)</th><th rowspan="2">Network length/ 1000 inh.</th><th rowspan="2">Nº of stops</th><th colspan="2">Nº of stops</th><th colspan="2">Average distance between stops (km)</th></tr>
<tr><th>Rural length</th><th>Urban length</th><th>Total length</th><th>/km^2</th><th>/1000 inh.</th><th>Rural lines</th><th>Urban lines</th></tr>
<tr><td>Oviedo</td><td>115.7</td><td>80.01</td><td>195.71</td><td>0,81</td><td>273</td><td>1.46</td><td>1.24</td><td>0.86</td><td>0.59</td></tr>
<tr><td>Tangier</td><td>313.4</td><td>481.6</td><td>767.2</td><td>0,5</td><td>386</td><td>1.28</td><td>0.41</td><td>1.14</td><td>0.58</td></tr>
</table>

Table 2 Supply indicators

3.2.2.3 Average distance between stops

The average spacing between stops must find a balance between cost and journey time.

This last one includes the passenger´s walking time, waiting time, boarding time, in vehicle time, alighting time and walking to destination time. It is important to notice that in the case or urban lines, at first sight, very small spacing could seem more comfortable for the user, however, it produces an increase in the total time, since each passenger journey would be interrupted by numerous intermediate stops. On the other hand, more spaced stops make the journey faster, but forces the users to walk longer distances to reach the bus. An acceptable distance between stops rounds 500 meters.

Table 2 shows that urban lines of both networks are quite close to this recommendation (580 and 590 metres for Oviedo and Tangier). On the other hand, and as expected, rural lines have longer distances between stops, which is completely normal due to density in the areas covered by these lines.

3.2.3 Accessibility

The accessibility of a transport system is the ability to reach the mode (bus in this case) within a reasonable time period, by a reasonable path (unobstructed infrastructure) and presence of information systems to access to the stop.

It can be expressed as a percentage of areas having a stop of public transport accessible within 500 metres by walking/cycling and walkability in areas being served by bus system (Abreha, 2007).

Table 3 presents the percentage of area of Oviedo and Tangier that has access to bus service within 500 metres. As can be seen, Oviedo has lower accessibility to bus service within this distance compared to Tangier.

City	(%) Area covered by the service
Oviedo	44
Tangier	54

Table 3. Oviedo´s and Tangier´s accessibility to bus service

Regarding the availability of user information. None of the networks has real time information on the bus stops, this fact has been identified as one of the most important issues to solve to improve users ´perception of the service quality.

3.2.4 Quality

The quality of the service is related to the comfort of the service offer during travel/ride. To analyse the quality of the service in the two cases studied, the bus occupancy and average commercial speed were considered.

3.2.4.1 Bus Occupancy

The standard bus size in Oviedo has 25 seats and takes 66 further standing passengers, while the standard bus in Tangier has 33 seats and takes 62 standing passengers. The capture ratio of the buses in the different lines of the two networks are presented in figure 3.

This ratio shows the average occupancy of the buses and was estimated by dividing the total number of passengers of each line by the number of buses that provided the service to that line.

The red line in the figures presents the seats available in a standard bus of each fleet. Figure 3 a) and b) shows that almost all urban lines in both networks have all their seats occupied most of the time which can influence the quality and comfort perception of the user. It is also possible to observe that the occupancy of line 20 in Tangier´s network is close to the full capacity of the bus including seating and standing passengers. On the other hand, lines like B in Oviedo´s network and L4, L13 and L23 in Tangier´s network register really low occupancy (below half the seating capacity of the average bus of their fleet) showing that they could be optimized.

Regarding rural lines, figure 3 c) and d) shows an irregular occupancy in Oviedo´s lines, with line L registering a capture ratio 40% higher than the seating capacity of an average bus, while line K registers an average capture ratio of only 4 passengers. Tangier´s lines present less pronounced differences between them; however, it is also possible to see lines with really high and really low occupancy levels (LI9 and LI7 respectively).

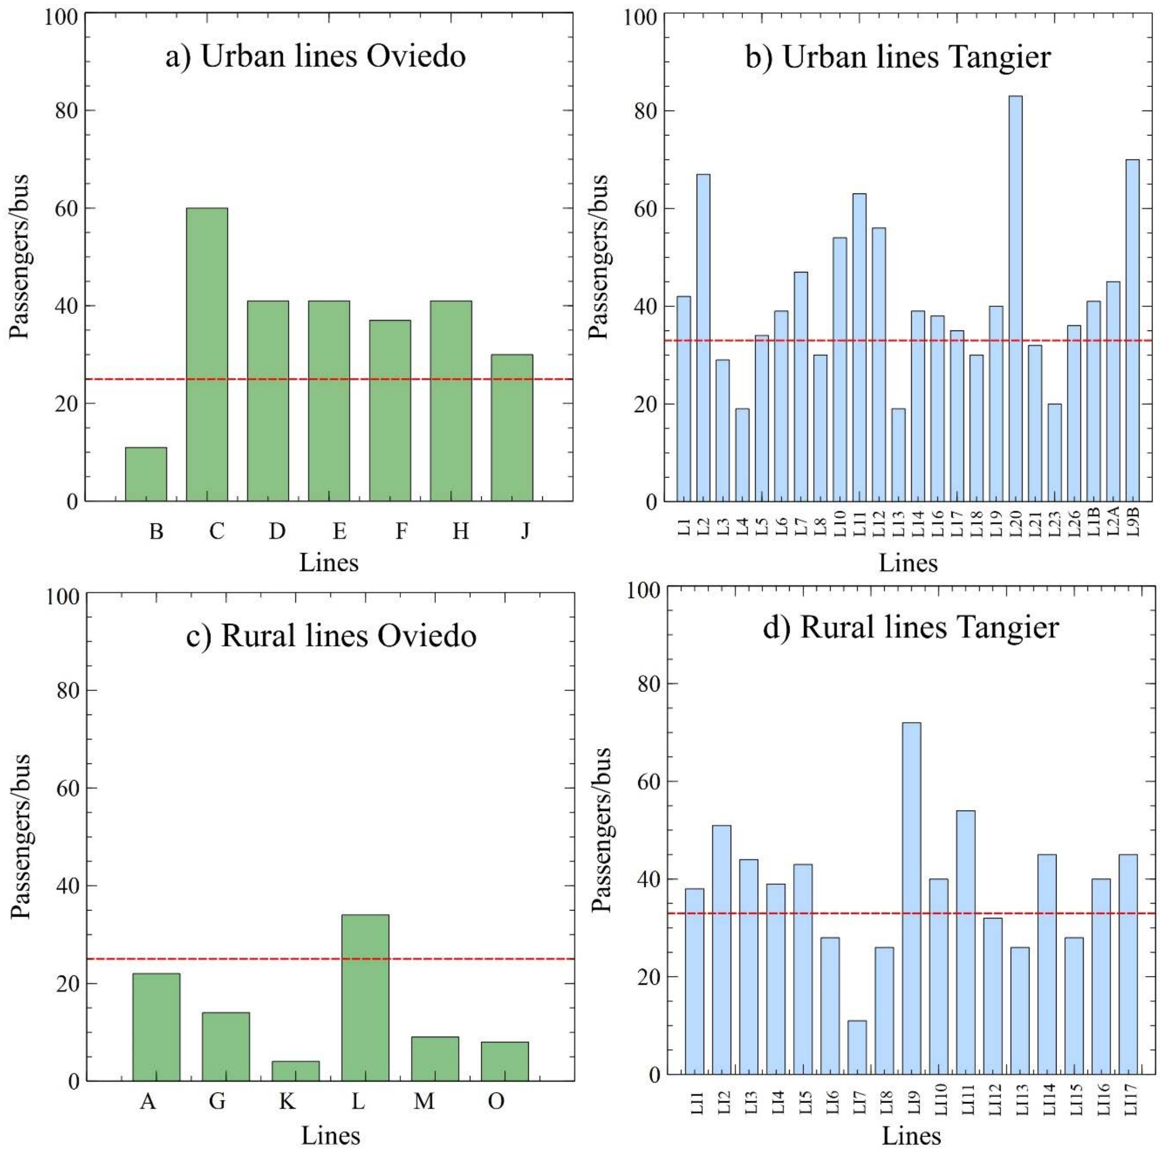

Figure 3 Capture ratio of urban lines a), b) and rural lines c), d)

3.2.4.2 Commercial speed

The bus operating speed is influenced by vehicle and alignment speed, as well as by stopping at passenger stops and traffic conditions. In this case, the average operating speed of bus travel along bus route was estimated dividing the total number of kilometres by the number of hours the bus was on service. Figure 4 presents the speed of all the lines of the two bus networks analysed (Oviedo and Tangier) and the average speed of each typology (urban and rural). It is possible to see that most of the lines with except of line B in Oviedo´s network have a commercial speed higher than 10-12 kph which according to Armstrong-Wrigth and Sebastian (1987) is the recommend minimum speed at which public bus systems should operate in dense areas with mixed traffic.

Figure 4 also shows a clear difference in the average speed of the lines depending on its category (urban or rural) as expected rural lines register higher average speeds due to traffic conditions and higher distances between stops in this typology.

For both categories, average commercial speed in Oviedo is lower than in Tangier.

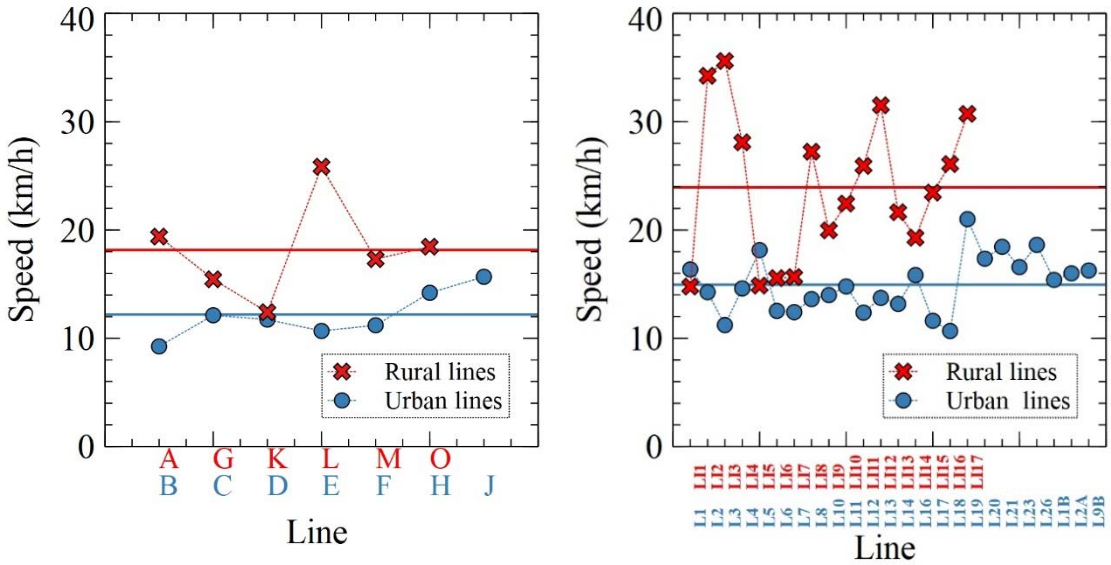

Figure 4 Commercial speed of the different lines of the networks.

3.2.5 Operational performance

To optimize the operational performance of the network is a major interest for the operator in order to get the highest profit offering at the same time a good service to the users. Three different KPIs were considered to determine the operational performance of the two networks:

3.2.5.1 Average users per month

The number of passengers per month of the different lines of the bus network is one of the most important data to take into account when analysing its performance. It allows the comparison among the lines of the network and helps to identify the ones that are beyond the average. Figure 5 a) and b) presents the average number of passengers registered per month in 2019 for the urban lines for Oviedo´s and Tangier´s networks. Although a uniform distribution of the number of passengers would be optimum, figure 6 a) and b) shows a considerable difference between the lines with the highest and the lines with the lowest ridership in the two networks. In fact, both networks have one special line (C in Oviedo and 20 in Tangier) that registers 2 and 5 times the average of passengers of the network, respectively.

Figure 5 shows that the highest ridership in Tangier´s network is almost three times the one of Oviedo. Despite the multiple differences between the urban lines of the two networks observed in figure 5, it is possible to observe that both register an average of 125,000 users per month.

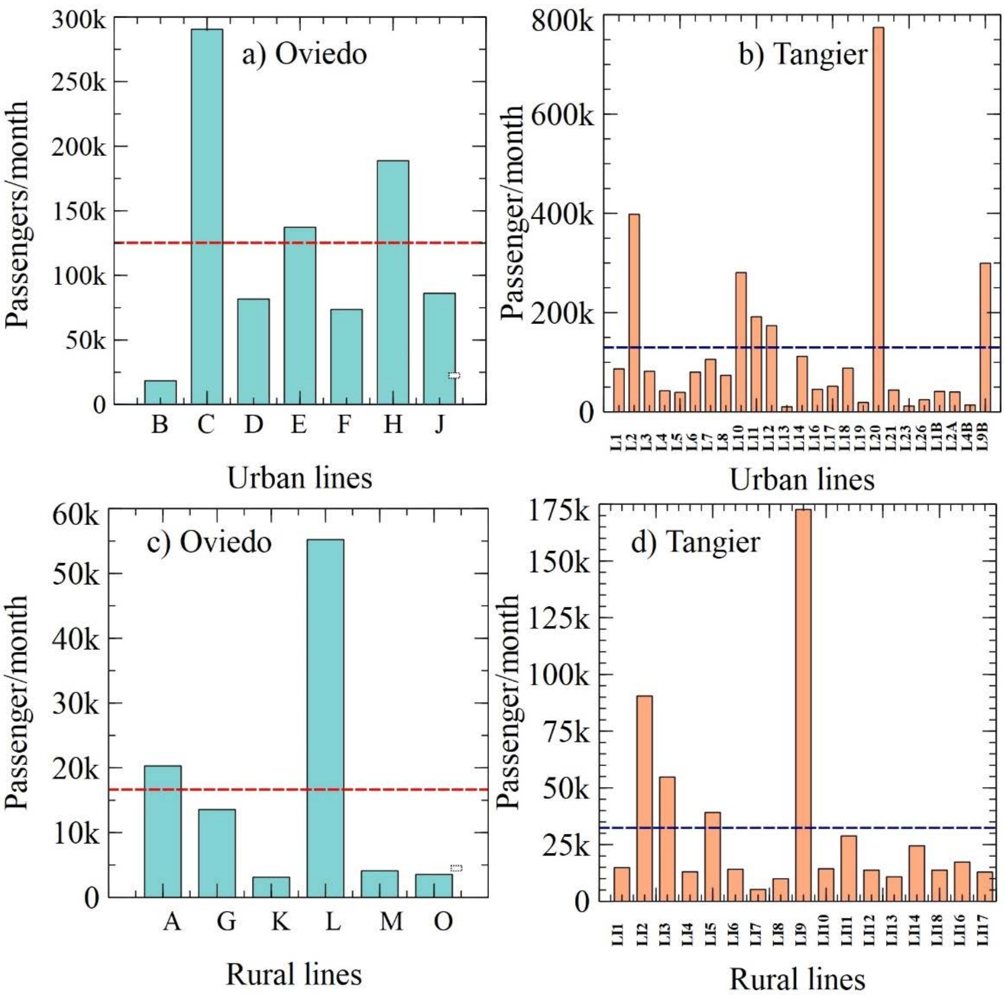

Figure 5. Average number of passengers urban lines a), b) and rural lines c), d)

With respect to rural lines, the same behaviour is observed, one line of each network hoards the passengers of the network. However, the average of users for this typology differs, Tangier´s rural lines have an average of passengers 80% higher than Oviedo´s lines.

3.2.5.2 Percentage of kilometres empty

This parameter presents the number of kilometres during the service in which the bus is empty, when it is not performing passenger transport service. This may be due to the routes to the fleet´s garages, to the service maintenance or because they are poorly planned. This is another very important factor to optimize the service of a bus line. The higher the percentage of empty kilometres, the worse the fleet operation will be, since empty trips are supposed to be journeys that in no case are generating any type of economic retribution for the operating company.

Figure 6 presents the percentage of kilometres empty of the urban and rural lines of the two networks.

Based on the operator's experience, values between 5 and 10% are considered acceptable for urban lines. In this research a limit of 10% was established for the entire network. It is possible to see that Oviedo´s network has no problems with the percentage of kilometres empty since all its lines have values lower than 10%. On the other hand, Tangier has 7 urban and 4 rural lines that exceed this value, so they should be deeper analysed to identify the causes and optimize their performance.

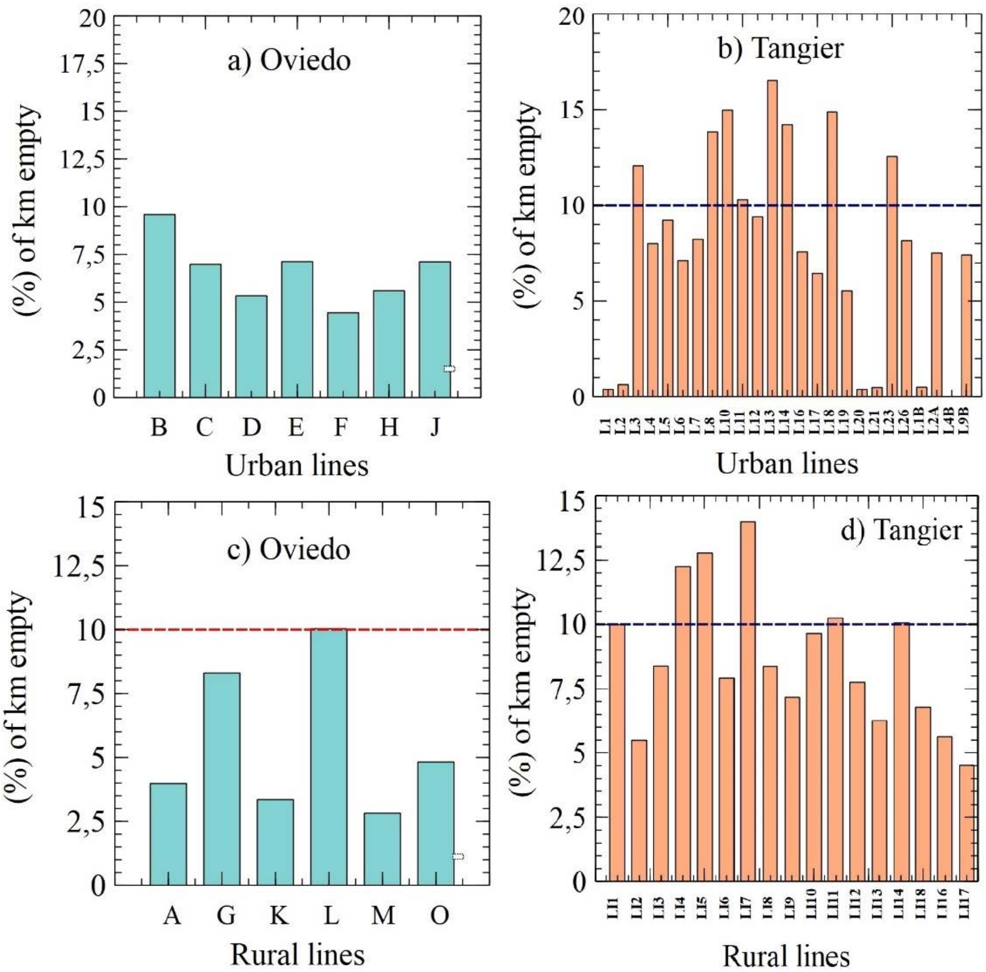

Figure 6. Percentage of kilometres empty for Oviedo´s and Tangier´s network.

3.2.5.3 Frequency

Frequency measures how often transit service is provided, either at a location or between two locations. The most commonly used measures are frequency (transit vehicles per hour) and its reciprocal headway (time interval between transit vehicles). Depending on the volume of transit vehicles and passengers moving through and stopping on a street, bus headways are recommended to be over 15 minutes for low volume, between 10-15 minutes for moderate volume, 2-6 minutes for high volume and combined headways under 2-3 minutes for very high volume (TCRP, 2003).

The average frequency of urban and rural lines is 21 and 65 minutes in Oviedo, and 33 and 120 minutes in Tangier respectively. As can be seen, the two networks analysed present higher headways than the recommended, which increases the passengers waiting time and makes them look for different transport alternatives.

4. OVERALL PERFORMANCE

The performance indicators presented in the previous sections, focused on specific aspects of the networks´ performance. In this approach, the indicators are readily measured and validated and are easy to interpret. However, there are two major drawbacks: they represent a partial indication of efficiency and they may provide conflicting message.

To estimate the overall performance of the two networks analysed, each of the indicators estimated in the previous section was compared with respect to efficient behaviour obtained from literature to identify the performance of each of the categories. As some of the variables are qualitative, the scores were given with personal judgment based on some characteristics.

Table 4 presents the summary of the qualitative evaluation of the two networks based on the values obtained for each of the KPIs estimated. Four different levels of efficiency were defined. Below poor (B.P.) when the system does not accomplish the minimum requirements, Poor to moderate (P-M) when the system satisfies the minimum requirements but there still is a lot to improve, Moderate to good when the performance is acceptable, and Above Good (A.G.) when there is no need to improve in any aspect.

Category		B.P.	P-M	M-G	A.G.
Infrastructure	Oviedo		P		
	Tangier		P		
Availability	Oviedo			P	
	Tangier		P		
Accesibility	Oviedo		P		
	Tangier			P	
Quality	Oviedo			P	
	Tangier		P		
Operational performance	Oviedo			P	
	Tangier		P		
Safety	Oviedo			P	
	Tangier			P	

Table 4 Qualitative summary of Oviedo´s and Tangier´s networks performance

Finally, as the scores given to the different categories of indicators are qualitative and subjective, a graphical technique was used to show the overall performance. Figure 7 presents the qualitative scores of all the categories studied in this analysis for the two networks analysed.

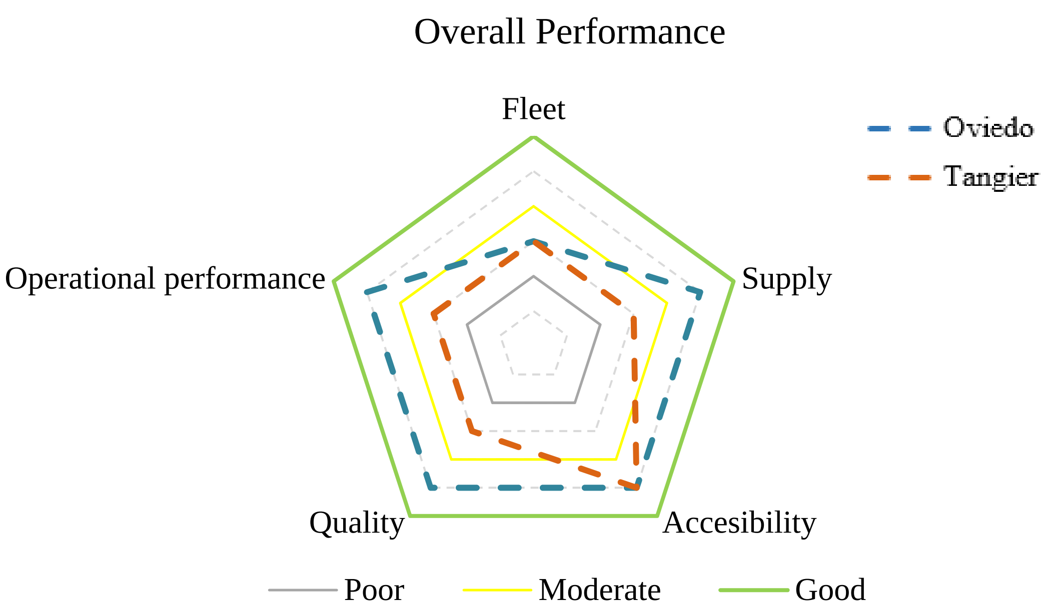

Figure 7 Overall performance of Oviedo´s and Tangier´s bus networks

5. CONCLUSIONS

This paper has aimed to realize a preliminary cross-case analysis of bus operation in different contexts, Oviedo (Spain) and Tangier (Morocco) through aggregated data provided by ALSA, the operator of both networks. Several indicators grouped into six main categories were estimated to evaluate the overall performance of the two networks operation. The results show gaps in the systems functioning that may be fixed through the implementation of some short-term solutions.

The infrastructure availability (mainly the vehicles of each network) can be considered insufficient to fulfil the needs of the population. According to the Public-Private Infrastructure Advisory Facility- World Bank, the ratio of buses per 1,000 inhabitants should be around 0.5 and 1.2 buses, but Oviedo has a ratio of 0.3 and Tangier of only 0.2.

This, together with the fact that in the two cities buses are the main public transport alternative, shows the need to increase the fleet of the networks. With respect to availability, Oviedo presents better indicators as higher frequencies and lower average distances between stops. Tangier´s network has higher distances between stops and really low frequencies existing lines where the buses pass every two hours, which is not comfortable for the users that end up looking for different transport alternatives.

Even though accessibility of both networks can be considered acceptable (more than 50% of the city has access to the bus service within 500 meters) it should be improved since one of the main characteristics and objectives of public transport, is to cover as much of the population as possible. Regarding the quality of the service provided, Oviedo´s network registers better quality indicators mainly due to its lower occupancy of the buses. The commercial speed of all the lines in the two networks meets the requirements of being at least 10-12 kph, and the average age of the fleet would never exceed the recommended limits due to contract conditions that force the operator to change the vehicles every certain number of years. Finally, based on accidents statistics and on the measures implemented by the operator (limited speed in Tangier and Speed control in Oviedo), both networks show a moderate to good safety in the service provided.

Oviedo´s network and services overall performance is better than Tangier´s. However, the problems identified through the analysis performed can be solve by implementing some changes in the network operation. Therefore, this work establishes the basis for two future works. The first one is to carry a quantitative analysis of the performance of the two networks including more data from other sources. The second one is aimed to propose a policy package to improve the performance of both networks according to each country´s reality.

ACKNOWLEDGMENTS
The authors wish to thank the Spanish Ministry of Science and Innovation (MCIU) and the State Research Agency (AEI) for the grant of the TrackBest-3S (RTC2019-007041-4) project from which this presentation comes.

RESUMEN

El objetivo del presente trabajo de investigación es estudiar los valores de eficiencia de una muestra de los doce principales puertos de contenedores del mundo junto con los puertos de Bahía de Algeciras, Valencia, Barcelona y Tanger Med (Lloyd's List, 2018) durante el periodo 2014 – 2018. Es importante realizar el análisis de comparación de estos cuatro puertos frente a los más importantes del mundo para ver el comportamiento de su eficiencia cuando forman parte de una muestra compuesta por el conjunto de las principales terminales de contenedores. En este estudio se aplica en primer lugar el Análisis Envolvente de Datos (DEA) con escalas retorno constante (CCR) y variable (BCC), con orientación input. En una segunda etapa aplicamos la metodología Bootstrap con el propósito de obtener la eficiencia corregida, además de los correspondientes intervalos de confianza para cada una de dichas eficiencias.

Los factores clave de competitividad portuaria, y que permiten a un puerto ser más eficiente, dependen del tipo de tráfico. Las variables elegidas, tanto inputs como output, dependen de la operativa y de ahí que las variables seleccionadas, de los puertos que conforman la muestra de nuestro análisis, influyen directamente en dicha operatividad.

Tras un riguroso y amplio análisis sobre las variables a emplear en estudios de eficiencia portuaria de los numerosos investigadores, gran número de autores han coincidido en el uso de la longitud de los muelles, sobre todo de los de calado superior a catorce metros, del número de grúas de muelle, y de la superficie de la terminal, como inputs.

Del mismo modo, muchos estudios optan por analizar dicha eficiencia tomando como dato de salida (outputs) el número de TEUs (Twenty Equivalent Units) manipulados.

Los puertos están en continuo avance, intentado automatizar las terminales que les sean posibles para así poder incrementar la eficiencia y ser más productivos, con el fin de mantenerse en el ranking de los principales puertos de contenedores del mundo. Este estudio tiene como objetivo analizar la eficiencia de los puertos seleccionados y comprobar en qué medida su eficiencia productiva corregida ha ido evolucionando a lo largo del periodo de los últimos 5 años.

Los resultados muestran que entre los puertos españoles el que presenta mayor eficiencia en los dos modelos estudiados es el puerto de Algeciras, que pese a tener menor volumen de equipamiento y capacidad que el puerto de Valencia. Otro puerto que presenta unos importantes valores de eficiencia es el puerto de Tánger, con resultados muy próximos a los puertos de Algeciras y Valencia. Tanger-Med está aumentando su número de contenedores manipulados progresivamente y en los próximos años se prevé que con las nuevas terminales dicho tráfico sea bastante más elevado, pudiendo ser una fuerte competencia para el puerto algecireño, debido también a la posición estratégica que presenta.

1. INTRODUCCIÓN

El transporte marítimo mundial ha ido experimentando en los últimos años un gran crecimiento. Desde 1985 viene aumentando de forma ininterrumpida y en el caso concreto del comercio marítimo en contenedor el desarrollo ha sido muy importante, debido también al gran incremento del tamaño de los buques, llegando a ser como uno de los pilares de la globalización.

Los puertos están adquiriendo cada vez más importancia en todo el mundo, ya que son centros de desarrollo económico y social y constituyen puntos de conexión esenciales entre el transporte marítimo y el terrestre. Debido a esto, la eficiencia de las actividades que se llevan a cabo en todo el recinto portuario es un factor de gran relevancia, para que la mercancía que es transportada por vía marítima pueda llegar a los distintos puntos finales de consumo, intentando que sea al menor coste y tiempo posible.

En cuanto al rendimiento de los puertos de contenedores, se ha ido incrementando continuamente desde los últimos diez años, aunque desde 2014 de manera más lenta que antes. En ese año, el transporte mundial de contenedores aumentó un 5,3 %, mientras que en 2015 tuvo un aumento menor, de un 2,3 %. Sin embargo, teniendo en cuenta algunos datos, se estima que en unos 30 años el volumen de transporte internacional pueda aumentar hasta cuatro veces más.

Después de que en los años 2015 y 2016 se produjeran aumentos moderados de volumen en los principales puertos de contenedores del mundo, en 2017 se registró un firme regreso a la trayectoria del crecimiento, tal y como lo muestra la edición de 2018 de la “Lloyd’s List’s One Hundred Container Ports”. Las instalaciones portuarias incrementaron el manejo de contenedores en 2017, representando un crecimiento del volumen de casi el 6% con respecto al año anterior, en el que fueron manipulados unos 700 millones de TEUs en los puertos de todo el mundo.

Con respecto al continente con la economía mejor conectada de la red marítima global en 2016 fue Asia. El dominio chino continúa teniendo un papel importante, ya que gran parte de sus puertos se siguen manteniendo entre los principales del mundo. En Europa destacan Rotterdam, Amberes y Hamburgo, encontrándose dentro de los veinte primeros puertos del mundo. Con respecto a España, los puertos de Algeciras y Valencia compiten por el primer puesto, estando en el listado de los 40 puertos más importantes del mundo. Con respecto al continente africano, el puerto que tiene mayor relevancia es el de Tánger.

El crecimiento económico mundial, que en 2016 registró la tasa más baja desde la crisis financiera mundial con un 3,2%, tuvo bastante fuerza en el año 2017. Hubo una reactivación de la inversión, del comercio internacional y de la producción industrial que fortaleció la recuperación, añadiéndose además la mejora de la confianza de las empresas y consumidores.

En el año 2017 los puertos asiáticos continúan siendo los más destacados, ya que sufrieron en ese año un notable aumento. El puerto de Shanghai (China) es actualmente el puerto más activo del mundo en relación al tráfico de contenedores. El puerto de Singapur está en segundo lugar, seguido del puerto de Shenzhen.

Con respecto al continente europeo el puerto más importante es el de Rotterdam, debido al gran volumen de contenedores que manipula, encontrándose en el listado de los 12 puertos más importantes del mundo.

Haciendo referencia al sistema portuario español en el año 2017, se han movido 15.992.613 TEUs, un 5,07% más que en 2016.

En el mundo existen entre 6000 y 7000 puertos, aunque solo unos pocos centenares tienen realmente una importancia en un contexto global, concentrando la mayor parte del tráfico marítimo. El objetivo del presente trabajo es estudiar la eficiencia técnica de un número determinado de puertos, los que manipulan las mayores cantidades de contenedores, junto con los puertos de Algeciras, Valencia, Barcelona y Tánger, empleando el Análisis Envolvente de Datos (DEA).

El método de Análisis Envolvente de Datos (DEA) es una técnica de programación matemática, no paramétrica y determinista, que permite establecer la estimación de fronteras de producción y evaluación de la eficiencia de un conjunto de muestras de unidades de producción o DMUs. En este tipo de análisis se calcula la eficiencia relativa para cada DMU comparando sus inputs y outputs (grupo de datos de entradas-salidas) respecto a todas las demás DMUs.

Dentro de esta metodología se puede diferenciar dos modelos básicos, como son el modelo DEA-CCR (Charnes, Cooper y Rhodes) y el modelo DEA-BCC (Banker, Charnes y Cooper), que son los modelos que se han empleado concretamente para este estudio.

Para el análisis de la eficiencia se han seleccionado los 12 puertos más importantes del mundo en relación con el tráfico de contenedores anualmente, como se ha dicho anteriormente, junto con los tres puertos más importantes de España, y con el puerto de Tánger. A continuación, se puede ver la clasificación de los puertos más importantes de los años 2017-2018 con su cantidad de TEUs, más los cuatro puertos citados (Tabla 1):

	Puerto	**TEUs 2017**	**TEUs 2018**	**Crecimiento 2017 – 2018**
1	Shanghai	40.233.000	42,010,200	+4.4%
2	Singapore	33.666.600	36,599,300	+8.9%
3	Shenzhen	25.208.700	25,740,000	+2.1%
4	Ningbo & Zhoushan	24.607.000	26,351,000	+7.1%
5	Hong Kong	20.770.000	19,596,000	-5.7%
6	Busan	20.493.475	21,663,000	+5.7%
7	Guangzhou	20.370.000	21,922,100	+7.6%
8	Qingdao	18.262.000	19,315,400	+5.8%
9	Dubai Port	15.368.000	14,954,000	-2.7%
10	Tianjin	15.040.000	15,972,000	+6.2%
11	Rotterdam	13.734.334	14,512,661	+5.7%
12	Port Klang	11.978.466	12,316,003	+2.8%
29	Valencia	4.779.749	5,128,855	+7.3%
34	Algeciras	4.389.836	4,773,079	+8.7%
46	Tánger Med	3.312.409	3,472,451	+4.8%
55	Barcelona	2.972.795	3,422,978	+15.1%

Tabla 1: Posición de los puertos en Lloyd’s List 2017-2018
Fuente: Lloyd’s List 2021

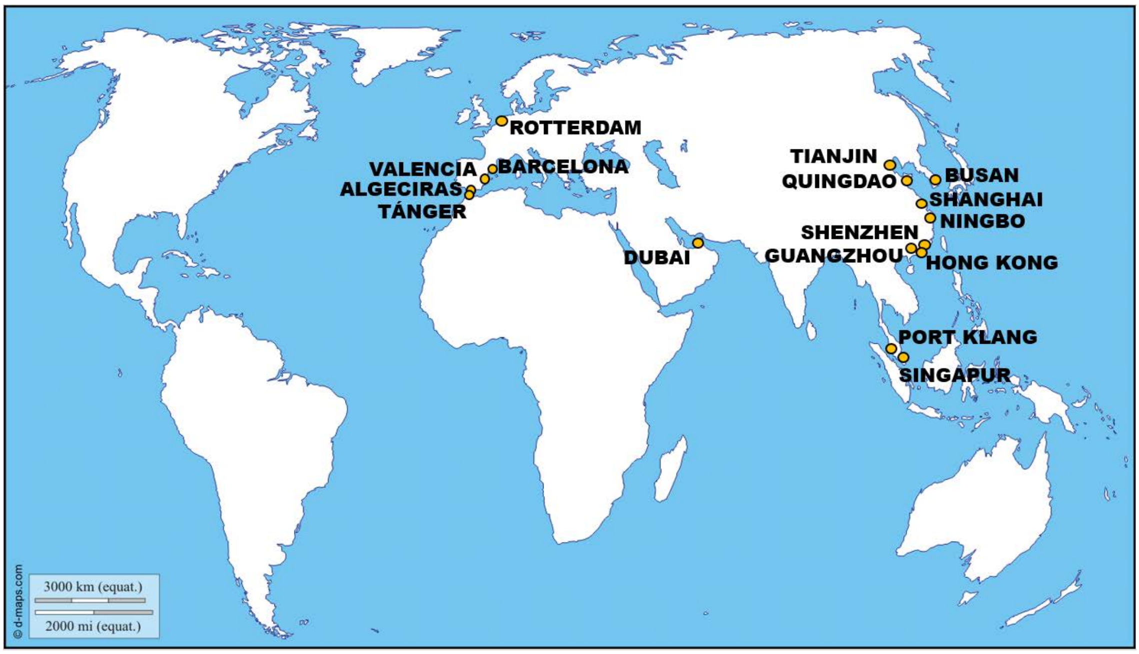

Figura 1. Puertos seleccionados para la elaboración del estudio.
Fuente: Elaboración propia.

Observando el gran número de contenedores que se manipulan en estos principales puertos y habiendo hecho referencia al volumen manipulado en el año anterior en todo el mundo, se entiende que el transporte marítimo por contenedor sea cada vez más importante y una de las principales vías para el desarrollo económico tanto a nivel regional, como nacional e internacional.

2. ESTADO DEL ARTE

La eficiencia portuaria es un tema que se ha ido estudiando a lo largo de los años. La metodología del Análisis Envolvente de Datos (DEA), ha sido tradicionalmente utilizada para la estimación de la eficiencia relativa de un conjunto de unidades productivas por numerosos autores y, en concreto, se ha empleado para estudiar diferentes aspectos de la actividad portuaria.

Farrell (1957) es considerado como el precursor en la medida de la eficiencia técnica, quien hace referencia a tres definiciones de eficiencia, tales como eficiencia técnica, eficiencia en precios y eficiencia global, que se construyen bajo el supuesto de una función de producción eficiente.

La tesis doctoral de Rhodes (1978), que se basó en el trabajo de Farrell (1957), plantea una programación matemática para la construcción de una frontera eficiente, para medir la eficiencia de las unidades evaluadas.

En un principio se contrastan solo entidades comparables, ya que el índice de eficiencia obtenido es relativo, por lo que se debe tener cuidado al definir la unidad de análisis (DMU) y las entradas que a través del proceso se transforman en salidas.

Hay una generación de estudios basada en medidas formales de eficiencia, que tiene como fuente el trabajo de Chang (1978), que se considera como el principio en la estimación de las funciones de producción en el sector portuario. Sin embargo, en los años siguientes no se desarrolla esta línea de investigación y destaca el uso de indicadores.

Dentro de la metodología no paramétrica DEA, los modelos más utilizados para su aplicación son los propuestos por Banker et al. (1984), que admite retornos variables de escala (BCC) y por Charnes et al. (1978), que asume retornos constantes de escala (CCR).
Martínez-Budría et al. (1999) y Pestana (2003) recurren al modelo BCC para las economías de escala y, por otro lado, Bonilla et al. (2002) y Tongzon (2001) utilizan el CCR. Ambos modelos son empleados y comparados por Cullinane et al. (2004), Park y De (2004), Pestana y Athannasiou (2004) y Cullinane et al. (2005).

A mediados de la década de los 90 la literatura sobre eficiencia, que ya se había aplicado a numerosas industrias, se introduce en el sector portuario. Los diferentes enfoques indican un desacuerdo para establecer el método que mejor pueda analizar este sector.

Cullinane et al (2002) analizan la estructura administrativa y de propiedad de las terminales de los 15 principales puertos de contenedores de Asia. Otro estudio que se centra en la relación que existe entre tipo de propiedad y eficiencia es el de Liu (1995), en su análisis se refiere a los puertos británicos, ya que en ellos coexisten varios tipos de propiedad.

Tongzon y Heng (2005) investigan si la privatización portuaria mejora la posición competitiva de los puertos. Para ello miden la eficiencia de terminales portuarias internacionales y estudian la relación que existe entre la eficiencia medida y la estructura de propiedad de las terminales. Cullinane y Song (2003) también analizan la relación entre la estructura de propiedad y eficiencia, siendo este objetivo compartido por Cullinane et al. (2005-a), pero con una muestra internacional de terminales portuarias.

Bichou (2012) realizó un análisis de eficiencia de 420 terminales de contenedores entre los años 2004-2010 a partir de los modelos DEA-CCR y DEA-BCC y, además, analizó la eficiencia de 10 terminales de contenedores con ambos modelos durante el período 2002-2008.

Notteboom et al. (2000) tenía como finalidad analizar la eficiencia de las terminales de contenedores más importantes de Europa, comparándolas con las cuatro terminales más grandes asiáticas.

Una vez tenidos los resultados, investigan los efectos que tienen algunos factores pudiendo afectar a la eficiencia de las operaciones (terminales grandes-pequeñas; puertos hub-feeder; privadas-públicas; norte de Europa-sur europeo).

El objetivo de Pestana (2003) es estudiar si los incentivos que se han introducido por la regulación portuguesa han aumentado la eficiencia. Haciendo uso del análisis DEA, se comprueba la eficiencia de cinco autoridades portuarias portuguesas (1999-2000). A partir de esto, Pestana y Athanassiou (2004) establecen un listado de autoridades portuguesas y griegas, cuyo objetivo es la detección de puertos que son capaces de ofrecer mejoras en su rendimiento dentro de los objetivos de la política portuaria europea.

Martín (2002) centra su estudio en las consecuencias que las reformas del sistema portuario español han tenido sobre la eficiencia y productividad. Para esta evaluación aplica un DEA a las 27 autoridades portuarias españolas (1990-1999).

González (2004) hace un análisis del impacto que tienen algunos factores en el entorno en que operan las principales autoridades portuarias españolas respecto al tráfico de contenedores.

El sistema portuario español es objeto de estudio de otros trabajos como Coto-Millán et al. (2000) que hacen un análisis de la eficiencia económica de las 27 autoridades portuarias en los años 1985-1989 a partir de una frontera de costes.

Martínez-Budría et al. (1999) emplean un DEA a 26 autoridades portuarias (1993-1997), con el fin de analizar su eficiencia. Hacen una comparación separando las autoridades portuarias en cuatro categorías, atendiendo a su dificultad. Bonilla et al. (2002) hacen un estudio con la misma finalidad, con la diferencia que son 23 autoridades portuarias durante los años 1995-1998.

El propósito de Tongzon (2001) es comparar la eficiencia de puertos internacionales de contenedores. Aplica un DEA para obtener los índices de eficiencia de cuatro puertos australianos, que compara con otros 12 puertos internacionales.

Roll y Hayuth (1993) intentan verificar que este método es útil para medir la eficiencia portuaria y la utilidad de los índices de eficiencia con el objetivo de mejorarla y así controlar la actividad de los operadores.

Como algunos estudios más recientes pueden destacar el de Gil Ropero et al. (2015) donde se hace un análisis de la eficiencia de 13 puertos españoles con mayor tráfico de contenedores aplicando DEA durante el período 2008-2011.

Camarero et al. (2016) que, a partir de una serie de indicadores caracterizadores de la actividad portuaria, clasifica los puertos españoles, o Ruiz Aguilar et al. (2016) en cuyo trabajo estudia predecir situaciones de congestión en el tráfico de mercancías, aplicándolo al Puerto de Algeciras.

En base a esto, se puede comprobar que la metodología DEA ha sido empleada por muchos autores a lo largo de los años. En sus estudios relacionados con el sector portuario, aplican este método para poder obtener la eficiencia y ver así la productividad de los puertos o terminales portuarias.

En la amplia revisión bibliográfica enfocada a los artículos que aplican la metodología Bootstrap, Barros et al. analizaron la eficiencia de una muestra representativa de los puertos africanos, durante el período 2004-2006, utilizando un enfoque DEA Bootstrap. Barros et al. (2012) en su estudio nos apuntan que en cuanto al análisis de la productividad y eficiencia portuaria en Brasil entre los años 2004 al 2010, se han utilizados dos técnicas DEA: paramétricas y no paramétricas, obteniendo como resultados que los puertos tuvieron una menor productividad en la eficiencia y reducción de los cambios tecnológicos. En este análisis, nos mencionan que DEA ha identificado las unidades ineficientes, tal como lejanía del puerto, falta de inversión y prácticas de gestión inadecuadas. Indican también que los puertos brasileños, que necesitan mejorar su producción, deberían enfocarse en la mejora de los procedimientos de inversión y nuevos métodos que aumenten el cambio tecnológico. Munisamy y Danxia (2013) analizan a través de la técnica Bootstrap la eficiencia de una manera más fiable a 69 principales puertos asiáticos. Se logró determinar que el 48% de los puertos de contenedores podrían ser considerados para una expansión con acuerdos de cooperación, mientras que el 35% de los puertos deberían considerar la mejora de sus eficiencias por medio de la mejora de sus operaciones.

Uno de los últimos artículos publicados sobre el análisis Bootstrap se ha realizado por Nguyen et al. (2015) que evaluaron la eficiencia de los 43 puertos más grandes de Vietnam. El análisis solucionó la sobreestimación de los índices de eficiencia generados por el DEA tradicional por medio de la técnica Bootstrap, pero a su vez conservando las ventajas del DEA. Wanke y Barros (2006) analizaron la eficiencia de 27 puertos principales de Brasil entre 2007 y 2011, a través de la técnica Bootstrap, utilizando varias estimaciones de DEA. Los resultados arrojaron un grado de deficiencia en la capacidad de dichos puertos, con respecto a las tareas que realizan, pero a su vez demostró tres impactos positivos: a) infraestructura de conectividad en los niveles de eficiencia de escala; b) la administración privada en los niveles de eficiencia de gestión; c) los niveles de eficiencia técnica más altas en los costes de manipulación y gestión en los tiempos de espera. Y más recientemente, Gil Ropero et al. (2018) propusieron un enfoque basado en DEA Bootstrap para evaluar la eficiencia de 16 puertos de la Península Ibérica (España y Portugal).

Este artículo es uno de los primeros estudios en aplicar Bootstrap para medir la eficiencia portuaria en el contexto del caso de España y Portugal. El documento proporciona información útil sobre la aplicación de un DEA Bootstrap como herramienta de modelado y como apoyo para ayudar a la toma de decisiones en la medición de la eficiencia del puerto.

3. OBJETIVOS

El objetivo de este trabajo es la aplicación del Análisis Envolvente de Datos (DEA), que propone la resolución de un programa lineal para cada unidad productiva o DMU observada. Optimiza cada observación individual con el fin de ver la eficiencia de cada puerto estudiado a partir de los datos que se han introducido en el análisis, como son una serie de variables de entrada o inputs y una o varias variables de salida u outputs, y así poder comprobar cuáles son los puertos más eficientes y establecer una comparación entre unos y otros.

En el caso de este estudio, se han establecido como variables de entrada o inputs las siguientes:

- La longitud de los muelles expresada en metros lineales, que es uno de los factores más representativos que tiene un organismo portuario, teniendo como condición en que el calado de los muelles sea mayor de 14 metros.
- El número de grúas muelles que tiene cada entidad portuaria a estudiar, siendo una variable de entrada importante a tener en cuenta.
- La superficie terrestre expresada en metros cuadrados, que viene relacionada con la capacidad que tiene cada terminal portuaria.

Y en cuanto a las variables de salida u outputs, se han considerado el número de contenedores anuales del período 2014-2016 que son manipulados en cada uno de los puertos del estudio.

4. METODOLOGÍA

La eficiencia es uno de los conceptos más importantes en la medición del desempeño. La eficiencia de un puerto, en el desarrollo de su actividad, está relacionada con la utilización de los recursos disponibles. De este modo, desde un punto de vista productivo, la eficiencia trata de describir el proceso de producción que emplea de forma óptima sus recursos, según la tecnología existente. Esta eficiencia en producción ese la conoce como eficiencia técnica.

Para la medición de la eficiencia destacan dos metodologías como son del Análisis Envolvente de Datos (DEA) y del Análisis de frontera estocástica (SFA).

El modelo SFA fue desarrollado por Aigner, Lovell y Schmidt (1977) y Meeusen y Van Den Broeck (1977), quienes exponen el concepto de frontera estocástica, a partir de la que se fundamenta la metodología del estudio sobre eficiencia, en la que se toma como origen la función de comportamiento eficiente, siendo de producción, de costos o de beneficios, según el caso a estudiar.

La metodología DEA, que es la que se ha optado mejor para utilizar en este análisis, se trata de una técnica de programación matemática, no paramétrica, basada en el trabajo seminal de Farrel y que fue propuesta formalmente por Charnes et al. (1978) y se ha seguido empleando a lo largo de los años. Esta metodología permite hacer una evaluación de la eficiencia de un grupo concreto de elementos (puertos, en el caso de este trabajo) a partir de la identificación de una frontera que incluye las que han obtenido el resultado más eficiente. Esta frontera eficiente revela una tecnología de referencia que se elabora a partir de los inputs y outputs de las observaciones de la muestra.

El conjunto de elementos mencionados anteriormente se conoce como unidades de toma de decisión (DMU: Decision Making Unit), utilizándose para hacer la evaluación de entradas y salidas para cada una de las DMUs que se consideren. Estas deben ser comparables, es decir, tanto las entradas como las salidas deben poder medirse en unidades homogéneas para todas ellas. La eficiencia de cualquier DMU siempre será menor o igual que la unidad, siendo aquella que tenga el valor de la eficiencia igual a uno la que se considera eficiente.

Aunque existen múltiples modelos DEA, estos se pueden dividir principalmente en dos alternativas como son la de retornos constantes a escala (DEA-CCR) y de retorno de escala variable (DEA-BCC). Los primeros miden la eficiencia puramente técnica y la ineficiencia de escala, mientras que los segundos solo evalúan la eficiencia puramente técnica. A su vez, cada uno de estos modelos puede tener orientación de entrada (input) o de salida (output).

4.1 Análisis Envolvente de Datos (DEA)

La utilización de la metodología no paramétrica DEA permite cuantificar una medida de eficiencia individual para cada una de las observaciones de la muestra a partir de su distancia respecto a la frontera de eficiencia. Esta frontera refleja una tecnología de referencia que se elabora a partir de los inputs y outputs de las observaciones de la muestra.

En el modelo inicial de Charnes et al. (1978), la medida de eficiencia es la razón entre el sumatorio ponderado de entradas y salidas de cada DMU, con la restricción de que este índice debe ser positivo y menor que la unidad.

En cuanto al modelo DEA-CCR fue el primer modelo DEA desarrollado y recibe el nombre por los que lo llevaron a cabo que fueron Charnes, Cooper y Rhodes (1978).

También se le conoce como modelo CRS o de rendimiento de escala constante.

Se emplea cuando las DMU a evaluar presentan rendimientos constantes a escala tanto para las entradas como para las salidas.

La fórmula orientada a las entradas se puede formular así:

$$Max \qquad h_0 = \sum_{r=1}^{s} u_r y_{r0} \tag{1}$$

Sujeto a:

$$\sum_{i=1}^{m} v_i x_{i0} = 1 \ ; \tag{2}$$

$$\sum_{r=1}^{s} u_r y_{rj} - \sum_{i=1}^{m} v_i x_{ij} \leq 0 \quad \forall j \tag{3}$$

$$u_r; v_i \geq \varepsilon \quad \forall \, r, i \tag{4}$$

Siendo:

j= 1,2,3,…,n

$x_{ij}(x_{ij} \geq 0)$ como la cantidad de entrada i (i= 1,2,3,…,m), consumida por la j-ésima DMU.

$y_{rj}(y_{rj} \geq 0)$ como la cantidad de entrada r (r= 1,2,3,…,s), consumida por la j-ésima DMU.

x_{i0} la cantidad de entrada consumida por la DMU_0.

y_{r0} la cantidad de salida producida por la DMU_0.

Unidad evaluada, *Unidad*$_0$.

u_r y (r= 1,2,3,…,s), v_i (i=1,2,3,…,m) representan los pesos o multiplicadores de salidas y entradas.

La siguiente formulación está orientada a la entrada, una DMU se considera eficiente si cumple dos condiciones: que el valor de θ_0 sea igual a uno y que las variables S^- y S^+ sean cero, en caso contrario la DMU se considera ineficiente.

$$Min \quad \theta_0 - \varepsilon(\sum_{r=1}^{s} S_r^+ + \sum_{i=1}^{m} S_i^-) \tag{5}$$

Sujeto a:

$$\sum_{j=1}^{n} \lambda_j x_{ij} + S_i^- = \theta_0 x_{i0}; \quad \forall \, i \tag{6}$$

$$\sum_{j=1}^{n} \lambda_j y_{rj} - S_r^+ = y_{r0}; \quad \forall \, r \tag{7}$$

$$\lambda_j, S_i^-, S_r^+ \geq 0 \ ; \quad \forall j \tag{8}$$

Donde:

θ es la eficiencia técnica de la DMU_0
λ es el vector de intensidades (nx1)
S^- es el vector de holgura de las entradas
S^+ es el vector de holgura de las entradas

Para la formulación orientada a las salidas se plantea matemáticamente de la siguiente forma:

$$Max \quad \gamma_0 + \varepsilon(\sum_{r=1}^{s} S_r^+ + \sum_{i=1}^{m} S_i^-) \tag{9}$$

Sujeto a:

$$\sum_{j=1}^{n} \lambda_j x_{ij} + S_i^- = x_{i0}; \quad \forall\, i \tag{10}$$

$$\sum_{j=1}^{n} \lambda_j y_{rj} - S_i^+ = \gamma_0 y_{r0}; \quad \forall\, r \tag{11}$$

$$\lambda_j, S_i^-, S_r^+ \geq 0\,; \quad \forall j \tag{12}$$

El segundo modelo destacado es el DEA-BCC, que fue desarrollado por Banker, Charnes y Cooper (1984) y lo que añadió a la metodología anteriormente explicada fue la inclusión de retornos variables de escala.

Para considerar esta variación, se incluye una restricción adicional al modelo DEA-CCR que permita que las DMU con rendimientos crecientes, constantes o decrecientes, puedan aparecer en la frontera de eficiencia por ser consideradas técnicamente eficientes. La superficie envolvente se considera representada por una combinación lineal convexa, producto del conjunto de observaciones de las DMU seleccionadas.

Este modelo tiene como origen la siguiente ecuación, que se le añade como restricción a la formulación del modelo DEA-CCR, y el conjunto da lugar a la formulación completa del modelo DEA-BCC:

$$\sum_{j=1}^{n} \lambda_j = 1 \tag{13}$$

4.2 Análisis Bootstrap

El Bootstrap es una herramienta que aporta estimaciones del error estadístico, introducida por Efron (1977), que ofrece una aproximación para el contraste de hipótesis en el modelo DEA. De hecho, es la única aproximación que existe con múltiples inputs y outputs.

La primera utilización dentro de un contexto de frontera fue Simar (1992), el cual en el modelo de datos incorporó la estimación semiparamétrica. Sin embargo, Simar y Wilson (1998) por primera vez adaptaron la técnica Bootstrap a las estimaciones del DEA.

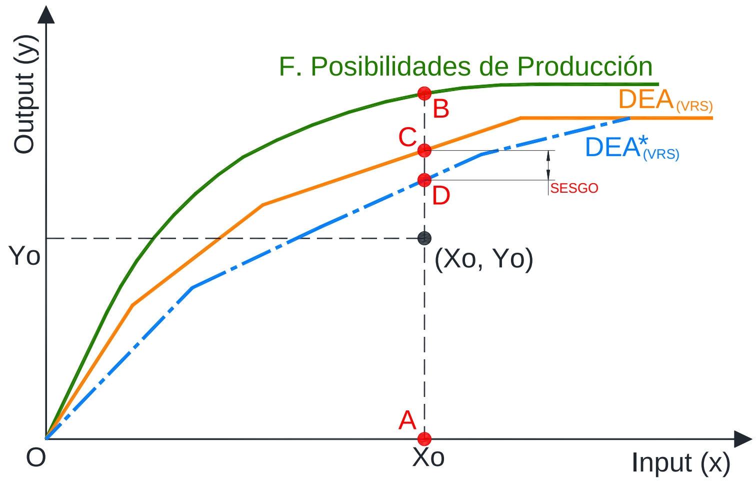

Figura 2. Representación gráfica de Bootstrap Orientación Output.
Fuente: Elaboración propia.

La Figura 1 representa gráficamente Bootstrap consistente en la orientación output. Como puede observarse de dicha representación el sesgo toma un valor negativo en las orientaciones output, debido al desplazamiento de la curva que representa la estimación de la Frontera de Posibilidades de Producción. Cuando el Bootstrap es consistente se cumple la siguiente expresión:

Bootstrap orientación output (BCC) $$\frac{AD-AC}{AY_O} = \frac{AC-AB}{AY_O} \qquad (14)$$

El principio general de la técnica Bootstrap se basa en la idea de que los valores empíricos son una representación de los valores poblacionales desconocidos. Genera una muestra con la que se puede acercar a la función de distribución empírica de los datos y estimar los niveles de confianza de las eficiencias DEA, en la cual se evita el uso de un estimador de sesgo, como es el ruido estadístico; sin embargo, la estimación del sesgo tiene interés por sí misma, que la denominamos como:

$$SESGO[\hat{\theta}(X_0, Y_0)] = E[\hat{\theta}(X_0, Y_0)] - \theta\,(X_0, Y_0) \qquad (15)$$

La estimación Bootstrap del sesgo del estimador original $\hat{\theta}(X_0, Y_0)$ considerando la versión empírica de la expresión anterior:

$$\widehat{SESGO}\;B\;[\hat{\theta}(X_0, Y_0)] = B^{-1}\sum_{b=1}^{B}[\hat{\theta}_b^*(X_0, Y_0)] - \hat{\theta}(X_0, Y_0) \qquad (16)$$

De la misma manera es adecuado elaborar un estimador de $\theta(X_0, Y_0)$ mejorado del sesgo, calculado. Así mismo parece razonable construir un estimador de $\theta(X_0, Y_0)$ corregido del sesgo, calculado.

$$\widehat{\hat{\theta}}(X_0, Y_0) = \hat{\theta}(X_0, Y_0) - \widehat{SESGO}\ B\ [\hat{\theta}(X_0, Y_0)] = 2\hat{\theta}(X_0, Y_0) - B^{-1} \sum_{b=1}^{B} [\ \hat{\theta}_b^*(X_0, Y_0)]$$

Sin embargo, según Eforn y Tibshirani (1993), esta corrección introduce ruido adicional. El error cuadrático medio de $\widehat{\hat{\theta}}(X_0, Y_0)$ puede ser mayor que el de $\hat{\theta}(X_0, Y_0)$.

5. DATOS OBTENIDOS

Este trabajo realiza un estudio de los 12 puertos más importantes del mundo junto con los tres puertos más importantes de España (Algeciras, Valencia y Barcelona) y con el puerto de Tánger. Los datos que se han utilizado para el análisis DEA se han obtenido de las diferentes páginas web de los puertos y de las autoridades portuarias respectivas, así como de las terminales que los conforman, atendiendo a los requisitos expuestos en el apartado *3 conclusiones* del presente trabajo. Para los datos respecto al volumen de contenedores de cada uno de los puertos se han utilizado las páginas web del puerto de Rotterdam y Lloyd's List, como se podrá ver en el apartado *Referencias.*

Como ya se ha mencionado, en los datos de entrada o inputs se introducen el número de grúas, la superficie de la terminal y los metros lineales, y como datos de salida u outputs se toma el número de TEUs anuales de cada uno de los puertos.

Estos datos se pueden apreciar a continuación (Tabla 2):

DMUs	Nº Grúas	S. Terminal (m2)	M Muelle
Shanghai	156	6.730.000	13.000
Singapore	228	7.470.000	19.769
Shenzhen	147	5.800.000	15.809
Hong Kong	99	2.788.500	7.694
Ningbo & Zhoushan	39	1.925.000	3.428
Busan	109	7.012.000	12.023
Guangzhou	79	6.730.000	4.800
Qingdao	37	5.560.000	3.400
Dubai Port	104	5.787.900	10.567
Tianjin	80	5.148.000	8.263
Rotterdam	102	8.340.000	11.300
Port Klang	67	1.870.000	4.900
Algeciras	27	1.043.732	2.591
Barcelona	24	1.594.000	3.000
Valencia	42	2.237.000	4.076
Tánger	16	800.000	1.612
Promedio	84,75	4.427.258	7.889,5
Máximo	228	8.340.000	19.769
Mínimo	16	800.000	1.612
S.D.	57,303	2.585.968,849	5.357,214

Tabla 2: Datos de los puertos analizados y análisis global.
Fuente: Elaboración propia

En el conjunto de datos de la tabla se puede observar que hay puertos en los que algunos de los valores de inputs son mayores que en otros, sin embargo, el volumen de TEUs es inferior, y al igual sucede en el caso contrario. Esto quiere decir que habrá puertos que, aun teniendo buenos resultados a simple vista, su equipamiento les permite ser aún más eficientes y productivos. Estos casos se podrán ver en el siguiente apartado, detallando el grado de eficiencia de cada uno de ellos.

6. RESULTADOS

Una vez introducidos los datos de la tabla del apartado anterior en el programa para realizar el análisis DEA, llamado DEA Frontier y desarrollado por Dr. Joe Zhu, los resultados que se han obtenido de eficiencia para los modelos DEA-CCR y DEA-BCC son los siguientes (Tabla 3):

Puertos	2014		2015		2016		2017		2018		PROMEDIO	
(DMUs)	CCR	BCC	CCR	BCC	CCR	BCC	CCR	BCC	CCR	BCC	CCR	BCC
Shanghai	0,5190	**1,0000**	0,5066	**1,0000**	0,4926	**1,0000**	0,4677	**1,0000**	0,4560	**1,0000**	0,4884	**1,0000**
Singapore	0,4487	0,9597	0,3863	0,8463	0,3694	0,8323	0,3526	0,8368	0,3579	0,8712	0,3830	0,8692
Shenzhen	0,4102	0,7460	0,3893	0,7232	0,3691	0,7028	0,3400	0,6775	0,3242	0,6604	0,3666	0,7020
Hong Kong	0,7879	0,9957	**1,0000**	**1,0000**	**1,0000**	**1,0000**	**1,0000**	**1,0000**	**1,0000**	**1,0000**	0,9576	0,9991

Tabla 4: Resultados obtenidos del análisis BOOTSTRAP BCC Orientación Output.

Se puede comprobar que el puerto de Ningbo-Zhoushan es el más eficiente durante los años que se han tomado para el estudio y para los dos modelos analizados. Y concretamente para el modelo BCC, que es el más significativo, también serían eficientes los puertos de Shanghai y Tánger, junto con el de Ningbo-Zhoushan como se ha comentado anteriormente.

El puerto de Hong Kong en el año 2014 es también bastante eficiente, teniendo un valor de eficiencia para el modelo CCR de 0.7879 y para el modelo BCC de 0.9957. En los años siguientes del estudio (2015 y 2016) la eficiencia se ve reducida debido a un descenso del volumen de TEUs de unos 2.000.000, lo que equivale a una diferencia del 10.75 % con respecto al volumen obtenido en 2014.

Con el puerto de Singapur ocurre lo mismo que en el caso del puerto de Hong Kong. Tiene una eficiencia con el modelo CCR de 0.4487 y con el modelo BCC de 0.9597 siendo en este caso bastante buena para el año 2014, pero sufre un notable descenso de la eficiencia en el 2015 ya que hay una bajada del número de TEUs de casi 3.000.000 y se mantiene prácticamente el mismo volumen en el año 2016.

El puerto de Qingdao es otro de los puertos que presenta mejor eficiencia en los dos modelos y para los tres años estudiados, con una eficiencia que va manteniendo entre los valores de 0.88 y 0.91 y el volumen de TEUs va incrementándose del 2014 al 2016.

Centrándonos en el modelo DEA-CCR, los puertos que tienen una eficiencia media, a parte de los puertos de Shanghai y Singapur anteriormente analizados, son el puerto de Shenzhen con 0.4102 en 2014 y se va reduciendo en los dos años siguientes, el puerto de Guangzhou con 0.6099 en 2014, que se mantiene constante en el siguiente año y aumenta en el último, ya que este puerto tiene un aumento en el volumen de TEUs de unos 2.000.000. En el caso de Port Klang tiene una eficiencia en el primer año del estudio de 0.5793 y se produce un aumento progresivo hasta llegar a una eficiencia en el año 2016 de 0.6288, por lo que el aumento en TEUs fue de un 16.89 %. Otro puerto que se puede considerar como eficiencia media es el puerto de Algeciras, el cual se va manteniendo más o menos constante durante los tres años.

Como podemos comprobar los puertos que tienen menos eficiencia en este método son los puertos de Busan, Dubai, Tianjin, Rotterdam, Barcelona, Valencia y Tánger, destacando el puerto de Barcelona como el que tiene la eficiencia más baja en los tres años estudiados.

En cuanto a las eficiencias obtenidas a partir del modelo DEA-BCC se puede comprobar que son mayores que las obtenidas por el anterior modelo, siendo este más significativo.

Los puertos que tienen eficiencia media son Shenzhen, Busan, Guangzhou y Algeciras, estando entre 0.64 y 0.79 a lo largo de los tres años. El puerto que experimenta cambios más relevantes es el puerto de Guangzhou, ya que aumenta su volumen de TEUs en algo más de 2.000.000.

En los puertos con menor eficiencia en este método se encuentran el puerto de Dubai, Tianjin, Rotterdam Port Klang, Barcelona y Valencia, siendo el puerto de Barcelona el que presentar menor eficiencia, como en el caso del modelo CCR.

Como complemento al análisis anterior, y únicamente con el objetivo de clasificar los puertos según sus resultados en los distintos modelos DEA y Bootstrap, se han agrupado según los valores promedios obtenidos de eficiencias.

Se han clasificado los puertos en cuatro categorías (Tabla 5). En primer lugar, aquellos puertos cuyo valor promedio de la eficiencia corregida Bootstrap es igual o superior a 0,90, a los que podemos considerar Puertos Eficientes (I). En segundo lugar, puertos cuya eficiencia está en valores comprendidos entre 0,70 y 0,90, a cuyos puertos denominaremos

Puertos con Eficiencia Media (II). Un tercer grupo es el formado por los puertos con valores de eficiencia entre 0,50 y 0,70, Puertos con Eficiencia Baja (III), y por último, aquellos puertos cuyas eficiencias corregidas son inferiores a 0,50, a los que consideraremos como Puertos Ineficientes (IV). Cada una de estas categorías está clasificada en la Tabla 5.

Grupo	Puertos (DMUs)	Valor Promedio Efic. DEA-BCC	Puertos (DMUs)	Valor Promedio Efic. BOOT-BCC
I (> 0,90)	Shanghai	1,00000		
	Tánger	1,00000		
	Hong Kong	0,99913		
II (0,70 - 0,90)	Singapore	0,86924	Shanghai	0,86173
	Qingdao	0,86646	Hong Kong	0,81953
	Guangzhou	0,77010	Singapore	0,77979
	Ningbo & Zhoushan	0,73177	Tánger	0,75276
	Busan	0,71905	Qingdao	0,74744
	Shenzhen	0,70198	Guangzhou	0,69963
III (0,50 - 0,70)	Algeciras	0,65369	Busan	0,65859
	Rotterdam	0,53095	Ningbo & Zhoushan	0,65477
	Tianjin	0,52775	Shenzhen	0,63259
			Algeciras	0,56613
IV (< 0,50)	Dubai Port	0,48887	Tianjin	0,48871
	Port Klang	0,46375	Rotterdam	0,47077
	Barcelona	0,30114	Dubai Port	0,45175
	Valencia	0,18407	Port Klang	0,42088
			Barcelona	0,25862
			Valencia	0,15729

Tabla 5: Agrupación de puertos según valores promedio DEA-BCC y DEA-BOOTSTRAP.

En el análisis del modelo DEA-BCC se comprueba que existen tres puertos en el primer grupo. Los puertos de Shanghai y Tánger MED con valores de eficiencia del cien por cien.

El puerto de Hong Kong obtiene un valor muy próximo a la unidad. Todo esto es debido a la capacidad técnica que poseen estas tres terminales.

En el grupo de Puertos con Eficiencia Media (II) se clasifican encuentran los puertos de Singapore y Qinddao, con valores casi idénticos y por encima del ochenta y cinco por ciento. En el mismo grupo, pero tampoco muy distanciados, nos encontramos con los puertos de Guangzhou, Ningbo & Zhoushan, Busan y Shenzhen con valores inferiores a los anteriores, aunque bien es cierto qué obtienen un valor por encima del setenta por ciento. Esto nos indica que todos los puertos de este grupo podrán estar muy cerca de conseguir el objetivo de ser puerto Eficiente.

En el tercer grupo formado por aquellos Puertos con Eficiencia Baja (III) se clasifican a los puertos de: Algeciras (0,65369), Rotterdam (0,53095) y Tianjin (0,52775). Valores muy discretos para puertos de esta entidad en el escenario mundial de tráfico de contenedores.

Por último, los puertos de Dubai Port, Port Klang, Barcelona y Valencia obtienen la clasificación de Puerto Ineficiente (IV). Resulta muy llamativas las posiciones última y penúltima de los puertos de Baercelona y Valencia, con un valor de apenas el dieciocho porciento el puerto levantino.

Los resultados muestran una importante homogeneidad en los valores de Eficiencia DEA dentro de cada uno de los grupos definidos, sin apenas diferencias entre ellos, siendo algo mayor en el grupo I y IV y apenas insignificante en los grupos II y III.

Si nos centramos ahora en el análisis de los valores obtenidos para la Eficiencia corregida Bootstrap, comprobamos que no hay ningún puerto que consiga superar la barrera del noventa por ciento de eficiencia y por consiguiente no se podría clasificar como puerto eficiente a ningún puerto de la nuestra. Con respecto al siguiente escalón, hay tres puertos que se mantienen en el grupo II, como es el caso de Singapore (0,77979), Qingdao (0,74744) y Guangzhou (0,69963). Sin embargo, los tres puertos que conformaban el grupo I en el análisis DEA, bajan a este grupo II cuando optimizamos los resultados aplicando la técnica estadística Bootstrap. Es el caso de los puertos de Shanghai (0,86173), Hong Kong (0,81953) y Tánger (0,75276). Hay que destacar que el ajuste producido entre los valores de Eficiencia DEA y los de Eficiencia Bootstrap es pequeño, del orden de un valor medio del 10%. Esto puede ser un indicador de que estos puertos se encuentran trabajado en un escenario muy próximo a su tamaño máximo productivo.

Hay que destacar que el puerto de Algeciras (0,56613), se mantiene constante en el grupo III, Puertos con Eficiencia Baja, y prácticamente en el mismo orden que se ha obtenido en el análisis DEA, y con un ajuste del 9%.

Por último, el cuarto grupo al que hemos denominado puertos Ineficientes, está formado por seis puertos, y entre ellos encontramos a puertos de la entidad de Rotterdam (0,47077), Barcelona (0,25862) y Valencia con un muy discreto valor de 0,15729.

7. CONCLUSIONES

Una vez comprobada la eficiencia técnica global de escala y la eficiencia técnica pura, se observa que los puertos asiáticos son bastantes eficientes, destacando el puerto de Shanghai que moviendo más de 42 millones de TEUs ocupa el primer puesto en la clasificación mundial. Tánger MED (puesto 46) y Hong Kong (puesto 5) se mantienen en la parte alta de los valores de eficiencia. Los puertos asiáticos deben estos valores de eficiencia a su posición estratégica y a las dimensiones de las terminales y muelles, así como al número de grúas. Por consiguiente, manipulan un número muy elevado de contenedores en comparación con otros puertos.

Las condiciones geoestratégicas de estos puertos y sus condiciones técnicas les permitiría atraer aún más volumen de tráfico. Del mismo modo, y debido a su situación en el Estrecho de Gibraltar, en los próximos años asistiremos a un crecimiento considerable del puerto de Tanger MED. Está aumentando su volumen de contenedores progresivamente y en los próximos años se prevé que con las nuevas terminales, el tráfico de contenedores sea bastante más elevado, pudiendo ser una fuerte competencia para el puerto de Algeciras con el que comparte posición estratégica.

Los puertos de Singapur y Shenzhen presentan características similares al de Shangai, pese a encontrarse entre los tres principales puertos, tienen una eficiencia baja con respecto a otros, lo que significa que sus puertos no son totalmente productivos, sino que podrían mejorar.

Centrándonos en los puertos europeos, se puede ver que siendo el puerto de Rotterdam el más importante del continente, al compararlos con los puertos más importantes del mundo, su eficiencia es bastante baja.

Esto que no quiere decir que obtenga malos resultados, sino que podrían ser bastantes mejores, pudiendo llegar a ser una fuerte competencia para los puertos asiáticos por su novedoso y gran equipamiento, aparte de por la localización en la que se encuentra, siendo la principal entrada de mercancía de toda Europa y debido a sus buenas conexiones con otros países.

Se puede comprobar que entre los puertos españoles el que presenta mayor eficiencia en los dos modelos estudiados es el puerto de Algeciras, que pese a tener menor volumen de equipamiento y capacidad que el puerto de Valencia, su volumen de TEUs es muy similar entre ambos puertos, teniendo años que está por encima y otros ligeramente por debajo del puerto valenciano.

En verano de 2018, se han introducción tres nuevas grúas en la terminal APM Terminals de Algeciras, lo que ha supuesto un aumento del número de contenedores manipulados en esa terminal, que beneficiará al rendimiento y eficiencia del puerto.

En definitiva, los puertos y las cadenas logísticas tienen como objetivo el crecimiento a partir de la inclusión de tecnologías y prácticas innovadoras para los procesos de organización, administración y de servicios. Los puertos están en continuo avance, intentado automatizar las terminales que les sean posibles para así poder incrementar la eficiencia y que sean más productivos, con el fin de llegar a ser de los principales puertos de contenedores del mundo.

ECOFLOTA: BUSINESS INTELLIGENCE SYSTEM FOR THE TRANSITION TOWARDS SUSTAINABLE MOBILITY FLEETS

Sergio Güerri
Head of Transport and Logistics Unit, ITENE, Spain
Javier Moya Polo
Project Officer, ITENE, Spain
José Ángel Rodríguez Álvaro
Project Officer, ITENE, Spain
Mireia Calvo Monteagudo
Project Manager, ITENE, Spain

ABSTRACT

The lack of knowledge about the possibilities of switching to sustainable fleets and their costs lead companies to prolong the life of their fleets as much as possible. Therefore, the overall objective of ECOFLOTA is to provide arguments for companies to decide to migrate their fleets towards new ones that provide more sustainable mobility.

Within this framework, this project proposes the development of an automated analysis, planning and forecasting system consisting of i) a support tool for the optimised migration towards cleaner vehicles to achieve the objectives of zero emissions and green transport; ii) a predictive model of the useful life of these new sustainable vehicles and iii) the development of an eco-driving model to optimise the performance of these new sustainable vehicles. Hence, the project proposes the design and development of a global system at all levels for the upgrade of fleets with low emission vehicles.

The project was developed over a period of 15 months, during which time last mile delivery companies were involved in the definition, design, development and validation of the system, in order to meet the technical specifications and functional requirements of their operations. As a result, 61 use cases were simulated considering three types of routes (urban, short distance and interurban), as well as three types of low emission vehicles (electric, gas and hybrid)

1. INTRODUCTION

In recent years, local governments have adopted several urban traffic and mobility management measures based on energy efficiency and environmental sustainability. The aim is to create a more liveable and friendly environment. Simultaneously, cities face this challenge while trying to increase the operational efficiency of urban goods distribution.

In many studies, low emission vehicles are considered the right solution to meet both needs. However, currently logistics operators do not have clear information about the advantages offered by these new sustainable vehicles. Likewise, it is difficult for them to calculate the costs of replacing their current fleet with these types of vehicles and to estimate the profitability that this fact could generate in the long term.

In this context, the ECOFLOTA tool is an automated system of analysis, planning and forecasting of sustainable mobility fleets. It comprises a support module for optimised migration to low emission fleets, a predictive life model of these new sustainable vehicles and an eco-driving model to optimise the performance of these type of vehicles.

Specifically, the migration module involves a multi-objective optimisation model that allows to determine, for an established time horizon, a fleet replacement plan that minimizes the total cost to invest considering all the economic, technical, operational, environmental, and regulatory restrictions.

In addition, the predictive maintenance model is based on a genetic algorithm that allows monthly maintenance of the new fleet to be planned considering both economic and technical criteria.

Finally, the system includes an eco-driving module that contemplates and quantifies the savings in fuel consumption, pollutant emissions and maintenance costs in vehicles, derived from a more efficient and safe driving.

For its validation, more than sixty use cases were simulated taking into account different types of routes (urban, short distance and interurban), as well as low emission vehicles (electric, gas and hybrid)

2 TECHNICAL AND FUNCTIONAL REQUIREMENTS OF THE SYSTEM

The first of the tasks carried out focuses on identifying the technical requirements of the project and its functionalities. Based on this, the system architecture and all associated components were designed.

2.1 System architecture

The following figure shows the general architecture of ECOFLOTA, which identifies the three components that interact within the tool, as well as the actors involved in it:

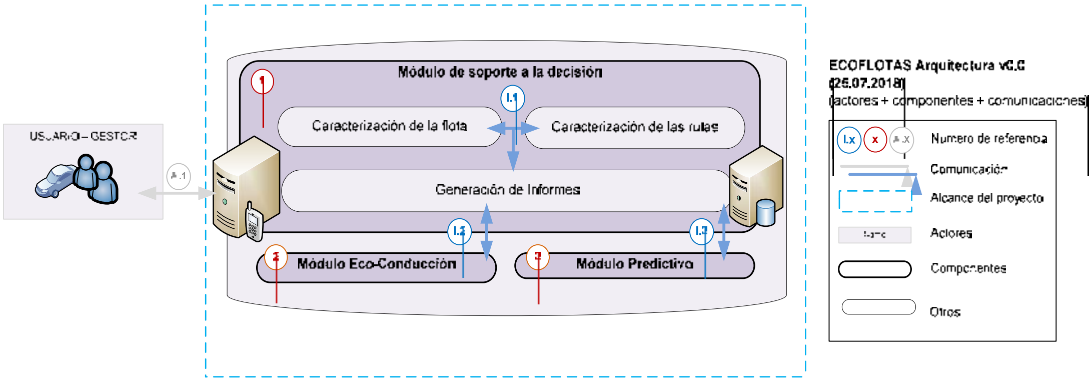

Fig. 1: ECOFLOTA architecture.

The table below identifies all system components, the communications between them and the graphical interfaces involved:

#	ECOFLOTA component	HMI	Communications
1	Decision Support module	User (Web)	I.1
2	Eco-driving Module	User (Web)	I.2
3	Predictive Module	User (Web)	I.3

Table 1: System components.

Considering both technical and economic feasibility, the aim is to obtain optimised solutions that demonstrate the benefits of the company's competitive, ecological, and sustainable development. With the use of predictive models, local regulations and standards in force or planned to be implemented, mobility patterns on historical routes, eco-driving models, among others, it will be possible to establish for the most common delivery routes where low-emission vehicles can be incorporated as a priority. This information, from the point of view of planning and logistics, is an added value of high performance of the tool.

The starting point for the definition and design of the tool, as well as its operation, is the characterisation of the company's operations, mainly related to the services provided (routes used and vehicles used). To complement the basic information of the data on its current operation and to provide a result more aligned with the company's needs, the user will also provide additional information, such as the city where it operates (to know municipal restrictions), critical mass of nearby recharging points, investment capacity and amortisation.

In order to propose an optimal development of the tool, some working sessions were held on Business Design and Lean Start-up, with the participation of companies, and in which the following objectives on their operation were identified:

- Minimising costs
- Optimising routes with mixed fleets
- Avoiding service incidents (breakdowns, accidents...)

Furthermore, some barriers relating to the different low emission vehicle typologies considered were also identified:

- Electric vehicles: high price; less autonomy; and limited recharging points
- Gas vehicles: less space and reduced power; greener, but polluting, vehicles; and limited refuelling stations
- Hybrid vehicles: high price; and not-definitive (transition to electric vehicle)

2.2 Decision Support Module

This is a support tool for logistics operators, vehicle dealerships or, in short, any company with a vehicle fleet. Its objective is to analyse the feasibility of migrating their fleets to less polluting vehicles, achieving the objectives of low emissions and green transport.

To this end, a multi-objective optimisation model has been developed that is capable of defining the optimal plan for replacing a current fleet, made up of conventional petrol or diesel vehicles, for a given time horizon of 5 to 10 years, or whatever the user estimates.

Thus, the optimisation model can define which vehicles of the current conventional fleet should be replaced by which type of more sustainable vehicle (that includes electric, hybrid or gas types)

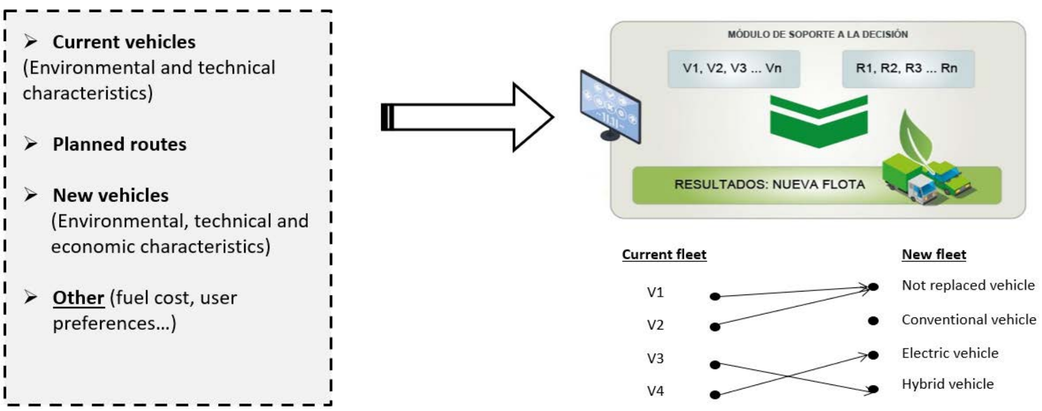

Fig. 2: Decision Support Module architecture.

With a view to define the replacement plan, the optimisation model developed considers all aspects or factors that may affect this decision to a greater or lesser extent. Specifically, all the technical, environmental, and economic characteristics of the current and new vehicles (sustainable and conventional) and the technical characteristics of the scheduled service routes. In addition, other non-economic and non-technical aspects have also been considered, such as user preferences in relation to the type of car they are willing to purchase, budget constraints, among other considerations. The table below shows all these technical, economic, and environmental aspects considered.

Current fleet	**Routes**	**New fleet**	**Other**
- Cost and maintenance - Fuel consumption - CO2 emissions	- Type - Km - Frequency - Cargo to be transported - Restriction on diesel?	- Age and km - Acquisition cost - Maximum permissible load - Range (km) - Fuel consumption - CO2 emissions	- Fuel costs - Bonuses for the purchase of sustainable vehicles - Reduction in maintenance operating cost and emissions by eco-driving - Maintenance cost - User preferences: > Car type > Car size (small, medium, and large) > Type of range (basic, mid-range and luxury)

Table 2. Economic, technical and environmental aspects considered in the substitution module.

Two different criteria, one economic and one environmental, have been considered for the optimisation model. This model seeks to minimise both the environmental impact of the new fleet and the total replacement cost. To define this cost, not only the acquisition cost but also the maintenance cost and the operating cost over the proposed horizon have been considered. The operating cost corresponds to the cost of charging the battery for hybrid and electric cars, or filling the tank in the case of gas, diesel or petrol vehicles. These two optimisation criteria can be completely opposite, i.e., the vehicle that pollutes the least, i.e., the electric vehicle, can be much more expensive than, for example, a hybrid that pollutes a little more. In this type of situation, the optimisation model will seek to minimise both criteria, but always giving greater priority to the environmental criterion, since the replacement module aims to replace the current fleet with a more sustainable one.

Through the optimisation model, the decision tool will be able to determine for each vehicle, i, in the fleet whether it needs to be replaced and if so, the type of sustainable vehicle, x, (electric, hybrid, or gas) and the corresponding range, g, (high, low and medium) by which it should be replaced.

Therefore, the decision variables of the model are the binary variables $n_{i, x, g}$ y n_i^{co}. More specifically, $n_{i, x, g}$ is a binary variable that will be equal to 1 if the vehicle i in the fleet is to be replaced by a sustainable vehicle of type x and range g:

$$n_{i, x, g} \begin{cases} 0 & \text{Vehicle i not replaced} \\ 1 & \text{Vehicle i replaced by a sustainable one of x type and g} \end{cases} \quad (1)$$

While the binary variable n_i^{co} will be equal to 1 if the vehicle i is not to be replaced and remains as a conventional type vehicle:

$$n_{i,}^{co} \begin{cases} 0 & \text{Vehicle i replaced by a sustainable one} \\ 1 & \text{Vehicle i not replaced} \end{cases} \quad (2)$$

For clarity, the following table specifies the indexes used in the nomenclature for the definition of both parameters and variables.

Indexes	**Description**
x $\{c, e, h, g\}$	Vehicle types {conventional, electric, hybrid, and gas}
k	Time period
i	Vehicles
r	Routes
$g =\{a ,m ,b \}$	Car type range {High, medium, low}

Table 3. Indexes used for the variables and parameters of the optimisation model.

The table below summarises all input parameters required for the development of the optimisation model:

Data	**Description**
T	Planning horizon
NC	Fleet size
B_x	Bonus for purchase of type *x* sustainable vehicle
β	Normalisation parameter
P	Vehicle procurement budget
$UL_{x,g}$	Lifetime (years) of type *x* vehicle and range *g*
UL_i^{co}	Useful life (years) of vehicle *i* of the original fleet
RUL_i^{co}	Remaining useful life (years) of vehicle *i* of the original fleet
Q_r	Average route load *r*
$Q_{x,g}$	Load that can be carried by type *x* vehicle and range *g*
$C_{x,g}^a$	Acquisition/replacement cost of type *x* vehicle and range *g*
$C_i^{a,co}$	Replacement cost of fleet *i* vehicle
$C_{x,g}^m$	Maintenance cost of type *x* vehicle and range *g*
$C_i^{m,co}$	Maintenance cost of fleet vehicle type *i*
$D_{i,x,g}$	Eco-driving discount factor for vehicle *i* when it is of type *x* vehicle and range *g*
D_i^{co}	Eco-driving discount factor for vehicle *i* when vehicle *i* is not replaced
l_r	Average route length *r*
$l_{x,g}$	Maximum km of type *x* vehicle and range *g*
fr_r	Route *r* frequency
$C_{k,x,g}^f$	Cost fuel of type *x* vehicle and range *g*
$C_i^{f,co}$	Fuel cost of fleet *i* vehicle
f_i^{co}	Fuel per km of fleet *i* vehicle
$f_{x,g,k}$	Fuel per km of car type *x* and range *g*
$E_{x,g}$	CO2 emission per km of vehicle type *x* and range *g*
E_i^{co}	CO2 emission per km of fleet i vehicle

Table 4. Required parameters for the optimisation model.

Finally, the following table describes parameters that are necessary for the optimisation model and that are calculated from the data defined in Table 3, i.e., fixed data, specified by the user or that can be collected from the database.

Parameter	**Description**
eco	Total emissions from existing vehicles
G	Total operating cost over the entire time horizon
$C_{i,k}^{co}$	Operational cost for original fleet vehicle *i* in period *k*
$C_{i,x,g,k}$	Operational cost of sustainable vehicle *x* of range *g* in period *k*
$k_{i,x,g}$	Total consumption on the routes by vehicle *i* of vehicle type *x* and range *g*
k_i^{co}	Total consumption on the routes by original fleet *i* vehicle

Table 5. Calculated parameters.

With the aim of defining the optimal fleet replacement plan, the optimisation model must consider the acquisition and maintenance costs of the different types of vehicles (current and those that could be acquired) as well as the future operational costs due to the energy consumption of the vehicles. Thus, the objective function of the optimisation model seeks to minimise all these costs according to the given replacement plan as well as to minimise the total emissions of the new fleet, but always giving higher priority to emission reduction. This priority is achieved by defining a very high emission cost, c.

Meanwhile the overall restrictions affecting the fleet are as follows:

- Avoiding of allocating more than one type of vehicle, sustainable or conventional (non-substituted), per vehicle.
- The total number of vehicles must be equal to that of the initial fleet
- Replacement of the current vehicle with sustainable vehicles based on the minimum weight they have be able to carry
- Replacement of the current vehicle by sustainable vehicles with the minimum autonomy required to carry out the assigned routes
- Limitation of access in certain areas due to regulations
- Load limitation for safety or danger reasons or due to regulations
- User requirements/preferences (e.g., user only wants electric and gas vehicles)
- Limitation in the budget for the acquisition of new sustainable vehicles

Additionally, another term can be added to the objective function to penalise the number of times the new fleet vehicles (sustainable and non-replaced) should be replaced over the time horizon according to their useful life. For example, if the lifetime of an electric vehicle is 8 years and the considered time horizon of the replacement plan is 10 years, the objective function should consider the cost of replacing this vehicle twice over the time horizon, in order to keep the number of vehicles in the fleet.

Many of the parameters that are considered within the optimisation model are user-defined, which can lead to infeasible solutions. In this case, the optimisation model will result in an infeasible solution. To warn the user about this type of error, in addition to the optimisation module, an error detection program has been developed to identify inconsistencies in the input parameters.

2.3 Maintenance module

The maintenance module is based on the development of the predictive maintenance tool. This consists of a genetic algorithm that allows monthly maintenance planning of the new fleet based on both economic and technical criteria of the new sustainable fleet.

For the development of the decision tool, a genetic algorithm based on metaheuristic techniques has been developed which can establish the monthly maintenance planning for the cars that make up the current sustainable fleet based on economic and technical criteria.

To do this, it has been necessary to identify, for each of the types of cars (electric, petrol, diesel, gas, hybrid), the critical elements, i.e. the elements whose breakdowns are the most frequent, most complex and, above all, most costly. In the case of petrol and diesel vehicles, the injection system and the steering system have been identified as critical elements. In the case of the injection system, its breakdowns are not the most frequent.

Specifically, it accounts for 16% of car breakdowns, but changing the injectors involves a large outlay of money. In the case of hybrid and electric cars, the car battery has been considered as a critical element, and in the case of hybrids, as an additional element, the injection system. Finally, for gas cars, only the injection system has been considered.

Based on the types of cars that make up the fleet, the genetic algorithm defines which months the user should perform the maintenance of its critical elements so that the total cost of preventive and corrective maintenance of the entire fleet over a predefined time horizon is minimal. Preventive maintenance refers to the maintenance of the element before its breakage and makes it possible to reduce the failure rate of the critical element, and therefore to avoid its replacement due to breakage, which could entail a high cost.

The only parameter defined by the user in the genetic algorithm is the time horizon (in years) to be analysed, the rest of the parameters will either be given by the substitution module or will be collected from the database. The parameters obtained from the previous module define some of the technical characteristics of the cars that make up the new sustainable fleet. In particular, the maintenance model only needs to know the type of car involved and the lifetime of the car, as it is not the same to plan the maintenance of a 10-year-old car with 1,000 km as a newly acquired one. In turn, the parameters defined in the database are those that characterise from an economic and technical point of view the critical elements of each of the types of car that may exist within the fleet.

More specifically, these parameters define the failure rate of each of the critical elements, and their corresponding preventive and corrective maintenance costs. In summary, the parameters considered are indicated in the following table.

Source	Description
User-defined	Number of years to be considered for planning purposes
Replacement module	Vehicle type
	Vehicle lifetime
Database	Failure rate of critical element of a vehicle depending on its type (petrol, diesel, gas, hybrid, or gas)
	Preventive maintenance cost of a critical element of a vehicle
	Corrective maintenance cost of a critical element of a vehicle

Table 6. Inputs to the genetic algorithm

The genetic algorithm aims to define the months of maintenance of each of the critical elements of the cars that make up the fleet given by the substitution module. In this sense, the only decision variables of the algorithm, i.e., the genomes that would compose everyone, are binary variables that will take the value equal to 1 when maintenance is scheduled for a specific critical element of a given car in a given month, and 0 otherwise.

In order to model the time evolution of the failure rate $\lambda_i^d(t)$of the critical element d of a car i, which is of petrol, diesel, electric, hybrid, gas or hybrid-electric type, based on what is suggested in the technical literature, the two-parameter Weibull function has been used, which adopts the following expression:

$$\lambda_i^d(t) = \left(\frac{\beta_i^d}{\alpha_i^d}\right)\left(\frac{t}{\alpha_i^d}\right)^{\beta_i^d - 1} \quad (2)$$

$\lambda_i^d(t)$: Failure rate of equipment i by critical element d at time t
β_i^d, α_i^d: Weibull function coefficients

2.4 Eco-driving module

The Institute for Energy Diversification and Saving (IDAE) points out that efficient or ecological driving, compared to aggressive driving, reduces emissions of carbon dioxide (CO2), one of the main gases involved in climate change, as well as other pollutant emissions: up to 78% of carbon monoxide (CO), 63% of hydrocarbons and 50% of nitrogen oxides (NOx). Noise pollution is also reduced: one car at 4,000 revolutions per minute (rpm) makes the same noise as 32 cars at 2,000 rpm.

In this context, eco-driving is a concept associated with the new way of driving, which focuses on achieving a more economical and safer way of driving, reducing environmental pollution, and improving comfort. To this end, the concept defines and sets out a series of rules and modes of behaviour that seek to take advantage of the possibilities offered by current car engine technologies.

Driving style is influenced by a complex mix of social, psychological and cultural factors that directly affect the driver. At the same time, eco-driving is also influenced by technical factors related to the vehicle. In this area, the main driving parameters affecting the emission of pollutants are speed, engine speed, idling time, power take-off time, acceleration breaking, tyres and air-conditioning use.

In line with the above, the following are a number of guidelines and driving behaviours that can save fuel while driving, and therefore also help to reduce emissions.
With simple changes in driving habits, most drivers can save 10-15% on fuel.

- Reduce speed: For every 10 km/h over 100 km/h, fuel efficiency is reduced by 10%. Driving at 120 km/h on the highway instead of 100 km/h is equivalent to a 20% saving on fuel. In addition, maintaining a constant speed means lower fuel consumption. Using the accelerator and brake pedals smoothly: Hard starts between traffic lights can save 2.5 minutes on a one-hour journey, but it increases fuel consumption by 37%.
- Reducing idling times: As noted above, 10 seconds at idle speed means higher fuel consumption than when starting the engine. In this context, 10 minutes at idle means a consumption of half a litre of fuel
- Warming up the engine on the move: today's vehicles do not require periods of idling to warm up the engine. Gentle driving for the first few minutes after starting allows the transmission, steering and engine to warm up at the same time.
- Combining journeys: Journeys of less than 5 km are the most polluting, as the engine and pollution control system never reach maximum operating temperature. Combining several trips into one can reduce fuel use and emissions by 20-50%.
- Avoid overloading: every additional 100 kg of load reduces fuel efficiency by up to 2%, so it is recommended not to carry unnecessary items
- Make the most of your transmission: using overdrive at high speeds saves fuel and reduces engine wear. With a manual transmission, smooth but quick shifting at higher speeds allows the engine to operate more efficiently.
- Consult the vehicle's on-board computer (if available): such devices provide real-time fuel consumption information. In general, drivers who learn to adjust their driving habits according to the information available can save up to 10% in fuel consumption
- Proper maintenance of the different elements of the vehicle: Aditionally to being a safety factor, also results in lower fuel consumption.

Eco-driving offers numerous benefits: it not only saves fuel and costs, but also improves road safety and the quality of the local and global environment. In addition, eco-driving provides direct benefits to drivers and passengers, i.e., more comfort and a more relaxed environment. All of this is associated with equal or shorter travel times.

In short, the eco-driving module aims to be a tool that complements the decision module, with the objective of, on the one hand, making recommendations on the way of driving, both sustainable and conventional vehicles, and on the other hand, estimating the effects that the practice of this driving style (savings) will have on the operational scenarios of the fleet. To do this, it is based on both the type of vehicle and the type of routes that the vehicle will carry out.

Thus, and as a synthesis of the possible benefits of this driving style, the following table is taken into account, depending on the different types of vehicles (propulsion):

SAVINGS	**CONVENTIONAL**	**GAS**	**HYBRID**	**ELECTRIC**
Fuel	15%	15%	18%	20%
Emissions	15%	15%	18%	N/A
Maintenance	5%	5%	5%	5%

Table 7. Percentage savings as a result of eco-driving by vehicle type

2.5 System validation

For the validation of the integrated system, 61 different tests were proposed, whose fleet was made up of three combustion vehicles (2 petrol and 1 diesel), and their operation included three different types of routes (Urban, Interurban and Short distance).. The results showed that:

- 7 of the cases did not result in a change of fleet. In other words, there was no substitution necessary in the scenario proposed. The specific cases were:
    - Only sustainable vehicles with a current full diesel fleet and with a budget constraint of €17,000
    - No sustainable selection with no vehicle selection. At least one sustainable vehicle must be selected, when only sustainable vehicles are selected
    - No range selection. The range must be selected
    - No size selection. The size must be selected
    - With a higher bonus than the budget for electric vehicles.
    - Routes currently undertaken are not viable for sustainable vehicles (1,000,000 km)
    - The weight of the current routes cannot be covered by the current sustainable vehicles.

- 38 replacement cases 1 fleet vehicle
    - 23 electric
    - 6 gas
    - 3 hybrids
    - 3 new diesel
    - 3 new petrol
- 10 replacement cases 2 fleet vehicles
    - 5 new diesel
    - 3 new petrol
    - 1 gas
    - 1 hybrid
- 6 replacement cases all 3 vehicles in the fleet
    - 3 new diesel
    - 3 new petrol

3. WEB INTERFACE DESIGN

The web platform is designed in such a way that any user can use it intuitively following good web design practices. In addition, it is designed to be "responsive" so that no matter what device is used to view it, whether mobile, tablet or monitor, the content of the page will adapt to the resolutions of each of these screens.

In order to access the platform, registration is required. Once registered, you can log in to access the platform. It contains different sections, which are always available in a fixed sidebar. Among the sections are some designed to create and visualise the initial fleet situation, both vehicles and route types. Also, a section to perform simulations, being able to vary different input parameters to generate different results.

Finally, a screen to visualise these simulations, and to generate the prediction of the maintenance module with respect to the associated simulation.
Below are a series of screenshots of all the screens mentioned above.

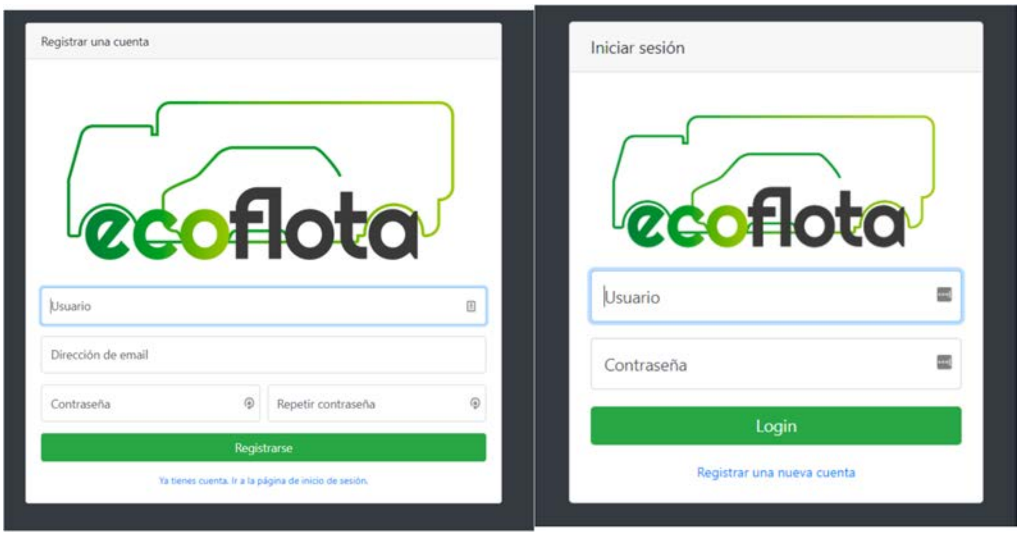

Fig. 3: Registering on the platform and logging in.

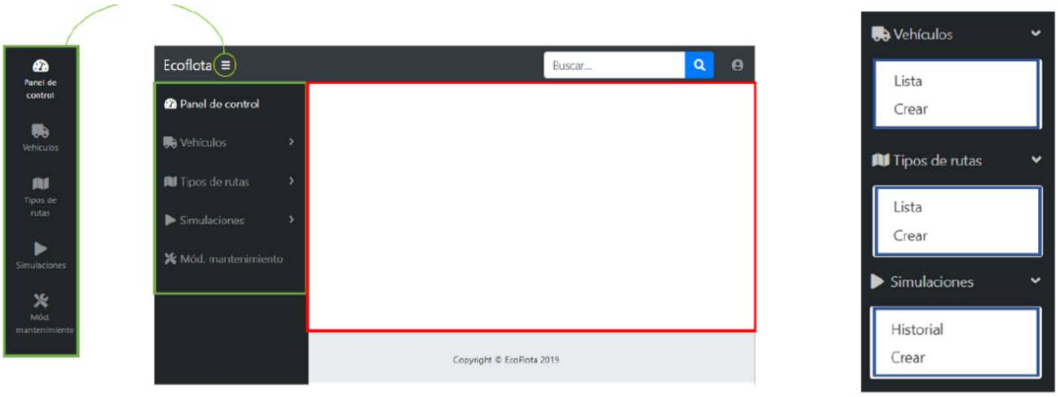

Fig. 4: Basic structure of the web platform.

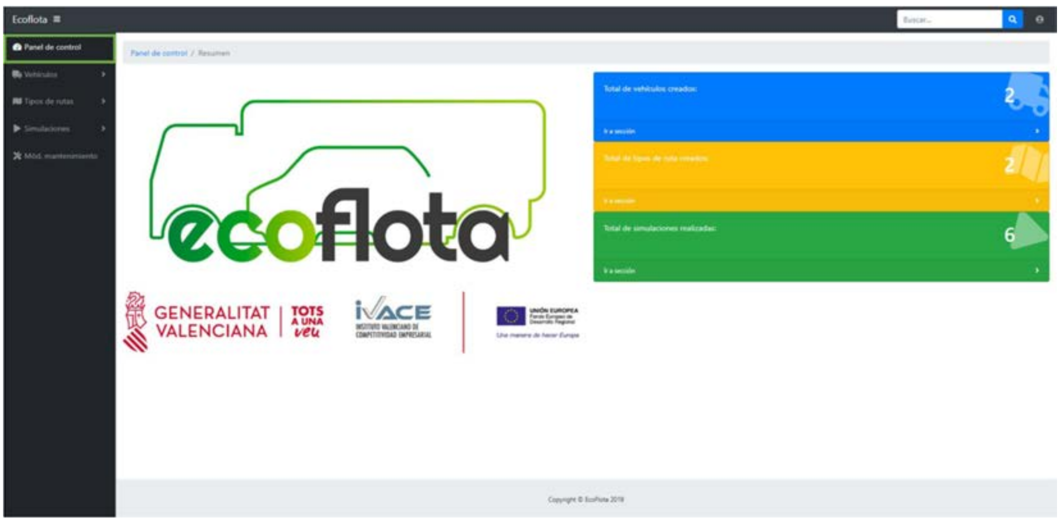

Fig. 5: Control pannel.

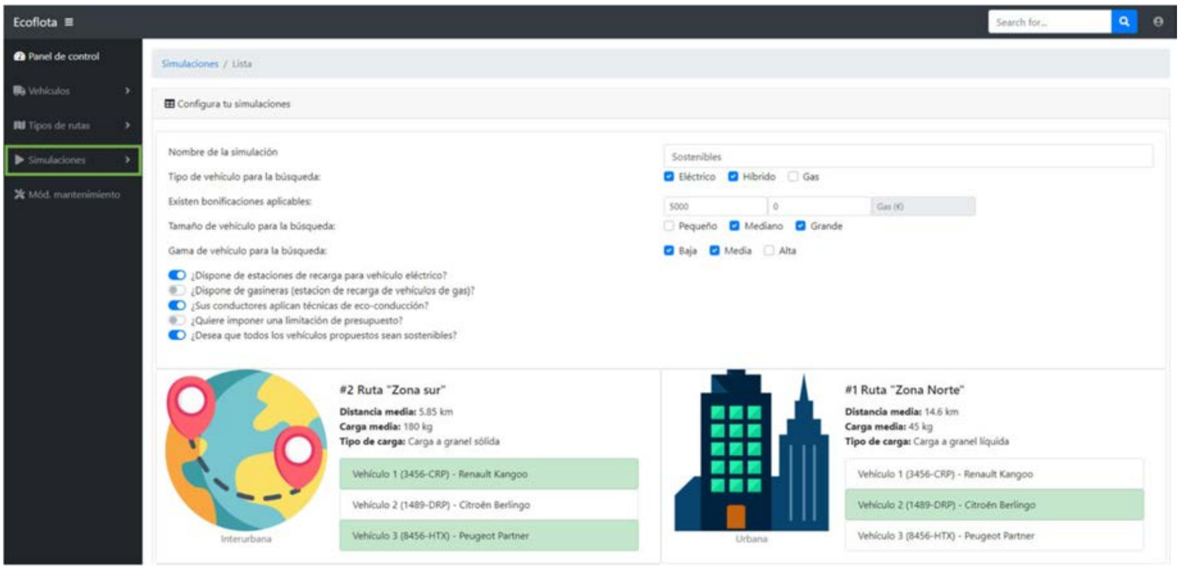

Fig. 6: Simulation creation.

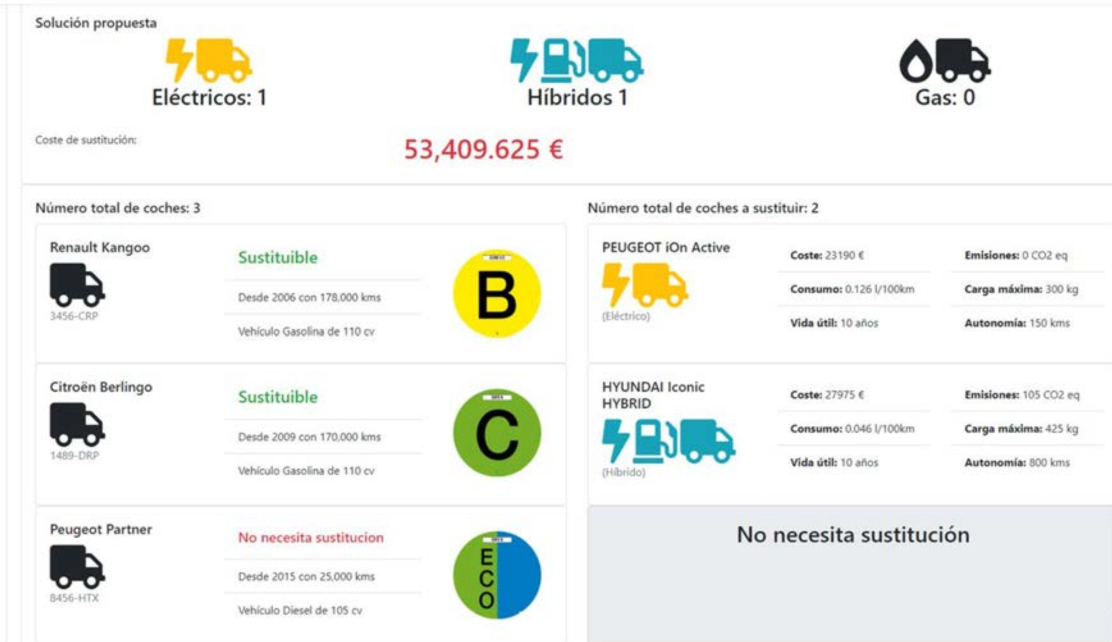

Fig. 7: Example simulation output.

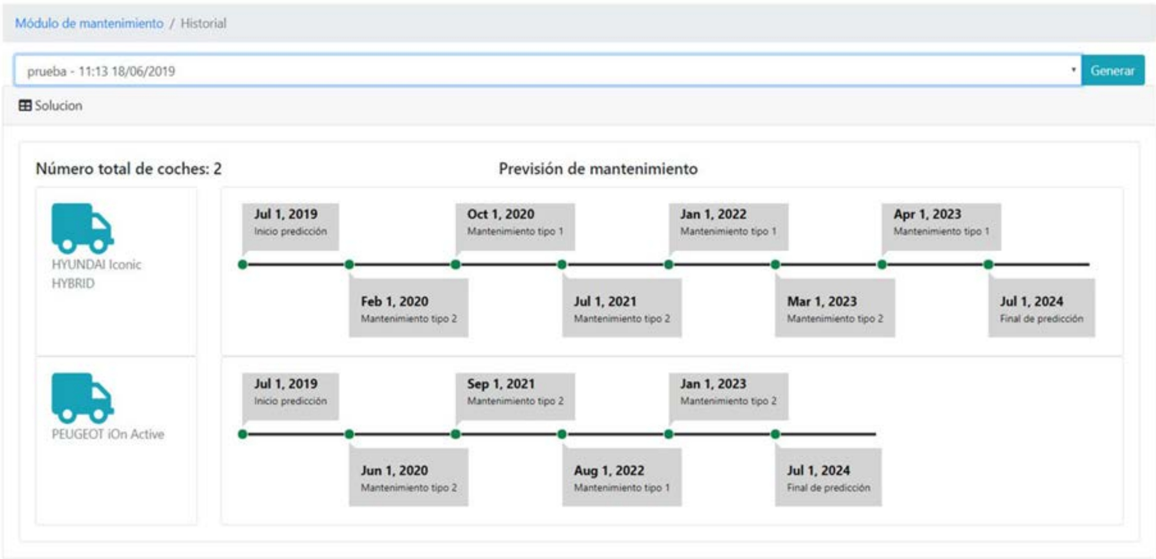

Fig. 8: Maintenance module simulation output.

4. CONCLUSION

To help the transition to a sustainable mobility model, ECOFLOTA has developed an intelligent decision support system, capable of interpreting the needs of both routes and vehicles, to provide the optimal result. In other words, the main objective is to facilitate the change from conventional fleets to sustainable fleets.

The decision has been based on the needs of the companies transferred directly to the architecture and design of the system. To this end, it has been obtained:

- Automated system for analysis, planning and forecasting of sustainable mobility fleets.
- Aimed at transport and logistics companies
- Contributes to reducing pollution and noise in cities.
-

It mainly consists of:

- A support tool for logistics companies for the optimised migration of their fleets towards cleaner vehicles to achieve zero emission and green transport objectives.
- A predictive model for the lifetime of these new sustainable vehicles.

In view of the results and feedback obtained, the tool could be further improved with:

- Include leasing and carsharing modalities in the model
- Extending the catalogue of vehicles
- Extend the topology of the vehicles. (Bicycles, motorbikes, scooters...)

FUNDINGS

This study is part of the research performed in the framework of the Regional project *ECOFLOTA: Business Intelligence system for the transition towards sustainable mobility fleets* financed by IVACE, Instituto Valenciano de Competitividad Empresarial de la

Generalitat Valenciana, through the European ERDF Regional Development Funds, within the framework of the aid programme aimed at technology centres under the IMDEEA/2018/106 file.

ACKNOWLEDGEMENTS

We would like to thank the support and assistance provided by Caterina Tormo, Javier Monreal, Christian Conca and Noemí González from the Instituto Tecnológico de la Energía-ITE. This this research centre collaborated jointly with ITENE in the project. development of the project.

RESUMEN

El sector del transporte es uno de los mayores causantes de las emisiones de contaminantes y de los gases de efecto invernadero (GEI). La conducción eficiente en los últimos años ha demostrado ser una herramienta eficaz para reducir el consumo de carburante y las emisiones de GEI a la atmosfera. Hasta ahora la mayor parte de investigaciones realizadas se han centrado en aplicar las técnicas de conducción eficiente a conductores corrientes en sus itinerarios habituales, sin embargo, existe muy poca investigación en la distribución de mercancías sobre conductores profesionales. Parece por tanto necesario analizar los efectos que la conducción eficiente produce sobre el consumo de combustible y emisiones de GEI de la distribución de mercancías de una ciudad pequeña como Cáceres. Para ello se han realizado un experimento en tiempo real con conductores profesionales conduciendo furgonetas de la empresa pública Correos. En un primer periodo se ha realizado una conducción en condiciones normales (non eco) donde se han registrado segundo a segundo mediante un dispositivo instalado en los vehículos (OBDKEY), distintos parámetros de la conducción (posición, velocidad, rpm, aceleración, deceleración, paradas, etc.). Después de un periodo de formación teórica en conducción eficiente, se ha realizado un segundo periodo de conducción (eco) donde se han vuelto a registrar los mismos parámetros y se han evaluado los efectos que produce sobre los mismos esta conducción. Esta investigación analiza los consumos y emisiones de GEI según la zona de reparto en la ciudad de Cáceres (urbanas, suburbanas y extrarradio) para ambos tipos de conducción (eco y non eco). A partir de este análisis se evalúa la reducción de consumos de combustible y emisiones a la atmósfera con la conducción eficiente y se comparan los resultados obtenidos con conductores no profesionales.

1. INTRODUCCION

El sector transporte representa el 25% de las emisiones totales de gases de efecto invernadero y casi el 40% de las emisiones de los sectores difusos.

Por modos de transporte, la carretera representa casi el 95% de las emisiones, mientras que la contribución de otros modos de transporte es bastante más minoritaria (EEA, 2019). Los turismos y furgonetas representaban el 73 % de las emisiones de GEI del transporte por carretera en 2015 (NU, 2019a).

El acuerdo de Paris (NU, 2015) marcó el objetivo de reducir las emisiones de los gases de efecto invernadero (GEI) un 40% en 2030 con respecto a las emisiones de 1990. Para poder alcanzar este objetivo, la ONU (NU, 2019b) ha advertido que a partir de 2020 las emisiones de carbono tendrán que reducirse a un ritmo de 7,6% al año para cumplir con la meta de un calentamiento global limitado a 1,5 grados.

En la COP-25 de Madrid (Conference of Parties of the United Nations Framework Convention on Climate Change) (NU, 2019b), 73 Estados se han comprometido a ser neutros en carbono en 2050, entre ellos, España. Para lograrlo, España se ha fijado reducir una de cada tres toneladas de CO_2 en la próxima década, duplicando el consumo final de energía renovable en 2030.

En España el modo mayoritario de transporte es sin duda el transporte por carretera, tanto en pasajeros como en mercancías, representado más del 80% de la movilidad total a nivel nacional (MITECO, 2020a). Existen circunstancias propiamente nacionales que han supuesto un incremento de la cuota modal de la carretera, como el modelo de crecimiento urbanístico disperso en el caso de la movilidad de pasajeros y el hecho de ser un país periférico en el caso de la movilidad de mercancías. Además, se caracteriza por el uso preferente de combustibles derivados del petróleo que representan más de 90% del total de energía consumida en el sector transporte en España (Pérez y Monzón, 2008).

Las emisiones de gases de efecto invernadero correspondientes al sector del transporte en España en el año 2014 fueron de 77,2 MtCO2-eq (MITECO, 2020b), habiéndose incrementado casi en un 50% desde 1990 como consecuencia del incremento en la demanda de movilidad de pasajeros y mercancías.

La búsqueda por tanto de medidas de reducción de emisiones de GEI es uno de los objetivos de cualquier país que persiga la neutralidad en carbono para el año 2050. En el caso del transporte de mercancías existen las siguientes medidas para reducir las emisiones de GEI:

1. Sistema de gestión de flotas. Las herramientas informáticas disponibles permiten organizar mejor el tráfico de mercancías y limitar el consumo de combustible y, en consecuencia, de emisiones de CO_2. Cada vez más empresas apuestan por estos sistemas para reducir los kilómetros en vacío y controlar la distribución de cada camión. Las empresas que los han utilizado han reducido las emisiones de sus procesos logísticos hasta en un 2% cada año (Demir et al., 2014).

2. Vehículos a gas natural. El gas natural se ha considerado durante muchos años como la energía de transición, hasta que la eléctrica consiga la autonomía suficiente. Jugará un papel destacado en la descarbonización de la economía mundial y cada vez tiene más aplicaciones en transporte terrestre y marítimo. En 2017 el consumo de gas creció un 9% en España y se espera que despegue a partir del 2020. En el transporte de mercancías por carretera, con cada vez más gasolineras de gas, el gas natural gana confianza para viajes de larga distancia. Los fabricantes de camiones también aumentan su apuesta por este combustible (NGVA, 2017).

3. Megacamiones. El megacamión (o camión euromodular) mide 25,25 metros de largo, pesa 60 toneladas y tiene una capacidad de 51 palés. El llenado pasa de un 54% a un 57,5%, lo que reduce el número de viajes, kilómetros y el consumo de combustible. Según un estudio de la Comisión Europea (CE, 2017), los megacamiones pueden ahorrar hasta un 20% de combustible, un 20% de las emisiones de CO_2 y un 40% de las emisiones de otros contaminantes como NOx (óxidos de nitrógeno).

4. Conducción eficiente. Cómo arrancar, cuándo empezar a frenar, mantener una velocidad adecuada… son conceptos que reducen el consumo de carburante y, por tanto, las emisiones de CO_2. Además, suponen ahorro económico y de energía, menos mantenimiento, mejora de la velocidad media, menos riesgo de accidentes y mejora del confort. La conducción eficiente permite ahorros medios del 10% en carburante, según la guía de conducción eficiente de vehículos industriales del Instituto para la Diversificación y Ahorro de la Energía de España (IDAE, 2011). Los programas de formación en conducción eficiente realizados a conductores de forma individual, suelen estar compuestos de dos partes, una teórica y otra práctica. En la parte práctica se hace hincapié en conducir de forma suave manteniendo una velocidad constante, cambiando de marchas a bajas revoluciones y evitando en la medida de lo posible las repentinas aceleraciones/deceleraciones (Wang y Boggio-Marzet, 2018).

En la literatura, las técnicas de conducción eficiente (Sivak y Schoettle, 2012) han demostrado distinta eficacia en el ahorro de combustible y emisiones de GEI en función de diversos factores externos y métodos de aprendizaje empleados. Los valores de reducción de emisiones de CO_2 oscilan entre el 0,5% y 10% en función del tipo de carretera -carreteras urbanas o autovías- (Alam y McNabola, 2014). La intensidad de tráfico o las pendientes por las que se circula el vehículo son factores que tienen una incidencia directa en el consumo (Kamal et al, 2012). Por tanto, las técnicas de conducción eficiente que se deben emplear son distintas en función del tamaño de la ciudad (Coloma et al., 2020), o el tipo de carretera recorrida (Coloma et al, 2019).

Las investigaciones realizadas hasta ahora sobre conducción eficiente se han centrado normalmente en conductores no profesionales, conduciendo turismos en distintos tipos de carretera, vehículo o ciudad, pero no se ha visto el efecto de la conducción eficiente en empresas de mensajería cuyos conductores son profesionales y tienen como objetivo realizar un reparto en el menor tiempo posible. Conocido este vacío en la literatura los objetivos de esta investigación serán:

1. Consumos y emisiones emitidas a la atmósfera por los vehículos de reparto de mercancías durante una conducción normal y posteriormente con una conducción eficiente.
2. Evaluación de la reducción de consumos de combustible y emisiones a la atmósfera en la conducción eficiente.
3. Comparación de los resultados obtenidos en esta investigación con los de conductores no profesionales que no tienen las obligaciones y exigencias del reparto.

Para cumplir estos objetivos se cuenta con la colaboración de la empresa pública de mensajería española Correos. La ciudad elegida ha sido Cáceres (España) ya que se en ella se ha llevado a cabo un experimento similar con conductores noveles (Coloma, et al, 2017) y puede servir para comparar la eficacia de estas técnicas de conducción en conductores profesionales.

Después de esta introducción el apartado 2 hace una descripción de la metodología seguía para realizar los ensayos con conductores profesionales antes y después de recibir formación en conducción eficiente, el apartado 3 describe los resultados y realiza un análisis de los mismos comparándolos con conductores noveles en Cáceres y con otras investigaciones publicadas en la literatura. Finalmente se adjunta un apartado con las conclusiones más sobresalientes de esta investigación aportando nuevas ideas para futuras investigaciones.

2. MATERIALES Y MÉTODOS

Los resultados favorables de anteriores investigaciones en el campo de la conducción eficiente animan a llevar a cabo un experimento de conducción “eco” en el sector de los vehículos pertenecientes a entidades profesionales donde el consumo de combustible tiene un impacto directo en el rendimiento económico de la empresa. Para ello se lleva a cabo un ensayo en cuatro vehículos pertenecientes a la empresa “Sociedad Estatal Correos y Telégrafos, S.A., S.M.E. (Correos)” en la ciudad de Cáceres (España).

La investigación consta de dos partes, unas pruebas de campo y un posterior estudio y análisis. En las pruebas de campo los vehículos realizan sus respectivas rutas con conducción normal la primera semana y con conducción eficiente en una semana posterior.

En ambas conducciones se realiza un almacenamiento y registro de los principales datos de conducción del vehículo (posicionamiento GPS, velocidad, aceleraciones/deceleraciones, etc). En la segunda parte, se elabora un análisis y estudio de los datos recogidos para poder analizar la eficacia de la conducción eficiente en conductores profesionales.

2.1. Primera fase: Recolección de datos de la actividad de los vehículos en carretera

El génesis de la investigación se sitúa a mediados del mes de septiembre de 2019 y se desarrolla hasta mediados de octubre, consistiendo en la recolección de datos a través de un dispositivo OBD (OBD-KEY, 2020) implementado en los vehículos, el cual almacenaba diferentes parámetros sobre la actividad de los automóviles en sus respectivas jornadas de reparto. En un primer lugar, los conductores ejercieron el tipo de conducción habitual que venían practicando hasta la fecha, después de esta primera extracción de datos, los conductores asistieron a una jornada de instrucción sobre conducción eficiente, con el fin de implementar en su sistemática de manejo del vehículo, actitudes típicas de este modo de conducción. Una vez adquiridos estos conocimientos, los conductores comenzaron a conducir en modo "eco" registrándose también los mismos parámetros de conducción que fueron extraídos en la fase anterior para poder llevar a cabo su comparación. Al final de estas jornadas, se recogieron las sensaciones al respecto en una encuesta realizada a los conductores participantes.

En este tipo de experimentos es necesario el compromiso de los conductores para realizar el ensayo, es decir, el factor humano tiene un peso muy importante en los resultados y eficacia de aplicación de estas técnicas. Adicionalmente, es necesario aclarar que en esta ocasión, las rutas no eran predefinidas, lo que si se hace en otros estudios (Zarkadoula, 2007), sino que estaban sujetas a los itinerarios que marcaban los repartos o bien a la metodología de distribución que los conductores consideraran oportuna. Por tanto, los conductores se enfrentaron a multitud de situaciones de tráfico, lo que afectó a variables que inciden en la investigación como pueden ser la velocidad, tiempos de espera por congestión de tráfico o el confort. No obstante, estos factores son necesarios para evitar sesgos en los resultados que, si son positivos, demostrarían la fácil implementación de la conducción eficiente en los sectores profesionales y lo beneficioso a nivel económico y ambiental que es este tipo de conducción con independencia de la tipología de la distribución de los repartos.

2.1.1. Caso de estudio: Cáceres, España

Cáceres es una ciudad localizada en el oeste de España, con una población de aproximada de 96.000 habitantes y que cuenta con una superficie de 30 km^2. La ciudad posee un significativo pasado histórico, contando con una densidad importante de monumentos y con una morfología urbanística característica de la Edad Media que resulta única, lo que le ha llevado a ser nombrada Patrimonio de la Humanidad por la UNESCO en el año 1986 (UNESCO, 1986).

Cáceres posee una Ciudad Monumental, situada en el centro, de carácter urbano peatonal protegido, a la que perimetralmente se han añadido, tras diversas actuaciones urbanísticas, nuevas zonas de ámbito civil que han ido desarrollándose de forma paulatina a lo largo del tiempo. Sin duda, el modo de transporte principal es el automóvil, representando un 55% de los movimientos dentro de la ciudad.

La orografía de carácter montañoso que posee el emplazamiento de la ciudad y sus dimensiones, no impiden que el desplazamiento peatonal suponga un tercio de los movimientos, a costa de los medios públicos que solo representan un 10% del total (AYUNTAMIENTO DE CACERES, 2014). La ciudad de Cáceres tiene tres franjas horarias punta en cuanto a los movimientos de transporte para acceso a la ciudad: entre las 8 y las 9h, entrada a los trabajos y los centros de enseñanza (10% por encima de la media), y entre las 18 y 19h, donde se produce el regreso a los hogares (15% superior a la media). Como ejemplo, la Avenida de España, situada en el centro de la ciudad, cuenta con un promedio de 1000 vehículos/hora por cada sentido, creciendo dicho valor hasta 1300v/h a las 14h (AYUNTAMIENTO DE CACERES, 2010).

El crecimiento sostenible de la ciudad pasa por implementar medidas que fomenten el uso del transporte público y la movilidad peatonal. A pesar de que ya se han estado aplicando políticas de protección del medio ambiente y reducción de las emisiones en el centro histórico de Cáceres, que en gran parte está dedicado a los peatones, se ve necesario aumentar el número de zonas con estas características, que excluyan los movimientos de automóviles para alcanzar nuevas y mejores metas de sostenibilidad.

2.1.2. Rutas y condiciones de tráfico

Cáceres es una ciudad pequeña que puede ser atravesada de lado a lado en tan solo 15 minutos. Como se ha dicho anteriormente, las rutas no siguen itinerarios definidos, se trata de rutas típicas de una jornada de transporte de repartos de un conductor profesional que se distribuyen por casi toda la ciudad y recorren diferentes tipos de vías urbanas.

Se definen cinco tipos de vías (USDT, 2013), para poder caracterizar los distintos tramos y analizar las rutas específicas de tamaño menor (micro-rutas).

1. Calle local (Local). Este tipo de vía urbana se dispone en el interior de la ciudad. La calzada tiene un carril por sentido de circulación, sin mediana ni aparcamientos. La velocidad máxima de la vía es de 50 km/h.
2. Colector urbano (Colector). Carretera que rodea el centro de la ciudad y conecta puntos neurálgicos de esta. Su calzada está compuesta por dos carriles en cada dirección, dispone de mediana y aparcamiento a cada lado. La velocidad está limitada a 30 km/h y en ocasiones está congestionada.
3. Carretera perimetral (Perimetral). Antigua circunvalación de la ciudad integrada ahora en la red urbana. Tiene doble calzada con dos carriles para cada dirección separados con doble línea continua o mediana, su límite de velocidad es 50 km/h y apenas crea congestión de tráfico.
4. Variante de población (variante). Se sitúa como circunvalación exterior rodeando las afueras de la ciudad. Las intersecciones se ejecutan por medio de glorietas y los pasos para peatones, en su mayoría, se regulan por medio de semáforos. Los límites de velocidad se sitúan en una horquilla de entre 40 y 80 km/h.

5. Vía interurbana (Interurbana). Carreteras situadas fuera de los límites del casco urbano que conectan puntos exteriores a este, ya sean núcleos poblacionales de menor entidad, núcleos industriales como puede ser polígonos o con otras carreteras nacionales o autovías. Sus límites de circulación varían entre 50 y 90 km/h.

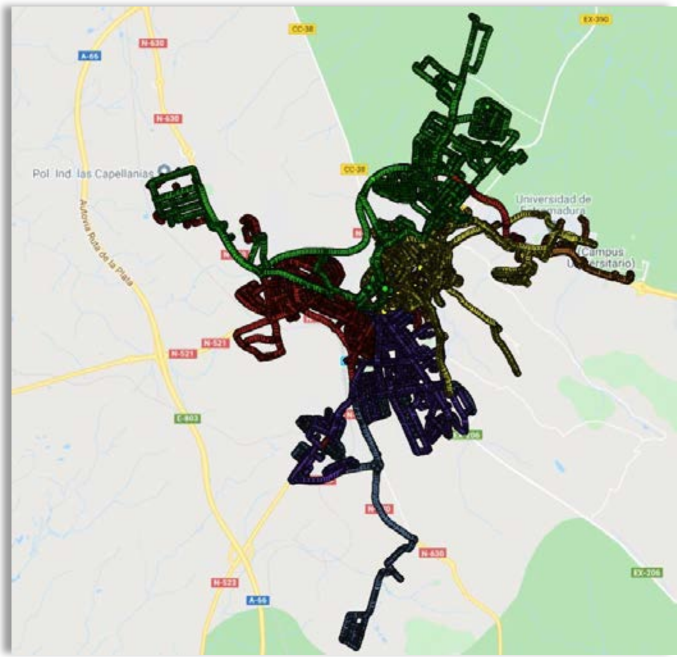

Figura 1. Visión global de las rutas de los vehículos que participan en la investigación.

2.1.3. Selección de conductores, entrenamiento en eco-driving y fechas

Para la realización del experimento fueron seleccionados cinco conductores de la sección de repartos de la empresa Correos en la ciudad de Cáceres. Todos los conductores eran varones con edades comprendidas entre los 35 y 60 años, por lo que la muestra es representativa en cuanto a la edad, pero no en cuanto al género. Durante la primera semana se registraron los viajes de estos conductores durante sus repartos con su conducción habitual.

Posteriormente, los conductores seleccionados recibieron un curso teórico acerca de las técnicas de conducción eficiente para poderlas implementar la semana siguiente en sus repartos diarios. Todos los viajes realizados con conducción “eco” fueron registrados de la misma forma que lo fueron los de la primera semana con conducción habitual.

El horario de las jornadas laborales se divide en dos franjas horarias correspondientes a los turnos de trabajo de mañana y tarde, un primer turno de 7:00 a 14:00 h y un segundo turno comprendido entre las 14:00 y las 21:00 h.

Cuatro de los conductores desarrollaron la experiencia en el primer turno, mientras que un solo individuo realizó el ejercicio en el turno de tarde.

El experimento tuvo lugar entre el 23 de septiembre y 2 de octubre de 2019 para la conducción habitual (non eco) y entre el 9 y 18 de octubre del mismo año para la conducción eficiente (eco). Entre ambos periodos se imparte la formación eco-driving a los conductores de la entidad pública.

2.1.4. Recolección de datos experimentales

Para el ejercicio de campo de la investigación se emplearon vehículos de tipo comercial, en este caso furgonetas diésel, con similitudes en sus características técnicas, tres de ellas pertenecientes a la gama Kangoo de la marca automovilística Renault y la cuarta correspondía a la gama Partner de la marca Peugeot (tabla 1). Los vehículos comerciales representan aproximadamente el 20% de los automóviles activos en la ciudad de Cáceres (DGT,2019).

CARACTERÍSTICAS	PEUGEOT	RENAULT
Clasificación comercial	PARTNER 1.6 HDi 75	KANGOO 1.5 DCi 70 CV
Tipo de cambio de marchas	Manual (5)	Manual (5)
Masa máxima autorizada	1960	2956
Potencia (CV)	75	70
Dimensiones (LxWxH) (mm)	4380 x 2890 x 1801	4213 x 2133 x 1799
Asientos	2 – 5	2 – 5
Emisiones (g de CO2/km)	143	147
Clasificación por consumo relativo	C	D

Tabla 1. Características técnicas de los vehículos utilizados en la investigación

2.1.5. Medición de variables

Para la obtención y almacenamiento de los parámetros necesarios para el posterior estudio, se dispuso a bordo de los vehículos el dispositivito ODB-Key, de esta manera se pudo obtener un perfil de conducción para cada automóvil. Se registró en todo momento la ubicación geográfica de los vehículos, de modo que se pudiera sintetizar de manera digital en el posterior análisis de datos. El proceso que sigue el sistema se representa a continuación:

Figura 2. Esquematización del proceso del sistema de obtención y almacenamiento de datos.

La obtención y almacenamiento de datos se resume en la tabla 2.

PROCESO	OPERADOR	FUNCIÓN
1	OBD-Key	Instalación en vehículo
2	OBD-Key	Obtención de datos
3	OBD-Key	Envío de datos a la aplicación
4	App	Almacenamiento y geolocalización
5	PC	Tratamiento de datos

Tabla 2. Características técnicas de los vehículos utilizados en la investigación

Los efectos de la conducción eficiente se evaluarán por un lado comparando el consumo de combustible y emisiones de CO_2 a la atmósfera y por otro, analizando los parámetros de conducción que tienen mayor influencia en el consumo. Según Coloma et al. (2018) y posteriormente Lois et al. (2019), los parámetros que tienen una mayor influencia en el consumo y que son capaces de representar más del 80% del consumo de fuel son la velocidad media, las revoluciones por minuto (rpm) medias y las aceleraciones y deceleraciones superiores e inferiores a 0,83 m/s2 respectivamente. Además de estos valores que justifican el consumo se registran otros parámetros que se consideran de interés para caracterizar las distintas rutas por su ubicación (posicionamiento GPS) y situación del tráfico (tiempos de recorrido y número de paradas). La siguiente lista muestra los parámetros que finalmente fueron utilizados para el análisis antes y después de que los conductores recibieran la formación sobre conducción eficiente:

Posición GPS (longitud y latitud) y distancia recorrida (km).
Tiempo de viaje (h) y número de paradas.
Velocidad media (km/h).
Rpm medias, aceleraciones y deceleraciones medias (m/s^2).
Consumo de combustible (l/100 km).

2.2. Segunda fase: Análisis y estudio de los datos recolectados.

En la fase de gabinete se reciben los datos almacenados que se procesan a partir de hojas de cálculo. Estos datos se filtran para eliminar los registros erróneos y las paradas para realizar los repartos. Posteriormente, es necesario llevar a cabo una discretización de los distintos parámetros seleccionados y organizarlos de modo que se puedan realizar sobre ellos cálculos como sumatorios, promedios, ponderaciones o cambios de unidades que nos permitan obtener resultados equiparables unos con otros y que nos faciliten la obtención de conclusiones fiables.

A la hora de enfrentarte al tratamiento de datos, en primera instancia nos encontramos con varios documentos pertenecientes a cada conductor, donde se registran por cada segundo de tiempo cada uno de los parámetros que monitoriza el OBD-Key.

Para poder sintetizar esta cantidad de información, se hace necesario obtener los resultados representativos de cada jornada de trabajo, de modo que obtengamos los resultados de los parámetros correspondientes a cada día de trabajo de cada conductor.

Una vez generadas estas hojas de cálculo, se comienza a realizar comparaciones entre las conducciones no ecológicas y las ecológicas entre los mismos vehículos, para ello, los datos más relevantes son el consumo de combustible y las emisiones de CO_2 a la atmósfera. Como cada conductor recorrió distancias diferentes y manejó el vehículo a velocidad también diferente, se hace necesario obtener los parámetros de consumo y emisiones de manera ponderada respecto al tiempo de trayecto de cada jornada. Así, los resultados se comparan con conducciones llevadas a cabo por el mismo conductor antes y después de la formación eco.

El compendio de datos obtenidos también permitió analizar pequeños tramos de rutas realizadas por los automóviles (microtrips). Para ello se obtenían los tiempos iniciales y finales en puntos truncados de los itinerarios de distribución, utilizando en este caso un software de almacenamiento y análisis de geolocalización (QGis, 2020), en el cual se podía apreciar gráficamente los recorridos realizados por los conductores y obtener datos de cada punto de trayecto. Este proceso permitía investigar sobre los beneficios del eco-driving en trayectos más pequeños.

Finalmente se realiza una encuesta a los conductores que permite valorar el estado de ánimo y actitud del conductor a aplicar las técnicas de conducción eficiente. Con los puntos descritos en este apartado sobre la metodología con la que se gestionó el proceso de obtención y análisis de datos, se pueden obtener resultados que nos permitan establecer conclusiones satisfactorias acerca de esta investigación.

3. RESULTADOS Y DISCUSIÓN

Los datos estadísticos del experimento han sido los incluidos en la tabla 3:

VEHÍCULO	MODO DE CONDUCCIÓN	DISTANCIA RECORRIDA (km)	TIEMPO DE CONDUCCIÓN (h)	Nº REPARTOS REALIZADOS
4121KDW	NON-ECO	195,241	46,938	379
	ECO-DRIVING	346,600	68,014	584
4414JKD	NON-ECO	123,100	33,144	266
	ECO-DRIVING	167,247	34,463	340
2790KRG	NON-ECO	96,840	31,665	328

	ECO-DRIVING	0,611	4,153	1,327	3,217
ACEL. MÁXIMA NEGATIVA (m/s2)	NON-ECO	-0,518	-2,515	0,417	-4,007
	ECO-DRIVING	-0,632	-3,730	-1,380	-3,469

Tabla 5. Parámetros de conducción para los distintos tipos de vehículo y conducción.

Eco-driving produce reducciones de rpm, velocidad y aceleraciones / desaceleraciones (Huang et al., 2018 y Saito el at., 2008). De los resultados obtenidos se puede concluir que solo el conductor 5 mejora sus parámetros de conducción con la conducción ecológica. Las velocidades, rpm y aceleraciones máximas y medias aumentan con la conducción ecológica en los parámetros de conducción de los otros 4 conductores.

La congestión o el estrés que implica la entrega de paquetes en el menor tiempo posible, hace que la mayoría de los conductores profesionales en el experimento no hayan obtenido mejoras en los parámetros de conducción al conducir eco.

3.2. Consumo y emisiones

La tabla 6 recoge los consumos y emisiones de CO_2 estimadas para cada uno de los vehículos y tipos de conducción.

	MODO CONDUCCIÓN	VEHÍCULOS 4121KDW	4414JKD	2790KRG	4118KDW
CONSUMO (l/100km)	NON-ECO	6,955	4,930	6,756	5,010
	ECO-DRIVING	4,918	4,005	6,807	5,071
EMISIONES DE CO2 (g/km)	NON-ECO	217,8500	150,186	205,201	157,891
	ECO-DRIVING	151,838	121,676	208,033	160,444

Tabla 6. Consumo y estimación de emisiones para los distintos tipos de vehículo y conducción.

El consumo de combustible y las emisiones de CO_2 muestran que la conducción ecológica en las ciudades pequeñas no es eficiente. El único conductor con parámetros de conducción ecológica ha obtenido un mayor consumo medio de combustible y mayores emisiones de CO_2. Tres de los otros cuatro conductores sin parámetros de conducción ecológica reducen el consumo de combustible y las emisiones. Esto muestra que en las ciudades pequeñas, las altas velocidades significan tiempos de viaje cortos que a su vez reducen el consumo medio de combustible (l/100 km) y, por tanto, las emisiones medias. La conducción ecológica reduce velocidades y aceleraciones, pero en ciudades pequeñas donde los recorridos son muy cortos, no reduce suficientemente el consumo instantáneo y esto provoca que los tiempos de conducción más largos produzcan un mayor consumo medio de combustible (l/100 km) y como consecuencia, mayor Emisiones de CO_2 a la atmósfera.

Esta afirmación coincide con Schall et al (2016), ya que no observaron mejoras en la reducción del consumo de combustible con conducción ecológica en una empresa de mensajería en Munich (Alemania). Sin embargo, estos resultados van en contra de la mayoría de las investigaciones realizadas hasta ahora con conductores no profesionales, ya que muestran resultados favorables en el consumo con conducción ecológica tanto en ciudades grandes como pequeñas, por ejemplo Dhaou (2011) logró un ahorro de combustible de aproximadamente un 20% con la conducción ecológica en 10 ciudades de Túnez y Andrieu et al. (2012) obtuvo un 11,3% de ahorro de combustible en una pequeña ciudad francesa llamada Pontchartrain.

3.2. Microtrips

Se ha realizado también un análisis por tipo carretera recorrida (local, colectora, perimetral, variante e interurbana) para ver si se pueden sacar conclusiones sobre la conducción eficiente de los conductores profesionales por tipo de ruta. Las características de las micro rutas seleccionadas (micro trips) se adjuntan en la tabla 7.

Tabla 9. Parámetros de conducción en las micro rutas seleccionadas.

Las investigaciones realizadas en diferentes tipos de carreteras normalmente reducen la velocidad, las rpm y las aceleraciones en la conducción ecológica (Beusen et al., 2009), sin embargo, hay otros estudios que muestran que en carreteras congestionadas, la conducción ecológica no reduce estos parámetros (Garcia-Castro y Monzón, 2014).

La tabla 10 incluye los consumos y la estimación de emisiones para las micro rutas seleccionadas.

	MODO	LOC.	COLECTOR		PERIMET.		VARIANTE		INT. URB.
		R 1	R 2	R3	R 4	R 5	R 6	R 7	R 8
CONSUMO (l/100 km)	NON-ECO	3,251	7,608	8,819	11,49	8,417	7,573	6,977	4,534
	ECO	5,844	13,73	9,931	17,27	8,474	8,545	4,497	4,191
EMISIONES DE CO_2 (g/km)	NON-ECO	97,49	236,2	270,6	361,2	259,2	227,8	218,1	139,8
	ECO	177,7	424,9	307,2	534,0	261,5	268,2	140,4	128,2

Tabla 10. Consumos y estimación de emisiones en las micro rutas seleccionadas

Los resultados de los micro viajes muestran que la conducción ecológica es más eficaz en carreteras menos congestionadas y con mayor capacidad (variante e interurbana). Las vías urbanas que sufren más congestión de tráfico (local y colector) no son efectivas para ahorrar consumo de combustible y emisiones de CO_2 en modo eco. La perimetral por su carácter mixto urbano y periurbano no deja claro el beneficio de la conducción ecológica sobre ella. Por lo tanto, sería bueno que el conductor profesional eligiera las rutas menos congestionadas y de mayor capacidad para que la conducción ecológica sea más efectiva.

Coloma et al en Cáceres (2017) y posteriormente Yang et al en Madrid (2018), obtuvieron resultados similares a los encontrados en esta investigación, ya que el ahorro de combustible aumentó con la capacidad de la carretera. Sin embargo, también hay otros estudios (Perez-Prada y Monzón, 2017) que muestran que las carreteras de alta capacidad pero congestionadas no son eficientes con la conducción ecológica.

3.3. Encuestas

La tabla 11 recoge el resultado de las encuestas realizadas después de la conducción.

PREGUNTAS	MODO	Nº	RESPUESTAS						
			1	2	3	4	5	6	7

	ECO	15	6	5	1	0	0	1	2

Tabla 11. Encuesta realizada a los conductores en todos los viajes registrados

La mayoría de los conductores (15 de 18) consideran que conducir es fácil. Esto es lógico ya que son conductores profesionales. Por otro lado, las condiciones de conducción también han sido “fáciles”, lo que significa que la congestión del tráfico y otros agentes externos no han afectado la forma de conducir de los conductores profesionales.

Finalmente, se ha aclarado si el modo de conducción estresa al conductor profesional. Los resultados muestran que la mayoría de los conductores (13 de 15) estaban relajados durante ambos modos de conducción, lo que significa que la conducción ecológica no aumenta su estrés. Sin embargo, la necesidad de realizar una entrega en un tiempo determinado hace estresar al conductor profesional y es muy difícil modificar su estilo de conducción para aplicar técnicas de conducción ecológica. García et al (2018) en su experimento observaron que los conductores no profesionales tampoco aumentaban su nivel de estrés cuando conducían en modo eco. No obstante, la conducción era más eficiente (en ahorro de combustible y emisiones de CO_2) cuando el conductor era más joven, por lo que sería necesario enseñar estas técnicas de conducción desde las escuelas de conducción (Stromberg, 2015).

4. CONCLUSIONES

Los países desarrollados intentan promover una gestión vial eficiente mediante el uso de tecnologías que reducen las emisiones de GEI en las ciudades, implementando modos de conducción para los conductores y decisiones de viaje sostenibles. Las ciudades tienen diferentes métodos para lograr estos objetivos ambientales, pero ninguno puede alcanzarse con éxito sin la cooperación de los conductores. Las políticas medioambientales deben ser aceptadas por el público en general, y algunas de ellas dependen fundamentalmente de su forma de conducir (eco-driving) y de cómo planifican sus viajes (eco-routing). La investigación hasta la fecha sobre conducción ecológica se ha centrado generalmente en las grandes ciudades debido a sus graves problemas de congestión. Sin embargo, las ciudades pequeñas también enfrentan estos problemas y deben ayudar a reducir las emisiones de GEI, que es un objetivo mundial.

En esta investigación se realizó un estudio sobre la efectividad de la conducción ecológica con conductores profesionales en una ciudad pequeña y poco congestionada como es Cáceres. Los resultados obtenidos confirmaron que la conducción ecológica con entrega por mensajería no suele generar ahorro de combustible. Un análisis de micro viajes refleja una tendencia en el ahorro de combustible a medida que aumenta la capacidad de las carreteras. La figura 12 resume las principales conclusiones de esta investigación.

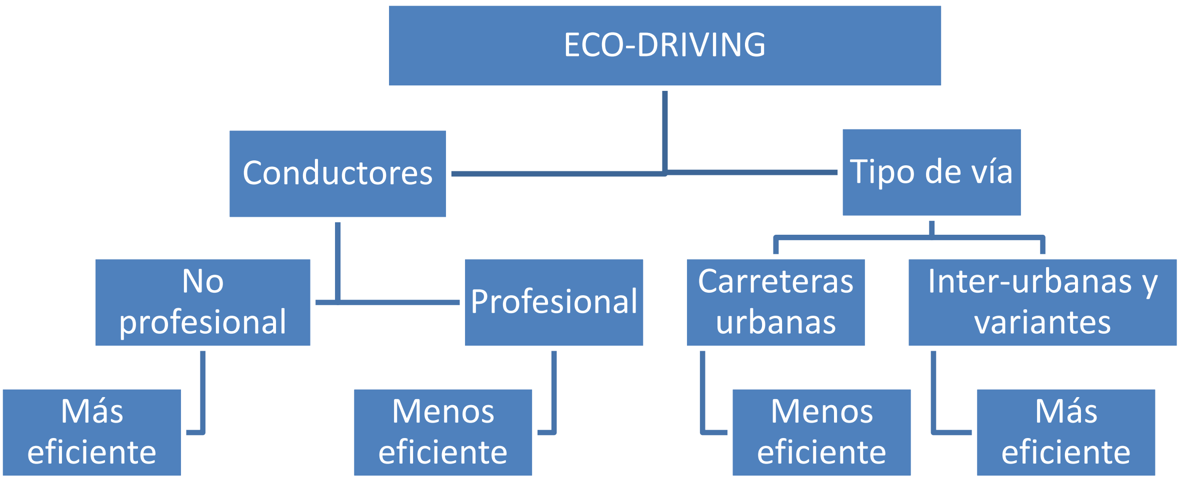

Figure 12. Conclusiones principales de la investigación.

En investigaciones futuras, los efectos de la conducción ecológica en los conductores profesionales podrían estudiarse con incentivos (monetarios y no monetarios), ya que Schall y Mohnen (2015) lograron ahorros de combustible de alrededor del 5% con los conductores de una empresa de flotas que había recibido incentivos. También podrían estudiarse otros tipos de vehículos ampliamente utilizados en el reparto por mensajería, como las motos (Seedam et al., 2017).

Además, también es necesario observar el efecto de la conducción ecológica en los vehículos eléctricos.
Este tipo de estudios requieren modelos teóricos de consumo de energía como la Potencia específica del vehículo (VSP) (Pitanuwat et al., 2020).

FINANCIACIÓN

Este trabajo fue financiado en parte por el Proyecto Nacional de I + D (Ministerio de Economía y Competitividad) en el marco del Proyecto Eco-Traffic “Medición y Modelización de Eco-Driving táctico y operacional”. Ref TRA2016-76485-R (AEI/FEDER, UE).

AGRADECIMIENTOS

Los autores quieren agradecer a la empresa Correos por su ayuda en la toma de datos de la investigación.

PREDICTING ON-TIME DELIVERIES IN TRUCKING: A MODEL BASED ON THE WORKING CONDITIONS OF DRIVERS

Luis David Berrones-Sanz
Universidad Autónoma de la Ciudad de México, México

ABSTRACT

Over a period of two years, 26.3 thousand road freight shipments were recorded. The records include information about truckload companies, drivers, and the causes of non-compliance and delays in deliveries. Logistic regression based in working conditions as independent variables was used to predict non-compliance deliveries attributed to cargo drivers. Results show that vehicle type, medical coverage and social security, level of stress, work dissatisfaction, and transit time were strongly associated with out-of-time-delays in deliveries. The proposed model is a promising tool to improve the performance of truckload companies and it may motivate to benefit working conditions of truckers.

1. INTRODUCTION

On-Time Delivery (OTD) is one of the key performance indicators in transportation service companies. Failure to comply with OTDs can lead to breakdowns in supply chains, loss of customers and, in general, high costs for transportation that are assumed both in the short and long term. Consequently, leading companies in the supply chain use data analysis to optimize their operations and prevent disruptions in their processes (Sanders, 2016); however, identifying the causes of deviations and preventing non-compliance in deliveries are an obligated task for companies involved in the transport of goods, since it is a highly competitive market with increasingly narrow profit margins.

In this regard, in the international literature there are studies to predict the arrival time and delays of trucks. Van der Spoel, Amrit, and Van Hillegersberg (2017) carried out a review of the literature in which they found 82 investigations related to predictors for arrival time.

In this investigation, a classification of the factors found in thirteen categories was made: congestion, weather, speed, distance, type of cargo, type of truck, time of day (week, month, and year), cumulative previous deviation, accidents, road work, traffic signal failures, road condition, and driving style.

The authors conclude that congestion, time of day, and accidents are the most frequently mentioned factors and that, in a negative way, they are the ones that most influence travel time. However, it stands out that, despite the relationship with the human factor, no variable refers directly to the working conditions of drivers.

Despite the fact people have a crucial effect in determining a successful supply chain (awcett, Magnan, & McCarter, 2005), the absence of the working conditions of truck drivers in the prediction models of on-time deliveries appears to be the predominant situation. It is undeniable that drivers are a decisive link in transport chains; and it has been established (Kemp, Kopp, & Kemp, 2013) that some working conditions of drivers lead to emotional exhaustion and, therefore, reduce commitment to the organization, negatively affect the service that drivers provide to the customer and, therefore, cause delays and non-compliance in deliveries on time.

Furthermore, previous studies have indicated that late deliveries are one of the main repercussions of drivers' working conditions in the supply chain (Berrones, González, Lámbarry, & Rocha, 2020). The driving activity subjects workers to risks and demands, derived from the organization and technical division of labor, which implies strenuous work rhythms, intense working hours, market structures and lifestyles that determine the health / illness of drivers and affect their physical and mental health (Berrones, 2017; Berrones & González, 2018). Likewise, these investigations focused on Mexican truck drivers have stated that drivers are in precarious working conditions, do not have social security, are prone to diseases, have high stress levels, are dissatisfied with their work, and are subjected to derived workloads work organization, which include the area where they work, the type of vehicle, the size of the company and the type of relationship they have with it (Berrones, 2017; Berrones et al., 2020; Berrones & González, 2018).

Then, the questioning arises of how the working conditions of the drivers of the freight transport are related in their performance, specifically, in the deliveries on time. In this way, this study aims to explore the relationship between work and drivers' performance, under the assertion that working conditions can explain out-of-time deliveries. Thus, a case study was carried out in a manufacturing company that seeks to reduce non-compliance in deliveries caused by causes attributed to drivers and, based on the availability of variables that determine their working conditions, the binary logistic regression was used to model and predict truckers' on-time deliveries.

2. METHODS

2.1 Description of variables

For two years, data of 26,312 shipments were kept track, that of a company which manufactures lightweight construction systems in Mexico. Variables such as the labor relationship (employee or owner-operator), access to social security, age and the results of subjective assessment of stress and the satisfaction of the truck drivers were used to determine the factors that affect the performance in the goods deliveries.

The variables considered in the study were determined according to previous studies on working conditions of trucks in Mexico (Berrones, 2017; Berrones & González, 2018), and with the availability of information from the company in the case study. Finally, eleven independent variables, which are shown in figures 1 and 2, were considered.

After examining the characteristics of the statistical distribution of the variables involved in the analysis, the bivariate and multivariate relationships, and the analysis of the differences between groups the data were tested in several models of multivariate type.

Finally, given that the dependent variable, which was named non-compliance of deliveries (Y_{ncd}) has the characteristic of being dichotomous (correct or incorrect delivery) a logistic regression approach was found adequate. In this way, to examine the contribution of the independent variables (figures 1 and 2) logistic regression based in working conditions as independent variables was used to predict on-time deliveries attributed to cargo drivers, its significance was verified, and a model of the parsimonious type was constructed.

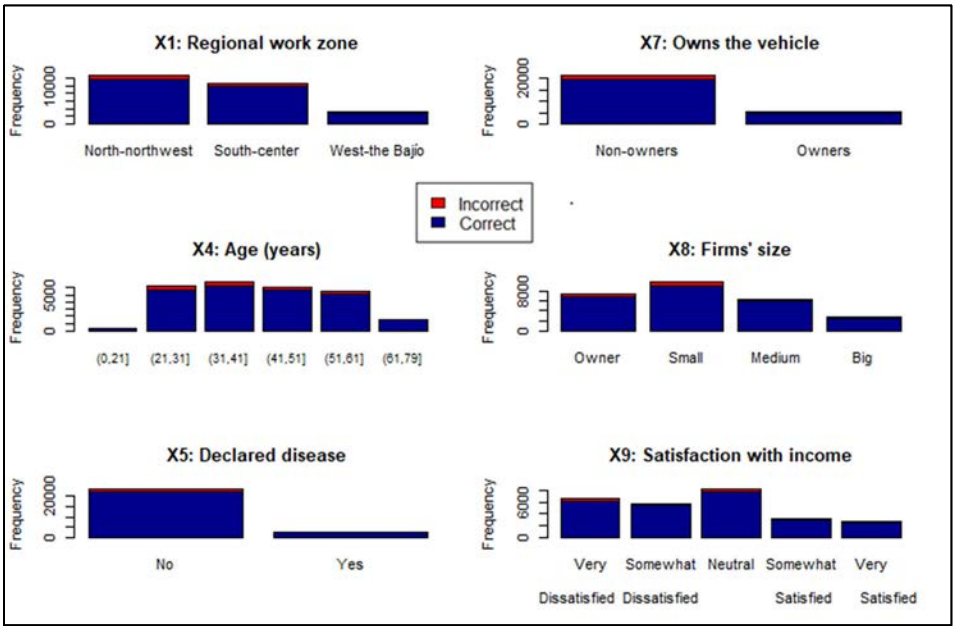

Fig. 1 Considered variables that are not in the final equation

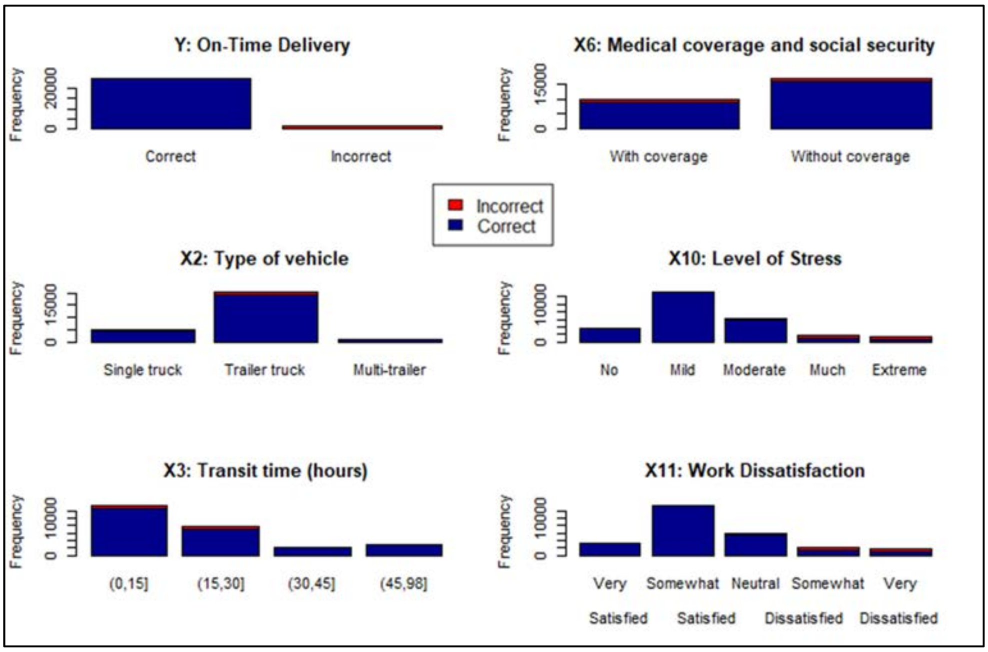

Fig. 2 Variables in the equation

2.2 The sending company

The manufacturing company, which produces approximately 80% of the total lightweight construction systems that are marketed in Mexico, makes its shipments in heavy vehicles that are loaded in three plants, located in the north, east and west of the country. The different locations manufacture the same products, with the same quality standards, and are shipped, to be distributed throughout the national territory under the same process in three types of vehicles: single trailer 6-axle truck (77.37%), single unit 3-axle trucks (18.17%) and multi-trailer 9-axle trucks (4.46%), with a capacity of 19, 30 and 56 tons of payload, respectively.

2.3 Truckload Trucking companies

The manufacturing company does not have its own vehicle fleet, so all the transportation of the goods is carried out as an outsourced activity. In total, 52 truck companies were used and were classified by the number and type of vehicles available (company size), the location or work area in which they provide the service (north-northwest, south-center and west-The Bajío), the access to social security, and vehicle ownership (is or not owner-operator).

2.4 Systematization of data

The information used in this study was obtained through systematic data recording, from a module named Shipment System -programmed and adapted as a complement to a system of Enterprise Resource Planning (ERP)- and whose main objective is creating indicators for transport services, that the sending company subcontracts. The data were divided into three components: shipment tracking, delivery information, and perception of the driver.

The shipment tracking module records the timetable the driver arrives at the loading point and is available to load, the time it is positioned on the loading platform, the start and end time of the loading process, and the departure time in which drivers start the trip to the final destination. In all these processes, several users use different computers and record the schedules by selecting a checkbox, which cannot be manipulated by the users, and where the schedules are captured in real time. These data are compared with the planned schedules and the fulfillment of time of the truck companies and loading dock personnel is verified.

The delivery information is verified through global positioning systems (if the carrier has the service) or telephone reports made by the drivers. Subsequently, they are verified through the delivery documentation (delivery note), in which the client signs the receipt, reports missing or apparent damage to the materials and establishes the date and time at which the carrier arrived, same that is contrasted with the date in which the delivery was promised.

Finally, to assess the perception of the driver, the documents included three mandatory Likert-type questions, with a scale of one to five, which assessed the level of work stress, dissatisfaction at work and satisfaction with income. Other information about drivers, such as the name, age and if he has social security or medical coverage, was previously entered in the drivers register and during the planning of the shipments.

For the logistic regression, R software and glm function (Fitting Generalized Linear Models) were used, and it was used as a dependent variable and it was coded with a one (Y=1) to shipments that were delivered incorrectly, that is, with damages, out of time, or any cause of non-compliance; and with a zero (Y=0) for the shipments that were delivered in a timely manner (on-time-delivery). This classification includes only the shipments whose causes of non-compliance were attributed to the carriers, and the derivatives for any other reason, such as programming errors or problems in the loading areas are excluded.

Finally, the logistic regression coefficients were used to elaborate an equation that allows calculating the probability of non-compliance in the timely deliveries of truck drivers. In this way, the categories or values taken by the variables that generate both the lowest and the highest probability of non-compliance were identified and, therefore, can be considered protective or risk factors for fulfillment of on-time deliveries.

3. RESULTS

De Of the 26,312 shipments, almost 14% (3,635) were registered as inaccurate deliveries that included any cause and not just transportation issues; that is, they were delivered with some missing, wrong materials, damaged or the promised delivery schedule was not met.

Of the non-compliances, 1,790 (6.81%) were attributed to causes related to the carriers; represent the event of interest and were coded with *Y*=1. The rest of the shipments were considered correct or on-time and were coded with *Y*=0.

The shipments frequency classified by correct or incorrect delivery is shown in figures 1 and 2. It can be seen that the highest percentage of incorrect deliveries occurs in small (2.6%) and owner-operators (2.4%) firms, in the south-center area (3.9%) and in the 6-axle truck type vehicle (5.1%). As for trucks drivers, just over a quarter (25.5%) are owners of the vehicle (owner-operator), a fifth (20.6%) have no social benefits or medical coverage, on average they have an age of 40.7 ± 12.99 years, and 8.4% indicated having a permanent disease; mainly of cardiovascular or chronic degenerative type. In addition, it can be seen that drivers who indicated an extreme level of stress got a higher frequency in inaccurate deliveries, whereas this does not seem to be related to drivers who were very dissatisfied with work or very dissatisfied with income.

3.1 Logistic regression and the probability model of non-compliance

Using R software, the parameters associated to Logistics Regression were calculated. In this way, Omnibus tests of model coefficients showed the probability of obtaining chi-square statistic (7,867.237), so that there is no effect of the independent variables, taken together, on the dependent variable ($p<.001$).

Meanwhile, the Hosmer-Lemeshow test of the goodness of fit suggested the model is a good fit to the data as $p=0.075$ and the hypothesis null was not rejected ($p>.05$). Thus, in general, the model has a high specificity (98.5%) and an average sensitivity (65.6%), so that the model generated through logistic regression offers an overall sample accuracy of 96.3% in the prediction of the event of out-of-time deliveries.

Table 1 provides variables in the equation in the final step; it contains estimated coefficients, standard error, the Wald statistic (*z* value), statistical significance and the Odds Ratio of the variables involved. Only five variables (figure 2) had statistical significance ($p<.05$); these are named: Transit time (X_3), Type of vehicle ($X_{2,j}$), Medical coverage (X_6), Level of stress ($X_{10,j}$), and Work dissatisfaction ($X_{11,j}$), strongly associated with the out-of-time deliveries.

4. DISCUSSION

Some research about drivers has demonstrated that stress affects the performance of workers (Kemp et al., 2013; Lámbarry, Trujillo, & Cumbres, 2016). Thus, it is not surprising that stress has been included as one of the factors in the model and that, to the extent that it increases, the probability of non-compliance of on-time-delivery also increases.

However, given that the stress is caused by labor journeys that do not adequately meet the needs of rest, the lack of training to drive their vehicles or other job demands (Lámbarry et al., 2016); trying to reduce the level of stress is a complicated task, because it already includes practically all the categories of working conditions.

However, it is well-known that an important part of the working conditions of drivers is determined by the characteristics of the vehicle in which they carry out their activities and which has an important influence on their satisfaction (Ordaz & Maqueda, 2014). Thus, given that in Mexico 88% of the vehicle fleet is more than twenty years old (DGAF, 2018); delays are evident in terms of ergonomics, comfort, noise, safety and technological devices that facilitate driving; so the old vehicles not only affect the working conditions and the satisfaction of the drivers, but also put in constant disadvantage the competitiveness of the companies.

In addition to the concerns about the characteristics of vehicles, the satisfaction comprises other dimensions such as job demands, organizational issues, work environment, remuneration, the nature of the tasks performed and even personal situations. In this study, satisfaction was evaluated from two perspectives: 1) subjective work dissatisfaction, which evaluates in a general way the feelings and emotions of the drivers (variable $X_{11,j}$); and 2)

Satisfaction with income (variable $X_{9,j}$) which assesses wellness or pleasure in relation to the money that drivers receive for their work. However, only the subjective dissatisfaction was included in the model as it was significant (p<0.01), and the variable related to satisfaction with income was excluded (p=0.735). For these reasons, it is deduced that the drivers are satisfied with their income, although not with other working conditions that are directly related to the inaccuracy of on-time deliveries, so it can be said that the higher levels of work dissatisfaction are related to the risk of out-of-time deliveries.

On the other hand, although the income satisfaction variable was not significant and therefore was not included in the model, it is known that the drivers' income is related to experience and the ability to drive larger vehicles.

For example, a driver of vehicles with multi-trailers obtains more income than that of trailer trucks and, in turn, higher income than those of a single unit truck. However, the model shows that vehicles that move more cargo (Multi-trailer 9-axle trucks) are more likely to fail on deliveries.

Other studies indicate that the relative odds of death in road accident increases with the size of the vehicle, and it increases up to 3.42 times for heavier vehicles (Berrones, 2019). Although the model does not delve into accidents, vehicle crashes are considered as non-compliance of deliveries, and the results agree on the risk that the size of vehicles (variable $X_{2,j}$) imposes on the flow of the transport chain.

Given that larger vehicles are more efficient in terms of costs and using the different vehicle configurations depends on the planning and specific needs -such as order size or market conditions- it is not feasible, only to use smaller vehicles. Therefore, training and promotion of road safety must be promoted, so that progressively, drivers have new skills that compensate the dimensions of vehicles and reduce risks in the supply chain.

As for work time, although the proposed model does not directly contemplate the workday, days worked per week or resting time; it incorporates within the variables with statistical significance the programed transit time, which is part of the work time. Transit time is related with to out-of-time deliveries and calculates its highest probability of default (97.18%) in the scheduled deliveries of 36 hours (X_3=36). During that time, a worker drives from the origin to the destination, is present during loading and unloading, he feeds, rests, sleeps, and travels about one thousand kilometers. In Mexico, it is common for truck drivers to work by piecework and under a lax regulation of driving hours, which also does not include working hours outside the wheel.

Although many hours worked per day can lead bad temper, physical and mental fatigue, excessive drowsiness or anxiety, inattention at work and road fatalities (Kemp et al., 2013), it is known that, a common practice for Mexican drivers is to work up to 76 hours per week and without a proper rest (Berrones & González, 2018). Consequently, the effects of transit time and long hours of work, not only put the logistics processes at risk through the inaccurate deliveries, but are associated with adverse health effects, such as chronic diseases, or permanent physical and psychological injuries(Beek, 2012).

Also, despite the fact that several studies around the world indicate that driving is among the professions that have the greatest suffering and risk factors associated with their occupation (Tse, Flin, & Mearns, 2006), the subjective condition of disease (Variable X_5) did not show statistical significance (p=0.276) and was not considered for the final model.

While in the opposite way, the medical coverage and social security (Variable X_6) had statistical significance (p<0.01) and are considered for the calculation of probability of non-compliance. However, the percentage of drivers who have medical coverage is high compared to the national total of land transit workers, 63.12% for the case study versus 42.09% of the registered drivers in the National Survey of Occupation and Employment (Instituto Nacional de Estadística y Geografía, 2020).

It is important to note that, for this case study, the amount is influenced by the number of companies with more than thirty vehicles, 17.31% against 2.2% in the national total (DGAF, 2018); since, on the contrary of the companies of type owner-operator, greater-sized companies provide these benefits to its employees.

Consequently, having the benefit of social security (X_6), represents that the driver is entitled to several privileges, which include access to health services, vacation, bonuses, pension systems, among others; that guarantee certain compliance in working conditions.

Thus, in spite of the fact that in many cases, as a strategy of evasion of labor taxes, the companies register only minimum wage and not the real remuneration of the driver, and so that in case of temporary or definitive disability, or retirement, they only perceive a minimum part of the usual income; the lack of social security is a factor that participates in the calculation of the highest probability of default on deliveries.

Finally, in comparison with other logistic regression models, and even though they have different objectives, it can be observed that these have some similar variables. Martínez, Oviedo, and Luna (2015) to explain the quality of working life, included variables of job stability, physical load, income, and some other stressors.

It highlights the similarity of the variables related to stress and physical load which are also considered in the proposed model through variables like X11,j and X3. In addition, in the same way as in the proposed model, neither Martínez et al. (2015) nor Villar, Delgado, and Barrilao (2015) had a statistical significance for the variable income despite the fact that income correlates positively with subjective work conditions; so you can say that income is not as important as other working conditions for the behavior of workers.

Likewise, Villar et al. (2015) did not find statistical significance in the region where employees work but indicates that the autonomy of workers influences their satisfaction. Given that in the inaccurate deliveries model the vehicle ownership variable ($X_{7,j}$) represents work autonomy, it is possible to consider some contradiction between the two studies. However, the comparison study refers to administrative employees, while the current is based on drivers; and the driving activity already implies a certain autonomy in the work.

For that reason, despite the different objectives of this research, the multi-variant analysis with logistic regression models seem to be a good alternative to explain and predict the relationships between working conditions and workers' behavior.

5. CONCLUSIONS

Si Although the different groups of drivers share risks and demands derived from their labor process, their working conditions vary according to different factors determined by technological, social, cultural, economic and regulatory aspects, including labor laws and traffic regulations; so, some other variables not included in the model could be relevant.

However, the five variables used to calculate the probability of non-compliance of deliveries can be considered as dimensions that encompass other factors, and these are related to other working and health conditions, both physical and mental. Thus, for example, the variable $X_{8,j}$ (firms' size) is associated with the longevity of the vehicle fleet, given the larger companies have vehicles with models under six years, while those of the owner-operators are over twenty years.

Briefly, to extrapolate the model to other types of industries, it is necessary to include a greater number of variables (demographic, health, work and organizational, among others), to rule omissions of factors or relevant characteristics, typical of certain industries or products, which may affect the inaccurate deliveries and, therefore, the competitiveness of companies.

In addition, data considered subjective variables. It is recommended that objective methods, as validated tests, are used to measure and reduce the level of stress, job dissatisfaction and the other subjective variables.

However, this study shows the relevance of the working conditions of truckers in terms of how they affect non-compliance in the delivery of goods by road.

The results will be used to create a conceptual model that generalizes, in any type of industry, the effect of labor conditions on inaccurate deliveries. And, finally, despite the limitations of the model, the results show that proposed model is a promising tool to improve the performance of truckload companies and it may motivate to benefit working conditions of cargo drivers.

EFFICIENCY OF SCALE OF LOGISTICS IN THE PRODUCTION OF THE WORLD'S COUNTRIES (2007-2018)

Miguel Angel Pesquera
Professor of Transport Engineering and Infrastructure. University of Cantabria. Spain

ABSTRACT

Logistics is an important factor in global production. However, this does not mean that we know the impact of logistics on production and its efficiency in the short and long term.

The content of the paper reflects the results of research conducted on the contribution of logistics to the scale efficiency of the world's countries.

This research uses a production function of the type proposed by Mankiw et al. (1992) to study the effect of logistics on scale efficiency through data envelopment analysis (DEA) for one hundred and thirty-three countries in the world during the period 2007-2018. This research establishes that logistics is an important channel for improving scale efficiency for the countries of the world in view of the estimation results.

This research contributes to the literature by estimating the contribution of each of the components of the Logistics

Performance Index (LPI), developed by the World Bank, to scale efficiency.

The results highlight the significant impact of logistics on global efficiency. Available World Bank data show that a 1% increase in the logistics performance index increases the current global level of the efficiency scale by 0.42%.

1. INTRODUCTION: EFFICIENCY AND ECONOMIC GROWTH

Today, there is no doubt that logistics is an important factor in global production.

However, this fact does not mean that the impact of logistics on production and its efficiency in the short and long term is known. There is even some controversy about the extent to which logistics affects production and efficiency. Ultimately, this is what Stiglitz (2014) calls a puzzle about the nature of the comparative advantage of technologies and logistics.

There are very few studies that analyze the contribution of logistics, there are only two works, Coto-Millán et al. (2013) and Coto-Millán et al. (2016), both of which provide an approximation of the contribution of logistics to economic growth and global technical efficiency. Even more striking is the lack of studies and research on the impact of logistics since the crisis of recent years.

An important question is how to accurately describe the aggregate production function.

Output growth is typically explained as the accumulation of factor inputs and growth in total factor productivity. Apart from the basic factors of production, growth accounting looks for additional determinants that can explain growth and efficiency. This leads to a regression that treats all determinants of output growth as inputs, which is conceptually incorrect, as many determinants that can be included can only indirectly affect output production (Miller and Upadhyay (2000)). However, using Data Envelopment Analysis (hereafter DEA) we can detect additional determinants of output growth (beyond the input factors) that affect the efficiency of real inputs, physical capital, human capital and employment, and thus directly affect the productivity factor.

First, by estimating the overall scale efficiency through DEA techniques, taking as a starting point the growth model proposed by Mankiw et al. (1992).

Secondly, by assessing the impact of global logistics and its components as explanatory variables of the global scale efficiency of the different countries. The objective is to analyse the impact, at least in part, of logistics on the overall scale efficiency of world production.

This question is considered of great interest, given that progress in logistics is one of the most significant social and economic issues in recent decades, to the extent that it has created what some call a new revolution in production, storage, distribution and transport.

For this purpose, and given data limitations, a panel of data from the years 2007-2010-2012-2014-2016-2018 for 133 countries has been studied.

According to Farrel's (1957) classical definition, an economy is considered technically efficient if it obtains the maximum achievable output (outputs) with the resources (inputs) used and the technology available. Graphically, this can be understood by viewing output growth from the perspective of a production possibilities frontier where countries may be operating within and, where the distance to the frontier reflects technical inefficiency (Ghosh and Mastromarco 2013).

The frontier literature is quite extensive and can be roughly divided into two groups according to the method chosen to estimate the production function frontier, namely deterministic versus stochastic frontiers (SFA) .

It is well known that the first work applying SFA and data envelopment analysis (DEA) to economic growth was by Rao and Coelli (1998). The authors conducted an updated analysis of productivity convergence and inequality around the world. Their finding showed that transition to thrift achieves inefficiency reduction in planned economies.

Following the analysis of Technical Efficiency (hereafter TE), Delgado and Álvarez (2003) conducted a study for the EU-15. The authors used the SFA to explore the determinants of TE in European economies.

The results of this research, estimating a translog function, show that larger endowments of public capital and education can facilitate access to productive activity at efficient levels for their members.

Deliktas and Balcilar (2005), using DEA, conducted a production frontier for one hundred and thirty countries over the period 1991 to 2000; however, they eventually focused on estimating TE for twenty-five transition countries. Their results revealed that public capital had a positive impact on private sector efficiency.

Lam (2010) used SFA methods to conduct a cross-sectional analysis of the role of institutions in TE in countries around the world. This research concluded that institutions play a positive role.

Alonso and Aubyn (2010) estimated a panel-based TE frontier for the output of the nineteen EU countries for the years 1970, 1980, 1990 and 2000. The authors used stochastic frontiers and semi-parametric approaches with the calculation of Malmquist productivity indices. The main conclusion was that inefficiency could be explained by government efficiency in investing in net capital stock with a positive coefficient.

Oliveira-Pires and Garcia (2012) estimated a world production function as well as its frontier for the period 1965 -2000, concluding that there was a set of explanatory variables that determined that of each country. Using a similar methodological approach, Ghosh and Mastromarco (2013) showed that the impact of human capital was important in increasing efficiency through trade flows and foreign direct investment flows, while immigration to countries richer in human capital improved their efficiency relatively more than immigration to countries with lower human capital.

2. INFORMATION AND COMMUNICATION TECHNOLOGIES, EFFICIENCY AND ECONOMIC GROWTH

Stiglitz (2014) stresses that the current situation is analogous to the developments that took place in the 1980s with the use of personal computers. Solow (1987) wrote: "What this means is that I, like everyone else, am a little embarrassed by the fact that what everyone feels has been a technological revolution, a dramatic change in our productive lives, has been accompanied for everyone, including Japan, by a slowdown in productivity growth, not a step forward. You can see the computer age everywhere, but not in productivity statistics.

The study of the effects of ICT on output and productivity growth was initiated by Bauer (1990), who decomposed the contribution to total factor and productivity growth of the world's countries in the presence of cost inefficiency, technological progress and no constant returns to scale. A few years later, Fereetal (1994) has analyzed the contribution of productivity, technological progress and efficiency to industrial growth across countries.

Most studies analyzing the relationship between ICT productivity and economic growth find positive correlations between the variables, although there are also some studies in which this relationship is not found or is negative.

In the context of findings of negative effects or spillovers, Berndt et al. (1992) examined the contribution of ICT capital to US industries, productivity growth and found a positive relationship. Another approach in the US, Olinery Sichel (1994) studied whether the positive impact of innovation in terms of ICT can leave a macroeconomic trace. He concluded that the macroeconomic impact on the productivity factor was minimal. Olinery Sichel (2000) incorporated ICT as a productive input in the overall production function and, as in his earlier work, found no positive macroeconomic impact for any variable proxy with ICTs.

Some of the studies have found a positive and significant relationship between ICT and economic growth. Brynjolfsson and Hitt (1996, 2002) find signs of a positive impact of ICTs on the microeconomic level of productivity. For a sample of US firms during the period 1987-1991, the authors found a positive correlation between ICT investments and changes in productive organization, process decentralization and the incorporation of skilled people. Schreyer (2000) has studied the contribution of ICTs to economic growth in the most developed OECD countries in 1996. His main result was that ICTs had a significant impact on economic growth in the United States, leading the ranking.

Meanwhile, Pilat and Lee (2001) studied OECD countries and concluded that the contribution of ICTs to labour productivity growth was high, with countries such as Finland, Ireland and the United States standing out.

The complexity of international logistics systems in many sectors has grown as a result of product variation and differentiation. Recent economic developments are thus linked to the creation of complex production networks (Ducruet and Beauguitte, 2013).

There is a relationship between the level of development of an economy and logistics costs. While logistics costs can be as high as 25% of shipping costs in some developing economies, they reach 8% to 9% in advanced economies (Roberts 2003).

Consequently, logistics costs in international trade directly affect international trade. If logistics costs are so high, they may outweigh the benefit derived from the price differential, so that international trade would not gain a positive economic benefit.

However, as Lin et al. (2014) have pointed out, there is also an environmental cost of traffic networks that needs to be considered.

There is a large literature assessing the spillover effect of transport and its external impact generated by transport infrastructure on economic development. Evidence from different countries (e.g. Munnell 1990; Aguas2004; Xiushan et al. 2015) as well as theoretical evidence (Illenberger et al. 2013; Batabyal and Nijkamp2014) supports the existence and importance of spillover effects. Other studies have focused on the relationships between the spatial structure of networks and their vulnerability and resilience in critical situations (e.g. Reggiani et al. 2002; Griffith and Chun 2014; Caschiliet al. 2015).

However, despite the importance of logistics, there are few papers assessing its impact on the growth of the global economy, and there are no studies considering the impact of logistics on the Scale Efficiency of global production.

Yang (2007) studied the relationship between logistics and economic development. Based on data from North America, Japan and Europe, he found that logistics and economic growth are cause and effect of each other by cointegration techniques.

Using an instrumental variable model, Czernich et al.(2011) estimates the effect of broadband infrastructure on economic growth. The author concludes that a 10 % increase in broadband penetration leads to an annual per capita growth of 0.9-1.5 %.

While some have argued that ICTs have been the main technological enabler of economic globalization, bringing about a 'death at a distance' (Cairncross 1997) in a 'flat world' (Friedman 2005), this perspective does not fully appreciate the role of transport innovation (Levinson, 2006).

It is precisely the combination of logistics and ICT that led to the reduction of transport costs and the growing importance of networks in the evolution of the global economy.

Moreover, Coto-Millán et al. (2013) have studied the impact of logistics on economic growth, focusing on the long-run equilibrium solution of a growth model and estimated that a 1 % increase in synthetic LPI could generate economic growth in a range of 0.011 and 0.034 %. Coto-Millán et al. (2016) estimate synthetic LPI efficiency for a sample of 34 developed countries. Finally, Tang and Abosedra (2019) estimate the influence of LPI for a model of export-led economic growth in Asia for the period 2010 to 2016 for 23 countries.

3. DEA METHODOLOGY

Statistical and econometric approaches can be used to assess efficiency. The measurement of efficiency in empirical research has myriad applications. The most commonly used methodological approaches are the parametric stochastic frontier analysis (SFA) method (Aigner et al., 1977) and the non-parametric approach of Data Envelopment Analysis (DEA) (Charnes et al., 1978). The latter methodology can be applied to obtain technical and scale efficiency. In addition, DEA measures the relative performance of organizational units presented by multiple inputs and outputs. In the method, if the output appears within the production set, the unit is considered technically inefficient. The Decision Making Unit (DMU) measure assesses inefficiency by the distance from its observed input and output values to the production frontier (Coelli et al., 2005).

The DEA model can be either input-oriented or output-oriented. In the study of global production efficiency, the choice is an output-oriented specification rather than an input-oriented model. The reason for this is that countries' economic policy is generally directed towards the growth of the country's output or income. Thus, for the j-n countries, the output-oriented technical efficiency with constant returns to scale (CRS) is obtained by solving the following linear programming problem.

$$\underset{\theta_j^{CRS},\lambda}{Máx} \quad \theta_j^{CRS}$$
$$sujeto\ a: \begin{cases} \theta Y_j \leq Y\lambda \\ X_j \geq X\lambda \\ \lambda \geq 0 \end{cases} \tag{1}$$

Where X is the vector of inputs and Y is the vector of outputs, and where $\varphi_j^{CRS} = 1/\theta_j^{CRS}$ is the technical efficiency (TE) of countries in the world under CRS and λ is an n x 1 vector of weights.

The efficiency contribution of the countries of the world as measured by non-negative weights λ is selected as a determinant of a benchmark for the world's countries. Generally, if the countries of the world are on the production frontier and within $0 \leq \varphi_j^{CRS} \leq 1$where

$\varphi_J^{CRS} = 1$is the maximum technical efficiency. Where $\varphi_J^{CRS} < 1$indicates that the country is technically inefficient.

In the case of variable returns to scale (VRS), the technical efficiency φ_J^{VRS} has the convexity constraint $\sum_{j=1}^{n} \lambda_j = 1$ for the linear program expressed in (1). All this can be seen in detail in Banker et al. (1984).

The estimation of the effect of the synthetic LPI and its six efficiency components will be carried out through the second stage method of a truncated regression with the application of Simar and Wilson (2007). It is performed by a process of data generation under a method consisting of two stages. An advantage that drives the method of Simar and Wilson (2007) is that it allows for obtaining unbiased coefficients in valid confidence intervals. The discriminatory power of the first stage is not affected as the explanatory variables are not included in the first stage (Liebert and Niemeier, 2013).

The second stage regression to explain efficiency levels is presented as follows:

$$\varphi_j = a + \delta\, z_j + \varepsilon_j \qquad (2)$$

Where a is a constant term, ε_j is the error term, z_j is a vector (row) of possible variables that are expected to explain the efficiency levels of each decision unit, φ. We will apply the homogeneous approach with 2000 iterations to overcome the potential problem of biased results in our second stage regressions, for further discussion see Simar and Wilson (2000) and Simar Wilson (2008).

The impact of the LPI and its six components on each country's production efficiency can now be measured from the estimation results of equation (2).

4. DATA

The Logistics Performance Index or LPI is an indicator defined by the World Bank, with the aim of assessing trends in logistics in the countries of the world. Data is available for the years 2007, 2010, 2012, 2014, 2016 and 2018.

The LPI was designed to measure the components of the supply chain, such as transportation, customs, timeliness of shipments, tracking, etc.. It measures the efficiency of each country's supply chain and how it performs in international trade with other countries around the world.

Figure 1 shows a representation of the components of the LPI. The components of the Logistics Performance Index (LPI) are:

1.- Customs: efficiency in customs processes and formalities.
2.- Infrastructure: related to trade and transport.
3.- Quality and logistics competences: in logistics services.
4.- Punctuality (Timeliness): shipments within the scheduled delivery times.
5.- International shipments: international trade transactions.
6.- Traceability and tracking: real-time location of shipments and their traceability throughout the logistics chain.

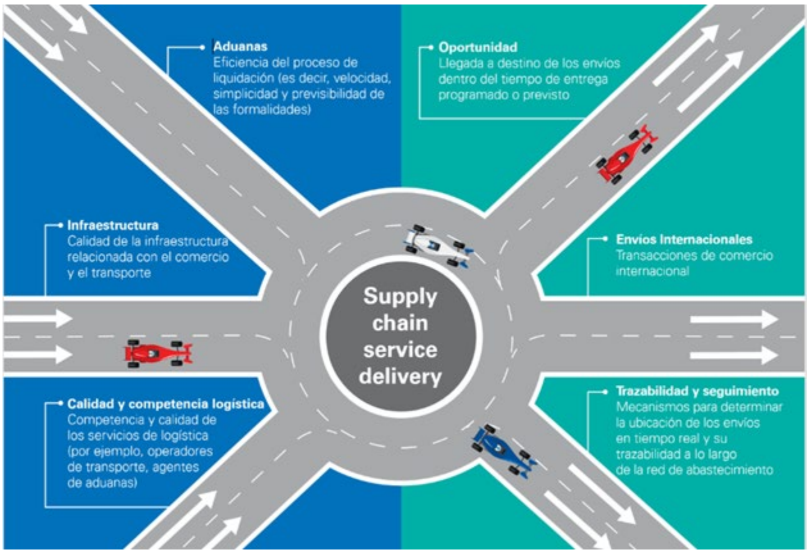

Figure 1 - Representation of the components of the Logistics Performance Index
Source: KPMG

The first three correspond to areas of regulatory policy and the last three to time, cost, and reliability.

The World Bank publication (2018) includes the LPIs in its sixth edition, which facilitates this research work from a scientific approach, and which, as will be seen, allows us to verify the theses that I am maintaining in this chair competition with coherence in the teaching and research aspects; adapting to the emerging reality as a result of digital transformation, sustainability and inclusion.

The LPIs for 2018 are shown at the world map level in Figure 2.

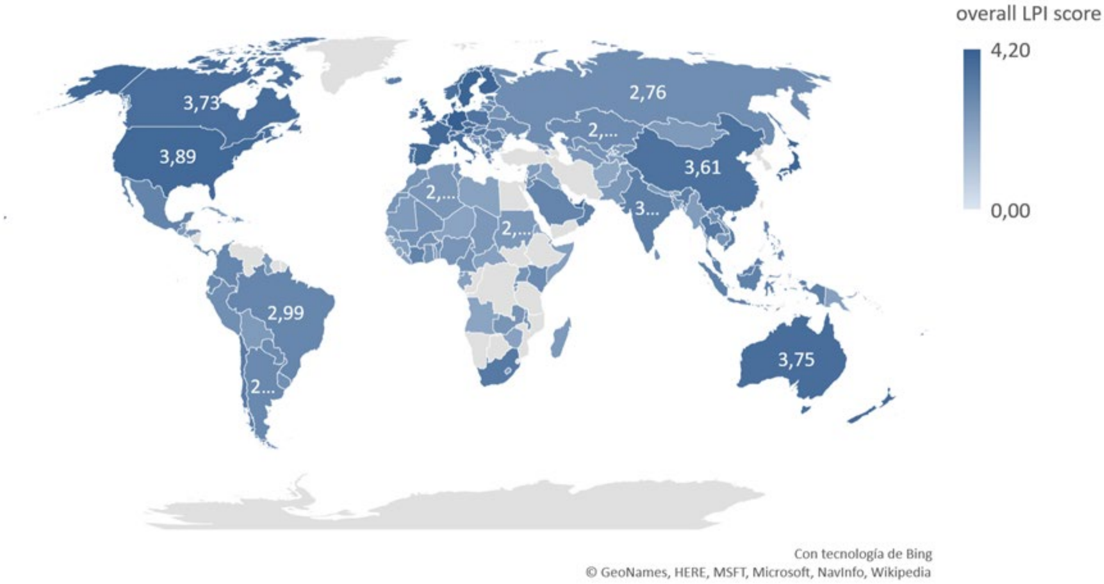

Figure 2. Logistics Performance Index (LPI) rankings by country in 2018

Figure 3 shows the top ten countries in the world with the highest LPI, as of 2018.

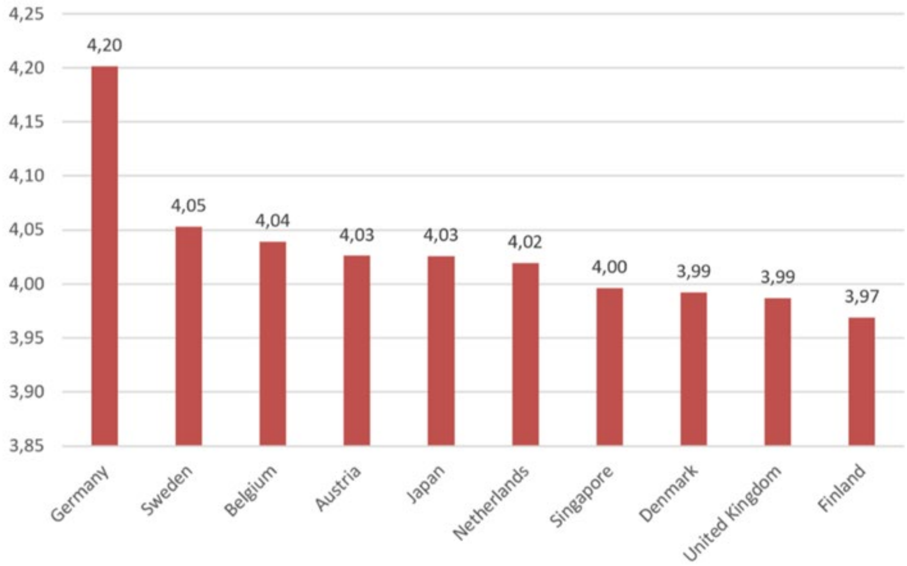

Figure 3 - Top ten countries in the world with the highest LPI in 2018

Figure 4 shows the ten countries in the world with the lowest LPI, for the year 2018.

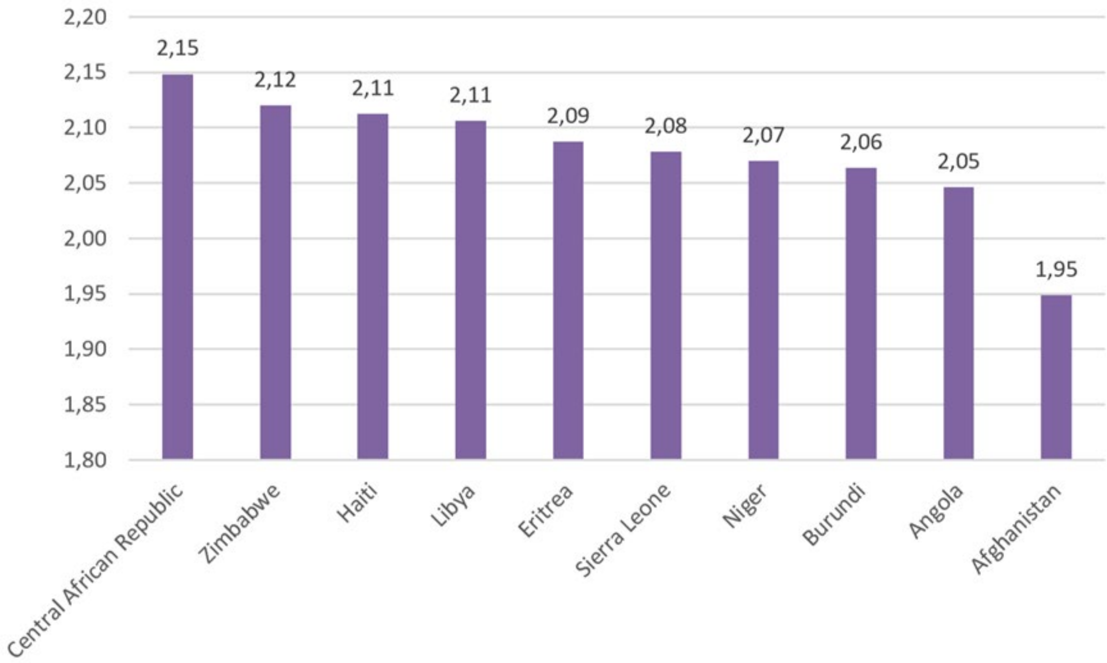

Figure 4 - Top ten countries in the world with the lowest LPI in 2018

An empirical test of the proposed model has been carried out with the indicators included in the World Economic Indicators (WDI) database created by the World Bank. The World Bank is an international organization with several objectives, most of which are closely related to poverty and economic development in all countries. Since its creation in 1944, it has devoted an increasing share of its resources to the collection of statistics and indicators, which are organized in databases.

For the empirical analysis, a sample of 133 countries has been used, for which complete logistics data is available for the years 2007, 2010, 2012, 2014, 2016 and 2018 .

Table 1 provides a detailed description of the variables included in the estimation of the production function and those as determinants in the Technical Inefficiency Effects Frontier model (hereafter TIE model).

Variable definition data		
Production function		
GDP	(in $)	WDI
EDU	% secondary school working age population.	WDI
EMP	% employed population	WDI
GBF	% of GDP of fixed capital in dollars.	WDI
For the efficiency explanatory stage of the production function, the following are used:		
LPI	logistics performance index	WDI
LPI1	infrastructures	WDI
LPI2	Customs	WDI
LPI3	Quality and Logistics Competence	WDI
LPI4	Tracking and Tracing	WDI
LPI5	Punctuality	WDI
LPI6	International Shipments	WDI

Table 2 - Principal statistics
Source: Own elaboration based on World Bank data.

The dependent variable is real GDP per capita and the independent variables are capital stock per capita for each country and human capital (which measures the percentage of the working-age population in secondary school).

To assess the efficiency of Logistics and Innovation in TE of global production we include the LPI variables. The Logistics Performance Index, as defined by the World Bank, is an interactive benchmarking tool.

To obtain the LPIs the World Bank conducted a worldwide survey of land operators (global freight forwarders and express carriers), providing feedback on the logistics co-modality of the countries in which they operate and those with which they trade. They combine in-depth knowledge of the countries in which they operate with qualitative assessments of other countries where they trade and operate in global logistics environments.

Operators' comments are complemented by quantitative data on the performance of key components of the logistics chain in the country. It is expected that an increase in LPI will decrease technical inefficiency. Similarly, we expect that each of the disaggregated indices, if functioning properly, will promote technical efficiency.

5. RESULTS

We will use the model of Mankiw, Romer and Weill (1992) to estimate the world production function. In essence it is to explain the world output measured by GDP, by the following world inputs: Human Capital (EDUC), Physical Capital (GFB) and Employment (EMP).

Once the variables have been defined and the main statistics for them have been provided, we proceed to estimate the world production function incorporating the indices relating to the different components of the LPI. This estimation is given in Table 3.

Variable	Coefficient	Standard deviation	Statistic t	p-value	Sig.
const	-0.0251427	0.400771	-0.06274	0.9500	
l_EDU	1.40084	0.0915710	15.30	<0.0001	***
