Table 3 – Perceived quality of campuses according to users

According to the users' assessment, type A campuses stand out for their good accessibility by car and public transport, the quality of public space and the security. Weaknesses are related to the low availability of car, motorbike and bicycle parking facilities.

Most Type B campuses also stand out for their good accessibility by car and public transport. The evaluation of public space and security varies from campus to campus. According to the users, some have a lack of vegetation and shade, as is the case of Alcorcón and Móstoles. Others, lack of lighting and security, such as Campus Sur.

Regarding type C campuses, the most notable strengths were road access by car and parking lots, as well as quality of public space. Weaknesses are poor accessibility by public transport and by bicycle.

All campuses have a low supply of charging points for electric vehicles.

5. CONCLUSIONS

The comparative study of the 14 campuses showed that besides good accessibility, type A campuses have a higher degree of compactness than the others, which is related to a more integrated and higher quality public space, as well as a stricter parking policy. These characteristics are associated with a lower proportion of trips by car and a higher number of walking trips, which coincides with the references of the consulted studies on the relationship between modal choice and the 6 Ds: “density”, “diversity”, “design”, “destination accessibility”, “distance to transit” and “demand management”.

On the other hand, type B and C campuses stand out for their dispersed configuration, lower quality of public space, when compared to type

A campuses, and absence of control over parking, which is associated with a higher proportion of car trips, and a lower proportion of walking trips. This situation is aggravated in the case of type C campuses, which have low accessibility by public transport.

These conclusions are reinforced by the perception of users, which reinforces the need to improve accessibility in public transport, pedestrian and cycling infrastructure and the quality of public space on university campuses.

RESUMEN

En el contexto de la economía colaborativa, están surgiendo distintas opciones de movilidad urbana a la demanda. Dentro de esta nueva tendencia, las motos de uso compartido o motosharing —conocidas por los términos en inglés moped scooter sharing— están experimentando un gran auge en muchas ciudades del mundo, particularmente en Europa.

Asimismo, estos servicios de motos eléctricas generarían una serie de beneficios, como la reducción del ruido, contaminación del aire o congestión vial, con importantes implicaciones en la mejora de la habitabilidad y la calidad de vida en las ciudades.

Hasta la fecha, se han realizado numerosas investigaciones sobre diferentes opciones de movilidad compartida, como es el caso del carsharing o bikesharing, pero apenas se han estudiado los servicios de motos compartidas. Por lo tanto, se ha realizado un modelo logit ordenado generalizado, a fin de identificar los factores clave que determinan la adopción y la frecuencia de uso de este sistema de movilidad en áreas urbanas. Para ello, se han explotado los datos recopilados de una encuesta online difundida en diferentes ciudades de España, el país con la mayor implementación de motos compartidas.

Los resultados del modelo muestran el papel fundamental de algunas variables sociodemográficas y atributos de movilidad urbana, como la edad, el nivel de educación o el número de viajes realizados en un día laborable, mientras que otras variables como las opiniones y actitudes personales, por lo general, no se han encontrado estadísticamente significativas. Asimismo, se proporciona una mejor comprensión de este sistema de transporte, así como algunas implicaciones en la movilidad, de gran interés tanto para los operadores como para los planificadores de transporte a la hora de diseñar acciones y políticas que aborden esta reciente alternativa de movilidad urbana.

1. INTRODUCCIÓN

Comprender los patrones de movilidad urbana de los habitantes es crucial para los planificadores urbanos, administradores y proveedores de transporte. De hecho, los cambios demográficos en las ciudades están cambiando los patrones de movilidad y buscando formas sostenibles de transporte urbano para abordar las externalidades provenientes del transporte urbano, como la contaminación, el cambio climático, la congestión o la falta de espacio urbano. La movilidad inteligente es uno de los componentes principales para lograr una ciudad inteligente, un concepto destinado a mejorar la calidad de los ciudadanos que ha adquirido una importancia cada vez mayor en las políticas urbanas (Neirotti et al., 2014).

En ese contexto, en muchos centros urbanos han aparecido servicios innovadores de movilidad compartida, como el uso compartido de automóviles, el uso compartido de bicicletas, el viaje en bicicleta o el uso compartido de scooters (tanto ciclomotores como patadas) y han aumentado su demanda progresivamente, causando un cambio notable en la oferta de transporte. y promoviendo una movilidad urbana más ecológica. Se pueden encontrar muchas contribuciones de investigación recientes en el campo de la movilidad compartida, en particular el uso compartido de automóviles, el uso compartido de bicicletas públicas o el alquiler de vehículos. Sin embargo, casi no se han dedicado esfuerzos a la literatura científica para explorar los servicios de uso compartido de scooters con ciclomotor, una alternativa de transporte que ha experimentado un auge en los últimos años en muchas ciudades del mundo, particularmente en países europeos.

Por lo tanto, se necesitan más esfuerzos para explorar la adopción de sistemas de uso compartido de scooter de ciclomotor en áreas urbanas. Esta investigación lleva a cabo una primera visión de la adopción y la frecuencia del uso del uso compartido del scooter ciclomotor. Como aspecto innovador, cubre tanto a los usuarios como a los no usuarios del uso compartido de scooters de ciclomotores para identificar los factores explicativos que determinan la adopción y el uso de esta alternativa de movilidad en áreas urbanas.

Además, también se analiza su relación e impacto en modos de transporte alternativos (por ejemplo, automóvil privado, transporte público, etc.). Esto nos permitiría identificar segmentos específicos del mercado de usuarios de esta alternativa de movilidad y dirigir adecuadamente los esfuerzos de políticas para promover este medio de transporte ecológico en las zonas urbanas. Con ese fin, desarrollamos un modelo *logit ordenado generalizado (gologit)* basado en una encuesta en línea realizada en diferentes ciudades de España, el país con la mayor presencia de servicios de uso compartido de scooters en todo el mundo hasta la fecha.

Este documento está estructurado de la siguiente manera. Después de este capítulo introductorio, la Sección 2 proporciona una base útil sobre la movilidad compartida en general y el uso compartido de scooters de ciclomotores en particular.

La encuesta realizada y la muestra de datos utilizada para esta investigación se describen en la Sección 3. La Sección 4 describe la metodología de logit ordenada generalizada adoptada para explorar la adopción de servicios de uso compartido de scooters por parte de las personas. La sección 5 presenta y discute los resultados. Finalmente, la Sección 6 trata las principales conclusiones.

2. REVISIÓN DE LA LITERATURA / ESTADO ACTUAL

2.1 Movilidad compartida y comportamiento de viaje

Los servicios de movilidad compartida están interrumpiendo los sistemas de transporte urbano al influir en los patrones de viaje y competir con modos más tradicionales (Henao, 2017). Según Shaheen Y Chan (2016), la movilidad compartida es una estrategia de transporte innovadora que permite a los usuarios obtener acceso a corto plazo a los modos de transporte según sea necesario, lo que ha traído grandes cambios en, p. propiedad del automóvil o cómo las personas planean y hacen sus viajes. La primera implementación de esta forma de servicios de movilidad urbana abarcó esquemas de bicicletas compartidas, seguidas de los sistemas de autos compartidos. Más recientemente, el uso compartido de scooters de ciclomotores se ha convertido en un modelo innovador para compartir vehículos en áreas urbanas, con algunas características específicas que lo convierten en una opción interesante a tener en cuenta al viajar o conducir por el centro de la ciudad. La introducción de estos servicios tiene implicaciones para el comportamiento del viaje y el cambio modal, así como los impactos en el sistema general de transporte.

Se pueden encontrar muchas contribuciones recientes en la literatura en el campo de la movilidad compartida y el comportamiento de viaje. Por ejemplo, en los Estados Unidos (EE. UU.), Se ha observado que los primeros en adoptar servicios de movilidad compartida tienden a ser adultos jóvenes altamente educados que viven en áreas urbanas (Buck et al., 2013, Rayle et al., 2014; Taylor et al., 2015). Otros estudios basados en estadísticas descriptivas como Circella, et al. (2018) mostraron que la popularidad de estos servicios es particularmente alta entre los millennials y aquellos que viven en las densas partes centrales de las ciudades. De acuerdo con Taylor et al. (2015), la oferta de movilidad compartida más amplia podría tener implicaciones para las preferencias del usuario, p. impactando decisiones de propiedad de vehículos privados o patrocinio de transporte público. La literatura actual ha cubierto principalmente el uso de bicicletas compartidas, autos compartidos y servicios de viajes a pedido, mientras que casi no se han dedicado contribuciones al uso compartido de motos. De hecho, la escasez de literatura científica sobre el uso compartido de motos es un punto subrayado por Howe y Bock (2017). Hasta donde sabemos, el estudio de Degele et al. (2018) es la única investigación científica existente sobre el uso compartido de scooters hasta la fecha. Identificó segmentos de clientes de uso compartido de scooters basados en el uso de datos en Alemania, pero no exploraron la adopción o las percepciones de las personas hacia esta alternativa de movilidad en áreas urbanas ni abordaron su impacto en los modos de transporte alternativos.

2.2 El reciente aumento del motosharing

Bicisharing fue el primer esquema de movilidad compartida introducido en las zonas urbanas, en la década de 1990, seguido de los sistemas de uso compartido de automóviles eléctricos que comenzaron a funcionar en la década de 2000. Luego, el uso compartido de scooters estilo ciclomotor se implementó por primera vez en San Francisco (EE. UU.) En 2012, y desde 2015 su desarrollo de mercado ha comenzado a extenderse por todo el mundo.

Durante 2016 y 2017, hubo un auge en el mercado internacional y se desplegaron 8,000 ciclomotores (Stephanou, 2017) alcanzando un total de 25,000 scooters de ciclomotores en todo el mundo (Howe, 2018). En 2018, más de 60 ciudades en todo el mundo adoptaron este tipo de servicios de movilidad, con una estimación de 1,8 millones de usuarios registrados (Howe, 2018), y muchas otras ciudades han planeado introducir sistemas de uso compartido de scooters en los próximos años. Hasta la fecha, España es el país con la mayor implementación de servicios de uso compartido de scooters en todo el mundo, alcanzando una flota de 9,000 ciclomotores y un crecimiento del mercado del 500% en 2018, y comprende el 35% de la flota mundial en todo el mundo (Howe, 2018).

Al igual que el carsharing, existen dos tipos principales de sistemas existentes: sistemas basados en estaciones y sistemas de flotación libre (Howe y Bock, 2017). Alrededor del 99% de los sistemas de uso compartido de scooters de ciclomotores existentes en todo el mundo son de libre flotación, y más del 97% de los ciclomotores son eléctricos (Howe, 2018).

Representan un modo de transporte atractivo para ciertos segmentos de la población urbana ya que, de manera similar a otras opciones de movilidad compartida, los usuarios de motonetas compartidas obtienen los beneficios de un vehículo privado sin los costos y las cargas de su propiedad (Shaheen et al., 2016 ; Shaheen et al., 2017b). Por lo general, las personas acceden a scooters de ciclomotores al unirse a una empresa que administra y mantiene una flota de ciclomotores en varios lugares. Los usuarios pagan una tarifa cada vez que usan un scooter, mientras que los operadores de estos proporcionan combustible, estacionamiento y mantenimiento (Shaheen et al., 2015). Los sistemas de uso compartido de scooters con ciclomotor generalmente están restringidos a áreas urbanas, debido a la menor velocidad de los scooters y su segmento de mercado más pequeño en comparación con otros modos compartidos, p. auto compartido. Sin embargo, en los últimos años, el mercado potencial está floreciendo a escala global (Keogh, 2017).

Este innovador servicio de movilidad también puede aumentar la accesibilidad y flexibilidad proporcionadas por los servicios de transporte público de ruta fija y horario fijo. En comparación con el uso compartido de bicicletas, un sistema en funcionamiento durante años en muchas ciudades, compartir ciclomotores es una opción más rápida, que permite a los usuarios cubrir distancias más largas y también con un mayor atractivo en ciudades no planas (Kafyeke, 2017).

En España, todos los operadores de uso compartido de scooters se basan en servicios de libre flotación, en los cuales los usuarios pueden elegir libremente sitios de entrega de scooters dentro de un área de servicio definida. Además, el cien por ciento de los ciclomotores operados en España son eléctricos, lo cual es particularmente relevante ya que en este país los vehículos eléctricos no tienen restricciones de estacionamiento en los centros de las ciudades y generalmente se benefician del estacionamiento gratuito en la calle. Luego, el uso compartido de scooters con ciclomotor proporciona una alternativa accesible y flexible para conducir por los distritos internos de las áreas urbanas. Dado su mayor atractivo en el centro de la ciudad, típicamente con calles estrechas y problemas de congestión recurrentes, esta es en realidad su principal área de operación en las ciudades españolas. Sin embargo, en ciudades medianas, el uso compartido de scooters también tiene una presencia notable en los distritos menos centrales.

Todos los operadores ofrecen precios similares y tienen un esquema basado en el tiempo de uso con una tarifa actual que generalmente se encuentra entre 0.24 € a 0.26 € por minuto. La estructura de precios podría verse como una barrera si el vehículo se alquila por un tiempo prolongado, pero los operadores con frecuencia ofrecen paquetes de promoción que se pueden adquirir por adelantado para obtener un mejor trato, como una forma de fomentar su uso. Como no hay una tarifa de suscripción mensual fija ni una tarifa de suscripción significativa en España, las personas tienden a ser miembros de varios operadores al mismo tiempo. Esto puede hacerlo económicamente favorable para las personas que usan estos sistemas regularmente, ya que algunas aplicaciones móviles ofrecen información integrada sobre el suministro de uso compartido de scooters con ciclomotores (que comprende varios operadores) en ciertas ciudades: la situación de los ciclomotores en tiempo real, el costo estimado de un determinado itinerario , etc. Sin embargo, los procedimientos de reserva y pago aún no están integrados entre los operadores.

Actualmente, hasta 9 empresas diferentes ofrecen servicios de uso compartido de scooters flotantes en España. Debemos recordar que el uso compartido de scooters coexiste con otras alternativas de movilidad compartida en muchas ciudades españolas. El uso compartido de bicicletas y el uso compartido de automóviles basados en estaciones están disponibles en muchas ciudades españolas, mientras que los servicios de alquiler compartido de automóviles son operados en Madrid por cuatro compañías privadas diferentes. Además, hay algunos operadores, como es el caso de Scoot y Movo, que no solo ofrecen scooters, sino que también suministran bicicletas o patinetes como parte de su concepto general de servicio de movilidad. Se espera que esta tendencia de integración de los servicios continúe en los próximos años.

Este reciente crecimiento de los servicios de movilidad compartida como una forma nueva y más sostenible de transporte está contribuyendo a cambiar las tendencias de movilidad de la propiedad al uso del servicio (Ferrero et al.2018).

Además, dado que estos sistemas generalmente emplean ciclomotores totalmente eléctricos, representa una alternativa de transporte ecológica para las zonas urbanas. El uso compartido de scooters de ciclomotores es un nuevo actor para la vida cotidiana de las ciudades que debe ajustarse a las estrategias actuales para la movilidad sostenible. Sin embargo, los instrumentos de planificación aún no incorporan estas formas de movilidad en la mayoría de las ciudades. El uso compartido del scooter presenta muchas incertidumbres, como los niveles de adopción, la rentabilidad, los impactos en la ciudad, etc. Por estas razones, comprender la adopción y el uso del uso compartido del scooter es crucial para que los planificadores, administradores y proveedores de transporte lo inserten correctamente en el sistema de transporte urbano, y lograr una movilidad urbana más sostenible.

3. METODOLOGÍA

3.1 Encuesta *online* sobre el uso de motos compartidas en España

Se realizó una encuesta en línea con el objetivo de capturar los principales factores que determinan la adopción y la frecuencia del uso de motos compartidas para viajes urbanos. Antes de diseñar el cuestionario, se realizaron algunas entrevistas con personas que viven en diferentes áreas urbanas españolas, incluidos usuarios y no usuarios de uso compartido de scooters, así como usuarios y no usuarios de scooters privados. Permitió capturar los principales controladores que influyen en el uso de esta alternativa de movilidad. En la encuesta, se preguntó a las personas sobre cuatro aspectos principales:

- Información socioeconómica y demográfica general: género, edad, ocupación, nivel de educación, ingresos mensuales, estructura del hogar y código postal.
- Movilidad y variables relacionadas con el viaje: propiedad del vehículo, posesión de un permiso de conducir o pase de transporte público, frecuencia de viaje para diferentes medios de transporte, patrones de movilidad en días laborables / fines de semana.
- Actitudes y preferencias personales: evaluación de los factores de elección del medio de transporte en viajes urbanos (precio, disponibilidad de estacionamiento, preocupaciones ambientales, transporte de equipaje, etc.), preocupaciones individuales hacia las nuevas tecnologías (disposición a descargar aplicaciones de noticias, compartir datos personales y compartir información de la cuenta bancaria) y percepciones sobre el papel de la propiedad del vehículo en el futuro.
- Percepciones y uso de servicios de uso compartido de scooter: frecuencia de uso, tiempo de viaje, propósito del viaje, factores de decisión, aspectos a mejorar en los sistemas actuales de uso compartido de scooter e intención de utilizar un ciclomotor o motocicleta compartidos.

Inicialmente se consideraron diferentes métodos para recopilar la información necesaria para el análisis. Las encuestas en línea fueron el enfoque finalmente seleccionado para difundir la investigación, debido a varias razones.

Primero, este método de encuesta permite contactar fácilmente a los usuarios de diferentes medios de transporte, lo cual es particularmente difícil en el caso del uso compartido de scooters dado que los sistemas operativos en España son flotantes. En segundo lugar, a diferencia de los cuestionarios cara a cara, las encuestas en línea permiten recopilar información de personas que viven en diferentes ciudades españolas sin dificultad. En tercer lugar, las encuestas en línea son un enfoque ya seleccionado en otra investigación previa que explora el uso de otras opciones de movilidad compartida (ver, por ejemplo, Casprini et al., 2014 o Shaheen et al., 2017 para compartir el viaje). Luego, las encuestas en línea fueron el método finalmente seleccionado a pesar de su limitación para obtener una mayor representatividad de la población urbana, particularmente aquellos segmentos más antiguos de la población que están menos familiarizados con los servicios basados en aplicaciones.

El cuestionario en línea se distribuyó entre abril y junio de 2018, combinando diferentes alternativas: diseminación a través de aplicaciones de mensajería, diseminación a través de sitios web de redes sociales enfocadas en el uso de diferentes modos de transporte, distribución en línea de desolladores incluyendo el enlace para acceder a la encuesta y explicando el propósito de la investigación, etc. Recibimos un total de 430 respuestas válidas.

3.2 Modelo logit ordenado generalizado

Esta investigación desarrolla un análisis de tipo *logit ordenado generalizado* (gologit) para explorar los factores de decisión que determinan la adopción y la frecuencia del uso de los servicios de uso compartido de scooters para la movilidad urbana diaria en las ciudades españolas.

En particular, los encuestados informaron en la encuesta en línea la frecuencia de uso del uso compartido de scooter, que representa la variable dependiente a modelar. Vale la pena señalar que solo los encuestados que expresaron su conocimiento de la existencia de servicios para compartir scooter de ciclomotor están incluidos en el modelo (n = 355). Dada la naturaleza ordenada y discreta de la variable dependiente, se ha adoptado un marco logit ordenado en lugar de otras alternativas disponibles, como logit multinomial. En el ámbito del transporte, diversa literatura académica ha empleado estos modelos (ver por ejemplo Irawan et al., 2018; Kaplan y Prato, 2012).

La adopción de los sistemas de uso compartido de scooters de ciclomotores se ha tratado como una variable discreta:

- 1 = sistemas de uso compartido de scooters nunca utilizados
- 2 = sistemas de uso compartido de scooters usados ocasionalmente, es decir, menos de una vez por semana
- 3 = sistemas de uso compartido de scooters utilizados con frecuencia, es decir, una vez por semana o más).

Como se señala en Wang et al. (2018), uno de los principales supuestos de los modelos logit ordenados es el de probabilidades proporcionales, es decir, se supone que la relación entre cualquier par de categorías de resultados es similar para todas las categorías de variables. Esta suposición puede violarse en ocasiones, llegando a resultados sesgados. Para evitar este fenómeno, se adopta un modelo *logit ordenado generalizado (gologit)*, que permite relajar el supuesto de probabilidades proporcionales para todas las variables. De este modo, si permitimos que la suposición se viole solo para un conjunto de variables explicativas, la probabilidad de usar sistemas de motosharing adopta la siguiente forma:

$$P(y_n > k) = (exp(\beta_1\, X_{1n} + \beta_{2n}\, X_{2m} - \tau_m))/(1 + exp(\beta_1\, X_{1n} + \beta_{2n}\, X_{2m} - \tau_m)) \qquad (1)$$

donde:

- $j = 1{,}2$
- β_1 es un vector de parámetros que no viola el supuesto de probabilidades proporcionales y está asociado a un subconjunto X1n de variables explicativas observadas
- β_{2n} es un vector de parámetros que varían de acuerdo con el punto de corte del modelo logit ordenado y está asociado a un subconjunto X2m de variables explicativas observadas
- $\tau_{1,2}$ representan los umbrales definidos entre las categorías.

Entonces, el modelo puede expresarse como:

$$y = \{[j_1 \quad if\ U_n \le\ \tau_1], [j_2 \quad if\ \tau_1\ \le U_n \le \tau_2], [j_3 \quad if\ \tau_2 \le U_n]\} \qquad (2)$$

y la probabilidad para cada elección se puede calcular de la siguiente manera:

$$P(y = j_k) =\ F(\tau_k - U_n) - F(\ \tau_{k-1} - U_n) \qquad (3)$$

Una descripción más detallada de los modelos logit y gologit ordenados está más allá del alcance de este documento, y se puede encontrar en Greene y Hensher (2010) y Washington et al. (2010).

4. DISCUSIÓN DE LOS RESULTADOS

Esta sección presenta los resultados del estudio exploratorio sobre las percepciones sobre la frecuencia de uso del uso compartido de scooters en ciudades españolas, a partir del conjunto de datos recopilados en la encuesta en línea. Por un lado, mostramos los resultados de modelado con respecto a la adopción de los usuarios y la frecuencia de uso de los servicios para compartir scooter. Por otro lado, se exploran los efectos en la división modal urbana y el papel en la reducción de la propiedad del vehículo.

4.1. Adopción individual de sistemas de uso compartido de scooters

A continuación, se comentan los resultados para el análisis de modelado que explora la adopción individual de los sistemas de uso compartido de scooter de ciclomotor. La mayoría de las variables explicativas utilizadas en el modelo son categóricas, por lo que es necesario elegir un caso base como referencia para interpretar adecuadamente los resultados del modelado (consulte la Tablas 1 y 2). En el caso de la variable dependiente, las personas que nunca han utilizado los servicios de uso compartido de scooter se consideran el caso base.

Además, los resultados de modelado se muestran una vez que se eliminan aquellas variables explicativas que no son estadísticamente significativas. Con ese fin, se han utilizado diferentes pruebas de razón de probabilidad (LR) para verificar que no se produzca ningún cambio en el ajuste general del modelo al eliminar estos parámetros. También se debe tener en cuenta que las Tablas 1 y 2 incluyen algunos resultados vacíos para el análisis de usuarios frecuentes (columna de la derecha) cuando no se viola el supuesto de probabilidades proporcionales. Por lo tanto, en esos casos se supone que los coeficientes de modelado para usuarios ocasionales y frecuentes son iguales.

Variables		**Occasional users**			**Frequent users**

Tabla 2: Adopción por parte de los usuarios de sistemas de uso compartido de scooter de ciclomotor en ciudades españolas: resultados de modelado.

Con respecto a las características individuales, la adopción de sistemas para compartir scooters está muy relacionada con la edad: las personas de 26 a 35 años muestran una mayor probabilidad de ser usuarios frecuentes de estos sistemas, lo que es consistente con la investigación de Degele et al. (2018) en Alemania.

Esto parece razonable, dado que los adultos jóvenes están más familiarizados con las nuevas tecnologías y generalmente están en buenas condiciones físicas, lo cual es un factor importante al conducir un scooter.

Además, solo aquellos individuos mayores de 50 años mostraron una menor probabilidad de usar esta alternativa de movilidad (coeficiente del modelo -2.43, valor p = 0.05). Vale la pena señalar esto, dado que, al menos en el caso de España, parece que el uso compartido de scooters también es penetrante, a pesar de una menor intensidad, por encima de los adultos de mediana edad.

Los resultados del modelado también señalan que, en comparación con los empleados, los estudiantes presentan significativamente una mayor probabilidad de adoptar sistemas de uso compartido de scooters.

Además, el nivel educativo también influye en la adopción del uso compartido de scooters, ya que tener o cursar un grado universitario aumenta la probabilidad de ser un usuario frecuente de uso compartido de scooters en un 400%, en comparación con tener educación no universitaria. Estos resultados pueden explicarse por la mayor proporción de jóvenes entre los estudiantes, así como por la tendencia más rápida a adoptar avances tecnológicos y servicios innovadores entre personas altamente educadas.

En cuanto a otras variables socioeconómicas, el nivel de ingresos no parece influir en el uso ocasional de los sistemas de uso compartido de scooters. Sin embargo, un mayor nivel de ingresos reduce significativamente la probabilidad de ser un usuario frecuente de esta alternativa de movilidad. Por ejemplo, las personas que ganan más de 2.000 euros son significativamente menos propensas (-480%) a ser usuarios frecuentes de compartir scooters, en comparación con las personas que ganan menos de 1.000 euros. Esto podría explicarse por la tendencia observada en España de un mayor uso del vehículo privado para la movilidad diaria entre las personas ricas. Además, compartir una casa con compañeros de piso / amigos también aumenta la adopción del uso del uso compartido de scooters con ciclomotor, lo que de nuevo estaría muy relacionado con las edades más jóvenes.

Los atributos relacionados con el viaje también mostraron un papel importante al explicar la adopción del uso compartido de scooters. Como era de esperar, las personas que alguna vez condujeron un scooter / motocicleta o utilizaron sistemas de uso compartido de automóviles son significativamente más propensas (500% y 20%, respectivamente) a utilizar el uso compartido de scooter. Por el contrario, la influencia de la frecuencia de los viajes durante los días de semana y fines de semana no está clara en el análisis.

Lo que es más interesante, el modelo también analiza cómo los patrones de movilidad habituales pueden influir en la adopción por parte de las personas del uso compartido del scooter ciclomotor. En particular, las personas que nunca usan un automóvil privado o una moto privada tienen una probabilidad significativamente mayor de haber utilizado el uso compartido de scooters, en comparación con los encuestados que rara vez eligen estas alternativas de movilidad.

Por el contrario, los encuestados que nunca viajan a pie tienen una probabilidad significativamente menor de haber utilizado el uso compartido de scooters eléctricos, lo que puede indicar algún tipo de complementariedad entre estas opciones de movilidad. Además, las personas que viajan a menudo (de una a dos veces por semana) a pie o en moto privada tienen más probabilidades de ser usuarios frecuentes de uso compartido de scooters, en comparación con los encuestados que rara vez utilizan estos medios de transporte.

Finalmente, parece haber algunas sinergias con el uso compartido de bicicletas, ya que las personas que usan con frecuencia sistemas de uso compartido de bicicletas son significativamente más propensas (cociente de probabilidad de 13.6) a haber utilizado alguna vez el uso compartido de scooter de ciclomotor. A partir de los resultados del modelado, no se pueden concluir interacciones entre el uso del uso compartido de scooters y el uso del transporte público.

Con respecto a las actitudes personales de los individuos, solo dos variables resultaron ser estadísticamente significativas al explicar la adopción del uso compartido del scooter ciclomotor. Como se esperaba, es más probable que las personas que deseen compartir información de la cuenta bancaria a través del teléfono celular usen el uso compartido de scooter. Esto parece obvio dado que el pago de servicios para compartir scooter a través del teléfono celular es un requisito para todos los sistemas que operan en España. Además, sentirse preocupado por los problemas ambientales al elegir un modo de transporte aumenta significativamente la probabilidad de ser un usuario frecuente de uso compartido de scooters.

Nuevamente, esto tiene sentido porque todos los scooters que operan en España son totalmente eléctricos, por lo que contribuyen a, p. reducir la contaminación del aire en los centros urbanos. Finalmente, podemos observar que ser sensible a llevar equipaje grande parece reducir la adopción del uso compartido de scooters, pero este efecto no es estadísticamente significativo. Puede considerarse de alguna manera sorprendente que otros factores que potencialmente afectan las opciones de modo, como el precio, la comodidad o la disponibilidad de estacionamiento, no se encontraron estadísticamente significativos al explicar la adopción del uso compartido de scooters.

4.1. Efecto en la movilidad urbana

La Figura 1 muestra la distribución de la división modal urbana durante una semana típica completa para cada grupo de usuarios de uso compartido de scooter. Se pueden observar diferencias notables en algunos casos. Los no usuarios de uso compartido de scooter muestran un uso más intenso del automóvil privado (19.8%) en comparación con los usuarios ocasionales (17.4%) y especialmente los usuarios frecuentes de uso compartido de scooter (13.1%). En este sentido, podríamos inferir que el uso compartido de scooter de ciclomotor parece sustituir en parte el transporte privado.

Luego, promover el uso compartido de scooters con ciclomotor mejoraría la calidad del aire en las zonas urbanas, dado que los vehículos utilizados en estos sistemas de uso compartido son totalmente eléctricos. Además, las condiciones actuales con respecto a la congestión vial y la escasez de espacio en los centros de las ciudades mejorarían si los automóviles privados fueran reemplazados en parte por ciclomotores.

De lo contrario, el uso compartido de scooter también parece capturar la demanda del transporte público y la caminata, ya que los usuarios ocasionales y frecuentes de uso compartido de scooter presentan un menor uso de estos modos en comparación con los no usuarios de uso compartido de scooter. Este hallazgo puede indicar que el uso compartido de scooters de ciclomotores no complementaría sino que sustituirá en parte la movilidad de los peatones y el transporte público, lo que puede conducir a un aumento de la motorización, las tasas de accidentes y la congestión de la carretera, y en consecuencia mover la movilidad urbana hacia la insostenibilidad.

Por lo tanto, el efecto neto del uso compartido de scooters de ciclomotores en la movilidad urbana parece no estar claro en su forma actual de implementación. Sin embargo, los beneficios potenciales del uso compartido de scooters de ciclomotores para la sostenibilidad urbana deberían impulsar a los encargados de formular políticas a promover su uso dentro de un suministro de movilidad integrado junto con los modos de transporte público.

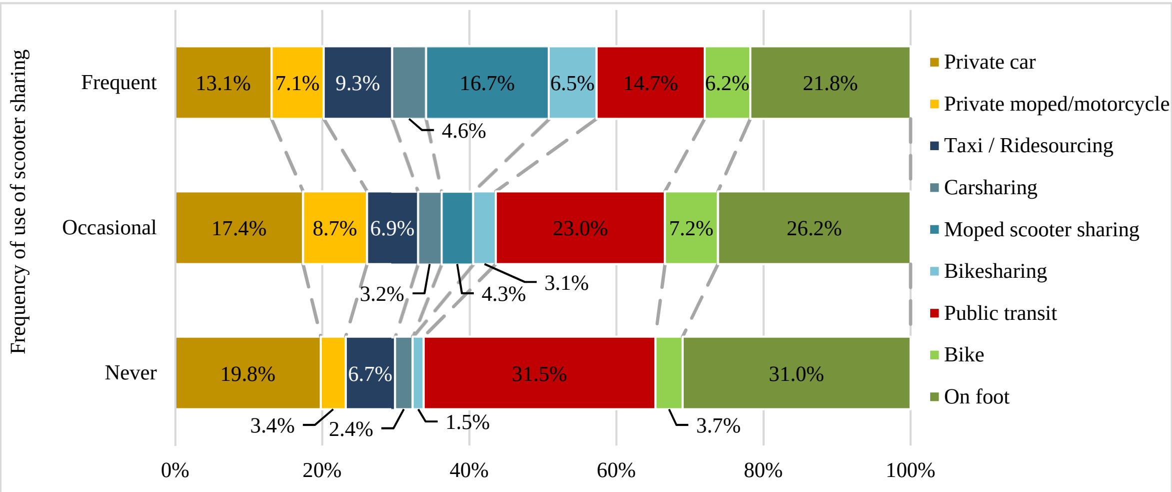

Figura 1: División modal por tipo de usuario que comparte scooter (% de viajes por modo durante una semana típica completa)

Además, podemos ver que los servicios ocasionales de movilidad y uso compartido de vehículos son utilizados con mayor frecuencia por usuarios ocasionales (17,5%) y frecuentes (37,1%) de uso compartido de scooters, en comparación con los no usuarios (10,6%). Esto sugiere que el uso compartido de scooters de ciclomotores es complementario para opciones como el uso compartido de automóviles o bicicletas compartidas, que constituyen alternativas de movilidad más sostenibles en comparación con el automóvil privado.

A este respecto, también puede representar una opción de movilidad atractiva en escenarios de políticas de restricción del uso de vehículos privados en los centros urbanos, como algunas ciudades europeas ya han implementado en los últimos años.

El uso compartido de scooters con ciclomotores es una nueva alternativa de transporte urbano que aumenta la accesibilidad y el suministro de movilidad y, en teoría, podría disminuir la flota existente de vehículos con motor de combustión convencional al impactar en las decisiones de propiedad de vehículos privados. En el cuestionario, se preguntó a los encuestados si consideraban que poseer un vehículo privado seguirá siendo una necesidad en el futuro. Del total de la muestra, el 64,6% de los encuestados declaró que la propiedad del vehículo ya no será una necesidad en el futuro. Sin embargo, los no usuarios de uso compartido de scooters parecen ser más escépticos sobre la renuncia de vehículos privados en el futuro según la Figura 2.

Se observó una mayor proporción de personas no preocupadas por poseer un vehículo en el futuro entre los usuarios de uso compartido de scooters (76.2%), y particularmente entre los usuarios frecuentes (81.6%). Como se discutió, el uso compartido de scooters podría desempeñar un papel en la reducción de la propiedad del vehículo, al proporcionar accesibilidad adicional cuando el transporte público no satisface las necesidades de los pasajeros. Esto puede alentar, al menos a algunos usuarios, a no ser propietarios de un vehículo privado. Este hallazgo puede aplicarse a los usuarios de otros modos de movilidad compartida, p. auto compartido

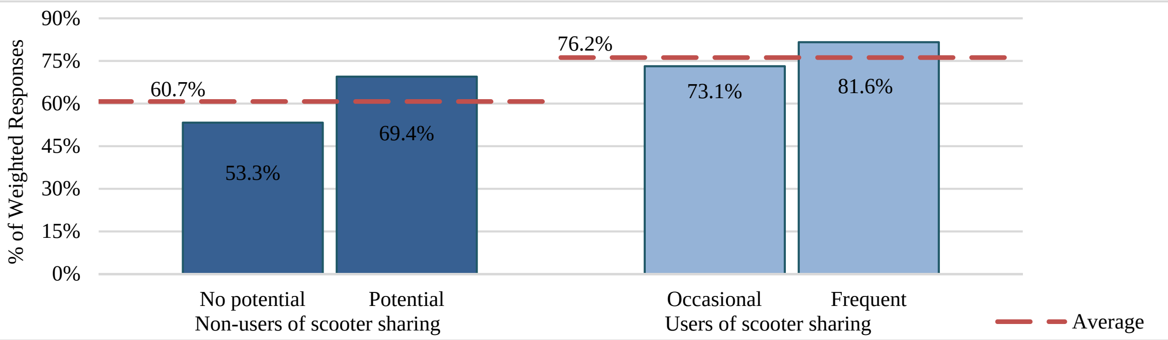

Figura 2: Opiniones sobre si será necesario tener un vehículo privado en el futuro (% de respuestas afirmativas)

Además, una mayor proporción de usuarios potenciales (69.4%) cree que la propiedad del vehículo no será un requisito en el futuro, en comparación con los usuarios no potenciales (53.3%). En lo que respecta a los consumidores potenciales, esta tendencia es relevante porque perciben que estos servicios pueden aumentar las oportunidades de elección de modo y pueden afectar la reducción de las tasas de propiedad de vehículos en las ciudades en los próximos años. En conclusión, el uso compartido de scooters puede capturar la participación modal de los automóviles privados en el futuro y traerá importantes beneficios a la habitabilidad y sostenibilidad urbana, como se ha mencionado.

5. CONCLUSIONES

El estudio exploratorio en esta investigación nos permitió explorar los factores de decisión que determinan la adopción y la frecuencia del uso de servicios de uso compartido de scooters para la movilidad urbana diaria en las ciudades españolas. La primera conclusión es que tanto las características socioeconómicas personales como los atributos relacionados con el viaje evidenciaron un papel importante al explicar la adopción de servicios de uso compartido de scooters entre las personas. Las personas jóvenes y altamente educadas demostraron ser el segmento de la población con una mayor probabilidad de usar esta alternativa de movilidad. Sin embargo, su uso también parece penetrar entre otros rangos de edad, como los adultos de mediana edad. Otras variables, como los niveles más altos de ingresos, parecen desalentar el uso compartido de scooters con ciclomotor, probablemente porque este segmento de la población prefiere usar un vehículo privado para sus viajes diarios en las zonas urbanas. Esto es importante para apuntar a segmentos específicos del mercado de usuarios de esta alternativa de movilidad, dirigir adecuadamente los esfuerzos de políticas para promover estos servicios amigables con el medio ambiente y prever el segmento de población urbana con una mayor probabilidad de adoptar esta alternativa de movilidad en los próximos años.

La segunda conclusión se refiere al estímulo de esta alternativa de movilidad en entornos urbanos. El uso compartido del scooter ciclomotor puede representar un elemento que contribuye a mejorar algunos problemas observados en entornos urbanos, como el aumento de la congestión vial, la contaminación del aire, la falta de espacio público, etc. modos como coche privado o moto, mientras que es complementario para opciones más sostenibles como la movilidad de peatones o bicicletas compartidas. A este respecto, también puede representar una alternativa de movilidad atractiva en escenarios de políticas de restricción del uso de vehículos privados en los centros de las ciudades, como algunas ciudades europeas ya han implementado en los últimos años. Por lo tanto, las administraciones públicas y las autoridades de transporte deben insertar el uso compartido de scooters dentro de sus programas estratégicos para lograr una movilidad urbana más sostenible y fomentar su uso entre otros sectores de la población.

La última conclusión se refiere al impacto del advenimiento del uso compartido de scooters en la movilidad urbana. Tiene impactos positivos en el transporte urbano, p. reduciendo el uso de vehículos y, por lo tanto, mejorando los problemas de congestión vial y la falta de espacio público. Sin embargo, los ciclomotores también captan la demanda del transporte público, por lo que tienen un efecto neto poco claro sobre la sostenibilidad urbana. Este hecho subraya la importancia de integrar los servicios de uso compartido de scooters con el transporte público para promover su uso complementario y llevar la movilidad urbana hacia la sostenibilidad.

ABSTRACT

The introduction of Autonomous Vehicles (AVs) in a realistic urban environment is an ambitious objective. AV validation on real scenarios involving actual objects such as cars or pedestrians in a wide range of traffic cases would escalate the cost and could generate hazardous situations. Consequently, autonomous driving simulators are quickly evolving to cover the gap to achieve a fully autonomous driving architecture validation. Most used 3D simulators in self-driving cars field are V-REP (Rohmer, E., 2013) and Gazebo (KOENIG, N. and HOWARD, A., 2004), due to an easy integration with ROS (QUIGLEY, 2009) platform to increase the interoperability with other systems.

Those simulators provide accurate motion information (more appropriate for easier scenes like robotic arms) but not a realistic appearance and not allowing real-time systems, not being able to recreate complex traffic scenes. CARLA (DOSOVITSKIY, A., 2017) open-source AV simulator is designed to be able to train and validate control and perception algorithms in complex traffic scenarios with hyper-realistic environments.

CARLA simulator allows to easily modify on-board sensors such as cameras or LiDAR, weather conditions and also the traffic scene to perform specific traffic cases. In Summer 2019, CARLA launched its driving challenge to allow everyone to test their own control techniques under the same traffic scenarios, scoring its performance regarding traffic rules. In this paper, the Robesafe researching group approach will be explained, detailing vehicle motion control and object detection adapted from Smart Elderly Car (GÓMEZ-HUÉLAMO, C., 2019) that lead the group to reach the 4th place in Track 3 challenge, where HD Map, Waypoints and environmental sensors data (LiDAR, RGB cameras and GPS) were provided.

1. INTRODUCTION

The development of Autonomous Vehicles (AVs) is continuously evolving. At this moment, none organization has proved a robust testing methodology for L4/L5 AV, levels in which the driver is not involved, at least in most driving situations. As reported by the autonomous driving research community, it is due to, in spite of legal regulations defined in terms of L4/L5 levels, a fully-autonomous driving architecture is still years away, not only due to technical challenges but also due to legal and social ones (Maurer, 2016).

Commonly, most part of the systems that conform an AV are based on Artificial Intelligence (AI), which are trained by extracting patterns of real-world scenarios in order to be used in future actions to produce a specific output. This reasoning force to obtain tons of high-quality data, increasing the development time and cost exponentially when applying a physical approach due to the associated cost of the automated vehicles, the cost of the on-board sensors and the huge driving hours supervised by human beings.

Moreover, the progression of computed-rendered AV simulators enables an alternative way to obtain high-detailed information to validate fully autonomous driving architectures on any traffic situation, being able to recreate specific locations, weather conditions or hazardous traffic conditions without putting in danger any human or material resource.

CARLA is a novel hyper-realistic open-source simulator for autonomous driving research based on Unreal Engine 4 (UE4). The simulator provides an ecosystem of interoperable plugins, realistic physics and image quality, composing scenes by using 3D models of static objects, conforming the environment, and dynamic objects such as pedestrians, cyclists or vehicles, which can be controlled to perform any desired situation (Fig. 1).

Figure 1: CARLA traffic junction.

This simulator provides a wide range of on-board sensors, including cameras (RGB, semantic segmentated and depth) and LiDAR, performing the most common AV perception sensors. These sensors are completely adjustable to project needing, being able to modify their location regarding to the vehicle and also their main features, such as pixels width and height, FOV and distortion for cameras, and number of channels, points-per-second and rotation frequency for LiDAR sensors.

Furthermore, these sensors information and other data relative to the dynamic objects in scene are published using CARLA ROS-bridge, a ROS package that allows communications between the simulator and ROS, enabling interoperability with extern systems such as control and perception modules.

Additionally, traffic scenes can be recreated by using ScenarioRunner, a CARLA developed platform based on OpenScenario (JULLIEN, J., 2009) to define environments of a pre-fixed scenario to allow repeatability, defining the town, static and dynamic objects, weather conditions and also driving behaviors to cope with.

2. CARLA AD CHALLENGE

Until now, realistic AV validation systems where only available for large corporations, preventing smaller research groups from testing their autonomous driving architectures. Taking advantage of CARLA simulator features previously described, CARLA launched the CARLA Autonomous Driving Challenge on February 2019 to democratize autonomous driving development.

CARLA AD Challenge is formed by a collection of routes that AD agents, submitted as Docker images, must complete safely, reaching a destination point following a pre-defined route without traffic infractions. The final score of an agent will depend on the percentage of completed route and the infractions committed during the evaluation (Table 1).

Infractions	Discounted points
Invading lane in the opposite direction	2
Invading a sidewalk	2
Running a stop sign	2
Running a red light	3
Hitting the static scenery	6
Hitting another vehicle	6
Hitting a pedestrian	9

Table 1: Discounted points according to AV committed infraction.

During the challenge, the autonomous agents have to cope with traffic situations inspired by the NHTSA typology, including lane merging and changing, negotiation at intersections and roundabouts, following traffic lights and traffic signs as well as dynamic pedestrians, cyclists and other elements. Same routes may be repeated under different weather and obstacle conditions to test the flexibility of the vehicle, being correspondingly weighed on Eq. 1, where performance score is calculated.

Participants could subscribe up to four different tracks, depending on the information needed by their traffic agent, according to Fig. 2. On Track 1, LiDAR point cloud, GPS and cameras are allowed. On Track 2, autonomous vehicle could only use cameras and location to complete the testing. Tracked 3 grants access to HD Map of the environment, route waypoints to achieve destination and all sensors defined in CARLA (LiDAR, cameras and GPS). Track 4 instead only provides a scene layout of the town where the vehicle is driving along with GPS location.

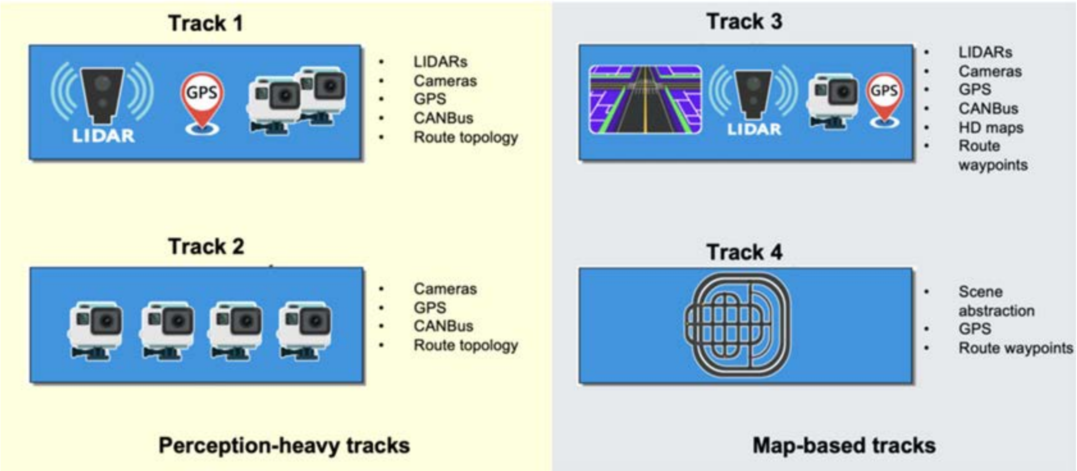

Fig. 2 – CARLA provided sensors information provided on each challenge track.

CARLA AD Challenge started on February 2019, publishing the rules that the candidates would have to follow in order to perform the challenge. The instructions explained how to run CARLA and ScenarioRunner, how to configure it, how to run the evaluation code in order to know the performance of the agent and some tools to analyze and develop car agents.

Later on, online validation stage began, submitting agents code to test their performance on a public server following the challenge rules, allowing for a finest agent tuning than offline stage. Agents must be contained in Docker images in order to be successfully evaluated.

Log files were provided in order to recover information about agent behavior, allowing to reproduce the behavior of the agent during the evaluation tracks in order to know the infractions committed by the vehicle, being able to solve them. Finally, the online testing stage arrived, starting the final evaluation of submitted agents.

In this phase only final score were provided without any log file, not being able to reproduce the behavior undertaken by the autonomous vehicle. The best score achieved by the subsequent agents submitted by the group will be the final score taken into account in CARLA AD Challenge results.

The performance score was calculated following the Equation 1,

$$Score(a) = 1/(R \cdot N) \sum_{i=1}^{R \cdot N} max(100 \cdot C(a, r_i) - I(a, r_i), 0) \quad (1)$$

where a represents the agent under evaluation, C is the amount of route completed for the i-th route, I is the total points discounted due to infractions according to Table 1, R represents the number of repetitions of a route, and N the total number of routes.

3. SUBMITTING CARLA AD CHALLENGE

As described before, CARLA AD Challenge is based on CARLA simulator, which is open-source and constantly evolving. For this reason, submitting to the challenge was a proposal which required much effort and dedication for all our research group.

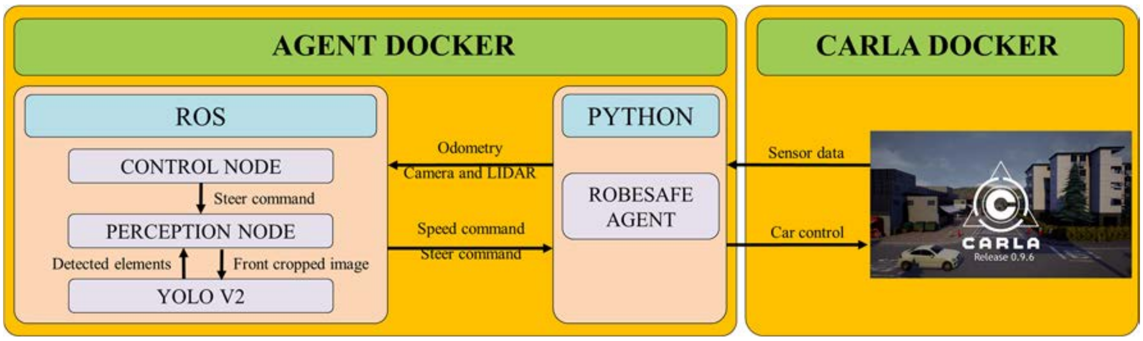

Figure 3: Autonomous agent approach on CARLA AD Challenge.

Since 2016 Robesafe has been developing the Smart Elderly Car, an open-source project to build an autonomous electric vehicle for elderly people to help them with the reduction of their abilities. The Smart Elderly Car was validated both on a real vehicle and V-REP simulator, reproducing use cases and testing its behavior.

When CARLA AD simulator was created, a huge leap in quality was made, freely releasing hyper-realistic simulated environments for autonomous vehicles training and validation. The switching between V-REP and CARLA was necessary to evolve in simulation realism, but it implied the adjustment of all developed systems to this new platform.

The Smart Elderly Car project was based on perception sensors to perceive the surrounding objects, avoiding dynamic obstacles, and GPS and odometry in order to navigate through a specified route.

The map was described using Lanelet 1, defining the context of the External Campus from Universidad de Alcalá.

As CARLA includes a wide range of on-board high-quality perception sensors, the perception module stayed invariable. RGB front camera, along with a YOLOv2 CNN, was used to detect traffic light and its state, vertical and horizontal traffic signs in order to respect traffic rules as well as crossing pedestrians to prevent personal injuries. A specific training was fulfilled in order to detect traffic light state directly as an output from the CNN, saving post-processing time. Also, a top LiDAR sensor was used to detect vehicles inside of the path in order to avoid car crashes.

CARLA simulator planification is based on waypoints, which are a series of points describing the path that the vehicle must follow instead of Lanelet approach, which defines lane edges. In furtherance of overcome this inconvenient, a new controller was implemented, following the waypoints provided by CARLA AD Challenge in Track 3 to successfully complete the route.

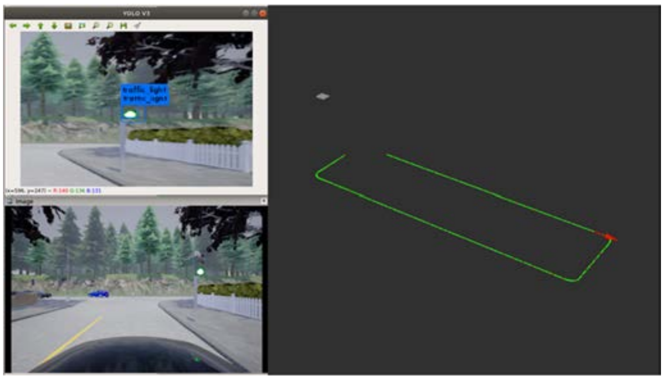

Figure 4: Autonomous agent YOLO image processing and waypoints trajectory.

The main described features can be observed in Fig. 4, showing YOLO image detection a traffic light on the upper left, front image from car dashboard on the lower left and waypoints trajectory (green line) along with car position and orientation (red arrow) on the right side.

4. RESULTS ON CARLA AD CHALLENGE

Moreover than 200 participants organized in 69 teams submitted to CARLA AD Challenge in some of its four available tracks, but only 10 of them could success. More than 5.700 hours of simulation were executed, travelling more than 6.500 km, which evidences the importance of simulation for autonomous vehicles validation.

In Track 3, Robesafe researching group achieved the 4th place over 200 participants worldwide. Furthermore, Robesafe proposal obtained the lowest penalty points among the 5 leaders of the final result, highlighting the correct behavior of the vehicle when moving in a complex urban environment.

The vehicle completed the 60% of the total route under different weather and obstacle conditions while respecting traffic rules and avoiding car crashes and pedestrian collisions.

Ranking	Route points	Infraction points	Total average
1^{st} Team	79.97	13.7	66.83
2^{nd} Team	77.48	11.87	66.05
3^{rd} Team	81.05	20.9	60.47
4^{th} Robesafe	**60.48**	**9.9**	**52.63**
5^{th} Team	48.93	13.67	35.87

Table 2: Results in CARLA AD Challenge Track 3.

4. CONCLUSIONS AND FUTURE WORKS

This paper presented the Robesafe research group approach for an autonomous vehicle navigation in CARLA AD Challenge, describing the migrating process between Smart Elderly Car project, based on V-REP and a real electric vehicle, and CARLA driving simulator. As shown, CARLA AD Challenge stablishes a benchmark to validate fully autonomous vehicles in complex urban environments by recreating hyper-realistic scenes, democratizing the accessibility to cutting edge validation technologies reducing time and cost. Robesafe proposal, based on environment perception through RGB front camera and LiDAR sensor in order to follow traffic rules and respect other dynamic objects, and pursue the provided waypoints to achieve a destination resulted the 4^{th} best of 200 submitted, obtaining the lowest penalty score of the top five.

As future works, 360 degrees object detection will be accomplished in order to acquire a higher safety degree, avoiding obstacles coming from all directions. Also, a tuned controller will be implemented to achieve better waypoint following to complete more route percentage without colliding with other obstacles, performing a safest behavior.

ACKNOWLEDGMENTS

RESUMEN

Los nuevos servicios de movilidad basados en aplicaciones están revolucionando el transporte urbano. En particular, el servicio de ride-hailing ha experimentado un auge mundial en la última década, ya que ofrece un servicio cómodo y a la carta para los desplazamientos urbanos. Paralelamente, se ha llevado a cabo un número creciente de estudios que analizan principalmente el comportamiento de los individuos hacia esta opción de transporte, los patrones de movilidad, así como los efectos del ride-hailing en la sostenibilidad urbana. Sin embargo, la mayoría de estas contribuciones se centran en ciudades estadounidenses, mientras que casi no se han dedicado esfuerzos a otras áreas geográficas, como Europa. Las ciudades de este continente presentan algunas características particulares que las convierten en un caso digno de ser investigado, como una mayor presencia de los modos de transporte público o una mayor preocupación ciudadana por las cuestiones medioambientales.

El objetivo de este trabajo es explorar el comportamiento de viaje hacia los servicios de ride-hailing en una ciudad europea. A partir de la información recogida en una campaña de encuestas en la ciudad de Madrid (España), estimamos un enfoque de Modelo de Datos Heterogéneo Generalizado para identificar los factores clave que motivan la adopción de ride-hailing y la frecuencia de uso.

El trabajo identifica una mayor adopción de los servicios de ride-hailing entre los jóvenes, con un buen nivel de estudios y ricos, que están familiarizados con las nuevas tecnologías.

Y lo que es más interesante, la investigación sugiere que la conciencia medioambiental desempeña un papel notable en la frecuencia de uso de los servicios de ride-hailing, en comparación con las ciudades estadounidenses. En particular, los individuos con menor conciencia medioambiental están más orientados al uso del coche, lo que también está relacionado con un uso más intenso del ride-hailing. Por el contrario, los individuos con una mayor conciencia medioambiental tienden a reducir el uso del transporte compartido, lo que refleja su propensión al transporte público en un entorno de tránsito intensivo.

1. INTRODUCCIÓN

El transporte urbano en todo el mundo ha experimentado cambios drásticos en los últimos años, paralelamente al desarrollo progresivo de las nuevas tecnologías. En particular, los nuevos servicios de movilidad basados en aplicaciones, como el carsharing, el scootersharing y el ride-hailing, están siendo cada vez más adoptados debido, entre otras razones, a un cambio parcial en la mentalidad del consumidor, que pasa de la propiedad a la accesibilidad (Dervojeda et al., 2013). Dentro de estos servicios de movilidad, el ride-hailing -también denominado ridesourcing en la literatura científica- ha experimentado un gran auge en los últimos tiempos, como demuestra el éxito empresarial de empresas de redes de transporte (TNC) como Lyft en Estados Unidos, Didi en China, Cabify en Latinoamérica y España, y Uber en todo el mundo. Según Statistica (2020), en septiembre de 2019, Uber alcanzó los 1.770 millones de viajes en todo el mundo, el doble de los reportados en julio de 2017 (889 millones de viajes). El atractivo de estos servicios de ride-hailing puede explicarse en parte por el hecho de que ofrecen una alternativa de transporte puerta a puerta barata, cómoda y bajo demanda en entornos urbanos (Dias et al., 2017). El servicio se ha convertido en un elemento integral del sistema de transporte urbano en muchas ciudades. Por ejemplo, en San Francisco (EE. UU.) se producen más de 170.000 viajes de ride-hailing en un día laborable típico, lo que representa alrededor del 15% de todos los viajes intravehiculares de la ciudad (SFCTA, 2017).

Como señalan Henao et al. (2017), más allá del comportamiento de los viajes, la evolución de los servicios de transporte como el ride-hailing puede tener un impacto significativo en los sistemas de transporte, la sociedad y el medio ambiente. Por ello, entender el papel que juega este nuevo actor en la movilidad urbana, así como sus efectos sobre los modos competidores y la sostenibilidad urbana, es crucial desde el punto de vista de la planificación del transporte. En este sentido, algunos autores como Calderón y Miller (2019) han indicado que las tendencias actuales sobre la creciente relevancia del ride-hailing proporcionan una justificación sustancial para considerarlo como una opción de transporte que debería incluirse en los modelos de previsión de la demanda de viajes regionales, a pesar de su proporción todavía limitada dentro de la cuota modal urbana en muchas ciudades.

Además, aparte de su tendencia creciente a corto plazo, el transporte de ida y vuelta también tiene implicaciones sustanciales para el futuro, ya que se espera que las flotas de vehículos autónomos (AV) funcionen de forma similar a los vehículos de ida y vuelta (Gerte et al., 2018).

En consonancia con la creciente adopción de los servicios de ride-hailing en todo el mundo, la literatura científica dedicada a esta opción de movilidad también ha crecido exponencialmente en los últimos años. Al igual que en el caso de otros servicios de movilidad compartida, las contribuciones anteriores sobre el servicio de transporte compartido se han dedicado principalmente a dos áreas principales: (i) la investigación de los factores asociados a su adopción y frecuencia de uso (véase, por ejemplo, Dias et al., 2017; Alemi et al., 218; Bhat & Lavieri, 2019), y (ii) la exploración de los impactos potenciales del ride-hailing en otras dimensiones relacionadas con los viajes, como la propiedad del vehículo, la elección del modo, la congestión del tráfico y la seguridad vial (véase, por ejemplo, Peck, 2017; Wenzel et al., 2019). Además, gran parte de este conjunto de investigaciones se centra en países muy concretos, sobre todo en Estados Unidos (véase Mohamed et al., 2019; Tirachini y del Río, 2019).

Por el contrario, se ha invertido poco esfuerzo en estudiar el comportamiento de ride-hailing en otras áreas geográficas del mundo que también están experimentando un crecimiento significativo en el uso de ride-hailing, como Europa. En este sentido, las ciudades europeas suelen presentar importantes diferencias relacionadas con la movilidad en comparación con las ciudades estadounidenses, incluyendo una mayor densidad de población y un mayor uso del transporte público. Estas diferencias pueden desempeñar un papel importante en la adopción y evolución de la demanda de ride-hailing y hacen de las ciudades europeas un caso interesante que merece la pena investigar.

Dentro de este contexto más amplio, el objetivo de este trabajo es identificar los factores clave que motivan la adopción y la frecuencia de uso de los servicios de ride-hailing en Madrid (España).

En particular, la investigación analiza la influencia de las características sociodemográficas, las preferencias psicológicas no observadas y los atributos relacionados con la movilidad en el uso de los servicios de ride-hailing, y compara los resultados con contribuciones anteriores centradas en ciudades estadounidenses. Para ello, analizamos la información recogida en una campaña de encuestas realizada en 2019 en la ciudad de Madrid.

Madrid es una de las áreas metropolitanas más pobladas de Europa, con una amplia oferta y demanda de transporte público, y una reciente y creciente penetración de servicios de movilidad basados en apps.

El documento se organiza como sigue. La sección 2 resume el estado actual del conocimiento científico sobre los servicios de ride-hailing, y señala algunas diferencias importantes relacionadas con la movilidad entre las ciudades americanas y europeas que motivaron la investigación. La sección 3 introduce brevemente el contexto de localización del estudio y presenta una visión general del enfoque de modelización. La sección 4 describe la encuesta que realizamos y presenta las estadísticas descriptivas de la muestra. La sección 5 describe la metodología empleada para explorar la adopción y la frecuencia de uso de los servicios de ride-hailing por parte de los individuos. La sección 6 presenta y discute los resultados de la modelización y, por último, la sección 7 resume las principales conclusiones e identifica otras áreas de investigación.

2. ESTADO DEL ARTE

Las contribuciones científicas anteriores sobre el servicio de ride-hailing se han centrado en un conjunto diverso de cuestiones de equidad y efficiencia, como el bienestar social, la congestión, la seguridad, la privacidad, el consumo de energía y los impactos ambientales relacionados (Sun y Ding, 2019). Estos esfuerzos de investigación anteriores han señalado tanto los efectos positivos como los negativos de los servicios de ride-hailing en la movilidad general del transporte. Como se menciona en Yu & Peng (2019), mientras que los partidarios han indicado el papel del ride-hailing en, por ejemplo, el fomento de estilos de vida sin coches (Jin et al., 2018) o la mejora de la seguridad vial (Peck, 2017), otras contribuciones han criticado los efectos negativos sobre la congestión del tráfico (Standing et al., 2019; Wenzel et al., 2019; Schaller, 2018) y la reducción del uso del tránsito (Gehrke et al., 2018).

En esta línea, algunos autores, como Hall et al. (2018), han señalado que las cuestiones políticas clave sobre los effectos del ride-hailing siguen sin respuesta. Para una visión general sobre el ride-hailing, incluyendo la demanda y la fijación de precios, las operaciones de la plataforma, la oferta y los incentivos, la competencia, los impactos y la regulación, se remite al lector a Wang & Yang (2019).

En el contexto de las cuestiones relacionadas con la demanda asociadas al ride-hailing, como señalan Lavieri & Bhat (2019), ha habido dos direcciones principales de investigación: contribuciones de investigación a nivel individual y contribuciones de investigación a nivel de viaje. A **nivel individual**, los trabajos de investigación han llegado a algunas conclusiones consistentes sobre la adopción y el uso de los servicios de ride-hailing. Por ejemplo, hay pruebas consensuadas de que los usuarios de ride-hailing tienden a ser más jóvenes, más educados, tienen mayores ingresos y viven en zonas urbanas (véase, por ejemplo, Chen, 2015 para Pittsburgh; Rayle et al., 2016 para San Francisco; Smith, 2016 para varias ciudades estadounidenses; Alemi et al., 2018 para California; Clewlow & Mishra, 2017 para múltiples ciudades estadounidenses; Chu et al., 2018 para seis grandes ciudades estadounidenses, Wang et al., 2019 para Hangzhou, y Lavieri & Bhat, 2019 para Dallas).

También se ha encontrado que la familiaridad con las nuevas tecnologías es un factor importante y consistente del estilo de vida que influye en la adopción del ride-hailing (véase, por ejemplo, Alemi et al., 2018; Lavieri & Bhat, 2019). La investigación también ha mostrado de manera uniforme que el ocio es el principal propósito de los viajes de ride-hailing (véase Rayle et al., 2016 para San Francisco; Zhong et al., 2018 para Shanghái; y Tirachini & del Río, 2019 para Santiago de Chile) y que esta opción de movilidad se utiliza más intensamente en las zonas más densas (Dias et al., 2017; Conway et al., 2018). Además, existe una conclusión generalizada de que el transporte público se encuentra entre las opciones de movilidad bastante afectadas por el ride-hailing. Esta conclusión se ha obtenido para los casos de San Francisco (Rayle et al., 2016; Shaheen et al., 2016), Denver (Henao, 2017), Santiago (Tirachini & del Río, 2019), Boston (Gehrke et al., 2018), así como Chicago, Los Ángeles, Nueva York, Seattle o Washington D.C. (Clewlow & Mishra, 2017), entre otros. Además, existen pruebas de que esta nueva opción de movilidad provoca un aumento de la congestión (véase, por ejemplo, Gehrke et al., 2018; Clewlow & Mishra, 2017). En cambio, algunos otros resultados presentados en la literatura científica son contradictorios.

Por ejemplo, algunos autores han establecido una relación negativa entre el uso de los servicios de ride-hailing y la propiedad del vehículo (véase, por ejemplo, Clewlow & Mishra, 2017, Gehrke et al., 2018). Sin embargo, otras investigaciones han encontrado una relación no significativa entre estas dos variables (Rayle et al., 2016; Tirachini & del Río, 2019), mientras que algunas contribuciones han llegado a la conclusión de que el ride-hailing está asociado a un aumento de la propiedad de vehículos (Schaller, 2018; Gong et al., 2017). C

abe destacar que los mencionados modelos de ride-hailing a nivel individual no han incorporado explícitamente los patrones generales de movilidad de los individuos como factores explicativos, como hacemos en nuestro presente trabajo.

A nivel de viaje, muchas contribuciones han utilizado datos de viaje obtenidos de operadores de ride-hailing para analizar la distribución espacial y temporal de la demanda, así como su relación con factores socioeconómicos y del entorno urbano. Las conclusiones de estos estudios a nivel de viaje son, de nuevo, en general, consistentes y en línea con la investigación a nivel individual.

Se ha comprobado que el Ride-hailing se utiliza más intensamente en las zonas más densas (Yu & Peng, 2019; Li et al., 2019; Goodspeed et al., 2019) y en los barrios con mayor presencia de personas jóvenes, bien educadas y adineradas (Goodspeed et al., 2019). Además, los análisis de los viajes geolocalizados han concluido en general un aumento de la congestión (Wenzel et al., 2019; Nie, 2017; Erhardt et al., 2019) y una reducción de la demanda de taxis (Nie, 2017) debido a la presencia de nuevos servicios de ride-hailing. Además, Li et al. (2019) descubrieron que el ride-hailing se utiliza con más frecuencia para los viajes que no son de ida y vuelta, mientras que Yu & Peng (2019) observaron una mayor demanda de ride-hailing para los viajes de fin de semana.

Sin embargo, algunos otros resultados no son concluyentes. Por ejemplo, Lavieri et al. (2018) señalaron un posible efecto de sustitución entre el ride-hailing y el uso del transporte público, mientras que el análisis de Hall et al. (2018) en varias zonas urbanas de Estados Unidos sugirió un efecto complementario entre el ride-hailing y el uso del transporte público.

Una observación importante de los numerosos estudios de investigación anteriores identificados anteriormente es que casi todos ellos se basan en una ciudad estadounidense, como también indican Mohamed (2019) y Tirachini & del Río (2019). En particular, hasta donde sabemos, no se ha realizado ningún estudio de este tipo en la literatura científica para analizar el ride-hailing en Europa. Mohamed (2019) exploró si las autoridades de transporte y los operadores en Londres (Reino Unido) entienden plenamente el impacto de los servicios de ride-hailing, mediante la realización de un enfoque de grupo focal. Aparte de eso, la mayoría de las contribuciones en Europa se han centrado en cuestiones de competencia y regulación relativas al funcionamiento del ride-hailing (véase, por ejemplo, Thelen, 2018; De Massi, 2018; Deighton-Smith, 2018; Geradin, 2015). Hay una escasez de investigaciones sobre el comportamiento de viaje en las ciudades europeas en el contexto del ride-hailing.

Al mismo tiempo, existen claras diferencias entre las ciudades europeas y las estadounidenses que pueden conducir a diferentes comportamientos de ride-hailing. En primer lugar, las ciudades europeas están más densamente pobladas. Según Kumar (2016), las ciudades europeas tienen una densidad media de 3.000 hab./km2, casi el doble que las norteamericanas. Este autor señala que las bajas densidades de las ciudades norteamericanas reflejan la mayor prevalencia de la vida suburbana y el predominio de los viajes en coche.

Estas variaciones en la densidad urbana pueden dar lugar a tendencias de ride-hailing bastante distintas, dado que investigaciones anteriores (véase, por ejemplo, Yu & Peng, 2019 y Goodspeed et al., 2019) han descubierto que la demanda de ride-hailing es mayor en las zonas más densamente pobladas de una ciudad. En segundo lugar, las ciudades europeas están mejor servidas por el transporte público, que funciona como columna vertebral para ayudar a apoyar otras formas de movilidad. Por lo tanto, en Europa predomina la cultura del transporte compartido, mientras que en muchas ciudades de EE.UU. se opta por el coche privado.Esto puede dar lugar a un panorama bastante diferente de competencia entre los modos de transporte en las ciudades europeas en comparación con las ciudades estadounidenses. En tercer lugar, la población de las ciudades europeas suele mostrar una mayor preocupación por las cuestiones medioambientales, como se ha señalado recientemente en una encuesta sobre el cambio climático realizada por el Banco Europeo de Inversiones (BEI, 2018). Como resultado de esta mayor preocupación medioambiental, muchos gobiernos locales de Europa han implementado numerosas medidas para reducir los atascos y las emisiones de gases de efecto invernadero de los automóviles privados, como el cobro por congestión (por ejemplo, Londres, Milán), las zonas de bajas emisiones (por ejemplo, Múnich, París) y las restricciones de aparcamiento en los centros de las ciudades.

El mayor nivel de preocupación por el medio ambiente que muestran las ciudades europeas puede dar lugar a diferentes estructuras de competencia entre los modos de transporte, especialmente entre las opciones de transporte público y los servicios de ride-hailing. Las tres diferencias entre las ciudades estadounidenses y europeas que acabamos de identificar, junto con el enfoque casi exclusivo de los estudios anteriores en un contexto estadounidense, apuntan a la necesidad de explorar la adopción y el uso de los servicios de ride-hailing en el contexto de una ciudad europea.

3. CASO DE ESTUDIO Y APROXIMACIÓN METODOLÓGICA

Madrid es la capital de España y su ciudad más poblada, con un total de 3,3 millones de habitantes (Ayuntamiento de Madrid, 2020) y una densidad media de 8.832 hab./km2. La concentración de población es especialmente intensa en los barrios interiores (24.326 hab./km2). El cuadro 1 presenta algunas estadísticas que comparan las ciudades estadounidenses con Madrid. En términos de densidad, Madrid sólo es superada por la ciudad de Nueva York en EE.UU., y está muy por encima de otras ciudades americanas investigadas anteriormente. Las dos filas siguientes de la Tabla 1 ofrecen indicaciones sobre el uso del sistema de transporte público y la infraestructura en Madrid y en las grandes ciudades de EE.UU. La cuota modal intraurbana del transporte público y de los modos activos en Madrid es sustancialmente mayor que en las ciudades estadounidenses, al igual que el número de estaciones ferroviarias en cada kilómetro cuadrado de superficie. La última fila de la Tabla 1 muestra la clara diferencia en la preocupación por el cambio climático entre los habitantes de España y los de EE.UU. (sólo se dispone de estadísticas a nivel nacional para esta dimensión).

INDICATORS		**Madrid**	**New York City**	**San Francisco**	**Boston**	**Chicago**	**Washington DC**
Population density (inhab./km^2)		8,832	11,056	7,388	5,549	4,550	4,506
Transit Use and Availability	**Modal share (intra-city trips): public transport + active modes (%)**	74.6	64.1	53.0	61.0	36.5	54.3
	Rail accessibility (stations/km^2)	0.81	0.58	0.64	0.41	0.25	0.51
Climate change perception: people concerned + alarmed (%)		87.5 (Spain)	65.6 (United States)				

Tabla 1: Indicadores comparativos de Madrid y varias ciudades estadounidenses

En el contexto de la alta densidad, la amplia oferta de transporte público y la gran preocupación por el medio ambiente, en los últimos años han empezado a funcionar en la ciudad nuevos servicios de movilidad compartida y de micromovilidad. Las operaciones de transporte en coche comenzaron a finales de 2014. Pero numerosos problemas con la legislación española sobre transporte obligaron a Uber, el principal operador de viajes compartidos en ese momento, a dejar de ofrecer viajes en el país.

Tras cumplir con todos los requisitos legales, las operaciones de Uber se reanudaron en 2016. El otro operador presente en Madrid, la empresa española Cabify, comenzó a operar en 2012, pero prestó una oferta insignificante hasta 2016. En la actualidad, más de 8.200 vehículos de ride-hailing operan en Madrid bajo las plataformas de Uber y Cabify (Ministerio de Fomento, 2020). Aunque el gobierno nacional mantiene registros de todos los viajes realizados por ride-hailing en España desde abril de 2019, no hay datos oficiales actualizados sobre estos servicios.

En la presente investigación, nuestra exploración del comportamiento de los individuos hacia la adopción y la frecuencia de uso de los servicios de ride-hailing implica la estimación de dos modelos de elección utilizando datos de encuestas recogidos en la ciudad de Madrid.

El primer modelo se estima a nivel individual basado en el Modelo Generalizado de Datos Heterogéneos (GHDM) desarrollado por Bhat (2015), mientras que el segundo modelo se estima a nivel de viaje. Los marcos de cada uno de estos modelos se analizan sucesivamente en las dos secciones siguientes.

3.1. El marco de modelización a nivel individual

3.1.1. Las variables de resultado endógenas

El primer análisis (nivel individual) modela la adopción del servicio de ride-hailing y la frecuencia de uso, junto con cuatro variables de resultado adicionales. La adopción del ride-hailing se representa como una variable binaria que indica si el individuo ha utilizado alguna vez los servicios de ride-hailing. La frecuencia de uso de los servicios de ride-hailing se representa como una variable ordinal en cinco categorías:

- (1) utilizado, pero no en los últimos seis meses,
- (2) utilizado, pero no en el último mes,
- (3) utilizado para 1-4 viajes en el último mes, y
- (4) utilizado para 5-8 viajes en el último mes, y
- (5) utilizado para más de 8 viajes en el último mes.

En comparación con estudios anteriores que solo tienen en cuenta los viajes realizados en los últimos 30 días (véanse, por ejemplo, Lavieri y Bhat, 2019; Dias et al., 2017), nosotros hemos optado por tener en cuenta un período de tiempo más largo.

Este enfoque nos permite incluir a los usuarios ocasionales y poco frecuentes de estos servicios, lo cual es importante en el caso de Madrid por dos razones principales.

En primer lugar, el ride-hailing es un servicio de movilidad relativamente nuevo en la ciudad, por lo que la familiaridad (y en consecuencia, la frecuencia de uso) observada para ciertos segmentos de la población puede ser bastante baja.

En segundo lugar, el uso intensivo del transporte público y de los modos activos en la ciudad, junto con una amplia variedad de otras nuevas opciones de movilidad (coche compartido, ciclomotores y patinetes compartidos, y bicicletas compartidas), es probable que intrínsecamente resulte en un menor número de usuarios frecuentes de ride-hailing en Madrid en relación con la mayoría de las ciudades estadounidenses.

Aparte de la adopción y la frecuencia de uso del ride-hailing, el modelo a nivel individual también tiene en cuenta cuatro variables adicionales coendógenas: la ubicación residencial, la disponibilidad de vehículos y las tasas de movilidad tanto en días laborables como en fines de semana. Estas variables se han incluido en el análisis para tener en cuenta la posibilidad de que la ubicación residencial, la disponibilidad de vehículos y las tasas de movilidad, junto con el comportamiento de ride-hailing, se determinen como un conjunto de elección, y para tener en cuenta cualquier efecto de autoselección en la influencia de la ubicación residencial y la propiedad de vehículos en el comportamiento de ride-hailing. Además, las tasas de movilidad general se han considerado como variables co-endógenas en el análisis, dado el impacto potencial del comportamiento de movilidad diaria en el uso de los servicios de ride-hailing. En este sentido, investigaciones anteriores han indicado que la mayoría de los viajes de ride-hailing se realizan durante los fines de semana (Yu & Peng, 2019) y por ocio (véase, por ejemplo, Rayle et al., 2016; Tirachini & del Río, 2019).

Por lo tanto, es importante tener en cuenta la influencia no solo del comportamiento de movilidad de los individuos durante la semana, sino también del comportamiento de movilidad durante el fin de semana, a la hora de modelar el ride-hailing.

En el cuestionario de la encuesta (que se comenta en el siguiente apartado), se pedía a los encuestados que indicaran su ubicación residencial entre las múltiples zonas de Madrid, definidas según la centralidad geográfica, la accesibilidad del transporte y la posición con respecto a las principales vías de circunvalación. Al final, teniendo en cuenta el bajo número de respuestas en algunas zonas específicas de la ciudad de Madrid y en zonas de escasa accesibilidad al transporte, la localización residencial se basó principalmente en la ubicación del hogar con respecto a las principales vías de circunvalación y en si el encuestado vivía dentro de los límites de la ciudad de Madrid o vivía más allá de los límites de la ciudad de Madrid en zonas colindantes. La ciudad de Madrid tiene dos circunvalaciones (una interior - M30 y otra exterior - M40), con una mayor densidad de individuos dentro de la primera.

En consecuencia, la localización residencial se basó en una representación nominal trinaria del espacio:

- (1) Vivía dentro de la circunvalación interior de la ciudad de Madrid,
- (2) Vivía fuera de la circunvalación interior de la ciudad de Madrid, y
- (3) Vivía fuera de la ciudad de Madrid.

La disponibilidad de vehículos se buscó en la encuesta preguntando a los encuestados si tenían frecuentemente acceso a un vehículo privado motorizado (coche/otro vehículo motorizado) en casa para uso personal. Dada la escasa presencia de vehículos motorizados distintos del coche en el hogar, creamos una variable binaria de disponibilidad de coche. En el resto de este documento, utilizaremos los términos disponibilidad de vehículos y disponibilidad de coches indistintamente para referirnos a la disponibilidad de coches motorizados. En nuestra muestra, el 69,1% de los individuos tienen un vehículo disponible para su uso personal.

El cuestionario también recogía información sobre los índices de movilidad de los individuos en días laborables y fines de semana. Los encuestados informaron del número de viajes que habían realizado en el último día laborable (de lunes a viernes) y no laborable (sábado y domingo), excluyendo los viajes a pie de menos de 15 minutos. A partir de esta información, se creó una variable ordinal para cada uno de los índices de movilidad en días laborables y fines de semana:

- (1) cero viajes,
- (2) 1-2 viajes, y
- (3) más de 2 viajes.

Se estableció un valor umbral de dos viajes al día, ya que suele indicar un patrón en el que sólo se realiza una actividad fuera del hogar en un día determinado.

Las seis variables endógenas de resultado de interés (adopción de viajes en coche de alquiler, frecuencia, elección de residencia, disponibilidad de vehículos y tasas de movilidad en días laborables y fines de semana) se modelaron conjuntamente en función de variables sociodemográficas exógenas y de un conjunto de constructos psicológicos latentes, los cuales se analizan a continuación.

3.1.2. Constructos psicológicos latentes

Las investigaciones anteriores han indicado claramente que las características relacionadas con la movilidad no sólo están determinadas por la demografía, sino también por las actitudes y las preferencias de estilo de vida. En consecuencia, el modelo incluye cuatro constructos latentes no observados que captan las preferencias psicológicas de los individuos. Estos constructos se identifican basándose en estudios anteriores sobre el transporte y en el campo de la etnografía, que reconocen que estos constructos psicosociales son importantes determinantes de los patrones de uso de la tecnología y los viajes. Los constructos latentes se introducen como determinantes de las seis variables endógenas de resultado de interés a través de variables indicadoras de los constructos recogidos en la encuesta (véase la siguiente sección para una visión general de la modelización).

El primer constructo latente se refiere a la propensión del individuo a tener un estilo de vida de búsqueda de variedad (VSL), es decir, una tendencia a comprar o probar nuevos bienes o servicios, así como una inclinación a adoptar un estilo de vida variado en términos de experiencias.

La inclusión de este constructo latente parece razonable dado que el ride-hailing puede considerarse todavía una opción de movilidad bastante nueva en Madrid, lo que lleva a ciertos individuos a percibirlos como una opción de transporte más atractiva o de moda.

Además, los individuos que siguen un estilo de vida más variado pueden tender a ser más extrovertidos, y por lo tanto pueden presentar mayores necesidades de movilidad. Este constructo latente ha sido ampliamente utilizado en el campo de la psicología para captar las diferencias en las tendencias de los individuos hacia la inercia del modo (Rieser-Schüssler & Axhausen, 2012), y también en el uso del ride-hailing (Alemi et al., 2018; Lavieri & Bhat, 2019).

Los indicadores utilizados para desarrollar el constructo VSL incluyen la apertura a los cambios en general, a las nuevas experiencias, a los nuevos productos y a los riesgos, y están adaptados de Schwartz et al. (2001).

El segundo constructo se refiere a la tecno-savviness del individuo, una variable latente ampliamente utilizada en la literatura previa cuando se explora el uso de nuevos servicios de movilidad urbana (véase, por ejemplo, Velázquez, 2019; Astroza et al., 2017). La inclusión de esta variable es clara dado que los servicios de ride-hailing solo pueden ser llamados a través de una app de smartphone. Por tanto, incluir la familiaridad del encuestado con las nuevas tecnologías y el uso de los smartphones es fundamental. Los indicadores de este constructo recogen la adopción o el uso diario de las nuevas tecnologías, en particular: las aplicaciones móviles para las tareas cotidianas, las redes sociales y la actitud para probar nuevas aplicaciones.

El tercer constructo se refiere a la conciencia ambiental del individuo, una variable latente ampliamente adoptada en la literatura científica sobre el comportamiento de viaje (véase, por ejemplo, Kamargianni et al., 2015; Davison et al., 2014; Astroza et al., 2017), y en particular el ride-hailing (Lavieri & Bhat, 2019). Este constructo es relevante en esta investigación debido a la mayor preocupación medioambiental que parecen mostrar los residentes europeos en comparación con los estadounidenses.

La variable latente tiene como objetivo capturar los comportamientos proambientales que pueden, por ejemplo, llevar a un individuo a reducir el uso del vehículo privado o mostrar una tendencia hacia las opciones respetuosas con el medio ambiente, como el transporte público, y por lo tanto potencialmente impactar en el uso de ride-hailing.

Los indicadores de este constructo recogen las preferencias por bienes y servicios respetuosos con el medio ambiente, la percepción del transporte público y el comportamiento de reciclaje en el hogar.

Por último, el cuarto constructo capta la propensión del individuo a compartir bienes y servicios en un sentido amplio. Algunos indicadores de esta variable latente también hacen referencia a la sensibilidad a la privacidad de los individuos. Se ha demostrado que tanto la propensión a compartir como la sensibilidad a la privacidad influyen en el uso de opciones de movilidad compartida como el carsharing (Velázquez, 2019). Este constructo latente pretende captar la propensión de los individuos a evitar los espacios compartidos con extraños, lo que puede influir en gran medida en que prefieran los vehículos privados en relación con el transporte público (Ripplinger et al., 2012). Además, dado que en el caso de Madrid no se dispone de viajes compartidos, una menor propensión a compartir reflejaría una mayor tendencia a los entornos privados, lo que podría fomentar el uso de los viajes compartidos en lugar del transporte público. En este sentido, mientras que en los Estados Unidos se ha observado que la sensibilidad a la privacidad puede desalentar el uso de los viajes en coche de alquiler, ya que el espacio es al menos compartido con el conductor (en relación con el uso de un vehículo privado).

La estructura de la competencia en Madrid puede ser tal que la sensibilidad a la privacidad en realidad fomenta el uso de los viajes en coche de alquiler, ya que la cantidad de compartir y estar con extraños es muy limitada en un vehículo de viaje de alquiler en comparación con los sistemas de transporte público más ampliamente disponibles en Madrid.

3.1.3. La estructura del modelo

La metodología de modelización adoptada se basa en el Modelo Generalizado de Datos Heterogéneos (GHDM) desarrollado por Bhat (2015), una metodología empleada anteriormente para analizar el comportamiento de los viajes de ride-hailing (véase, por ejemplo, Lavieri & Bhat, 2019; Vinayak et al., 2018; Lavieri et al., 2017). El GHDM representa un enfoque integral que permite analizar múltiples variables de interés y sus relaciones con otras variables relacionadas con el transporte, al tiempo que controla los factores observados y no observados que pueden afectar a las elecciones de los individuos.

Además, dada su flexibilidad, el GHDM permite la estimación conjunta de resultados continuos, nominales, ordinales, múltiples-discretos y de conteo. Para ello, el modelo establece una estructura de dependencia parsimoniosa a través de los constructos latentes estocásticos.

El modelo GHDM tiene dos componentes:

- el modelo de ecuaciones estructurales de variables latentes (SEM), y
- el modelo de ecuaciones de medición de variables latentes (MEM).

Como se ilustra en la figura 1, el componente SEM define cada constructo latente (representado como óvalos en el panel central de la figura) como una función de variables sociodemográficas exógenas (lado izquierdo de la figura) y un término de error no observado (no mostrado en la figura). Cada término de error representa el efecto de los factores individuales no observados sobre un constructo latente específico. Dejemos que estos factores no observados se denoten por η1, η2, η3 y η4 (correspondientes a uno de los cuatro constructos latentes de la figura 1) y los recojamos en un vector η.

Suponemos que η es normal estándar multivariante con un vector de media de 0 y una matriz de correlación de Γ con seis posibles elementos de correlación (debido a consideraciones de identificación, las varianzas de los elementos individuales de η deben normalizarse a 1; véase Bhat, 2015). Los constructos latentes son estocásticos debido a la presencia de los elementos aleatorios y, por definición, no se observan.

Por lo tanto, la relación del modelo SEM entre las variables sociodemográficas y los constructos latentes, así como los elementos de la matriz de correlación de Γ, no se pueden estimar directamente, sino que se estiman a través de las observaciones de los indicadores de los constructos latentes (véanse los indicadores ordinales VLS, de ahorro tecnológico, de conciencia medioambiental y de propensión a compartir que figuran en las variables endógenas del panel derecho de la figura 1; los indicadores reales se analizan en la sección 4.4) y los resultados endógenos de interés (mostrados hacia el lado derecho de la figura 1).

Los constructos latentes estocásticos, junto con las variables sociodemográficas exógenas, sirven como determinantes de las utilidades/propensidades latentes subyacentes de los resultados discretos ordinales/binomiales y nominales observados que caracterizan las variables endógenas de interés y las variables indicadoras. Esto está representado por la relación MEM en la Figura 1.

Es importante destacar que, además de captar los efectos de las preferencias de estilo de vida y de las actitudes sobre el comportamiento de transporte en coche y los patrones de movilidad, los constructos latentes estocásticos también sirven como vehículos para permitir el modelado conjunto parsimonioso de múltiples resultados en el componente MEM.

En concreto, los términos de error de la parte SEM, que definen las variables latentes, penetran en la parte MEM y establecen una estructura de dependencia parsimoniosa entre todas las variables endógenas. Por ejemplo, tal y como se desprende de nuestros resultados empíricos, si el constructo de búsqueda de variedad influye tanto en las tasas de movilidad de los días laborables como en las de los fines de semana, implica inmediatamente una covarianza de errores entre las tasas de movilidad de los días laborables y las de los fines de semana.

Del mismo modo, si el constructo de conciencia medioambiental influye tanto en la disponibilidad de vehículos como en la frecuencia de viajes en coche, genera inmediatamente una estructura de covarianza entre la disponibilidad de vehículos y la frecuencia de viajes en coche. Una descripción detallada del GHDM, así como su proceso de estimación, va más allá del alcance de este documento, pero puede encontrarse en Bhat (2015).

En resumen, las variables endógenas del modelo incluyen los indicadores de los constructos latentes y las seis principales variables de resultado de interés mencionadas anteriormente (enumeradas en el panel derecho de la Figura 1).

El GHDM controla la correlación de errores debido a la modelización conjunta de estas variables, y acomoda los efectos recursivos entre ellas. En esta investigación se han probado múltiples direccionalidades recursivas entre las variables endógenas.

El mejor ajuste de los datos se obtuvo en la especificación causal que considera que la ubicación residencial influye en las tasas de movilidad, ambas influyen en la disponibilidad de vehículos y, finalmente, estas cuatro variables influyen en la adopción y la frecuencia de uso del servicio de ride-hailing.

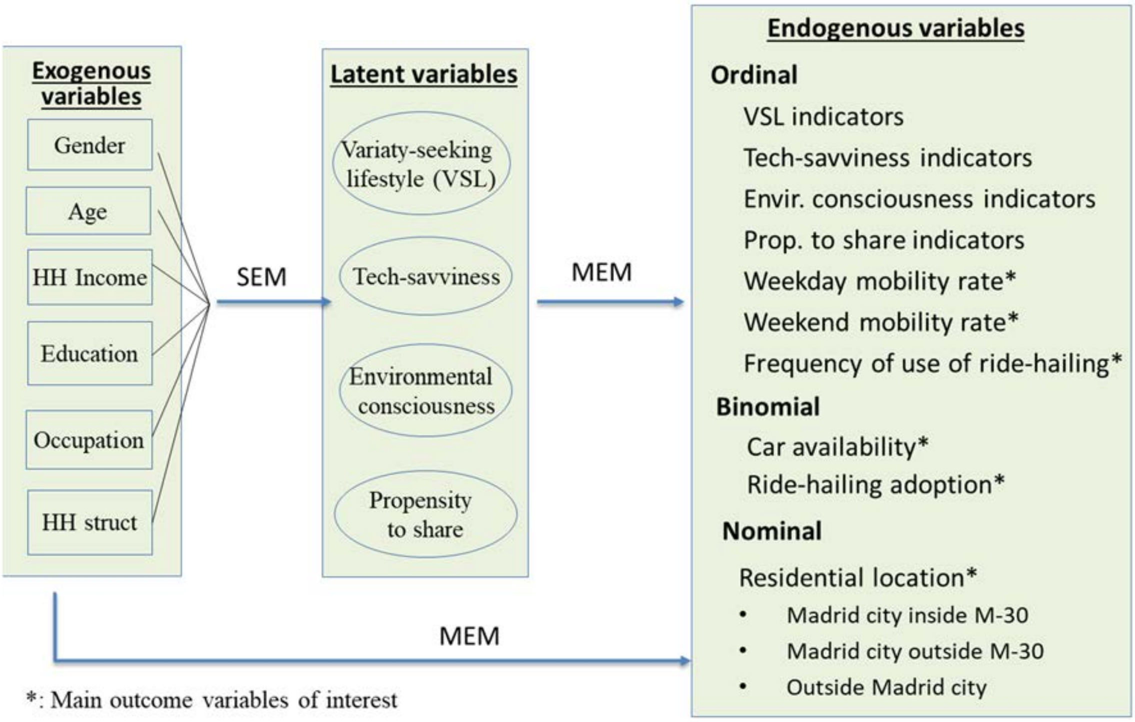

Figure 1: Visión general del modelo a nivel individual adoptado para explorar la adopción y la frecuencia de uso del ride-hailing

3.2. El marco de modelización a nivel de viaje

El segundo análisis (a nivel de viaje) caracteriza la movilidad por ride-hailing en la ciudad de Madrid, explotando la información detallada sobre el último viaje por ride-hailing proporcionada por los encuestados que habían utilizado ride-hailing en los últimos 30 días.

Se adopta un enfoque de análisis de elección para modelar múltiples características del viaje en función de las características sociodemográficas individuales, las variables psicológicas no observadas y las características relacionadas con la movilidad. En la figura 2 se presenta un esquema del modelo a nivel de viaje, que se discute a continuación.

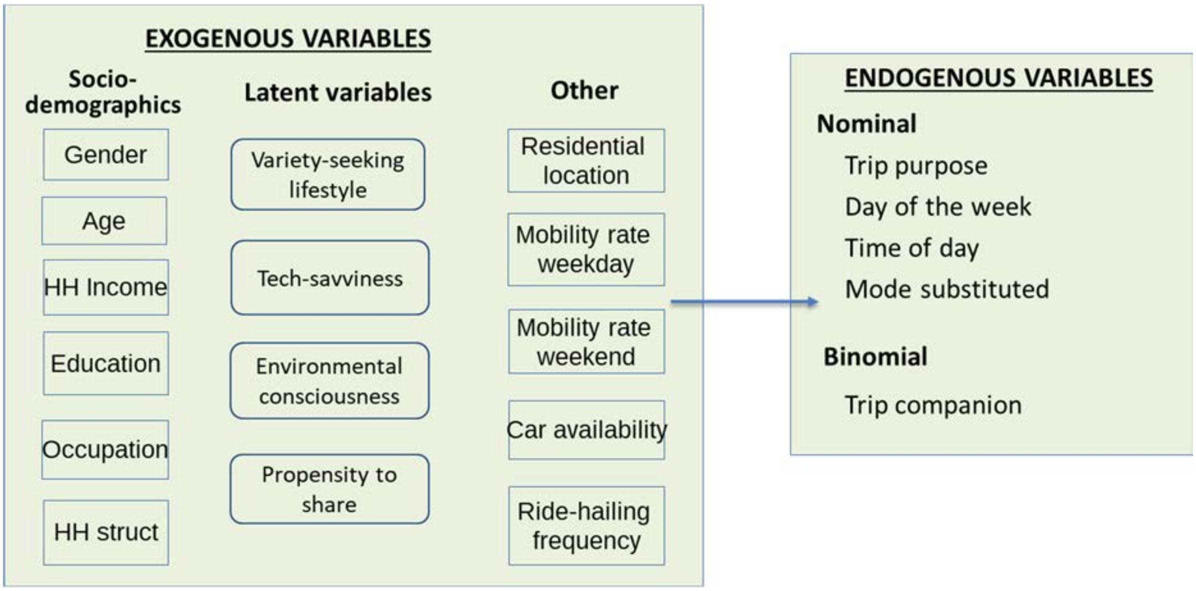

Figura 2: Visión general del modelo a nivel de viaje adoptado para explorar la movilidad en ride-hailing

Es necesario hacer una nota importante. Dado que estamos modelando viajes aislados realizados por los individuos en lugar de analizar los viajes en coche como una parte integral de los patrones de movilidad en general, los resultados de nuestro modelo a nivel de viaje deben ser interpretados con precaución.

Este segundo análisis es intrínsecamente de naturaleza exploratoria y tiene como objetivo principal complementar el primer modelo sobre la adopción y la frecuencia de uso del ride-hailing.

3.2.1. Las variables endógenas de resultado

El análisis a nivel de viaje considera cinco variables endógenas relacionadas con el último viaje de ride-hailing realizado por el encuestado, todas ellas modeladas como funciones de variables exógenas (sociodemográficas y variables latentes).

Las cinco variables endógenas son el propósito del viaje, el día de la semana, la hora del día, el acompañante del viaje y el modo de transporte sustituido para el viaje. La primera variable de resultado, el propósito del viaje, se recoge en las cuatro categorías nominales de:

- (1) viajes a la estación de autobús/tren o al aeropuerto (a/desde las estaciones de autobús/tren y los aeropuertos),
- (2) viajes de trabajo (incluyendo el viaje al trabajo o al centro educativo, y la asistencia a reuniones de trabajo/educación fuera del lugar típico de trabajo/educación),
- (3) viajes de ocio (incluyendo actividades recreativas, sociales y deportivas), y
- (4) viajes de recados (incluyendo las compras).

El segundo resultado es el día de la semana, en la categorización nominal triple de :

- (1) lunes-jueves,
- (2) viernes y
- (3) sábado-domingo.

El tercer resultado es la hora del día, que originalmente se caracterizaba por las cinco franjas horarias que se suelen seguir en España:

- (1) por la mañana (06:00 - 13:00h),
- (2) por la tarde (13:00 a 15:00h),
- (3) a primera hora de la tarde (15:00-19:00h),
- (4) a última hora de la tarde (19:00-23:30h), y
- (5) por la noche (23:30-06:00h).

Sin embargo, sólo 25 de un total de 466 personas declararon que su último viaje en coche de alquiler se había realizado por la tarde (de 13:00 a 15:00), por lo que esta categoría se combinó con la de primera hora de la tarde (de 15:00 a 19:00) para obtener un total de cuatro alternativas horarias.La cuarta es la compañía, en las dos categorías de "solo" o "con otros". La quinta dimensión es el modo sustituido por el ride-hailing (basado en la respuesta a la pregunta "si el ride-hailing no estuviera disponible, ¿qué modo habría utilizado para el viaje?"), en las cuatro categorías de:

- (1) taxi,
- (2) vehículo privado,
- (3) transporte público y
- (4) otros (incluyendo caminar, ir en bicicleta y "no habría hecho este viaje si el ride-hailing no estuviera disponible").

El número de personas que indicaron que no habrían realizado el viaje si no existiera el servicio de ride-hailing fue de sólo 7 de un total de 466 personas para el modelo a nivel de viaje (esa es la razón para combinar esta categoría con los modos de caminar y montar en bicicleta). Este resultado respalda la idea de que existen opciones de transporte público asequibles y convenientes para los madrileños, y que no hay una cantidad sustancial de supresión de viajes por falta de buenas opciones de transporte.

3.2.2. Las variables exógenas

Al igual que en el modelo a nivel individual, las características del viaje se modelan en función de los datos sociodemográficos y los constructos latentes. Además, incluimos otras variables explicativas ya presentes en el modelo anterior: ubicación residencial, disponibilidad de vehículos, patrones de movilidad (tanto en días laborables como en fines de semana), y frecuencia de uso de ride-hailing. Dado que este análisis sólo tiene en cuenta a los individuos que utilizaron el servicio de ride-hailing en los últimos 30 días, la frecuencia de uso del servicio de ride-hailing se trata como una variable binaria exógena en este análisis, diferenciando entre:

- individuos que han utilizado el servicio de ride-hailing menos de 5 veces en los últimos 30 días; y
- individuos que han utilizado los servicios de ride-hailing 5 veces o más (este último grupo se considera usuario frecuente).

Mientras que la ubicación residencial, la disponibilidad de vehículos, los patrones de movilidad y la frecuencia de uso de los servicios de ride-hailing se trataron como variables endógenas en el modelo a nivel individual, aquí se introducen como variables exógenas porque pueden considerarse como decisiones a largo plazo relativas a las características específicas de un viaje que condujeron al uso de los servicios de ride-hailing para el último viaje realizado por el modo.

Además, esto se hizo también por razones prácticas, teniendo en cuenta el tamaño limitado de la muestra para este análisis a nivel de viaje, así como la naturaleza exploratoria del análisis. Por razones similares, también incluimos los constructos latentes caracterizados a partir del modelo a nivel individual como variables exógenas desarrollando un valor esperado para cada variable latente (basado en las estimaciones del modelo SEM del modelo a nivel individual) y cada individuo de la muestra.

3.2.3. La estructura del modelo

En este análisis exploratorio, modelamos cada una de las cinco dimensiones a nivel de viaje de forma independiente utilizando modelos logit binarios y multinomiales. Se adopta la siguiente estructura secuencial: el propósito del viaje influye en el día de la semana, y estos dos influyen a su vez en la hora del día.

Además, se supone que estas tres dimensiones del viaje influyen en el acompañamiento del mismo. Por último, se considera que el modo sustituido por el transporte en coche es una función de las demás características del viaje.

4. LA ENCUESTA Y LA DESCRIPCIÓN DE LA MUESTRA

4.1. Administración de la encuesta

Realizamos una encuesta con el objetivo de captar los principales factores que podrían influir en las elecciones y comportamientos de los individuos hacia la adopción y la frecuencia de uso de los servicios de ride-hailing en Madrid (España). La población objetivo es el conjunto de individuos que viven y/o se desplazan a la ciudad de Madrid.

Se realizaron dos oleadas de encuestas para recoger los datos y obtener un conjunto heterogéneo de encuestados. La primera oleada fue gestionada por una empresa encuestadora e incluyó:

- entrevistas personales en la calle en el centro de la ciudad y en los suburbios,
- cuestionarios en línea. En esta oleada se hizo un esfuerzo especial para incluir una adecuada heterogeneidad en términos de sociodemografía individual. La segunda oleada fue gestionada por los autores e incluyó
- distribución física en la calle de volantes (en el centro de la ciudad y en los suburbios) que explicaban el propósito de la investigación e incluían un enlace para acceder al cuestionario en línea; y
- difusión del enlace de la encuesta a través de sitios web de medios sociales y aplicaciones de mensajería.

Ambas oleadas de encuestas se realizaron entre junio y octubre de 2019, los 7 días de la semana, evitando el mes de agosto, dada su menor representatividad en cuanto a patrones de movilidad en la ciudad de Madrid.

El diseño final del cuestionario buscaba respuestas sobre cuatro categorías de datos demográficos, patrones de movilidad y atributos de estilo de vida:

- Información socioeconómica y demográfica general: género, edad, ingresos anuales del hogar, nivel de educación, ocupación, estructura del hogar y ubicación residencial.
- Tendencias de movilidad diaria y variables relacionadas con los viajes: disponibilidad de coche para uso personal frecuente, posesión de permiso de conducir, patrones de movilidad urbana (número de viajes en el último día de la semana y fuera de la semana, propósito principal del viaje en el último día de la semana y fuera de la semana), percepción de la accesibilidad a la actividad en transporte público.

- Adopción y uso de los servicios de ride-hailing: uso de los servicios de ride-hailing alguna vez, uso del ride-hailing al menos una vez en los últimos 6 meses y número de viajes en los últimos 30 días. Además, se pidió a las personas que habían utilizado el servicio de transporte por cable en los últimos 30 días que informaran sobre su último viaje, incluyendo: el propósito del viaje, la hora del viaje, el día de la semana, la hora del día, el acompañante del viaje, quién hizo la reserva del viaje, las principales razones para elegir el servicio de transporte por cable y el modo de viaje que se habría utilizado si el servicio de transporte por cable no hubiera estado disponible.
- Actitudes personales y preferencias de estilo de vida: se pidió a los individuos que calificaran su nivel de acuerdo con múltiples afirmaciones utilizando una escala Likert de cinco puntos. Los temas incluían:

    - propensión a adoptar un estilo de vida que busque la variedad;
    - conocimiento de la tecnología;
    - conciencia medioambiental; y
    - propensión a utilizar bienes compartidos. Estos cuatro conjuntos de indicadores de preferencias de estilo de vida constituyeron la base para desarrollar los cuatro constructos latentes utilizados en nuestro estudio (véase la sección 5), que captan las preferencias psicológicas de los individuos.

Se recogieron un total de 1.246 respuestas válidas. Las estadísticas descriptivas básicas de los datos demográficos y los patrones de movilidad se presentan en la Tabla 2 para algunas de las variables recogidas, y se analizan brevemente en las secciones siguientes. En la Tabla 2, también proporcionamos estadísticas para variables seleccionadas que estaban fácilmente disponibles a partir de los datos del Censo de España para 2019 (Ayuntamiento de Madrid, 2020; Agencia Tributaria, 2019) para proporcionar una comparación de las características de la muestra con las características generales de la población de Madrid.

4.2. Datos sociodemográficos individuales y características del hogar

El cuadro 2 muestra una distribución bastante heterogénea de las características sociodemográficas individuales y de los hogares en la muestra. Sin embargo, en relación con los datos del censo, la muestra presenta una mayor proporción de hombres (55,2% en la muestra, frente al 46,0% de las estadísticas locales) y de individuos menores de 35 años (51,1% frente al 26,3%). Además, la muestra indica una sobrerrepresentación de individuos con un nivel educativo alto (el 69,3% de la muestra ha completado estudios universitarios en relación con el 34,5% del censo) y niveles de renta altos. Cabe destacar que alrededor del 25% de los encuestados de la muestra declaran no conocer los ingresos de su hogar, o no están dispuestos a comunicar esta información. Esta reticencia a informar sobre los ingresos está en línea con muchas encuestas anteriores relacionadas con el transporte que recogen datos sobre los ingresos en España (véase, por ejemplo, Heras-Molina et al., 2017; Cantos y Álvarez, 2009).

			Total sample		Census data	
			Individuals	%	Population/ *Households*	%

		Used in the last month (>8 trips)	68	5.5		
TOTAL			1,246	100.0		

Tabla 2: Resumen de las características de la muestra

En relación con la estructura de los hogares, hay una parte importante de familias con hijos menores de 24 años (36,7%) y de parejas sin hijos (19,0%). Las personas empleadas son mayoría en la muestra (69,3%).

Entre las características de los hogares, la ubicación residencial es una de las variables endógenas de interés en nuestro modelo (véase la sección 3.1.1). Como se indica en la Tabla 2, la mayoría de los encuestados de la muestra viven en la ciudad de Madrid (85,1%).

4.3. Variables relacionadas con la movilidad

Las variables relacionadas con la movilidad de la Tabla 2, junto con la ubicación residencial, constituyen los resultados endógenos de interés en nuestro modelo a nivel individual. La Tabla 2 muestra que el 69,1% de los individuos tienen un coche disponible con frecuencia para su uso personal.

Las estadísticas relacionadas con la movilidad en días laborables y fines de semana muestran una intensidad de actividad fuera del hogar generalmente mayor en días laborables que en fines de semana, lo que no es sorprendente debido a la contribución de los viajes al trabajo en días laborables. Lo más interesante es que la tabla indica que 788 encuestados (63,2%) han utilizado el servicio de ride-hailing al menos una vez, y una proporción no significativa de la muestra (alrededor del 13%) parece utilizarlo al menos una vez a la semana (como se obtiene sumando las dos últimas categorías de frecuencia de ride-hailing de la tabla).

VARIABLE		**Trips**	**% Sample**

TOTAL		**466**	**100.0%**

Tabla 3: Resumen de las características del último viaje en ride-hailing

Como se ha señalado anteriormente, se pidió a los encuestados que declararon haber utilizado los servicios de ride-hailing en los últimos 30 días que proporcionaran información detallada sobre su último viaje de ride-hailing, en particular: el propósito del viaje, el día de la semana, la hora del día, el acompañante del viaje y el modo de transporte que habrían elegido en caso de que el ride-hailing no hubiera estado disponible para ese viaje específico. 466 encuestados indicaron que habían realizado al menos un viaje en coche de alquiler en los últimos 30 días, y estos son los individuos que constituyen la muestra para el análisis a nivel de viaje. Las características descriptivas de los viajes de ride-hailing declarados en la muestra, así como las categorías consideradas para cada variable, se incluyen en la Tabla 3.

Como se puede observar, los viajes de ocio son el propósito de viaje más común en la muestra (41,6%), lo que está en línea con los hallazgos anteriores en la literatura de ride-hailing. El resto de propósitos de viaje están representados de forma bastante uniforme en la muestra. En el análisis, sólo hemos tenido en cuenta los cuatro primeros propósitos enumerados en la Tabla 3: estación de autobús/tren o aeropuerto, trabajo, ocio y recados. En cuanto a los patrones de día de la semana y hora del día, está claro que la intensidad de los desplazamientos es mayor los viernes y en los períodos de tarde y noche. En cuanto a la dimensión de la compañía, hay un reparto equitativo entre los viajes en solitario y los viajes en compañía.

Finalmente, como parece razonable para el caso de Madrid, el taxi es el principal modo sustituido por el ride-hailing (50,6%), seguido del transporte público (33,3%) y, en menor medida, el coche privado (9,0%). Se obtienen resultados similares sobre la sustitución de modos debida al ride-hailing en otras zonas de tránsito intensivo como San Francisco, especialmente en lo que respecta al taxi y al transporte público (Alemi et al., 2018; Rayle et al., 2016). Por el contrario, la proporción de la demanda captada del transporte público es significativamente mayor en Madrid que en lugares dominados por el coche como Dallas (véase Lavieri y Bhat, 2019). Solo el 5,6 % de la muestra declaró que el ride-hailing sustituyó a los modos activos (caminar o ir en bicicleta) y solo el 1,5 % declaró no haber podido realizar el viaje si el ride-hailing no hubiera estado disponible (esto contrasta con el aproximadamente 6 % en el área de Dallas-Fort Worth que afirma que no podría haber realizado el viaje si no fuera por el ride-hailing).

4.4. Constructos latentes

La tabla 4 muestra los indicadores de cada constructo latente, así como sus distribuciones muestrales. Las estadísticas relativas al estilo de vida de búsqueda de variedad sugieren que la fracción más alta de individuos se encuentra en la categoría neutral. Por otro lado, los encuestados se inclinan claramente por ser conocedores de la tecnología, lo que parece razonable dada la alta proporción de adultos jóvenes con niveles de educación altos en la muestra. Como era de esperar, la conciencia medioambiental declarada es especialmente alta en la muestra.

Los encuestados se sienten sobre todo muy o totalmente identificados con los comportamientos orientados al medio ambiente relacionados con el reciclaje (73,4%), la compra de productos respetuosos con el medio ambiente (48,5%) y la elección del modo de transporte (57,3%). Asimismo, es razonable que la mayoría de los individuos crean que tienen una buena accesibilidad al transporte público. Por último, en cuanto a la propensión a compartir (introducida en una escala invertida en el análisis), se observa de nuevo que la mayoría de los individuos se sitúan en la categoría media, con proporciones aproximadamente iguales a ambos lados del centro.

		Identify very little	Identify somewhat	Neutral	Identify Strongly	Identify completely
VARIETY-SEEKING LIFESTYLE	I think it is important to have all sorts of experiences and am always trying new things	4.9%	16.1%	30.9%	30.3%	17.9%
	I love to try new products before anyone else	10.3%	25.8%	31.5%	20.4%	12.0%
	Looking for adventures and taking risks is important to me	10.3%	25.4%	29.1%	25.0%	10.4%
TECH-SAVVINESS	I frequently use online social media (e.g. Facebook, Twitter, Instagram, Snapchat, etc.)	10.4%	11.1%	18.0%	25.7%	34.9%
	I regularly use internet services or mobile applications to facilitate my daily life: banking services, online purchases, GPS navigation, email, etc.	3.5%	4.8%	14.8%	27.4%	49.6%
	Learning how to use new smartphone apps and testing them is easy for me	2.8%	6.6%	19.0%	33.3%	38.3%
	I regularly use sharing economy apps or websites: Airbnb, Wallapop, Couchsurfing, etc.	17.5%	20.7%	25.5%	21.3%	15.0%
ENVIRONMENTAL CONSCIOUSNESS	When choosing my transportation mode, I try to be environmentally friendly	3.7%	12.3%	26.7%	37.4%	19.9%
	I recycle at home	5.2%	7.7%	13.6%	28.5%	44.9%
	Generally, I am willing to spend more to buy a product that is more environmentally friendly	4.4%	13.7%	33.3%	34.5%	14.0%
	My household accessibility by public transport is good	0.7%	4.6%	11.2%	21.9%	61.6%

	I am reluctant to use / put on objects that have been used by many people before me	9.8%	27.4%	30.1%	20.5%	12.3%
	I do not like travelling with strangers	11.2%	24.0%	28.4%	21.4%	14.9%

Tabla 4: Distribución de indicadores de actitud en la muestra

5. RESULTADOS DE LA MODELIZACIÓN Y DISCUSIÓN

Esta sección resume los principales resultados del análisis realizado en esta investigación. En las estimaciones, en lugar de imputar un valor de ingresos para el 25% de la muestra que no declaró ingresos en la encuesta, creamos una categoría de variable ficticia separada para dichos individuos al probar el efecto de los ingresos.

Esto tiene como resultado el uso de individuos con valores de ingresos declarados para evaluar los efectos de los ingresos apropiados, mientras que también se utilizan todos los individuos cuando se estiman los efectos de otras variables del modelo. También quisiéramos señalar que se intentó realizar toda una serie de especificaciones diferentes, y la especificación final se obtuvo a partir de un proceso sistemático de pruebas de combinaciones alternativas de variables explicativas (y diferentes formas funcionales de las variables) y de eliminación de las que no eran estadísticamente significativas, al tiempo que se avanzaba hacia especificaciones parsimoniosas. En la especificación final del modelo, no todas las variables incluidas son estadísticamente significativas a un nivel de confianza del 95%, pero se mantuvieron algunas de ellas porque proporcionaban interpretaciones y conocimientos intuitivos.

También es importante señalar que, como se indica en la sección 3.1.3, sólo se puede estimar una estructura recursiva de influencia de los resultados endógenos de interés entre los seis resultados. En nuestras especificaciones, probamos sistemáticamente todas las combinaciones posibles de efectos recursivos entre los seis resultados, y nos decidimos por la combinación que proporcionaba el mejor ajuste de los datos. Sin embargo, hay que tener en cuenta que el modelo sigue siendo un modelo conjunto que considera todas las variables endógenas como un único proceso de elección agrupado, debido a la correlación de errores generada entre los resultados endógenos a través de las construcciones latentes estocásticas.

5.1. Modelo a nivel individual

5.1.1 Parte del SEM

Los resultados del modelo a nivel individual se presentan en la Tabla 5 (parte SEM) y en la Tabla 6 (parte MEM). De la parte SEM, podemos observar que el estilo de vida de búsqueda de variedades (VSL) varía significativamente según el género, la edad y la ocupación. Con respecto al género, la literatura sobre el comportamiento del consumidor y los valores humanos ha identificado que los hombres son más propensos a mostrar un comportamiento de búsqueda de variedad que las mujeres (McAlister & Pessemier 1982; Tscheulin, 1994) ya que están más abiertos a nuevas experiencias y cambios. Algunos autores como Stasiuk et al. (2018) indican que esto puede explicarse en parte por los roles y estereotipos de género aún existentes, en los que las mujeres siguen siendo más responsables de mantener las cosas unidas en la familia, lo que se traduce en no "agitar el barco" y, por lo tanto, evitar la novedad. Otros autores (como Croson y Gneezy (2009) y Loewenstein et al. (2001) sugieren que esta reticencia de género a la variedad se basa en la noción de "riesgo como sentimiento", que afirma que nuestras emociones instintivas e intuitivas dominan los enfoques razonados cuando nos enfrentamos a un riesgo (en nuestro caso, ver la variedad a través de un cambio constituye un riesgo). Además, dado que las mujeres experimentan sentimientos de nerviosismo y miedo más que los hombres en previsión de resultados negativos, el resultado neto puede ser una mayor aversión a la búsqueda de variedad entre las mujeres. Además, la relación que indica un estilo de vida de menor búsqueda de variedad a medida que aumenta la edad estaría en consonancia con muchos hallazgos de la literatura sobre psicología social.

Por ejemplo, autores como McCrae et al. (2000), Srivastava et al. (2003) y González-Gutiérrez et al. (2015) han indicado que la apertura de un individuo a nuevas experiencias disminuye con la edad. En particular, a medida que los adultos avanzan hacia la edad media y avanzada, los individuos están cada vez menos interesados en, por ejemplo, recopilar nueva información o conocer a nuevas personas, lo que implica una disminución de la apertura (Carstensen et al., 1999). Además, Hoyer y Ridgway (1983) y McAlister y Pessemier 1982 señalaron que la infancia y la juventud se caracterizan por un mayor nivel de curiosidad y estimulación, mientras que el deseo de cambio disminuye a medida que las personas envejecen debido a una mayor experiencia de la vida. El resultado estadísticamente significativo de una menor búsqueda de variedad en el estilo de vida de los jubilados parece estar muy relacionado con la edad. No obstante, Srivastava et al. (2003) indicaron que se pueden encontrar resultados contradictorios entre los estudios respecto a la asociación entre la apertura y ciertas características sociodemográficas.

Nuestro análisis también encuentra una fuerte conexión entre el conocimiento de la tecnología y los ingresos y la edad. Estos resultados están en consonancia con investigaciones anteriores que analizan la adopción de tecnología entre la población española (Garrido et al., 2016; Moreira, 1998), así como con estudios sobre la demanda de ride-hailing en Estados Unidos (Astroza et al., 2017). La relación entre la adopción de tecnología y el nivel de ingresos está ampliamente referenciada en la literatura (véase, por ejemplo, Kalba, 2008; DiMaggio & Cohen, 2005; Carey, 1989) y se explica normalmente por la mayor capacidad financiera de los consumidores ricos para adquirir o renovar accesorios y servicios tecnológicos (por ejemplo, teléfonos móviles).

Además, nuestros resultados relativos a una menor predisposición a la tecnología a medida que aumenta la edad están respaldados por Morris & Venkatesh (2000), que indican que los jóvenes son mucho más propensos a estar expuestos a las tecnologías de la información a una edad temprana. Investigaciones más recientes (p. ej., Rogers et al., 2017; Berjowsky et al., 2017) también han identificado el papel que desempeñan las percepciones de facilidad de uso y utilidad en la menor predisposición a la tecnología de las personas mayores. Otros resultados con respecto a la tecnociencia en la Tabla 5 se refieren a los efectos positivos de la educación y de "vivir con compañeros de piso", y a los efectos negativos de las personas que no estudian/no trabajan y de las que tienen hijos mayores.

En cuanto a la conciencia medioambiental, la única variable estadísticamente significativa está relacionada con los ingresos. Los resultados sugieren una especie de efecto en forma de U invertida de los ingresos sobre la conciencia medioambiental, alcanzando esta conciencia un pico en el rango de ingresos medios de 30.000-60.000 euros, pero disminuyendo en los ingresos más altos. La menor conciencia medioambiental entre el segmento de ingresos más bajos puede explicarse basándose en la teoría de Maslow sobre la jerarquía de las necesidades humanas, que establece que los seres humanos se centran primero en el instinto de supervivencia de satisfacer sus necesidades materiales básicas, y consideran las necesidades de mayor nivel, como la necesidad de calidad medioambiental, sólo después de satisfacer las necesidades básicas.

En el otro extremo del espectro, se ha investigado ampliamente que el consumo de lujo está asociado a las motivaciones socioculturales de señalización de riqueza, poder y estatus, y al acceso privilegiado a recursos limitados (Kastanakis y Balabanis, 2014 y Nwankwo et al., 2014), que pueden eclipsar las consideraciones de conciencia medioambiental.

Tabla 5: Resultados del modelo a nivel individual sobre el uso del transporte compartido: Parte SEM

Por último, los resultados de la propensión a compartir, que también puede considerarse como un indicador de la sensibilidad a la privacidad, son razonables. Por ejemplo, la menor actitud de compartir entre las mujeres estaría en consonancia con muchas investigaciones anteriores que concluyen, por ejemplo, que las mujeres están más preocupadas por la privacidad y, en particular, por la privacidad cuando utilizan servicios relacionados con Internet (véase, por ejemplo, Sheehan, 1999; Milne et al., 2004; Wills & Zeljkovic, 2011). Del mismo modo, el análisis SEM concluye una menor propensión a compartir entre los segmentos de población de mayor edad. Además, el modelo concluye una relación positiva entre el nivel de ingresos y la sensibilidad a la privacidad. Contribuciones anteriores como la de Chevalier & Gutsatz (2012) indican que esto puede deberse a la mayor accesibilidad de los individuos ricos a la propiedad privada, a su necesidad de sentirse seguros y preservar sus bienes materiales, y/o a su tendencia a separarse o diferenciarse de los demás como señal de exclusividad.

Cuatro de las seis correlaciones entre las variables latentes son estadísticamente significativas (véase la parte inferior de la Tabla 5). El estilo de vida que busca la variedad, la avidez por la tecnología y la conciencia medioambiental están correlacionados positivamente, mientras que existe una correlación negativa entre la propensión a compartir y la avidez por la tecnología. Las relaciones positivas entre los estilos de vida que buscan la variedad y la avidez por la tecnología han sido ampliamente referidas en la literatura sobre psicología social. Por ejemplo, Khare et al. (2010) descubrieron que los comportamientos de búsqueda de innovaciones/novedades estaban fuertemente relacionados con actividades orientadas a Internet, como las compras en línea. Además, Lee et al. (2013) han señalado que las actividades basadas en la web, como la búsqueda en línea, sirven para satisfacer las necesidades emocionales de las personas que buscan aventuras. Los conocimientos tecnológicos también se han relacionado intrínsecamente con la conciencia medioambiental de los individuos. Seçken (2005) llegó a la conclusión de que las actitudes hacia la tecnología y su utilización, así como el nivel de educación asistida por ordenador, influyen en las actitudes de conciencia medioambiental.

En cuanto a la correlación entre la conciencia medioambiental y la VSL, se ha demostrado que la búsqueda de variedad y los valores hedonistas influyen en la compra de productos ecológicos (Ceriak et al., 2010; Chen y Chang, 2012). Por último, muchas contribuciones en la literatura científica han concluido una relación positiva entre el conocimiento de la tecnología y la preocupación por la privacidad. Para el caso de España, Gómez-Barroso et al. (2019) han concluido recientemente que a medida que los usuarios se vuelven más conocedores de la tecnología, su sensibilidad a la privacidad también suele aumentar. Del mismo modo, Liao et al. (2011) concluyeron que la alfabetización en Internet tiene un impacto positivo en la preocupación por la privacidad, ya que los individuos con conocimientos tecnológicos suelen ser más conscientes de cómo se transmite y utiliza su información personal.

La estimación SEM es posible gracias a las observaciones de las variables endógenas, que incluyen los indicadores del constructo latente y los cuatro resultados endógenos de interés (véase la Figura 1). Para ahorrar espacio, y dado que estas cargas de los constructos latentes en los indicadores de constructo no son de interés primordial en este trabajo, suprimimos estos resultados de carga. Basta con mencionar aquí que estas cargas eran todas las esperadas.

5.1.2 Ubicación residencial

La parte del MEM (véase la Tabla 6) analiza la influencia tanto de los datos sociodemográficos exógenos como de los constructos latentes en las variables endógenas. En cuanto a la localización residencial, resulta interesante que nuestra mejor especificación indique que esta dimensión de la elección se ve afectada principalmente por la sociodemografía y no por los constructos latentes actitudinales. A medida que aumentan los niveles de renta, existe una tendencia a elegir vivir fuera de la ciudad de Madrid. Este resultado refleja fielmente la distribución espacial de la renta per cápita en el área metropolitana de Madrid (véase Comunidad de Madrid, 2020), ya que Madrid capital limita con siete de los 10 municipios más ricos de España (Pozuelo, Boadilla, Las Rozas, etc.). La edad también influye en la elección residencial, ya que los individuos no jóvenes (mayores de 49 años) prefieren vivir más lejos del centro de la ciudad. De forma equivalente, los adultos jóvenes parecen "acudir" más al centro de la ciudad, quizás por la mayor accesibilidad a las actividades y los deseos de mayor vitalidad social. Un resultado similar se encuentra con respecto a la educación, ya que los individuos con un alto nivel de estudios prefieren el centro de la ciudad en lugar de la periferia, mientras que lo opuesto parece ser el caso de los hogares de tipo de nido vacío.

5.1.3 Índices de movilidad y disponibilidad de vehículos

Las tasas de movilidad, incluidas explícitamente como variables endógenas en el modelo, presentan algunos resultados interesantes. En primer lugar, se observa una mayor propensión a la movilidad en días laborables y fines de semana entre los encuestados con altos niveles del constructo de estilo de vida de búsqueda de variedad (VSL).

Esto parece razonable dado que las personas con un VSL alto pueden estar más dispuestas a realizar actividades de ocio o recados (por ejemplo, ir al gimnasio, reunirse con amigos, etc.) antes o después de su turno de trabajo, o durante los fines de semana. También podemos observar que muy pocas variables exógenas resultan ser estadísticamente significativas, lo que indicaría una cierta inelasticidad en los patrones de movilidad de los individuos durante la semana y el fin de semana a través de la sociodemografía. Los individuos de hogares con ingresos medios y las parejas sin hijos tienen una propensión significativamente menor a realizar viajes durante los días laborables, mientras que los individuos de más de 50 años muestran una mayor propensión a la movilidad durante los días laborables, pero una menor propensión a la movilidad durante los fines de semana.

Este último resultado puede apuntar a una menor responsabilidad familiar entre los individuos no jóvenes, de modo que pueden realizar más actividades fuera de casa durante el día en los días laborables, mientras que, los individuos más jóvenes (especialmente los del grupo de edad más joven de "menos de 25 años"), al estar relativamente "encadenados" en los días laborables, participan en más actividades sociales/recreativas durante los días de fin de semana. Aparte de estos efectos demográficos, la ubicación residencial influye de forma muy significativa en las tasas de movilidad de los días laborables y de los fines de semana, siendo la propensión a la movilidad mucho mayor entre los individuos que residen en el centro de la ciudad que fuera de él, lo que tal vez indique las importantes oportunidades de actividad que se ofrecen a los que residen en el centro de la ciudad.

Los resultados de la modelización de la disponibilidad de vehículos indican que, salvo la conciencia medioambiental, ningún otro constructo latente influye en la disponibilidad de vehículos. La conciencia medioambiental reduce significativamente la probabilidad de disponibilidad de vehículos. Dada la fuerte conexión encontrada entre las actitudes pro-ambientales y el uso del transporte público, este resultado puede reflejar la menor propensión a tener un coche de los individuos orientados al tránsito. Este resultado contrasta con el de Lavieri y Bhat (2019), que no encontraron una relación estadísticamente significativa entre la disponibilidad de coche y la conciencia medioambiental en Dallas, una zona dominada por el coche y con escasa presencia de transporte público. Como cabe esperar, las variables sociodemográficas exógenas, como los ingresos, la edad y la educación, influyen en la disponibilidad de coches, siendo más probable que los individuos de más edad, más ricos y con mayor nivel educativo tengan un coche disponible para su uso personal. Los encuestados que viven con compañeros de piso tienen menos probabilidades de disponer de un coche, mientras que ocurre lo contrario en los hogares con niños pequeños.

En cuanto a la ubicación residencial, como parece razonable, la propensión al coche es significativamente mayor para los residentes que viven más alejados del centro de la ciudad. Además, existe una relación negativa estadísticamente significativa entre la disponibilidad de vehículos y las tasas de movilidad tanto en días laborables como en fines de semana. Este resultado debe interpretarse a la luz de los problemas que suele plantear la conducción de un vehículo privado en la ciudad de Madrid, sobre todo en los desplazamientos puramente intraurbanos. Además de los recurrentes problemas de congestión y de las restricciones al vehículo privado aplicadas recientemente por el gobierno local, el aparcamiento en la calle en Madrid es escaso, está sujeto a una tarifa por minuto y está limitado a una determinada cantidad de tiempo. Todos estos factores dificultan en gran medida el uso del vehículo privado en la ciudad de Madrid. Este resultado es realmente muy interesante, y bastante diferente de lo que cabría esperar de una ciudad típica de Estados Unidos. Indirectamente, los resultados también indican el efecto negativo del constructo VSL sobre la disponibilidad de vehículos, ya que un VSL más alto aumenta las tasas de movilidad, y las tasas de movilidad reducen la disponibilidad de vehículos.

Tabla 2: Resultados del modelo a nivel individual sobre el uso del ride-hailing: Parte MEM

5.1.4 Adopción y frecuencia de uso del ride-hailing

El modelo presenta resultados interesantes en relación con la adopción y la frecuencia de uso de los servicios de ride-hailing cuando se compara con investigaciones anteriores sobre ciudades estadounidenses. La capacidad tecnológica es la única variable latente que influye de forma estadísticamente significativa en la adopción del servicio de ride-hailing. Este resultado parece evidente, ya que el servicio de ride-hailing sólo se puede utilizar a través de un teléfono inteligente, por lo que es razonable esperar que estos servicios sean adoptados en mayor medida por los segmentos de la población que están más familiarizados con las nuevas tecnologías (jóvenes, personas con un buen nivel educativo y adineradas). La relación entre la adopción de ride-hailing y el tech-savviness ha sido ampliamente citada en la literatura (véase, por ejemplo, Rayle et al., 2016; Alemi et al., 2018; Lavieri & Bhat, 2019).

Aparte de la influencia indirecta de las variables exógenas a través del constructo latente tech-savviness, hay efectos directos adicionales sobre la adopción de ride-hailing de los datos sociodemográficos exógenos. Como se puede observar en la Tabla 6, las mujeres muestran una mayor tendencia a adoptar el ride-hailing, lo que también es coherente con la menor tendencia de este segmento de la población a compartir bienes (indicador de sensibilidad a la privacidad). Los individuos con altos ingresos, menor edad y alta educación son más propensos a adoptar el ride-hailing que sus correspondientes compañeros, resultados que son consistentes con varios otros estudios de ride-hailing (véase, por ejemplo, Chen, 2015; Rayle et al., 2016; Smith, 2016; Clewlow & Mishra, 2017; Alemi et al., 2018; y Wang et al., 2019, entre otros). Por lo tanto, concluimos que, al igual que en otros estudios de caso ya analizados en Estados Unidos, los usuarios de ride-hailing en Madrid también tienden a ser individuos jóvenes, bien educados y ricos, que están familiarizados con las nuevas tecnologías.

Según los resultados, la ubicación residencial también juega un papel importante en la adopción de ride-hailing, siendo los individuos que viven fuera del centro de la ciudad (es decir, fuera de la primera circunvalación) menos propensos a adoptar ride-hailing que los que residen dentro de la primera circunvalación. Este hallazgo es razonable debido a la mayor oferta de servicios de ride-hailing en el centro de la ciudad y la asociación positiva entre la densidad residencial y la adopción de ride-hailing (Dias et al., 2017; Conway et al., 2018; Yu & Peng, 2019; Li et al., 2019; y Goodspeed et al., 2019). Lo más interesante es que el modelo establece una relación positiva y significativa entre la disponibilidad de coches y la adopción de ride-hailing. Este resultado contrasta con muchos hallazgos habitualmente comunicados para las ciudades estadounidenses (véase, por ejemplo, Gehrke et al., 2018 para Boston; Alemi et al., 2019 para San Francisco), que indican que el ride-hailing es utilizado con mayor frecuencia por individuos que no poseen un vehículo o que planean reemplazar o deshacerse de uno de los vehículos de su hogar. Sin embargo, en el contexto europeo, en particular para el caso de Madrid, parece razonable una relación positiva entre la disponibilidad de coches y la adopción del ride-hailing.

Los individuos que utilizan su coche privado con más frecuencia son probablemente más sensibles a los viajes cómodos de puerta a puerta, de modo que pueden encontrar una opción alternativa conveniente en los servicios de ride-hailing cuando el coche privado es menos atractivo (por ejemplo, salir a comer y beber, o acceder a zonas con restricciones para el coche privado como el centro de la ciudad). Dado que la disponibilidad de coches está correlacionada negativamente con la conciencia medioambiental, este resultado también puede indicar indirectamente que los individuos con una mayor propensión al transporte público son menos propensos a adoptar el ride-hailing.

Por último, la Tabla 6 muestra que hay relativamente pocas variables exógenas que influyan en la frecuencia de uso del ride-hailing, una vez que se ha controlado la adopción del mismo. El resultado más notable es que la conciencia medioambiental reduce la frecuencia de uso del transporte compartido. Esto es coherente con la noción de que los individuos con actitudes pro-ambientales probablemente tienen una mayor propensión a preferir seguir utilizando el transporte incluso en presencia de una amplia disponibilidad de oferta de ride-hailing, particularmente en un entorno con una oferta intensiva de transporte público. La relación negativa entre la conciencia medioambiental y la frecuencia de uso contrasta directamente con otros resultados de ciudades estadounidenses.

Para el caso de San Francisco, un área metropolitana con una alta presencia de transporte público, Alemi et al. (2019) encontraron una relación positiva entre la conciencia ambiental y la frecuencia de uso de ride-hailing, pero no proporcionaron una interpretación para ello. La única variable sociodemográfica con un impacto estadísticamente significativo en la frecuencia de uso de ride-hailing es la ocupación; concretamente, los estudiantes presentan una menor propensión a utilizar frecuentemente el ride-hailing.

El lugar de residencia también influye en la frecuencia de uso del ride-hailing, además de su impacto en la adopción del ride-hailing. Los individuos que residen en el centro de la ciudad muestran un uso más intensivo de los servicios de ride-hailing en comparación con las personas que viven en otras zonas. Una vez más, este resultado confirma la relación entre la frecuencia de uso y la densidad de población encontrada en la literatura.

Según los resultados correspondientes a los efectos de las tasas de movilidad, los encuestados que realizan más de dos viajes durante el fin de semana tienen una propensión estadísticamente significativa a utilizar el servicio de ride-hailing con frecuencia. Este resultado subraya la importancia de incluir explícitamente los índices de movilidad general como variables explicativas en los modelos de frecuencia de uso del transporte compartido. La disponibilidad de vehículos presenta efectos similares en la propensión a la frecuencia de viajes en coche de alquiler, así como en la propensión a la adopción de viajes en coche de alquiler, ya que una mayor disponibilidad conduce a una mayor propensión al uso de viajes en coche de alquiler. En este contexto, las observaciones de Henao (2017) son especialmente relevantes.

Henao subraya el punto de que una persona que normalmente considera el coche como el principal modo de transporte puede ser más propensa a tomar ride-hailing para viajes de ocio (porque el ride-hailing se percibe como relativamente similar a los viajes en vehículo privado). Pero, en el caso de San Francisco, Alemi et al. (2019) observaron una relación negativa entre el uso de ride-hailing y la disponibilidad de vehículo propio. En la zona de Dallas, dominada por los coches, Lavieri y Bhat (2019) también observaron que la disponibilidad de vehículos reducía significativamente la frecuencia de ride-hailing.

5.1.5 Comparación del ajuste del modelo

La metodología GHDM utilizada en este modelo a nivel individual considera las seis variables endógenas de interés como una elección conjunta. La mejora en el ajuste de los datos a partir de la modelización conjunta de estas seis dimensiones de elección puede evaluarse comparando el modelo GHDM con un Modelo de Datos Heterogéneos Independientes (IHDM) que no considera la unión de las seis dimensiones (es decir, se ignoran las covarianzas generadas por los constructos latentes estocásticos en el modelo GHDM). En este modelo IHDM, introducimos las variables exógenas (variables sociodemográficas) utilizadas para explicar los constructos latentes como variables exógenas en las ecuaciones de la dimensión de elección. De este modo, la contribución a la parte observada de la utilidad debida a las variables sociodemográficas se mantiene (y se permite que varíe en relación con el GHDM para absorber, en la medida de lo posible, las covarianzas del GHDM debidas a los efectos no observados). El IHDM resultante puede compararse con el GHDM utilizando el criterio de información de probabilidad compuesta (CLIC) introducido por Varin y Vidoni (2005). El CLIC adopta la siguiente forma (tras sustituir la probabilidad marginal compuesta (CML) por la CML máxima aproximada (MACML)):

$$\log L^{*}_{MACML}(\overleftrightarrow{\widehat{\boldsymbol{\theta}}}) = \log L_{MACML}(\overleftrightarrow{\widehat{\boldsymbol{\theta}}}) - tr[\hat{J}(\overleftrightarrow{\widehat{\boldsymbol{\theta}}})\hat{H}(\overleftrightarrow{\widehat{\boldsymbol{\theta}}})^{-1}] \quad (1)$$

Se prefiere el modelo que proporciona un valor más alto de CLIC. Los valores del log $L_{MACML}(\overleftrightarrow{\widehat{\boldsymbol{\theta}}})$ para los modelos GHDM e IHDM se estimaron en -585.985 y -593.563, respectivamente, con los correspondientes valores del estadístico CLIC de -588.973,57 y -594.555,84. Estos estadísticos CLIC favorecen claramente al GHDM sobre el IHDM. Las variables indicadoras ordinales utilizadas en la ecuación de medición se incluyen únicamente con el fin de identificar el modelo y no sirven para predecir el conjunto de elecciones endógenas de interés una vez estimado el modelo. Por lo tanto, también podemos utilizar la conocida prueba de razón de verosimilitud no anidada para comparar informalmente los dos modelos. Para ello, evaluamos un valor de log-verosimilitud predictiva $L(\hat{\hat{\boldsymbol{\theta}}})$ de los modelos GHDM e IHDM utilizando los valores de los parámetros en los valores convergentes de GHDM, excluyendo las variables indicadoras y centrándose sólo en las cuatro variables endógenas de interés. Entonces, se puede calcular el índice de relación de verosimilitud ajustado de cada modelo con respecto a la log-verosimilitud con sólo las constantes:

$$\bar{\rho}^2 = 1 - (L(\hat{\boldsymbol{\theta}}) - M)/L(c) \quad (2)$$

donde $L(\hat{\boldsymbol{\theta}})$ y $L(c)$ son las funciones de log-verosimilitud predictiva en la convergencia y en las constantes, respectivamente, y M es el número de parámetros (sin incluir la(s) constante(s) para cada dimensión y sin incluir los indicadores ordinales) estimados en el modelo. Si la diferencia en los índices es $(\bar{\rho}_2^2 - \bar{\rho}_1^2) = \tau$, entonces la probabilidad de que esta diferencia pueda haber ocurrido por azar no es mayor que $\Phi\left\{-[-2\tau L(c) + (M_2 - M_1)]^{0.5}\right\}$ en el límite asintótico (sin embargo, esto es sólo una prueba informal, porque el uso del enfoque de inferencia MACML en lugar del enfoque tradicional de máxima verosimilitud cambia las propiedades asintóticas). Un valor pequeño de la probabilidad de ocurrencia del azar sugiere que la diferencia es estadísticamente significativa y que se debe preferir el modelo con el valor más alto del índice de relación de verosimilitud ajustado.

Los valores $L(\hat{\boldsymbol{\theta}})$ (número de parámetros) para los modelos GHDM y IHDM se calcularon en -2.657,58 (número de parámetros= 103) y -2.707,24 (número de parámetros= 95), respectivamente. El valor fue de -2.989,93. La prueba de razón de verosimilitud ajustada no anidada (en su versión informal utilizada aquí) devuelve un valor de Φ(-8,67), que es literalmente cero, lo que refuerza el resultado del estadístico CLIC más formal al rechazar el modelo IHDM en favor del modelo GHDM y subraya la importancia de considerar los constructos latentes estocásticos que generan covariación entre las dimensiones de elección.

5.2. Modelo a nivel de viaje

En esta sección se analizan los resultados del modelo correspondientes a las cinco dimensiones del último viaje en coche de alquiler del individuo: propósito, día de la semana, hora del día, compañía y modo sustituido. Los resultados de estas cinco dimensiones se presentan en la Tabla 7 y la Tabla 8, y se discuten a continuación. Estas tablas también proporcionan la log-verosimilitud en la convergencia de cada modelo individual, la log-verosimilitud sólo con constantes y el valor de la barra rho al cuadrado calculado como en la ecuación (2).

Todos los modelos muestran una clara mejora del valor de la log-verosimilitud en la convergencia con respecto a la log-verosimilitud con constantes solamente, por lo que no discutiremos los problemas de ajuste del modelo en el resto de esta sección.

5.2.1 Propósito de viaje

Los resultados del componente del modelo que representa el propósito del viaje se presentan en la Tabla 7. En la primera categoría de constructos latentes, sólo la variable VSL influye en el propósito del viaje, ya que los individuos con un VSL más alto están más inclinados a participar en el ocio en relación con otros propósitos.

Este resultado confirma la fuerte relación observada en el modelo a nivel individual entre el VSL, la movilidad de fin de semana, las actividades de ocio y el uso del transporte compartido.

Además, la propensión a compartir tiene un impacto positivo en la probabilidad de que el anterior viaje en coche compartido se realizara con fines de ocio. Las mujeres y las personas que no son estudiantes ni están empleadas parecen tener más probabilidades de haber utilizado el servicio de ride-hailing en su último viaje con fines de ocio. Este último resultado puede ser simplemente una manifestación del hecho de que aquellos que no están empleados y no son estudiantes son propensos a hacer más viajes de ocio en general que los que están empleados y/o son estudiantes. Por último, los viajes por encargo parecen ser menos probables entre los encuestados con un buen nivel de estudios, mientras que los viajes por encargo de los residentes que viven fuera de la ciudad de Madrid parecen realizarse más por motivos de trabajo que por otros motivos de viaje.

Tabla 7: Caracterización de la movilidad del ride-hailing en Madrid: resultados a nivel de viaje (Parte 1)

5.2.2 Día de la semana y hora del día

En cuanto al día de la semana en que se realizó el último viaje en coche de alquiler, la edad y la estructura del hogar parecen tener cierto impacto. Las personas de entre 24 y 35 años parecen ser más propensas a utilizar el servicio de ride-hailing durante los fines de semana, tal vez como resultado de que las actividades de ocio se concentran en los fines de semana y, en consecuencia, se incrementa el uso del servicio de ride-hailing durante los fines de semana.

El hallazgo más interesante es la fuerte relación entre los viajes de ocio por medio de ride-hailing y un uso más intensivo durante los últimos viernes o los días de fin de semana. Esto refuerza el fuerte vínculo entre los viajes de ride-hailing, el ocio y la movilidad de fin de semana. Por el contrario, los resultados indican un menor número de viajes relacionados con el trabajo por ride-hailing durante los fines de semana, de nuevo simplemente un reflejo de un menor número de viajes de trabajo realizados durante los días de fin de semana.

Los resultados relativos a la hora del día son coherentes con algunas de las observaciones ya realizadas, con:

- (1) menos viajes de ride-hailing por motivos de trabajo durante el período nocturno,
- (2) un mayor nivel de viajes orientados al ocio realizados por ride-hailing durante los períodos de tarde/noche y un menor nivel de viajes de ocio y recados en el período de la mañana, y
- (3) menos viajes de ride-hailing los viernes durante el período de la mañana, y mucho más viajes de ride-hailing durante los períodos de tarde/noche durante los fines de semana.

5.2.3 Acompañamiento y sustitución de modo

Los resultados de la compañía en los viajes indican que los encuestados con una menor propensión a compartir tienden a viajar solos. Como era de esperar, los individuos en hogares con pareja muestran una mayor probabilidad de no viajar solos, mientras que los viajes de ride-hailing para el ocio y los recados (en relación con los viajes al aeropuerto y al trabajo) son más propensos a realizarse en compañía. Asimismo, es más probable que los viajes de fin de semana se realicen en compañía.

Por último, presentamos los resultados para el modo sustituido por el ride-hailing. Curiosamente, los individuos con una mayor propensión a un estilo de vida de búsqueda de variedad habrían elegido el transporte público o la opción "otros modos", que incluye caminar, ir en bicicleta o "no habría hecho este viaje" (aunque esta categoría de "otros modos" está dominada por los modos activos). Este resultado implicaría que, dado que los hombres y los individuos más jóvenes tienen un VSL más alto, estos individuos tenderían a reducir su uso del transporte público o de los modos potencialmente activos en presencia del ride-hailing.

Este resultado también es coherente con el hecho de que, según el modelo a nivel individual, los encuestados con un estilo de vida más variado estarían menos orientados al coche en términos de propiedad/disponibilidad de vehículos privados, lo que llevaría a mayores niveles de sustitución entre el ride-hailing y el transporte público/los modos activos.

No obstante, este efecto puede anularse en parte en el caso de los individuos con mayor conciencia medioambiental, que son menos propensos a sustituir la "otra" opción por el ride-hailing. Además de los efectos latentes del constructo, las mujeres son menos propensas a abandonar el vehículo privado en presencia de los servicios de ride-hailing, mientras que las parejas sustituyen los viajes anteriores en vehículo privado por el ride-hailing.

La relación positiva entre vivir en un hogar con compañeros de piso y sustituir el transporte público refuerza el hallazgo de que los jóvenes perciben el ride-hailing como una opción atractiva frente al transporte público siempre que el coste del viaje pueda compartirse.

Tabla 8 –Caracterización de la movilidad del ride-hailing en Madrid: resultados a nivel de viaje (Parte 2)

Los resultados también muestran que el transporte de ida y vuelta ha sustituido al transporte público principalmente para los viajes de ocio y de recados, mientras que el transporte de ida y vuelta ha sustituido al coche privado para los viajes de recados.

Esto parece razonable porque las opciones de transporte de puerta a puerta son más convenientes cuando los viajes están encadenados (como es el caso típico de los recados) o cuando el individuo tiene que llevar mercancías pesadas (por ejemplo, los viajes relacionados con las compras). También podemos observar que el transporte público o los modos activos serían altamente sustituidos durante los fines de semana, lo que sugiere una alta demanda de viajes en coche durante el sábado y el domingo que puede aumentar la congestión del tráfico en los días de fin de semana. Por último, los resultados para el periodo "nocturno" indican que es menos probable que el "ride-hailing" reste opciones al vehículo privado y al transporte público, pero más probable que reste opciones al taxi y al modo activo durante el periodo nocturno. Esto puede ser el resultado de la percepción de una mayor seguridad asociada a los viajes en coche en comparación con los taxis y los desplazamientos a pie o en bicicleta por la noche. Por supuesto, aunque se puede explicar este resultado y todos los anteriores de más de una manera, existe una clara necesidad de investigar estos efectos con mucho más detalle en futuros estudios dentro del contexto de los patrones generales de actividad-viaje. Como se ha indicado en múltiples ocasiones, este análisis a nivel de viaje no es más que de carácter exploratorio.

5.3. Implicaciones de política

De los resultados del análisis a nivel individual y de viaje se pueden extraer algunas implicaciones políticas. Debemos señalar que se basan en los resultados de un contexto muy específico, en particular: una ciudad compacta con una presencia intensiva de transporte público, que ha implementado restricciones al uso de vehículos privados en algunas partes de la misma, y cuyos residentes presentan una notable conciencia medioambiental.

5.4 Transporte en coche y alternativas orientadas al automóvil

Según el modelo a nivel individual, el ride-hailing es adoptado y utilizado con mayor frecuencia por individuos con alta disponibilidad de vehículo privado. Henao (2017) se refirió a este comportamiento como bi-estilo, según el cual los conductores frecuentes utilizarían los servicios de ride-hailing más a menudo para viajes de ocio, pero no necesariamente para otros propósitos de viaje. De hecho, el análisis a nivel de viaje mostró que alrededor del 60% de los viajes de ride-hailing fueron captados desde alternativas orientadas al automóvil (es decir, vehículo propio y taxi; ver Tabla 3).

El efecto neto de esto sobre la demanda de tráfico y la congestión todavía necesita una evaluación adicional. Por un lado, el servicio de ride-hailing puede tener efectos positivos en caso de que los vehículos privados se mantengan fuera de las calles. En particular, se reduce la congestión relacionada con la búsqueda de aparcamiento por parte de los vehículos privados. Se estima que la búsqueda de aparcamiento contribuye a alrededor del 15-30% del total de los desplazamientos en el núcleo central de Madrid, por lo que su reducción sería muy beneficiosa para la congestión vial y la sostenibilidad urbana.

En caso de que el uso del ride-hailing crezca drásticamente y capte gran parte de los actuales viajes en vehículo privado, también se producirá un aumento de los viajes en vehículos vacíos (es decir, que viajan vacíos para recoger a un pasajero), lo que podría provocar por sí mismo graves problemas de congestión (véase Nair et al., 2020). Este hecho se ha observado en muchas ciudades como San Francisco (Rayle et al., 2016), NYC (Schaller, 2017), Denver (Henao & Marshall, 2019) o Shenzen en China (Nie, 2017), entre otras. Por otro lado, la sustitución del taxi por vehículos de ride-hailing es relativamente neutral desde el punto de vista de la sostenibilidad urbana.

5.5 El ride-hailing y el transporte público

Parece que el servicio de ride-hailing llena un vacío de servicio bastante importante al proporcionar oportunidades para participar en actividades de ocio durante los fines de semana y las noches. Durante los fines de semana y las noches, la oferta de transporte público es significativamente menor en Madrid, y por lo tanto el ride-hailing proporcionaría más oportunidades de movilidad en escenarios de baja accesibilidad. Por supuesto, el impacto sobre las empresas de taxis y los conductores sigue siendo un problema, y, como en los EE.UU. y otros países, las consideraciones de regulación justa y equitativa deben ser continuamente pensadas en este sentido.

A pesar de este efecto positivo de la accesibilidad, una parte bastante importante de la demanda de ride-hailing se capta del transporte público tanto en los días laborables como en los fines de semana, lo que contrasta con los valores más bajos de sustitución del transporte público por el servicio de ride-hailing en contextos dominados por el coche dentro de los Estados Unidos (Lavieri y Bhat, 2019). Por lo tanto, mientras que algunos usuarios del transporte público (especialmente los que tienen una alta conciencia ambiental) pueden no alejarse del transporte público, los usuarios previamente raros/ocasionales del transporte público podrían alejarse aún más de estos servicios, y potencialmente podrían dejar de considerar el tránsito como una opción para moverse por la ciudad después de la llegada de una alternativa cómoda de puerta a puerta. Esto también puede tener un impacto, aunque limitado, en los ingresos del tránsito. En cualquier caso, mientras los viajes en transporte público (e incluso los modos activos) sean sustituidos por el "ride-hailing", se producirá un aumento del kilometraje, la congestión y la contaminación atmosférica en los contextos urbanos. Una cuestión especialmente preocupante a este respecto es que, según nuestros resultados, el servicio de ride-hailing no sólo restará viajes al transporte público, sino también a los modos activos, especialmente durante los fines de semana.

Esto tiene la doble desventaja de aumentar la demanda de tráfico, así como de tener impactos potenciales relacionados con la salud debido a la reducción del modo activo (caminar y montar en bicicleta) de los viajes.

Una estrategia para reducir el uso del transporte público durante los fines de semana puede ser rediseñar el sistema de transporte público durante los fines de semana para complementar el sistema de transporte fijo reducido (desde los días laborables) con un patrón de servicio limitado que responda a la demanda para un mejor servicio puerta a puerta durante el fin de semana.

Una estrategia para desalentar la sustitución de los viajes de corta distancia "a pie" por el ride-hailing puede consistir en diseñar un sistema de precios para el ride-hailing que ponga un precio bastante elevado al primer kilómetro (excepto si el usuario tiene problemas de movilidad).

5.6 Consideraciones sobre la accesibilidad a la actividad y el ride-hailing

Una de las consecuencias de nuestros resultados es que, en Madrid, los servicios de ride-hailing parecen especialmente atractivos para realizar recados (como compras y otros asuntos personales). En concreto, los viajes de recados realizados en vehículos privados o en transporte público parecen ser sustituidos por el ride-hailing.

El cambio de los vehículos privados a los viajes a domicilio puede explicarse por una experiencia sin complicaciones y sin necesidad de conducir, mientras que el cambio del transporte público a los viajes a domicilio puede explicarse por la comodidad de llevar la compra. Pero otra de las razones de este cambio hacia el ride-hailing para los recados es que hacer recados suele implicar el encadenamiento de múltiples actividades en la misma salida de casa y/o implica llevar y almacenar alimentos y otros productos perecederos durante el viaje.

El servicio de transporte compartido no es el más conveniente para este tipo de encadenamiento porque es más un servicio de consumo basado en el viaje que una opción de transporte más amplia que permite un servicio de consumo rentable basado en el tiempo (en el que el mismo vehículo está disponible para llevar a cabo múltiples actividades y durante un período de tiempo prolongado).

Tal vez los proveedores de servicios de ride-hailing deban pensar en ofrecer también una opción basada en el tiempo, que combinaría efectivamente los actuales servicios de ride-hailing y de coche compartido en un solo servicio. Esto también puede tener la ventaja de reducir la congestión al hacer que un solo vehículo recorra la ruta de varias paradas deseada por un solo cliente en lugar de que varios vehículos hagan lo mismo. Con múltiples vehículos, los kilómetros de viaje en vacío aumentan a medida que cada vehículo se desplaza hasta el cliente en cada punto de parada.

Nuestros resultados también apuntan al hecho de que las personas mayores tienden a tener un menor conocimiento de la tecnología, así como a utilizar los servicios de transporte en coche mucho menos que sus compañeros más jóvenes.

Al mismo tiempo, la posible exclusión social debida a la disminución de la accesibilidad física de los mayores es una preocupación importante, ya que los países desarrollados, incluida España, se enfrentan al envejecimiento de la población (véase, por ejemplo, Walsh et al., 2016 y King, 2016). Dado que no parece probable que este segmento de edad avanzada se beneficie sustancialmente de los servicios de ride-hailing como una mejora general de la accesibilidad con el statu-quo, pueden ser beneficiosas las campañas de información y las acciones para aumentar sus niveles de conocimiento de la tecnología y la aceptación del ride-hailing como un nuevo servicio que puede abrir nuevas posibilidades de socialización para ellos.

5.7 El ride-hailing y la sostenibilidad urbana

En general, el ride-hailing puede mejorar la accesibilidad de determinados segmentos de la sociedad y la seguridad en las carreteras. Sin embargo, las posibles consecuencias del ride-hailing en la futura sostenibilidad urbana siguen siendo motivo de gran preocupación y requieren un análisis más detallado para diseñar una vía sostenible que permita integrar estos servicios en el panorama de la movilidad urbana. Al fin y al cabo, es probable que la adopción y la frecuencia de uso de los servicios de ride-hailing aumenten en los próximos años con el aumento de los conocimientos tecnológicos de la población. Además, la evolución del cambio climático aumentará la conciencia medioambiental de los residentes, lo que llevará a una mayor implantación de las restricciones al uso del coche en los centros urbanos y a un menor uso del vehículo privado. Además, el parque automovilístico tenderá a ser más limpio con el paso de los años.

En este escenario futuro, el ride-hailing se convertiría en una alternativa más atractiva y podría aumentar sustancialmente su demanda respecto a su nivel actual. Por esta razón, buscar la coordinación o integración con los servicios de taxi será esencial para evitar el exceso de flotas y limitar el impacto en la congestión debido a los viajes en vacío. Además, es necesario regular la evolución del ride-hailing en entornos de tránsito intensivo para evitar que se produzcan desplazamientos masivos de las alternativas de transporte público; al fin y al cabo, el transporte público representa en última instancia la columna vertebral de la movilidad general en las ciudades grandes y densas.

6. CONCLUSIONES Y FUTURAS INVESTIGACIONES

En este trabajo se han estimado dos modelos de elección para explorar la adopción y la frecuencia de uso del ride-hailing en una ciudad europea, tomando como caso de estudio Madrid (España). A partir de la investigación, hemos podido obtener algunas conclusiones interesantes.

En primer lugar, al igual que en otras partes del mundo, los usuarios de ride-hailing de Madrid también tienden a ser individuos jóvenes, bien educados y ricos, que están familiarizados con las nuevas tecnologías.

Además, el análisis reveló la importancia de separar los patrones de los días de la semana y de los fines de semana al modelar la demanda de ride-hailing. Esto se debe a la fuerte relación que existe entre el uso del ride-hailing y las actividades de ocio, especialmente en las sociedades extrovertidas como la mediterránea.

En segundo lugar, la investigación mostró el papel clave de la conciencia medioambiental y la propensión al uso del coche en las ciudades de tránsito intensivo. Ambos presentan efectos significativos en relación con el uso del ride-hailing. En comparación con las ciudades estadounidenses, las actitudes favorables al medio ambiente reducen el uso de las opciones orientadas al coche (tanto el vehículo privado como el ride-hailing) en favor de modos respetuosos con el medio ambiente como el transporte público. En consecuencia, la adopción y la frecuencia de uso del servicio de "ride-hailing" fueron significativamente mayores entre las personas propensas al uso del coche, para las que la comodidad ofrecida por los servicios de puerta a puerta es crucial, y que pueden adoptar el servicio de "ride-hailing" para viajes relacionados con el ocio. Estos resultados se encuentran en un contexto con una oferta intensiva de transporte público y restricciones al vehículo privado en el centro de la ciudad, lo que difiere de los anteriores estudios de casos estadounidenses analizados en la literatura.

En tercer lugar, la mayoría de los viajes de ride-hailing de la muestra sustituyeron a las opciones orientadas al coche (vehículo privado y taxi), aunque también se capta una parte importante de los modos respetuosos con el medio ambiente, como el transporte público y los modos activos. Esta conclusión pone de manifiesto que, junto con los aspectos positivos del ride-hailing (aumento de la accesibilidad para algunos segmentos vulnerables de la población o mantenimiento de los vehículos privados fuera de las calles), pueden surgir algunos efectos negativos, como una disminución de los ingresos de los operadores de transporte público o un aumento de los viajes en vacío realizados por los vehículos de ride-hailing, como se ha observado en muchas ciudades de todo el mundo. Por lo tanto, las compensaciones también deben ser evaluadas cuidadosamente. Aunque el ride-hailing parece elegirse actualmente en situaciones muy específicas, el atractivo de estos servicios frente al transporte público debería reconsiderar el futuro papel de este nuevo actor dentro de la movilidad urbana y la sostenibilidad.

Nuestras conclusiones sugieren varias direcciones futuras de investigación. Son necesarias futuras contribuciones para ampliar la investigación actual a otros países europeos en los que las dinámicas sociales y de movilidad difieren de las del Mediterráneo, como en Europa Central o del Este. Además, habría que estudiar cómo cambian las percepciones y el uso de los servicios de ride-hailing en escenarios con mayores restricciones al vehículo privado (por ejemplo, las políticas de tarificación de la congestión en Londres o Singapur) en comparación con los estudios de caso ya analizados. Por último, la competencia entre el servicio de ride-hailing y los principales modos de transporte sustituidos (el taxi y el transporte público) debería explorarse más a fondo, dada su importancia para comprender el papel actual y futuro del servicio de ride-hailing en la sostenibilidad urbana.

AGRADECIMIENTOS

Esta investigación se ha desarrollado dentro del proyecto Co-Mov (Caracterización de las nuevas formas de movilidad urbana colaborativa a través del procesado de fuentes de datos: diseño de medidas para que contribuyan a una movilidad conectada y eficiente), cofinanciado por la Comunidad de Madrid (España), el Fondo Social Europeo y el Fondo Europeo de Desarrollo Regional, con número de subvención [Y2018/EMT-4818].

ABSTRACT

The acceleration of technology evolution is changing urban mobility at a much faster pace than we have seen in previous decades, leading to an increasingly uncertain future within this field. It is very likely that current transport planning tools and techniques will have to be adapted to the increasing number of innovative mobility forms in order to maintain their usefulness in the urban policy cycle. In this paper, we present a series of explorative scenarios for European urban mobility and the consequent challenges that they imply for such tools and techniques. Two groups of scenarios have been developed for assessing two different uncertain relations. First, a set of exogeneous scenarios has been defined for studying how different urban mobility socioeconomic contexts could affect the evolution of emerging mobility solutions. These scenarios are adaptations of the IPCC's Shared Socioeconomic Pathways. Second, a set of pathways that these mobility innovations may follow has been shaped in order to determine to what extent each innovation will potentially pose new requirements on transport data sources, models and decision support tools. The methodology used for developing the scenarios started by a literature review covering the most prominent urban mobility trends.

Then, policy-makers and modellers were engaged in the process through a series of workshops and a Delphi poll. This served to gather inputs from a wide range of end-users and practitioners. The paper covers the results from these methodologies, unveils the resultant scenarios, and outlines the conclusions in terms of future plausible requirements for transport planning tools and techniques.

1. INTRODUCTION

Urban mobility is a dynamic field that is subject to continuous innovation. Different technologies and business models arise to meet the increasing demand for transportation in cities. In recent years, the rapid development of automation and digitalization technologies together with the expansion of shared economy has fuelled the emergence of new mobility solutions. Smartphone connectivity and advanced fleet management strategies based on GPS positioning have boosted the potential of vehicle sharing, either by providing users with a vehicle to drive (e.g., car sharing, bike sharing, e-scooter sharing) or by attending a trip request providing a car with a driver (e.g., ride hailing). In parallel, Mobility-as-a-Service (MaaS) platforms provide travellers with access to a unified gateway to plan, book and pay for a full multimodal door-to-door journey, so the user does not have to worry about who operates each service. All these innovations will face further transformations due to vehicle automation. CAVs are expected to revolutionise bus operation and boost services such as ride hailing, which is likely to become cheaper than current taxi-like services once no driver will be needed.

It has been recently acknowledged that the data analysis techniques, modelling frameworks and decision support tools used by transport planners require major adaptations to properly address emerging mobility solutions (Franco et al., 2020). The requirements guiding these adaptations depend on which will be the indicators and analyses most demanded in the future. Some prominent challenges that are highly likely to arise in any case have been already identified, such as the supply-demand interaction mechanisms in shared mobility services (Li et al., 2018) or the empty trips modelling in the context of vehicle automation (Friedrich et al., 2019).

However, any attempt to improve transport planning tools and techniques in this direction would benefit from more knowledge on the plausible future needs of transport stakeholders. This encompasses two main questions. First, it is highly uncertain how the societal and technological trends surrounding transport systems will evolve. Hence, it is not possible to anticipate a narrow development path for emerging mobility solutions. Second, it is highly uncertain which are the impacts and challenges that cities will face due to the expansion of mobility innovations. This implies that it is difficult to establish requirements for the tools and techniques that will assist transport planners in the implementation and management of new mobility solutions.

Given the importance of anticipation when evaluating the impacts of their decisions, transport stakeholders have usually resorted to scenario-making techniques. The provision of transport infrastructures and services has been traditionally based in deterministic estimations of future demands (Owens, 1995). These forecasts rely on the observed relation between historic travel demand trends and external socioeconomic variables. This approach has been criticized for failing to account for the inherent uncertainties of future travel behaviour (Lyons & Davidson, 2016). In the case of emerging mobility solutions this critique becomes more evident, as there is simply no enough historical data to infer how the demand for the new services will respond to different contexts. As a consequence, deterministic forecasting is ill-suited for anticipating the requirements that transport planning tools and techniques will face as a consequence of the expansion of mobility innovations. Instead, the development of alternative plausible futures seems to provide richer requirements that will lead to more resilient tools and techniques. In line with the two questions mentioned above, two types of scenarios have been developed:

- Exogeneous scenarios, which propose different alternative futures for a series of relevant external factors that shape transport systems (e.g., demographics, economics, etc.). These scenarios can be used to reflect upon the evolution of new mobility solutions in relation to those variables (e.g., for a given socio-demographic situation, what is the expected penetration of vehicle automation?).
- Endogenous mobility-related scenarios, which set up a range of different possible futures for emerging mobility solutions themselves (e.g., business models, levels of adoption, etc.). These scenarios can be used to reflect upon the adaptations that transport planning tools and techniques require depending on the role of these solutions in cities (e.g., for a given modal share of micromobility services, which improvements in transport models are needed?).

The use of these scenarios in stakeholder involvement opportunities facilitates the anticipation to the plausible range of demands that transport stakeholders will pose on data analysis techniques, modelling frameworks and decision support tools.

This paper explains how these future images can be created, describes the scenarios developed and shows how they can be used for exploring the future impact of mobility innovations in transport planning tools and techniques, taking shared mobility services as an example. The document is organised as follows: Section 2 provides the theoretical background for the scenario-making process, Section 3 explains the methodology followed for developing the scenarios, Section 4 presents the exogeneous scenarios for European urban mobility, Section 5 presents the endogenous scenarios related to shared mobility services, Section 6 shows how the scenarios were used to explore the uncertainties associated to shared mobility and its impacts on transport planning tools and techniques, and Section 7 summarises the research conclusions.

2. MOBILITY FUTURES AND SCENARIO-MAKING TECHNIQUES

The acceleration of societal and technological transformations during the 20th century led to a growing interest in the development of rigorous methods for foresighting (Masini, 2006). Future reflections have evolved from individual practices, linked to instinct and survival, to research approaches able to make meaningful contributions to humankind development (Slaughter, 1996). The scientific foundations of this task have been developed by the field called 'futures studies' (Bell, 1997), where the plural 'futures' is emphasized to acknowledge that is hardly ever possible to anticipate a deterministic future (Sardar, 2010).

Scenarios are the main product of futures studies. The notion of scenario is not free from polysemy. Although it clearly resembles the idea of reflecting upon the future, there is no consensus on whether it includes any image of the future or only images drafted under certain conditions or for certain purposes. One of the most common approaches is to embrace a broad definition that includes any 'possible, probable or preferable future' (Amara, 1981; Bell, 1997). This conceptualisation is often accompanied by taxonomies that help to interpret existing scenarios or guide the processes towards new scenarios. Börjeson et al., (2006) provides a synthetic classification that is suitable to many contexts, based on what is the underlying question that motivates the use of scenarios (Table 1).

Predictive scenarios *What will happen…?*	Forecasts	*…if the most likely development unfolds.*
	What-if	*…on the condition of near future events.*
Explorative scenarios *What can happen if…?*	External	*…if an external factor develops.*
	Strategic	*…we act in a certain way.*
Normative scenarios *How can a desired future be reached…?*	Preserving	*…by adjusting the current situation.*
	Transforming (or 'backcasting')	*…by changing current structures.*

Table 1: Scenario types (Börjeson et al., 2006).

The scenarios developed in this paper fall under the category 'explorative scenarios'. They provide a range of possible alternative futures. First, there are no prior assumptions about their likelihood. All of them must be plausible, to pose meaningful questions to transport practitioners, but none is developed to accurately predict the future. Second, there are no prior assumptions about their desirability. There is no prescription of a certain future associated to certain policies, since the goal is to test how transport planning tools and techniques would respond to different future mobility contexts and situations.

More specifically, all the alternative futures addressed in this paper can be classified as 'explorative external scenarios', given that the images are not based on decisions made by the target agents -those who develop transport planning tools and techniques-. Rather, the images are a result of complex societal changes and policy trends that provide a framework for action.

3. SCENARIO-MAKING METHODOLOGY

The scenario-making process conducted to generate the futures presented in this paper involved three steps:

- a desk research phase, which consisted of a literature review of previous initiatives that provide referential scenarios
- a generation phase, which produced an initial version of the scenarios by tailoring the ideas and concepts selected from the referential scenarios; and
- an stakeholder involvement phase, which included a Delphi poll aimed at refining the initial version of the scenarios with target agents.

3.1 First phase: referential scenarios from desk research

A total of 22 references were selected as a basis for the scenario-making process (Table 1). The selection of documents prioritised those focusing on transport sector, as well as those having Europe as geographical scope. As a result, a large number of different types of scenarios were reviewed.

Normative scenarios and R&D roadmaps	(Dotter et al., 2019; Eckhardt et al., 2017; ERTRAC, 2011a, 2011b, 2013, 2017; ERTRAC-ERRAC-Waterborne-ACARE-ECTP Task Force, 2013; European Commission, 2011; Lindsay, 2016; MaaS Alliance, 2017, 2019; Mobility4EU, 2019)
Explorative scenarios	(de Stasio et al., 2013; European Commission, 2017; Hill & Bates, 2018; Lutz et al., 2019; POSSUM, 1998; Seibt et al., 2012; Transport for NSW, 2016; TRANS-TOOLS, 2009)
Predictive scenarios	(de Stasio et al., 2013; Holden & Goel, 2016)
Mobility indicators	(WBCSD, 2015)

Table 1: References used as a basis for the scenario-making process.

The literature review was not restricted to the above selected references. In some cases, the documents led to discover other initiatives that have also worked with scenarios. Thus, a 'snowball sampling' technique was followed to ensure that a wide range of relevant scenario-making processes were reviewed. For each scenario contained in these documents, the following aspects were explored:

- the factors and elements that inform each scenario
- the temporal scope of the scenario and the criteria employed for its selection; and
- the links established between mobility futures and the evolution of socioeconomic variables.

3.2 Second phase: generation of the scenarios

The generation of the scenarios involves three tasks. First, certain factors identified in the referential futures are selected as candidates for their inclusion in the scenarios, together with predefined factors that may not be part of previous studies. In the case of exogeneous scenarios, the criteria that drives the selection is the impact of each factor on urban mobility. In the case of the endogenous scenarios, the criteria focus on how the factors contribute to a complete description of alternative mobility futures.

Second, all the factors that are expressed in global terms in the referential scenarios have to be geographically downscaled to the European urban context. Most of the quantitative factors are already segmented by continent in the original source (e.g., demographic figures) and others have been previously analysed either at European or at urban level by additional studies. Moreover, most of the qualitative trends refer to common situations in the well-developed countries, so no particular adjustments are needed (e.g., digitalisation). The factors that are not appearing in previous sources can be derived from the evolution of other dependent factors.

Finally, the resultant evolution of the factors is put together into narratives that provide a short description of the alternative future. In the case of the exogeneous scenarios the narratives are complemented with some basic quantitative figures.

3.2 Third phase: stakeholder involvement

The involvement of target agents is crucial for achieving robust scenarios (Larsen & Gunnarsson-Östling, 2009). In this case, the scenarios were contrasted with transport experts through a two-round Delphi poll conducted during Autumn 2019. This process engaged 16 respondents from transport administrations (50%), transport consulting firms (25%) and academia (25%). The feedback got from the participants in the first round was taken into account to provide a final version of the narratives.

4. EXOGENEOUS SCENARIOS FOR EUROPEAN URBAN MOBILITY

4.1 Socio-shared Socioeconomic Pathways (SSPs) and urban mobility

The desk research phase revealed that climate change research is a valuable source of exogeneous scenarios for transport applications. Anthropogenic climate change research deals with complex systems with a high degree of uncertainty. This implies that these researchers often rely on future scenarios to pose alternative evolutions of the systems involved in climate change (Moss et al., 2010). The production of climate change scenarios has been coordinated by the International Panel on Climate Change (IPCC). This organisation promotes and certifies a set of official scenarios that can be used as a common language by the climate change research community. It is possible to identify two strategies in the production of scenarios along the history of climate change research.

Until 2008, IPCC worked with sequential cause-effect scenarios, which posed certain assumptions on socioeconomical factors to justify different emission levels, which in turn produce different effects and impacts in climate. In 2008, IPCC decided to decouple socioeconomical scenarios from emission scenarios. Two reasons are behind this move (Moss et al. 2010):

- shorten the long process required by the sequential approach; and
- explore with more detail certain relations that were demanded by scenario users, such as adaptation measures effects (van Vuuren et al., 2011).

Therefore, there are currently two groups of climate change scenarios:

- Shared Socio-economic Pathways (SSPs), which focus on population, GDP and urbanization rate. They provide five alternative narratives describing how the societal, political, cultural and economic context may develop, in order to represent five levels of mitigation and adaptation challenges towards climate change (O'Neill et al., 2014).
- Representative Concentration Pathways (RCPs), which focus on the concept of radiative forcing, an indicator of the changes of energy flows into the Earth system caused by greenhouse gases (IPCC, 2014). These scenarios integrate the research conclusions about the possible evolutions of greenhouse gases concentrations and land uses (van Vuuren et al. 2011), which are the main components of radiative forcing.

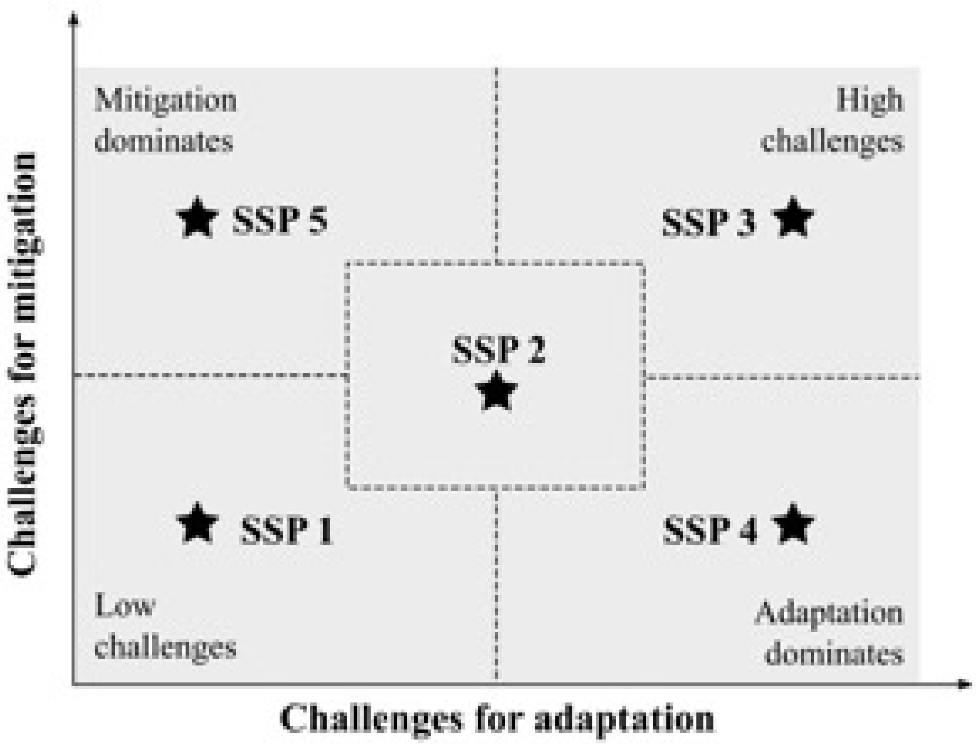

Figure 1: SSPs in the 'adaptation-mitigation challenges space' (O'Neill et al., 2014)

In this context, it is clear that the SSPs developed by the climate change research community have a great potential for inspiring exogeneous scenarios that provide several alternative contexts where urban mobility will have to operate.

There are five SSPs. Each of them produces different challenges for adaptation and mitigation of climate change (Figure).

A complete description of the narrative and the quantitative figures associated to each scenario is available in O'Neill et al. (2017). Each scenario can be summarised as follows:

- SSP1 represents low challenges both for mitigation and adaptation, since society embraces Sustainable Development Goals (SDG) which facilitates an environmental and social sustainable growth.
- SSP3 represents high challenges both for mitigation and adaptation, since the high rivalry among worldwide regions would limit growth and governance capacity for achieving robust agreements.
- SSP4 implies high challenges for adaptation but low challenges for mitigation. This represents a two-speed society, where an upper class would be able to adopt sustainable life-styles helping to mitigate climate change, but the material restrictions suffered by the lower class would limit their capacity to adopt mitigation measures.
- SSP5 implies high challenges for mitigation but low challenges for adaptation. It assumes that technology will be ready to adapt society to climate change, but also that there are no incentives for mitigation.
- Finally, SSP2 is an intermediate scenario where neither mitigation nor adaptation challenges dominate.

It is possible to identify a set of advantages for the application of SSPs in the generation of exogeneous scenarios for European urban mobility:

- There are many studies that already make references to SSPs as a source for further scenario-making processes, providing values for indicators that are relevant to urban mobility.
- IPCC is a very well-known institution and the reports they produce using SSPs as a basis are highly disseminated among research communities and public opinion.
- Many climate change adaptation and mitigation factors are also relevant for the future of transport (Banister, 2011).

There are also some limitations that need to be taken into account when using SSPs for the purposes stated in this paper:

- Given that SSPs have been produced for the specific field of climate change research, there might be mismatches between the needed contents for the scenarios (Kok et al., 2019). However, it is expected that the aforementioned relation between climate change impacts and the transport sector will limit this effect.
- The spatial scope of SSPs is global, while the application seeked in this paper is European. Therefore, SSPs contributions need to be downscaled to European urban areas for being relevant to urban mobility. Downscaling can be problematic, since it assumes that the resulting local scenario will not deviate significantly from the original scenario (Absar & Preston, 2015; Pedde et al., 2019). The consistency during the downscaling process can be ensured by adopting similar approaches to previous research. In this case, there are examples of both European (Kok et al., 2019) and urban (Rohat et al., 2019; Terama et al., 2019) downscaling processes. In addition, the stakeholder involvement phase represents an additional opportunity to improve the adjustment of the alternative futures to the European urban context.

4.2 Adapting SSPs to European urban mobility drivers

The literature about SSPs and their applications provide a set of factors that can be included in the exogeneous scenarios. Each factor selected has specific needs in terms of geographical downscaling and sectoral application, as mentioned in the Methodology section. The following factors are selected to take part of the exogeneous scenarios:

4.2.1 Population growth, urbanisation rate and ageing

These quantitative factors are included in the global SSPs. The models from the International Institute for Applied Systems Analysis (IIASA) provide population forecasts for each SSP at continental level, and a detailed discussion of the results can be found in Kc & Lutz (2017). The US National Center for Atmospheric Research model has produced indicators related to urbanisation rates for each SSP. A discussion of the results can be found in Jiang & O’Neill (2017).

4.2.2 Education levels.

The proportion of citizens with tertiary education is provided also by IIASA models and discussed by Kc & Lutz, (2017) and Kok et al., (2019).

4.2.3 Gross Domestic Product (GDP)

This economic indicator is forecasted for each scenario by IIASA model, and discussed by Crespo Cuaresma (2017). Economic development is also part of European SSPs (Kok et al., 2019).

4.2.4 Technological development

The levels of technology advancements associated to each scenario are included in the SSPs global narratives (O'Neill et al., 2014) and in the European version by Kok et al. (2019).

4.2.5 Environmental consciousness

Each SSP implies a level of environmental consciousness among society. This is described in the global narratives (O'Neill et al., 2014) as well as in the European version (Kok et al., 2019).

4.2.6 Consumption levels

Depending on the economic trends, each SSP is linked to certain consumption trends, which are described in the narratives (Kok et al., 2019; O'Neill et al., 2014).

4.2.7 National income inequality

Income distribution is included in the global SSPs narratives (O'Neill et al., 2014) and is part of the definition of each European scenario in Kok et al. (2019). The role of inequality has been further analysed by Rao et al. (2019), leading to the following conclusions:

- SSP1: low inequality
- SSP2: medium inequality
- SSP3: medium-high inequality
- SSP4: high inequality
- SSP5: low inequality

4.2.8 Land use in cities and urban form

Land uses interact with transport supply and demand features. SSPs include urbanisation rates but they do not address how population is allocated in urban areas. However, the narratives and quantitative features of SSPs suggest correlative trends in urban form evolution.

The evolution of consumption preferences and the population pyramid can be related to preferred residential settlements and availability of land for other purposes (Rohat et al., 2019; Terama et al., 2019):

- SSP1: urban + suburban preference / overall increasing density
- SSP2: not addressed
- SSP3: suburban preference / decreasing density in suburban areas
- SSP4: urban preference / increasing density in urban areas
- SSP5: rural + suburban preference / decreasing density in suburban areas

4.2.9 Pride of ownership vs. shared economy

A contextual factor that is perceived as relevant for emerging mobility solutions is to what extent shared economy is going to challenge (vehicle) ownership models.

This aspect is not addressed by studies based on SSPs, but it is possible to look at the factors behind the intensity of the adoption of shared economy (Hawlitschek et al., 2016): there is a motivation for saving money (Böckmann, 2013) and it is driven by a trust-based collaborative lifestyle (Heinrichs, 2013).

Since economic prosperity and incentives to collaboration are central elements to SSPs, there is an opportunity for formulating an evolution of the pride of ownership in contrast to adoption of shared economies for each scenario:

- SSP1: much higher trust + higher growth → lower pride of ownership
- SSP2: medium trust + medium growth → medium pride of ownership
- SSP3: much lower trust + stagnated growth → high pride of ownership
- SSP4: lower trust + medium growth → medium pride of ownership among higher class, high pride among lower class
- SSP5: medium trust + much higher growth → high pride of ownership

4.2.10 Digital divide

Many emerging mobility solutions depend on the use of smartphones and Internet for the interaction of the end users with the services providers. Hence, the evolution of the digital divide plays a role in the spread of the new mobility options.

While SSPs do not address the evolution of the digital divide, it is clear that this is related not only to age but to income distribution (Haight et al. 2014). Economic indicators related to each SSPs and ageing can be associated with the intensity of the digital divide in each scenario:

- SSP1: high ageing + low inequality → medium divide
- SSP2: medium ageing + medium inequality → medium divide
- SSP3: low ageing + medium-high inequality → medium divide
- SSP4: limited ageing + high inequality → high divide
- SSP5: medium ageing + low inequality → low divide

4.2.11 E-commerce

Shopping trips generation rates might be lower due to the generalisation of e-commerce (Shi et al., 2019). While e-commerce is not directly addressed by SSPs, there are many factors included in these scenarios that have an impact in the potential evolution of e-commerce.

Societal trust, technology advances, urbanisation rate, education, consumerism, interest in diverse products and availability of a wide range of payment methods has been linked to e-commerce adoption (Chaparro-Peláez et al., 2016; Markus & Soh, 2003):

- SSP1: low consumption + high-tech advances + high trust → moderate expansion of e-commerce
- SSP2: medium consumption + medium tech advances + medium trust → moderate expansion of e-commerce
- SSP3: medium consumption + stagnated tech advances + much lower trust → limited expansion of e-commerce
- SSP4: unequal consumption + high-tech advances + lower trust → moderate expansion of e-commerce
- SSP5: very high consumption + high-tech advances + high trust → wide expansion of e-commerce

4.2.12 Teleworking

Work trips generation rates can change if teleworking gains popularity (Alonso et al., 2017; Larson & Zhao, 2017). Telework is feasible in job positions that are largely based in ICT.

The technological development achieved by future societies may ease telework or expand its application to other sectors (Messenger, 2017). Furthermore, it has been observed that telework is more frequent in households with children (Vilhelmson & Thulin, 2016), so a link with fertility can be established as well. Fertility rates are part of the demographic forecasts of each SSPs (Kc & Lutz, 2017).

It has to be noted that this research was conducted before the COVID-19 pandemic, that has boosted teleworking at a much faster pace than expected. Regardless of the expansion driven by the pandemic consequences, the following can be expected:

- SSP1: high-tech advances + high rate of tertiary educated + low-medium fertility → moderate expansion of telework
- SSP2: medium tech advances + medium rate of tertiary educated + medium fertility → moderate expansion of telework
- SSP3: stagnated tech advances + low rate of tertiary educated + low fertility → limited expansion of telework
- SSP4: high-tech advances + low rate of tertiary educated + low-medium fertility → moderate expansion of telework
- SSP5: high-tech advances + high rate of tertiary educated + high fertility → wide expansion of telework

Apart from the downscaling and application process behind the conceptualisation of the factors, two additional aspects have to be defined:

- The scenarios have to be related to a specific time horizon. A SSPs-based approach provide flexibility given that the models for quantitative figures are publicly available and can be used up to 2100. In this case 2050 was used, according to the European urban mobility policies furthest horizon.
- The convenience of a middle-of-the-road scenario. SSPs do include an intermediate scenario (SSP2). In this case only extreme scenarios have been used: by developing an even number of scenarios there is no central future that can be confounded with a predictive scenario (Moss et al., 2010).

4.3 A set of exogeneous scenarios for European urban mobility

The result of the generation phase is a set of four narratives for alternative future context of urban mobility in Europe, together with quantitative figures coming from the corresponding SSP model (Table 2).

Indicator	Sc. 1	Sc. 2	Sc. 3	Sc. 4
EU GDP/PPP annual average growth	+3.0%	+0.9%	+2.5%	+4.9%
EU population total growth	+6.9%	-9.1%	-1.1%	+18.1%
EU urban population growth	+20.7%	-4.4%	+9.3%	+33.4%
EU population over 65 years (2018: 19.7%)	33.8%	31.3%	32.9%	30.7%
EU population aged 30-34 years with tertiary education (2018: 40.7%)	70.5%	31.9%	26.5%	70.6%

Table 2: Quantitative figures associated to each exogeneous scenario (2050).

4.3.1 Scenario 1 – Mixed compact cities in a sustainable Europe (SSP1)

“European society shifts towards sustainability driven by the generalisation of environmental concerns and the popularity of sustainable development goals in public opinion. Changes are reflected both in urban daily life, with lower consumption and higher trust among citizens, and in urban governance, with higher cooperation between authorities. Access to public services is generalised limiting urban segregation and inequalities. The strong efforts for completing the energy transition have boosted European economy, with cities demanding many qualified workers for the green industry. Renewable energies and small-scale storage solutions provide relatively cheap and versatile energy to European cities. The benefits generated by high-tech green industry are reinvested in improving public services, increasing social equality across urban areas. Improvements in life expectancy of all population layers result in an elder population, but with a limited digital divide thanks to the integration measures. Specialty products are delivered by green e-commerce but convenience products are based on proximity and purchased through local consumer communities. Telework is a feasible tool for improving work-life balance, but it is not highly demanded.

Pride of ownership is declining and urban citizens seek collective solutions to daily-life problems. Urban sustainable life-styles are popular and accessible, attracting people to densified urban cores. The high demand for residential areas impacts suburban rings, that become much denser, and are also attractive for certain people given the proximity to natural parks. There are almost no greenfield developments. Mixed compact developments within urban cores host offices and high-tech industry."

4.3.2 Scenario 2 – Stagnant individualist cities in a nationalist Europe (SSP3)

"European society becomes dominated by a climate of distrust where individual and national interests have priority over collective and global targets. Environmental concerns are a residual driver for citizens, so people consume as much as their limited economic resources enable. Few households have managed to improve their living conditions, even in the upper classes. Clean energy research programs suffered from a lack of funding, so fossil fuel dependency remains stable. Tensions between global regions have an extraordinary impact on energy prices in Europe given the lack of own resources. E-commerce becomes standard for specialty products but the limited growth is a barrier for a definite expansion. Telework is only used by qualified workers. Elderly people have limited access to the latest technological developments. Ownership is not only related to a certain social status but also key for feeling safe given the successive economic crises and the security concerns in cities.

The degradation of urban cores intensifies and there is limited demand for living in dense areas, which are associated with high crime levels and high pollution. Urbanisation rate slows down in Europe and the increasing need of national supply of food and energy have reactivated rural areas and the suburban ring of small cities, where low density developments become more and more extensive. Industries remain in current locations and do not need more space due to the economic stagnation. However, offices and institutions tend to move from urban cores to suburban areas."

4.3.3 Scenario 3 – Segregated green cities in an unequal Europe (SSP4)

"European society is unable to limit the growth of inequality in the continent. On the one hand, a highly educated cohort achieves high incomes thanks to the flourishing green economy. Business and political power are concentrated in this exclusive population layer, which is worried about climate change. On the other hand, large sectors of the society fail to improve their conditions due to limited public education investments. They struggle to access a European labour market where old low-tech industry is not generating as many jobs as in the past. There is progress in the energy transition towards renewable sources, but these are still not accessible to everyone due to high prices. Elites rely on e-commerce for almost all products but face-to-face trade still holds for the rest of the population. Similarly, upper classes are familiar with telework, while unemployment and precariousness are the rule among lower income communities. The limited fertility rates lead to an ageing population.

Retirees from higher-income classes have much better access to technology than those from lower-income groups. While ownership is not trendy among urban upper-class, larger lower-income population perceives ownership as positive for achieving social status. The taste of upper classes for creative environments have fuelled the completion of gentrification processes in European urban city centres, limiting suburban growth and low-density developments both in large and small cities. Lower-income groups tend to live in high-density neighbourhoods with stretched social services. Leading high-tech industry settles in the renovated industrial areas within the urban cores, since proximity to the workplace is highly valued by qualified workers."

4.3.4 Scenario 4 – Sprawling technological cities in a vibrant Europe (SSP5)

"European society experiences a period of prolonged growth thanks to the development of climate change adaptation technologies and the cheap energy prices. There is no special consciousness on the effect of the lifestyle on the environment, since technology keeps most people away from the consequences of the nature degradation. As a result, consumption trends move towards resource intensive lifestyles. Fossil fuels are still the main energy source since the exploitation of new deposits is now possible and much cheaper than before, opening the room for the large-scale extraction of shale gas. This benefits European countries and cheapens energy.

There is extensive and promising research related to adaptation measures to issues such as sea level rise or extreme weather effects, with big investments in new smart infrastructures.

E-commerce and teleworking boost allow people to live in small cities and work for companies based in big cities, causing small cities to grow above average. Face-to-face commerce is residual. The high fertility rates spurred by good economy perspectives limit European population ageing. The efforts to enhance human and social capital limit digital divide, although rapid changes in technology make it hard to keep the pace for some elder people. Given societal convergence, pride of ownership is not related to social status but to a strong sense of freedom in cities and their surroundings. Suburban areas become attractive and host the major part of the urban population growth in large cities. Larger properties are highly demanded and therefore many rural municipalities become suburban."

5. ENDOGENEOUS SCENARIOS FOR EUROPEAN URBAN MOBILITY

5.1 'Plausible yet challenging' scenarios

The purpose of endogenous scenarios is to depict different implementation levels and business models of the mobility innovations. As it is the case with exogeneous scenarios, these are explorative alternative futures that have to be plausible but challenging, in order to stimulate creative thinking among the target agents (Banister & Hickman, 2013). The factors analysed for the development of the endogenous scenarios are discussed in detail in Burrieza-Galán et al. (2021).

Three elements were crucial:

- *Particular coverage of each innovation*. In order to emphasize the particularities of each solution, it was decided to separate them and prepare tailored groups of scenarios. Hence each of the following innovations are associated to a group of scenarios: carsharing services, micromobility services, Demand Responsive Transport services, Connected Autonomous Vehicles, Urban Air Mobility and Mobility-as-a-Service.
- *Number of scenarios for each innovation*. In order to keep the number of scenarios manageable but cover alternative evolutions, the approach selected was to provide two opposite scenarios for each innovation. This allows the target agents to better perceive the full range of effects that the development of emerging mobility solutions may entail for the tools and techniques under evaluation (Schwartz, 2012).
- *Temporal scope*. Some developments can take decades to materialize while others may require less time. This implies that the richness of the set of scenarios can benefit from using two different temporal scopes. Following the same criteria than for the exogeneous scenarios, 2050 was set as a limit and 2030 was used as an intermediate milestone, in line with European policy targets.

5.2 Endogeneous scenarios for shared mobility service in Europe.

As mentioned above, the endogeneous scenarios cover up to six different mobility innovations. The complete set is reported in (Burrieza Galán et al., 2021). Here, the two pair of scenarios most closely related to shared mobility services are presented (carsharing and micromobility).

5.2.1 Alternative scenarios for carsharing services

5.2.1.1 Medium term

The electric carsharing operates as an additional transport mode in the cities. The implementation of stricter urban vehicle access regulations and parking management policies in the metropolitan areas imposes limitations in the use of the private cars.

The transport sector is characterized by multimodality, combining mass transport for long-haul trips and individual transport for last-mile. This situation combined with the high acquisition cost of the electric cars benefits the integration of sharing schemes in the transport sector increasing its modal share up to 20-25%.

Electric vehicle infrastructure has also been developed at certain urban areas in order to serves the increasing use of electric vehicles sharing schemes. Electric carsharing is fully integrated with public transport modes and the new mobility services offer more flexibility and better quality of combined transport options.

5.2.1.2 Long term

A holistic housing solution has been developed, which integrates aspects such as mobility, housing, energy distribution and ICT networks. In this scenario the electric sharing vehicle schemes are included in the modern collective housing policies. The different urban electricity needs throughout the day are balanced through smart energy grids. Thus, the holistic housing-mobility approach leads to an easily accessible community-based electric vehicle scheme are developed with low parking requirements. The large-scale implementation of this approach contributes to the homogeneous modal share of electric vehicle solutions.

5.2.2 Alternative scenarios for micromobility services

5.2.2.1 Medium term

Micromobility mainly substitutes other transport modes in short distance trips. The safety regulatory framework for micromobility has been defined in most cities and dedicated lanes for e-scooters and similar vehicles are provided to road users.

Thus, they are used for daily short distance trips instead of car and taxi rides since car ownership appears a decline especially in young people who prefer new transport modes based on pay-per-use rather than a car purchase mode. In addition, and once the policy framework has become mature, operators will be able to explore new business schemes openly pursuing pilot projects and market’s needs, since all of the competitors in the field are subjected to the same regulation.

5.2.2.2 Long term

Micromobility becomes a part of a longer combined trip providing most flexible, efficient, and sustainable transport options. It is combined with public mass transport and following a strict regulatory framework it is completely integrated in the transport system. The mobility packages provided to travelers through MaaS platforms include the micromobility option mainly as a mode to reach or leave the transition stations or combined with the private car in Park&Ride solutions. The design has evolved to be more user friendly for people suffering from motor impairment such as those with injuries, disabilities, or even just old age.

6. MAKING USE OF THE SCENARIOS: RESILIENT TOOLS AND TECHNIQUES FOR TRANSPORT PLANNING

6.1 Basic mobility indicators under different exogeneous scenarios

There are some transport-related factors that are very much linked to the variables that characterise each exogeneous scenario. Hence, the Delphi poll started by exploring how car ownership, trip rates and average trip distances would change under each scenario. **Table 3** shows the average estimations among respondents and **Table 4** shows the variability across the panel.

The main results are the following:

- Sustainable futures are perceived by the experts as linked to decreases in car ownership, average trip distance and even trip generation rates. The remaining scenarios would lead to increases in the three indicators.
- The variable that produces more diverging opinions and also more differences between the four scenarios is car ownership.
- Scenario 4 is associated to a higher relative dispersion, where somewhat contradictory drivers (e.g., telework versus income growth) may introduce additional uncertainties. This suggests that further research on the mobility impacts of the interaction between digitalisation effects and increased purchase power is likely to be welcomed.

These conclusions were already clear after the 1st Round of the poll, but the dispersion of the opinions decreased in the 2nd Round, in particular for the responses to the average trip distance estimation (-25% in the standard deviation).

Exogeneous scenario	Car ownership	Trips / person	Avg. trip distance
1 - Mixed compact cities in a sustainable Europe	Moderate to large decrease	Slight decrease	Slight to moderate decrease
2 - Stagnant individualist cities in a nationalist Europe	Slight to moderate increase	Slight increase	Slight increase
3 - Segregated green cities in an unequal Europe	Unchanged	Slight increase	Slight increase
4 - Sprawling technological cities in a vibrant Europe	Slight to moderate increase	Slight increase	Moderate to large increase

Table 3: Average estimation of the evolution of basic mobility indicators

Exogeneous scenario	Car ownership	Trips / person	Avg. trip distance
1 - Mixed compact cities in a sustainable Europe	Low dispersion	High dispersion	Medium dispersion
2 - Stagnant individualist cities in a nationalist Europe	High dispersion	Medium dispersion	Low dispersion
3 - Segregated green cities in an unequal Europe	Very high dispersion	Very low dispersion	Low dispersion
4 - Sprawling technological cities in a vibrant Europe	Very high dispersion	Very high dispersion	Very low dispersion

Table 4: Relative dispersion among estimations of the evolution of basic mobility indicators

6.2 Shared mobility services under different exogeneous scenarios

The participants in the poll were asked about the expected modal share for these services. More than 70% of participants convey that it will raise above 10% in large cities, regardless of the scenario considered. The average estimation for this figure ranges from 15% in Scenario 2 to 30-35% in Scenario 1, although opinions appeared to be dispersed for most scenarios. Interestingly, there are no major differences in the estimations with regard to city size, as they were are only slightly lower for smaller cities. The 2nd Round produced less disperse results, but converging in the average estimations already obtained in the 1st Round (Figure 1 and Figure 2).

Assuming that not all shared mobility trips are induced demand, part of these trips were based on different transport modes prior to the implementation of the services. According to the participants, the impacts of shared mobility services on other modes would not be the same under all alternative futures. Participants consider that Scenario 1 opens the room for shared mobility services that compete with car instead of with public transport, which would not be the case for the remaining scenarios (Figure 3). Trip induction rates would be low (Figure 4). The results with regard to these impacts did not change from the 1st Round to the 2nd Round.

Figure 1: Shared mobility modal share in large cities across scenarios

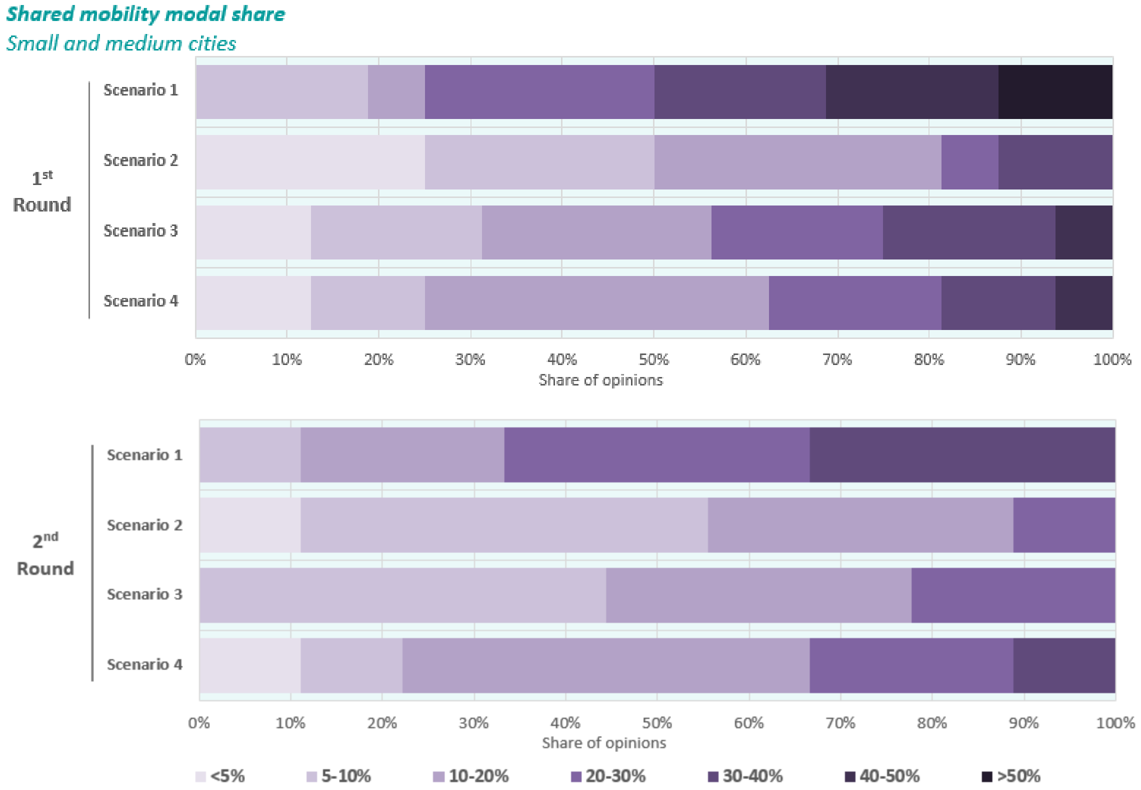

Figure 2: Shared mobility modal share in small and medium cities across scenarios

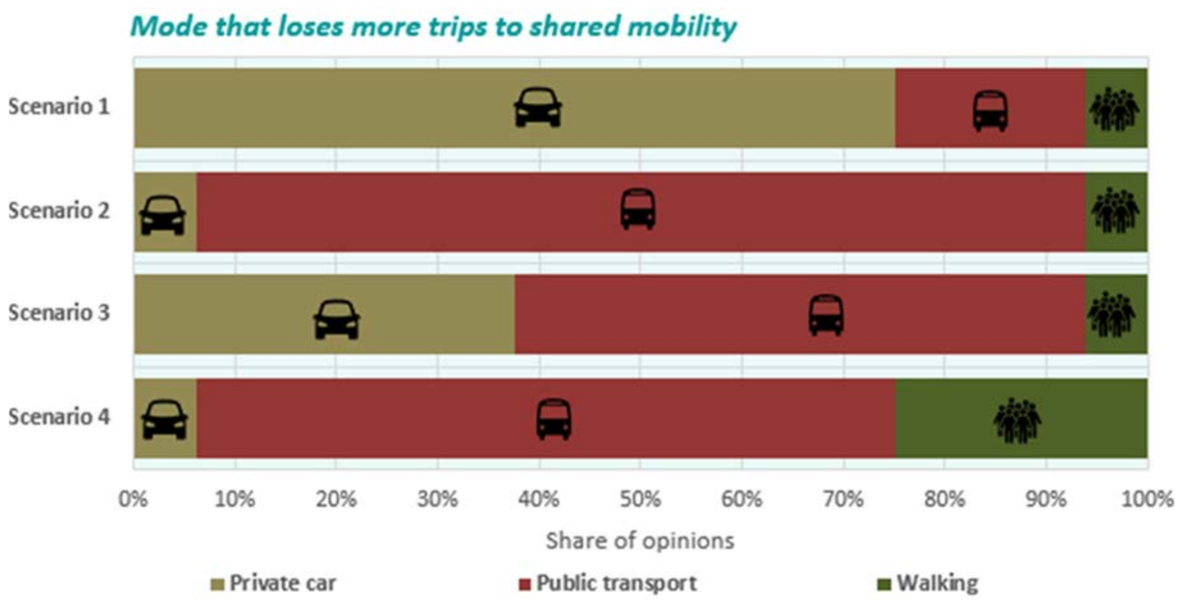

Figure 3: Relative modal shifts to shared mobility across scenarios (1st Round)

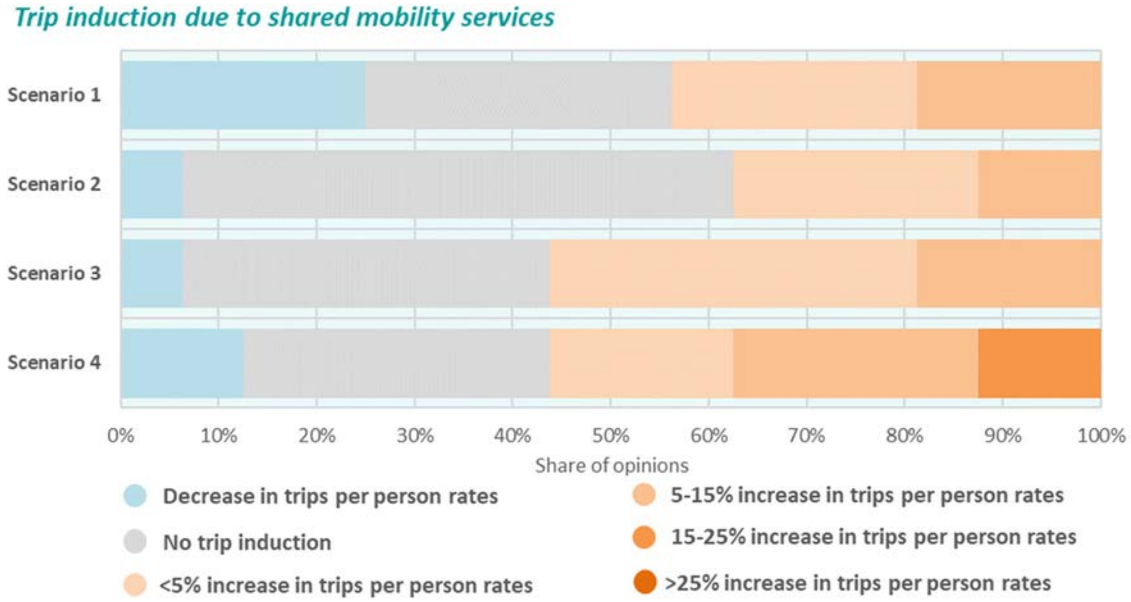

Figure 4: Trip induction estimations due to shared mobility services (1st Round)

The participants were asked also about the likelihood of some trends in how shared mobility systems are provided:

- the achievement of stable agreements between cities and operators,
- the public operation of the services,
- the integration in MaaS platforms,
- the convergence between car sharing and ride sharing due to vehicle automation an
- a general increase in prices to meet profitability targets.

The integration of the services in MaaS platforms is the trend regarded as most probable (Table 5), with low dispersion of opinions within and among scenarios already in the 1st Round (Table 6).

The evolution of the remaining trends seems to be more uncertain, since the dispersion was higher and did not decrease significantly after the 2nd Round. Some trends would depend a lot on the future scenario or present higher dispersion among opinions, such as the agreements between operators and cities to complement public transport.

All scenarios would lead to an increase in prices of these services in order to reach profitability, but the dispersion is higher for this trend than for the ones related to MaaS integration and public transport complementarity.

Exogeneous scenario	Agreements operator-city	Cities as operators	Integration in MaaS	Carsharing = Ridesharing	Increase in prices
1 - Mixed compact cities in a sustainable Europe	Likely to very likely	Likely	Likely to very likely	Slightly likely	Slightly likely
2 - Stagnant individualist cities in a nationalist Europe	Slightly unlikely to unlikely	Slightly likely	Likely	Slightly unlikely	Slightly likely to likely
3 - Segregated green cities in an unequal Europe	Slightly likely	Slightly unlikely to unlikely	Likely to very likely	Slightly unlikely	Slightly likely to likely
4 - Sprawling technological cities in a vibrant Europe	Slightly likely to likely	Slightly unlikely	Likely to very likely	Slightly unlikely	Slightly likely

Table 5: Likelihood average estimation of trends in shared mobility systems (1st Round)

Exogeneous scenario	Agreements operator-city	Cities as operators	Integration in MaaS	Carsharing = Ridesharing	Increase in prices
1 - Mixed compact cities in a sustainable Europe	Very low dispersion	Medium dispersion	Very low dispersion	High dispersion	Medium dispersion
2 - Stagnant individualist cities in a nationalist Europe	Low dispersion	High dispersion	Medium dispersion	Low dispersion	High dispersion
3 - Segregated green cities in an unequal Europe	Medium dispersion	High dispersion	Very low dispersion	Low dispersion	Medium dispersion
4 - Sprawling technological cities in a vibrant Europe	High dispersion	Very high dispersion	High dispersion	Medium dispersion	High dispersion

Table 6: Relative dispersion among the estimated likelihood of trends in shared mobility systems (1st Round)

6.3 The impacts of shared mobility services in cities

Once the participants had reflected about how the exogeneous scenarios will have an influence on the evolution of shared mobility services, they evaluate which impacts these services have on cities. The scenarios are not directly used in the questions of this section of the poll, but had served to put the participants in a creative mode of thinking that allows them to be aware of all plausible impacts. In the 1st Round the opinions were gathered through two open questions addressing current and future impacts, and in the 2nd Round rankings of adverse and positive impacts were requested. Table 7 summarises the answers to the open questions, Figure 5 shows the importance of adverse impacts and Figure 6 shows the importance of positive impacts.

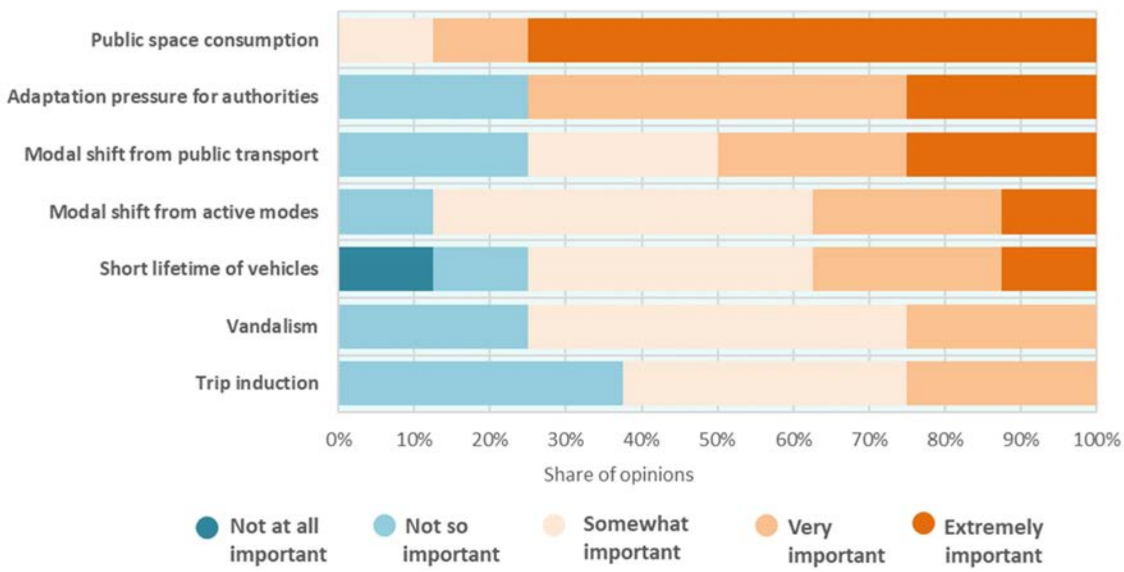

Figure 5: Importance of adverse impacts of new mobility options for cities

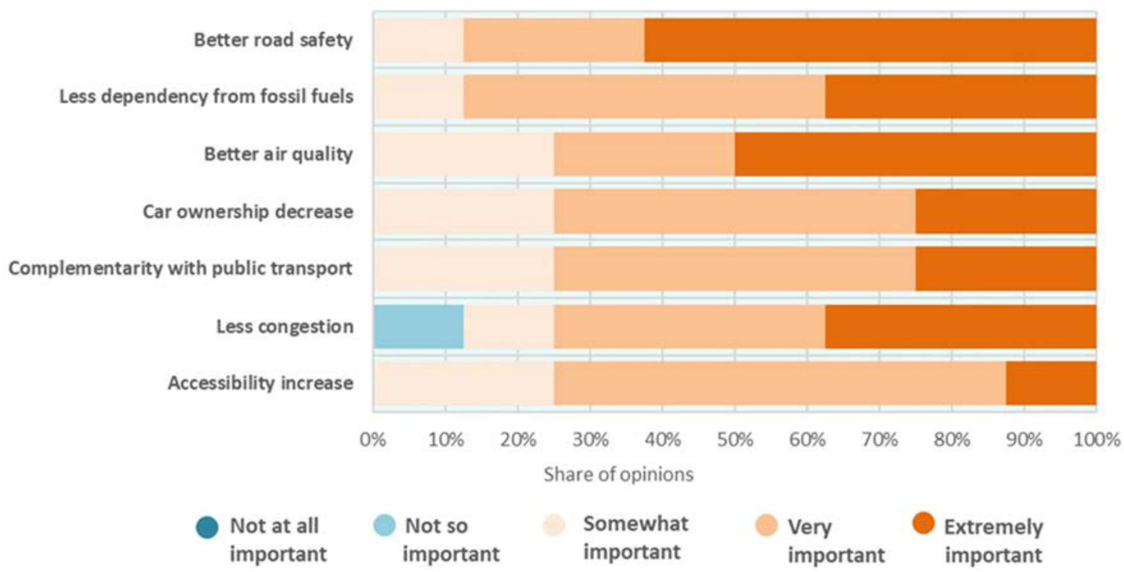

Figure 6: Importance of benefits of new mobility options for cities

Current impacts	Future impacts
Modal shift from public transport services.	A reduction in private car use and ownership. This would lead to an increase in walkability of inner-city areas, less need for parking space, less congestion and better air quality.
Modal shift from active mobility modes (i.e., walking and cycling).	An improvement of accessibility, especially in suburban areas.
Public space consumption, leading to conflicts with pedestrians in sidewalks and with other traditional modes	A replacement of scheduled public transport services, especially in low-density areas.
Short life time of micromobility vehicles drive cities away from sustainable mobility principles.	A reduction in the dependency of urban mobility in fossil fuels.
Increased pressure to public authorities for adaptation to new solutions.	An improvement in road safety.
Vandalism	An improvement of the overall economic performance of the city.
Trip induction.	A series of regulatory challenges for public authorities.
Increase of accessibility.	Modal shifts from traditional modes to emergent modes.
Car ownership decrease.	

Table 7: Potential impacts of shared mobility services in European cities according to participants, from most to least mentioned.

In the 1st Round, a quarter of them reported no current impacts but were aware that they may have impacts in the future. Among those that cited effects of these solutions that are already in place, negative aspects prevailed. Modal shifts from sustainable modes were the ones most mentioned. Interestingly, the answers to the future impacts of emerging mobility solutions were by far more positive, with few exceptions that report that no positive impacts are to be seen. The role of emerging mobility options as a potent alternative to private car use stand out as the most mentioned future impact. The 2nd Round positioned the pressure on public spaces as the most relevant negative impact and safety and energy improvements as the most relevant positive impacts.

6.4 Consequences for transport planning tools and techniques

The final section of the Delphi poll addressed the consequences of emerging mobility options for the transport planning tools and techniques. This subsection reports the results for shared mobility services. First, the participants were asked to evaluate when do they consider that shared mobility services are challenging for data analysis techniques, modelling frameworks and decision support tools. Table 8 shows the results of the analysis. Two thirds of the participants conveyed that shared mobility is already posing significant challenges. About

43% of the respondents consider that a 4% modal share is enough to consider adaptations in the tools and techniques used in transport planning. This percentage climbs up to 68% if the threshold is situated at 6%. This question was also presented as a temporal matter. All respondents considered that shared mobility should be included in supply models before 2040, and a majority of respondents considered that this should have happened before 2020 (the Delphi poll was conducted in late 2018).

Question	Options	% respondents
1. At current implementation levels in your city, do you think that shared mobility is already challenging transport planning tools and techniques?	Yes	66,7
	No	33,3
2. From which implementation level (in terms of modal share) do you expect that the following mobility solutions will require major changes in transport planning tools and techniques?	>2%	25,0
	>4%	18,8
	>6%	25,0
	>8%	6,3
	>10%	25,0
3. When do you think that shared mobility services should be added as a mode option in the transport models with a suitable treatment of the provision of their level of service (supply model)?	Now	43,8
	Before 2020	56,3
	Before 2030	93,8
	Before 2040	100

Table 8: Consequences of shared mobility for transport planning tools and techniques

Second, the participants were asked about the research gaps they find in the area. Data sharing between operators and policy-makers was highlighted by many respondents. Apart from this repeated issue, the following gaps seem to be relevant according to the 1st Round:

- The lack of solid and stable agreements with operators introduces uncertainties to the approaches needed for coping with these solutions. There is a lack of monitoring tools and normative models that would be valuable for policy-makers and regulators.
- The limited cooperation of urban planning and transport planning is also perceived as a gap in relation to this particular issue of emerging shared mobility services.
- The nature of the new options requires disaggregated demand modelling approaches taking into account improved behavioural models and the household context, e.g., in terms of car availability.
- The dynamism of shared mobility supply requires improvements in supply modelling techniques to be useful for the management of these systems.
- The lack of models for assessing specific impacts of these solutions, such as empty trips modelling or car type choice in shared mobility systems.
- The lack of strategies for data fusion, e.g., generation of synthetic populations from mobile phone data and household survey data.
- The limited real-life data available for performing analyses.
- The lack of skills by transport planners to deal with the advances in transport modelling tools.

The 2nd Round served to prioritize these gaps in terms of importance for the accurate modelling of the new mobility options. Figure 7 shows the results for the aspects related to the context of modelling practices, Figure 8 shows the results for data analysis techniques, and Figure 9 reports the results for modelling approaches. Technical skills, data sharing agreements and disaggregated modelling are perceived as most relevant factors.

7. CONCLUSIONS

The rapid development of new technologies and solutions in the transport sector calls for a continuous update of our data analysis techniques, modelling frameworks and decision support tools. This paper shows how the development of explorative scenarios for European urban mobility can facilitate a discussion about the impacts that emerging mobility options have on transport planning tools and techniques. The extensive literature on climate change research provides a good starting point for defining exogenous scenarios that cover the relevant variables that have an influence on how the emerging mobility options will develop in the following decades. The exogeneous scenarios can be complemented with endogenous scenarios that set different implementation levels for the different innovations.

In order to identify which are the requirements that future transport planning tools and techniques will have to meet in order to effectively support cities in the implementation of shared mobility services, a Delphi poll was organised. The poll engaged 16 transport experts and used the exogeneous scenarios as a tool for creative thinking among the participants. The results show that shared mobility is likely to reach modal shares above 10% before 2050 in any scenario.

The societal progress towards sustainability goals and the associated measures will define if the captured demand will come from private cars or from public transport and active mobility. Indeed, a potential modal shift from sustainable modes was the adverse impact most highlighted by the experts. At the same time, the role of shared mobility as an attractive alternative to private car use is seen as the most relevant potential positive aspect.

In order to assess these impacts, the experts claimed that shared mobility services should be included in the transport modelling tools in the next years. The majority agreed that this should happen before they reach modal shares above 4-6%.

Finally, the participants in the poll noted that the main gaps for achieving the integration of the new modes in transport models are the difficulties for reaching data sharing agreements with service providers, the availability of fine-grained data about the demand of the services and the challenges associated to disaggregated modelling. This will require not only technical adaptations but also new skills among practitioners.

ABSTRACT

The global challenge to reduce emissions of polluting gases and greenhouse gases has forced the development of alternatives to the traditional internal combustion engine vehicles, such as electric or hybrid vehicles.

The electric powertrain are the most efficient for delivery trucks or urban buses, due to acceleration and deceleration patterns make them inefficient for using internal combustion engines. Despite this, its range and purchase cost are the main factors limiting the use of electric vehicles in these applications.

Range and purchase cost of an electric vehicles are mainly related to the energy storage system. Therefore, the optimum size of the battery pack should be considered as the design goal of a vehicle when its application is known.

This paper presents a methodology to optimize the battery pack of an electric vehicle according to a given route run in a target time. Therefore, it would be applicable to delivery vehicles, buses and any vehicle whose route and travel time are known in advance. The proposed methodology allows minimizing the energy consumption by determining the optimal powertrain ratio for a given track, setting the travel time as an objective. A full vehicle model and a multi-objective genetic algorithms are used for this matter.

1. INTRODUCTION

Vehicle manufacturers, R&D centers, Universities and so on have started projects about electric vehicles to reduce carbon emission and the dependence to fossil fuel energy. Many configurations of electric vehicles are designed to attain these objectives (Bayindir, 2001). There are many of applications where an electric vehicle can be use in a very efficient way.

For example, in delivery trucks, acceleration and deceleration patterns makes them inefficient for using internal combustion engines, it can be optimized using electric trucks (Zhao, 2016). Other optimal use can be urban buses, in which the zero tail pipe emissions make them the best actual option (Qin, 2016). Something similar happened in racing electric vehicles, where the track is known and a reference time for the lap is set.

Already knowing the route and an estimated time, gives the chance of designing the vehicle especially for it proposes. In what concerns to electric vehicles, one of the most relevant decisions is made during the powertrain design. A regular approach to the design of the powertrain in electric vehicles, start with selecting the proper motor power and transmission parameters requirements (Yu, 2017). This approach can be a simple solution to this problem, but for many other scenarios, it does not achieve an optimal configuration.

Hand in hand with the lack of transmission, clutch or gears, the electric vehicle needs to be extremely efficient, in order to minimize the consumption of energy. For this matter, the influence of including a gearbox with a gear ratio can be determinant on its efficiency (Ren, 2009). This is highly related to the range and performance of the vehicle (Abdelrahman, 2017).

In some studies, (Basso, 2019) the authors focus the effort on planning the most efficient route, in order to minimize the energy, consume. Other papers establish the necessity of designing an efficient gearbox for the powertrain, which play a key role in the design of electric and hybrid electric vehicles (Dagci, 2018). In Kulik (2018), they pose the option of estimating the requirements for a hybrid electric powertrain base on analysis of the city vehicle GPS track together with accelerometer data.

In relation with the techniques use for the optimization of the powertrain, some studies have explored the option of using genetic algorithm as a strategy for optimization the parameters of the powertrain of a hybrid vehicle. Among that, the use of multi-objective design for different systems of vehicles, it is widely use (Callejo, 2015) for optimization a response.
This multi-objective genetic algorithm can also be used to define operational strategies of, for example, fleets of trucks, reducing its operational cost, for an early amortization of the expensive hybrid electric vehicles (Fries, 2017).

It can be seen the appropriateness of developing an optimization method, that defines the optimal powertrain for an electric vehicle and a determined route. An already defined path and time, allows the designer to find a solution adapted to the specific need of the vehicle. The use of multi-objective genetic algorithms for this matter, would serve as a reliable generic method of finding the optimal configuration for the powertrain, for a case given the particularities of the route.

In this paper a methodology is proposed that allows to calculate the optimal transmission for a given route, setting the travel time as a target. This would allow the transmission ratio to be adapted to the route, being applicable to transport vehicles in one or more given routes. It would allow the design of optimal powertrains or gearboxes for each route or the definition of an automatic change strategy based on the selected path.

2. METHODOLOGY

This work proposes an optimization methodology for powertrain design. The minimization of the weight of the battery pack is established as design objective. Problem constraints are a given route and the travel time. The proposed flowchart is the one shown in figure 1.

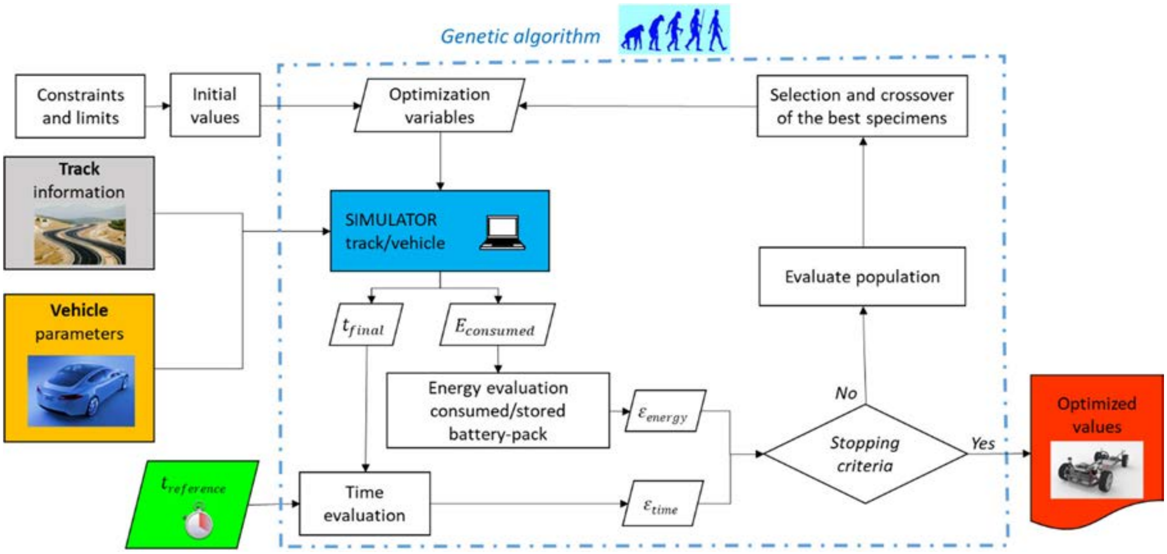

Figure 1: Flowchart of proposed methodology

The characterization of the route, the vehicle to be optimized and the reference time are established as a starting point. With all this in mind the possible design constraints and limitations, a first set of initial values of the parameters to be optimized is proposed. These values include aspects of the powertrain design, such as transmission ratio or engine characteristics. In addition, the mass of the battery is another parameter to optimize.

These parameters allow to obtain, after calculation with the module "simulator", the results of time (t_{final}) and consumed energy ($E_{consumed}$). These obtained values are evaluated with the time set as a reference ($t_{reference}$) and the stored energy, obtaining the values error of time (ε_{time}) and energy (ε_{energy}). By using a multi-target genetic algorithm, the modification of the design parameters is proposed in order to minimize the errors obtained. When the stopping criteria have been reached, the optimization process stops.

3. ANALYSIS OF ELECTRIC VEHICLE DYNAMICS

The electric vehicle under study has a powertrain that can be characterized by the following parameters:

- Maximum torque (T_{max})
- Maximum power (p_{max})
- Maximum engine speed
- Total transmission ratio (i_t)

These values are supposed to be optimized according to the needs of the study. It may be that some of these values are set at the beginning of the study, having, for example, restrictions on the type of motor to be used. Another characteristic parameter of the motor is the cut-off speed ($v_{cut-off}$). This speed sets the limit between maximum torque and constant power traction. Various yields and efficiencies will also be taken into account in the powertrain design. The powertrain design allows to obtain, in every location of the route, the traction force (F_T), including the effect of all drive axles.

$$F_T = F_f + F_r \tag{1}$$

In addition, the mass in running order of the vehicle is known and the load status. Regarding the battery pack, the type and therefore the voltage of each cell, cell unit weight and energy density are taken as initial information. The full weight of the battery pack (m_b) is considered a design variable that is intended to minimize for the given route.

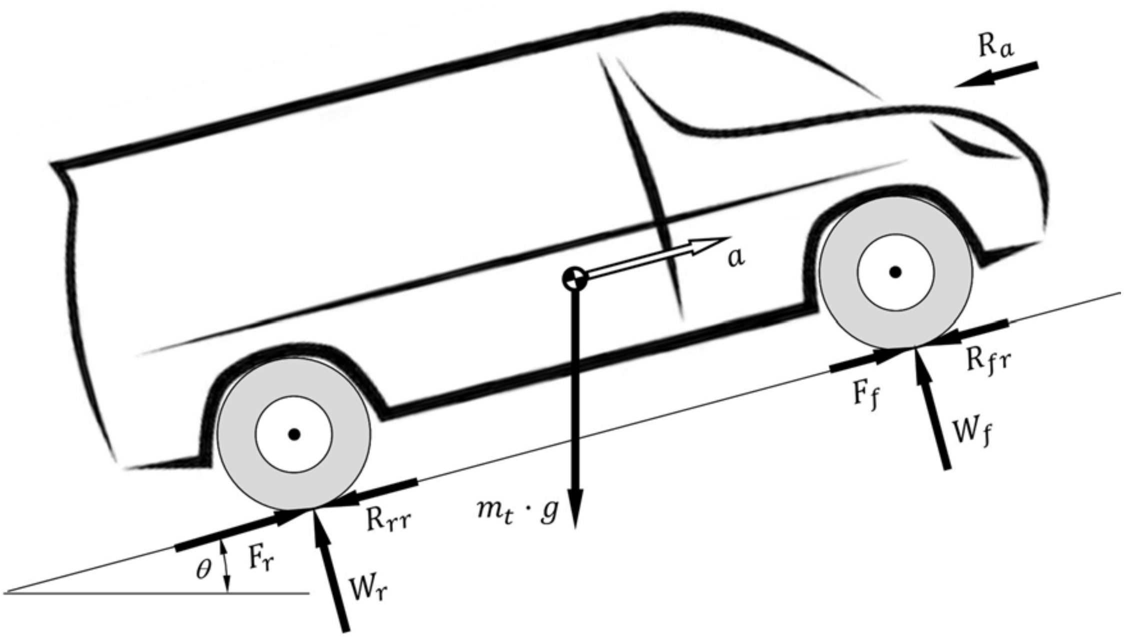

Figure 2: Vehicle dynamics

On the other hand, the dynamics of the vehicle, according to Figure 2, is characterized by resistances or drag forces that include both the rolling resistances on the axles (R_{fr}, R_{rr}), as well as the aerodynamic resistances (R_a), other mechanical losses, and the grade resistance (Allonca, 2019). The over-all drag forces are characterized by the following expression:

$$R = A + B \cdot v(t) + C \cdot v^2(t) + m_t g \cdot sin\theta \quad (2)$$

The total mass of the vehicle (m_t) can be expressed as the sum of the mass of energy storage systems (m_b), such as batteries and auxiliary systems and the rest of the vehicle's masses (m_v).

$$m_t = m_v + m_b \quad (3)$$

Depending on the powertrain design, drive shaft position, wheelbase, weights in every shaft (W_f, W_r) and center of gravity position, the vehicle's traction capacity may be limited by the adhesion of the drive wheels to the rolling surface. It should therefore be checked, both the performance of the powertrain and the limitations of the environment.

4. ROUTE ANALYSIS

As already mentioned, the method proposed on this paper has the objective of defining an optimization method for designing the powertrain of an electric vehicle, knowing its final propose. This includes knowing a reference time for the route and the route itself. A route, can be a complex consecution of different sections like strait lines, open curves, closed curves, uphill or downhill. This makes the study of the route quite complex, taking in mind the necessity of apply the equations to the entire track.

To simplify this problem, a solution is proposed. If we can find a method to typify every section of a route, and then apply the calculation process to it summing up all the sections at the end, will be easier, more precise and more efficient.

The general methodology implies that the complete route for which you want to optimize the vehicle must be divided into sections that are characterized by having the constant values of the section parameters. The parameters that characterize each section are:

- Start point
- End point
- Ramp/slope
- Radius of curvature. In the case of a straight section, the radius is considered to be infinite (∞).
- Adhesion

If a change of ramp/slope or adhesion occurs on the same constant radius curve, it must be divided into as many sections as there are different values.

After the analysis of the route, there is a division of sections characterized by its starting and ending point. If distances to the origin are taken, it is clear that the endpoint of a section (n) coincides with the start of the next one (n+1).

Each section must be characterized by a maximum speed (v_{max}) which is function of the vehicle and the road. The vehicle has a circulation limit according to the powertrain. The road imposes a limit that is a function of the maximum lateral acceleration radius of curvature and the posted speed. Once the route partition has been defined, the behaviour of the vehicle within each section must be analyzed.

The simulator considers that the initial speed of the section (n) is the final speed of the stretch $(n-1)$, so when it reaches that section, the speed is assumed to be known. In general, it is established as a condition that when it under traction force, the powertrain will be considered the maximum tractive effect (considering both the limit of the powertrain and the adhesion). The maximum speed in every section cannot be exceed. At the end of the section (n) cannot be exceed the starting limit speed of the next section $(n+1)$, which will be taken by default the maximum speed.

If the vehicle is driving at a speed higher than the final speed, a braking procedure must be established. The point from which braking must start must be determined to reach the end of the run at the defined speed.

As a conclusion, a complex and long track can be automatically segmented into an undefined number sub-tracks or sections, each one also defined by its parameters that can be its length l, its slope θ, its initial speed $v_{initial}$, its maximal speed v_{max} and its final speed v_{final}.

In general, each section can be defined by its maximal speed v_{max}, that restrict the circulation throw that section. For example, if the maximal speed of the section is greater than the cutoff speed of the motor of the vehicle, it can be defined four different dynamic behaviors:

- The vehicle accelerates from $v_{initial}$ to v_{cut_off} at constant torque. The acceleration in this subsection is:

$$a_{Tmax}(t) = ((T_{max}i_t/r) - (A + B \cdot v(t) + C \cdot v^2(t) + m_t g \cdot sin\theta))/(m_t\gamma) \tag{4}$$

- The vehicle accelerates from v_{cut_off} to v_{max} at constant power. The acceleration in this subsection is:

$$a_{pmax}(t) = ((P_{max}/v) - (A + B \cdot v(t) + C \cdot v^2(t) + m_t g \cdot sin\theta))/(m_t\gamma) \tag{5}$$

- The vehicle circulates at constant speed v_{max}. The acceleration in this subsection is 0. In this case the tractive force must be such that it equals the drag resistances, resulting in zero acceleration
- The vehicle breaks from v_{max} to v_{final}. The acceleration of this subsection is:

$$a_b(t) = (-F_b - (A + B \cdot v(t) + C \cdot v^2(t) + m_t g \cdot sin\theta))/(m_t\gamma) \tag{6}$$

A general sequence of speed variation is shown in figure 3.

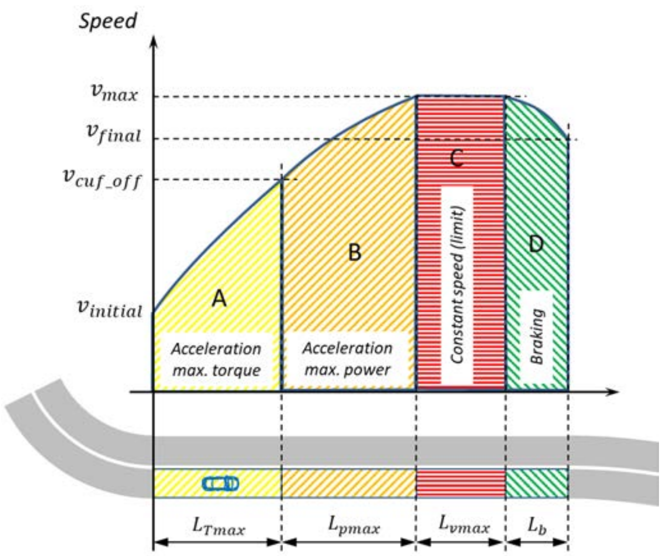

Figure 3: Speed variation in a general section.

The simulation module analyzes the dynamic response of the vehicle in every section of the given track. The calculation procedure include la classification of the different subsections, according to the vehicle response. The total length of a section, is described by 4 subsections, having each one its own length:

- L_{Tmax}: Subsection length associated to the maximal torque.
- L_{pmax}: Subsection length associated to the maximal power.
- L_{vmax}: Subsection length associated to the maximal speed.
- L_b: Subsection length associated to the braking phase.

At the end, the total length of a i-section $L(i)$ is the sum of the length of this 4 subsections:

$$L(i) = L_{Tmax}(i) + L_{pmax}(i) + L_{vmax}(i) + L_b(i) \tag{7}$$

These lengths can be calculated based on the dynamic behaviour of the vehicle.

$$L(i) = \int_{v_{initial}}^{v_{cut\_off}} (v \cdot dv/a_{Tmax}(v)) + \int_{v_{cut\_off}}^{v_{max}} (v \cdot dv/a_{pmax}(v)) + v_{max} \cdot t_{vmax} + \int_{v_{max}}^{v_{final}} (v \cdot dv/a_b(v)) \tag{8}$$

The total time spend in go across a section is describe by 4 subsections, having each one its own time:

- t_{Tmax}: Time spend going throw the section of maximum torque.
- t_{pmax}: Time spend going throw the section of maximum power.
- t_{vmax}: Time spend going throw the section of maximum speed.
- t_b: Time spend going throw the breaking section.

At the end, the total time spend going throw a section is the sum of the time needed for the 4 subsections:

$$t_{total} = t_{Tmax} + t_{pmax} + t_{vmax} + t_b \tag{9}$$

The total time (t_{total}) to travel the section will be:

$$t_{total} = \int_{v_i}^{v_c} (dv/a_{Tmax}(v)) + \int_{v_c}^{v_{max}} (dv/a_{pmax}(v)) + t_{vmax} + \int_{v_{max}}^{v_f} (dv/a_b(v)) \tag{10}$$

As it can be seen, a general section of the route or track, can be composed by the combination of this 4 types of subsections. In case of vehicle and route limitations, in each study section in which the route has been divided, one or more subsections may disappear. Some special cases could appear, as follows:

- The maximum speed is not reached: This implies that the maximum speed phase (C) disappears. In that case $t_{vmax} = 0$. It can be expressed mathematically as:

$$v < v_{max}, \forall t \tag{11}$$

- The maximum speed acceleration of the run is not reached (B): This implies that the maximum speed phase disappears. Speed (v) never exceeds the change rate (v_{cut_off}). It can be expressed as:
-

$$v < v_c, \forall t \tag{12}$$

This can occur with or without maximum speed phase. If you the maximum speed phase is not reached, an additional constraint should be considered:

$$v_{max} < v_c \tag{13}$$

- No braking phase: This implies that the braking phase (B) disappears. In that case the speed does not reach the final speed.

$$v < v_{final}, \forall t \tag{14}$$

This can be achieved in three different ways:

  - Finishing the section in maximum speed
  - Finishing the section at maximum power
  - Finishing the section at maximum torque

- It starts from acceleration at constant power: This implies that the acceleration phase at maximum torque (A) disappears. In that case the initial speed exceeds the cut-off speed.

$$v_{cut\_off} < v_{initial} \tag{15}$$

- The run starts at constant speed and equal to the maximum: This implies that the acceleration phase disappears. In that case, the initial speed is equal to the maximum speed.

$$v_{max} = v_{initial} \tag{16}$$

All this logic is implemented in the simulator. Initially the simulator has the information that characterizes each section. This information is relative to the length of each section, slope, maximum speed and braking deceleration. The simulation module starts from an initial speed of the first section. Every simulation step the vehicle is located in a section (i).

This allows you to know the maximum section speed, the maximum permissible final speed and the braking acceleration. If the speed is less than the maximum speed, it accelerates. If the speed is lower than the cut-off speed, acceleration with constant maximum torque is assumed. Otherwise, the engine is considered to drive at constant power. In this case the torque is a function of the power and engine speed.

At each point of the section it is necessary to check that the speed does not exceed the maximum, so in that case, the torque will be necessary to counteract the losses due to the resistance forces when driving at constant speed.

In parallel, it should be noted, depending on the final speed, that the braking distance required is no less than the distance to the end of the run.

With these conditions, a simulation of the route of each vehicle configuration is obtained based on the design variables. Differences between the times obtained and the reference time are evaluated. It is also checked that the energy consumed is at least equal to that stored in the battery pack. With all this, a set of new vehicle configurations is proposed, using a genetic algorithm. The ultimate goal is to get a weight-optimized solution.

4. RESULTS AND CONCLUSIONS

As an example of application of the proposed methodology, the analysis of a given route is shown in Figure 4.

Figure 4: Given track used to methodology implementation.

After entering all the characteristic parameters of the vehicle and the sections of the route the genetic algorithm is run. The different powertrain configurations of the vehicle are iteratively simulated. Finally, a configuration with a minimized weight of the battery pack is obtained. Figure 4 shows the different points at which a change of status occurs in the dynamics of the vehicle.

As conclusions, can be stated that a new methodology is proposed to optimize the chassis of electric vehicles. This methodology focuses on minimizing the energy consumption for a given track and travel time.

A simulated model of an electric vehicle behavior on a certain track, to use on a multi-objective genetic algorithm, has successfully accomplished in order to optimize the powertrain of an electric vehicle. This method is reliable and can be used in many applications, in where the time and the route are already known.

The design variables are composed by the battery pack mass and the transmission ratio, both optimized to guaranty the best performance in the track. The multi-objective model is validated with the use of a real-life case that confirms its functionality.

RESUMEN

El grado de autonomía en los vehículos ha crecido significativamente en la última década debido a la aparición de nuevas tecnologías, que permiten conocer en cada instante de tiempo, tanto las condiciones del entorno, como las del vehículo, dejando en un segundo plano el factor humano.

Ya son una realidad en los vehículos que circulan por nuestras carreteras, el sistema de mantenimiento de carril (LKAS – Lane Keeping Assistance System), el sistema de ayuda de permanencia en la carretera (RDM – Road Departure Mitigation) o el control de crucero adaptativo inteligente (ACC – Adaptative Cruise Control), aunque la idea, es ir más allá, a vehículos totalmente autónomos capaces de transportar con seguridad a personas entre dos localizaciones sin la implicación de éstas.

En el presente artículo, se desarrolla la optimización del tiempo de ejecución de una maniobra de adelantamiento, utilizando campos potenciales para el cálculo de la trayectoria y las regiones de estabilidad (velocidad de guiñada – ángulo de deriva) para determinar el nivel de seguridad.

Los campos potenciales, son una herramienta utilizada en la generación de trayectorias, permiten conocer en cada instante de tiempo, el entorno y las situaciones que rodean al vehículo, adaptando así sus movimientos. Por otro lado, con las regiones ($\dot{r} - \beta$) es posible conocer los límites de estabilidad de los vehículos, además de detectar situaciones comprometidas durante la conducción.

La combinación de ambas herramientas permite realizar maniobras de adelantamiento, no solo rápidas, sino seguras. Para el desarrollo, se realizan simulaciones con un modelo 3D complejo en el software de simulación dinámica multicuerpo MSC Adams® y se implementa el control en Matlab Simulink®.

1. INTRODUCCIÓN

En los últimos años, los vehículos autónomos y sus tecnologías han sufrido un gran desarrollo (Kuramoto, 2018; Somogyi, 2018; Park, 2016). La utilización de este tipo de vehículos supone muchos beneficios para la circulación vial (European Commission, 2016), desde la reducción del número de accidentes/incidentes en la carretera (de factor humano) (National Highway Traffic Sfety Administration, 2015; Rowley, 2018), pasando por la reducción de los atascos o la aparición de nuevos servicios de transporte.

A la hora de hablar de conducción autónoma, es necesario distinguir entre 6 niveles de autonomía (SAE International, 2018), según el grado de intervención del ser humano (Figura 1).

Nivel de Automatización	Denominación	Control de los actuadores	Monitorización del entorno	Capacidad del sistema
0	Sin automatización	Conductor humano	Humano	n/a
1	Asistencia del conductor	Sistema + Humano	Humano	Algún modo
2	Automatización parcial	Sistema	Humano	Algún modo
3	Automatización condicionada	Sistema	Sistema	Algún modo
4	Automatización alta	Sistema	Sistema	Algún modo
5	Automatización total	Sistema	Sistema	Todos modos

Figura 1: Niveles de automatización para vehículos (SAE)

A pesar de los claros beneficios que tienen hoy en día los vehículos autónomos, su uso en la actualidad, está reducido a entornos controlados, aunque cada día incrementan sus posibilidades (Jiménez, 2018). Un ejemplo de esto, de aplicación en el transporte de mercancías, es la agrupación de vehículos en un pelotón, siendo el primero del grupo el que controla a los demás (Jia, 2017; Santini, 2017). Además, surgen nuevas opciones de negocio, car-sharing o taxis autónomos (Bischoff, 2016), vehículos militares (Naranjo, 2019) y nuevas posibilidades para gente de avanzada edad o con discapacidades (Harper, 2016).

En un vehículo autónomo, se distinguen tres etapas durante la conducción, que se desarrollarán cíclicamente, percepción (del entorno), toma de decisión y acción (Figura 2).

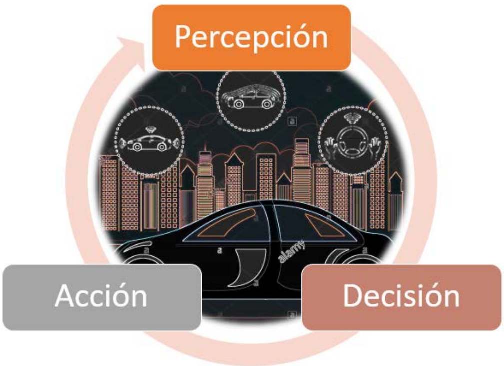

Figura 2: Etapas vehículo autónomo

De las tres etapas que se distinguen, la que más desarrollo está sufriendo en la actualidad es la percepción. Son múltiples las tecnologías utilizadas para el reconocimiento del entorno o del tráfico, visión artificial (Bertozzi, 2000), ultrasonidos (Alonso, 2011), radar (Eltrass, 2018) o/y LiDar (Kidono, 2019; Baras, 2019).

Como se ha visto, el vehículo autónomo, lleva asociado, una red de telefonía (redes 4G-5G, WiFi) (Wang, 2019) y periféricos (sensores, microcontroladores) (Faouzi, 2016; Khaleghi, 2013) e infraestructura (posicionamiento por satélite) (Milanés, 2008), que hacen posible su funcionamiento (Brown, 2014).

A la hora de abordar la toma de decisiones, intervienen varios factores, planificación de trayectorias, tipo de carretera y geometría, obstáculos en la vía, peatones, entre otros, por lo que se trata también de una etapa de gran complejidad. (Jiménez, 2018; Rasekhipour, 2017; Aldibaja, 2018).

Lo que se pretende en este trabajo, es combinar los campos potenciales (técnica para la toma de decisiones) con las regiones de estabilidad del vehículo ($\dot{r} - \beta$) (definidas por la velocidad de guiñada y el ángulo de deriva) de forma que se consigan maniobras, en este caso de adelantamiento, más rápidas y seguras. Por un lado, los campos potenciales posicionan el vehículo en la vía e inducen cambios en el movimiento de este, mientras que las regiones de estabilidad condicionan la velocidad con la que se realiza la maniobra, de forma que nunca se superen los límites asociados a cada vehículo y condición operativa.

2. METODOLOGÍA

El uso de modelos tridimensionales y simulaciones virtuales son ampliamente utilizados tanto para la comprobación de las capacidades técnicas de los vehículos, como para la modelización de escenarios de tráfico.

2.1 Modelo virtual de vehículo

En la Figura 3 se muestra el modelo 3D complejo, definido en el programa de simulación dinámica multicuerpo MSC Adams View® y utilizado para la modelización del vehículo.

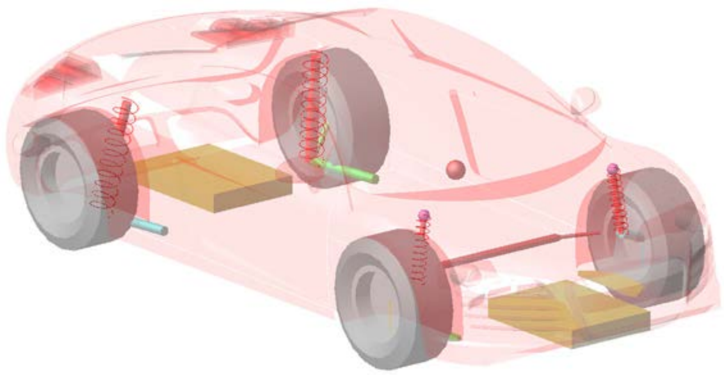

Figura 3: Modelo virtual utilizado para los ensayos

Se trata de un modelo con 16 grados de libertad y 21 partes móviles, capaz de reproducir fidedignamente el comportamiento dinámico del vehículo real. El vehículo tiene una suspensión delantera de tipo McPherson y trasera de brazos arrastrados. En este caso, el modelo de neumático utilizado es un Pacejka 2002 (Pacejka, 2002).

El modelo virtual utilizado para las simulaciones se exporta desde el software de simulación hacía el software en el que se realiza el control Simulink®. El bloque generado en la exportación (planta), es el que se muestra en la Figura 4.

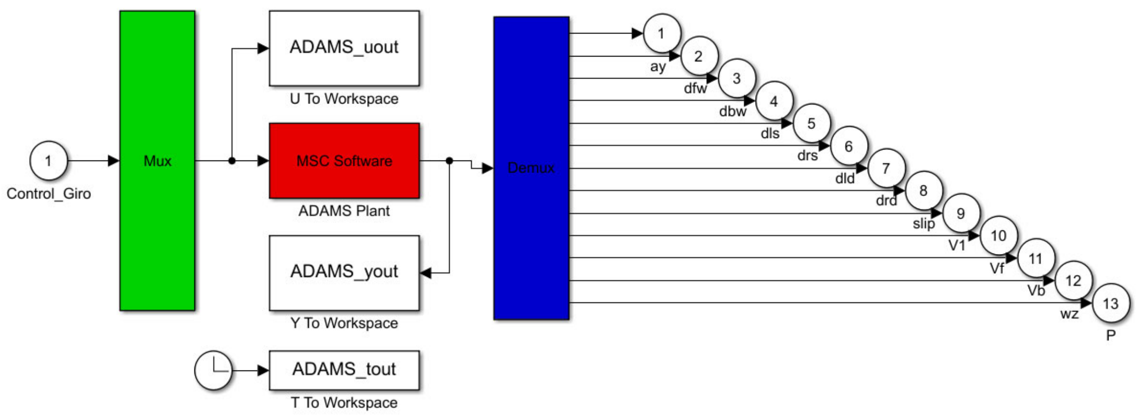

Figura 4: Planta del modelo 3D de simulación

De la simulación se obtienen datos de distancias entre vehículos, distancia a los límites de la carretera, datos sobre la dinámica vehicular, como pueden ser la velocidad de guiñada y el ángulo de deriva, datos de la geometría del vehículo como la posición del centro de gravedad (cdg) o la masa de este.

2.2 Diseño del sistema de control

Para la realización de las simulaciones se ha considerado una velocidad de circulación constante, por lo que la variable de control del modelo es el giro de volante durante la maniobra de adelantamiento. El modelo de control se divide en tres partes, Figura 5:

- Control en base a la sobreaceleración lateral
- Control aplicando campos potenciales (Martínez, 2019)
- Control aplicando regiones de estabilidad (Beal, 2013; Bobier, 2013; Bobier, 2012, Erlien, 2015)

Una vez se tiene definido un ensayo para un modelo dado, se exporta la planta desde Adams View® a Matlab Simulink® para realizar el control, Figura 5, ya que es más flexible para trabajar y da más opciones.

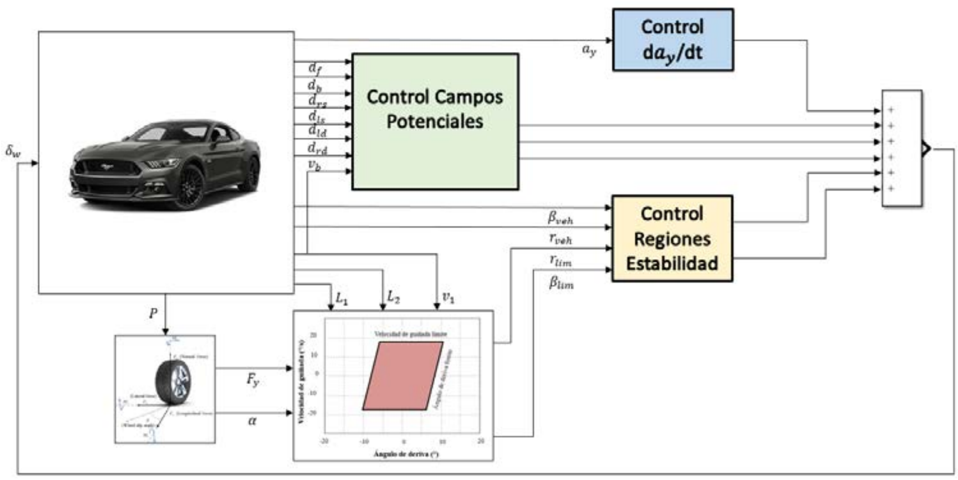

Figura 5: Control para el adelantamiento del vehículo

Mediante los campos potenciales, se define el giro de volante necesario que hace posible la maniobra de adelantamiento, mientras que el control de a_y y las regiones de estabilidad, determinan que ésta, se haga con total seguridad.

2.3 Control en base a la sobreaceleración

Para el control en base a la sobreaceleración lateral, se toman como referencia los límites que se establecen en la Norma 3.1 – IC Trazado sobre la sobreaceleración que sufren los pasajeros durante la circulación. En la Figura 6, se muestran los diagramas de bloques que llevan a cabo el control.

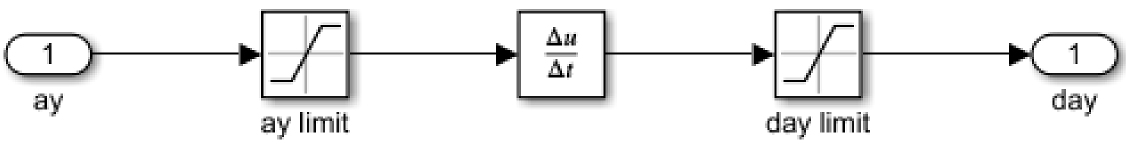

Figura 6: Diagrama de bloques para el control a partir de a_y

Al tratarse de una maniobra de adelantamiento, en la que el cambio de carril se realiza de forma brusca, se limita esta sobreaceleración a ±2 (m/s^3). En la Figura 7 se muestran los valores de aceleración lateral y sobreaceleración para el vehículo utilizado durante una maniobra de adelantamiento.

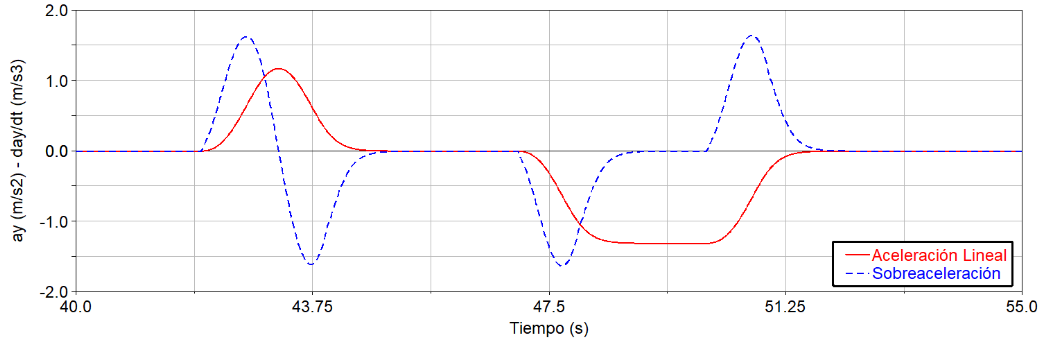

Figura 7: Aceleración y sobreaceleración para un vehículo

La aceleración lateral límite, para que sea común en todos los vehículos, se considerará un valor de ±5 (m/s^2).

2.4 Control aplicando campos potenciales

A la hora de abordar la toma de decisiones en la conducción autónoma, se puede recurrir a varias técnicas, tele-operación, navegación por waypoints o control difuso entre otras. Para este análisis se ha optado por utilizar técnicas reactivas, campos potenciales, donde el vehículo responde en todo momento a la situación actual generando el movimiento adecuado.

Como se puede ver en la Figura 8, cada elemento del entorno (carriles, otros vehículos o los propios límites de la vía) produce un campo potencial con el vehículo. Según el tipo de potencial, el vehículo modificará su comportamiento.

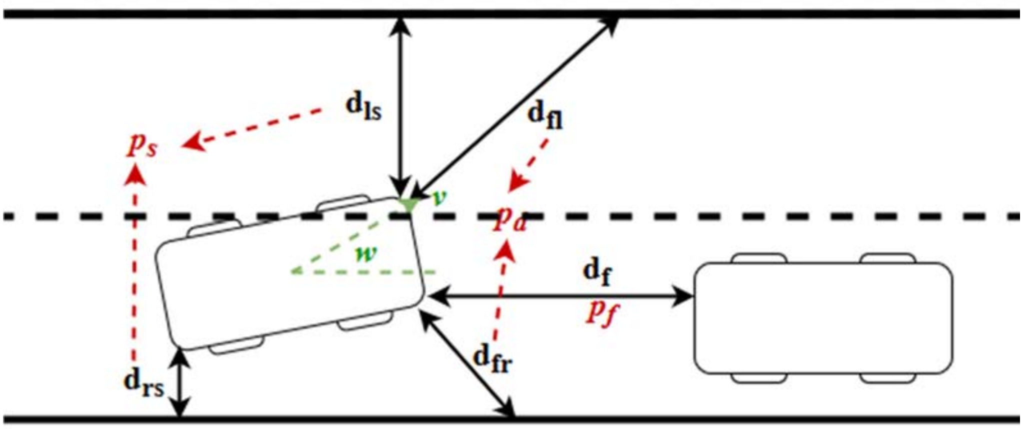

Figura 8: Distancias que definen los potenciales entre el vehículo y el entorno

En la Figura 9, se representan sobre el vehículo los potenciales frontales/traseros, laterales y diagonales, que permiten posicionar el vehículo en la vía y respecto al resto de usuarios.

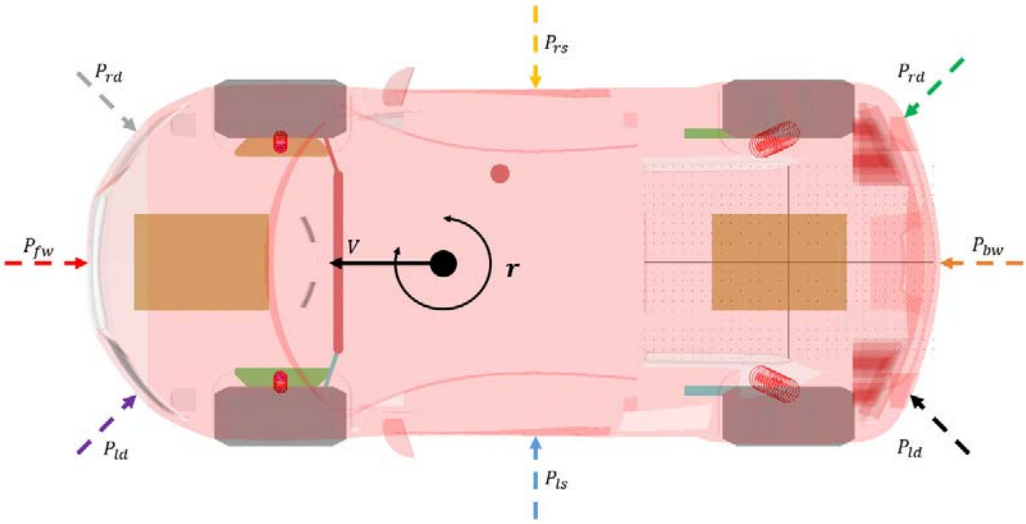

Figura 9: Diagrama de campos potenciales sobre el vehículo

Para el cálculo de los potenciales, se utilizan las siguientes expresiones.

2.4.1 Potencial respecto al vehículo a adelantar:

$$P_{fw} = \{[0\ si\ v_{B1} \geq v_{max}], [(v_{max} - v_1)/d_f \ \ si\ v_{B1} < v_{max}]\} \quad (1)$$

donde:

- v_{max} – velocidad máxima de la vía
- v_1 – velocidad del vehículo que va a ser adelantado
- d_f – distancia frontal entre los vehículos

2.4.2 Potencial respecto al vehículo que se tiene detrás:

$$P_{bw} = \{[0\ si\ v_A \geq v_{B2}], [v_2 - v_A)/d_{bw} \ \ si\ v_A < v_{B2}]\} \quad (2)$$

donde:

- v_2 – velocidad del vehículo que ejecuta la maniobra de adelantamiento
- v_A – velocidad del vehículo que le sigue
- d_{bw} – distancia trasera con el vehículo que le sigue

2.4.3 Potenciales respecto a los límites de la vía:

$$P_s = P_{rs} + P_{ls} = 1/d_{rs}^2 - 1/d_{ls}^2 \quad (3)$$

donde:

- d_{rs} – distancia lateral derecha
- d_{ls} – distancia lateral izquierda

2.4.4 Potenciales diagonales:

$$P_d = P_{rd} + P_{ld} = 1/d_{fr}^2 - 1/d_{fl}^2 \quad (4)$$

donde:

- d_{fr} – distancia diagonal derecha
- d_{fl} – distancia diagonal izquierda

2.4.5 Potencial total:
El potencial total es la suma de cada potencial, multiplicado por el valor de su ganancia:

$$P_T = \sum K_i \cdot P_i = K_s \cdot P_s + K_d \cdot P_d + K_{fw} \cdot P_{fw} + K_{bw} \cdot P_{bw} \quad (5)$$

Siendo K_i la constante de proporcionalidad.

Del modelo virtual se obtienen las distancias entre los vehículos, las cuales son las entradas del control de giro con potenciales. En la Figura 10, se muestra el diagrama de bloques para el control según los campos potenciales. Si la propuesta se llevase a cabo en un vehículo real, sería necesario la instrumentación de este, con LiDAR, visión artificial, u otras tecnologías que permitan medir distancias. La salida del control es directamente el giro de volante.

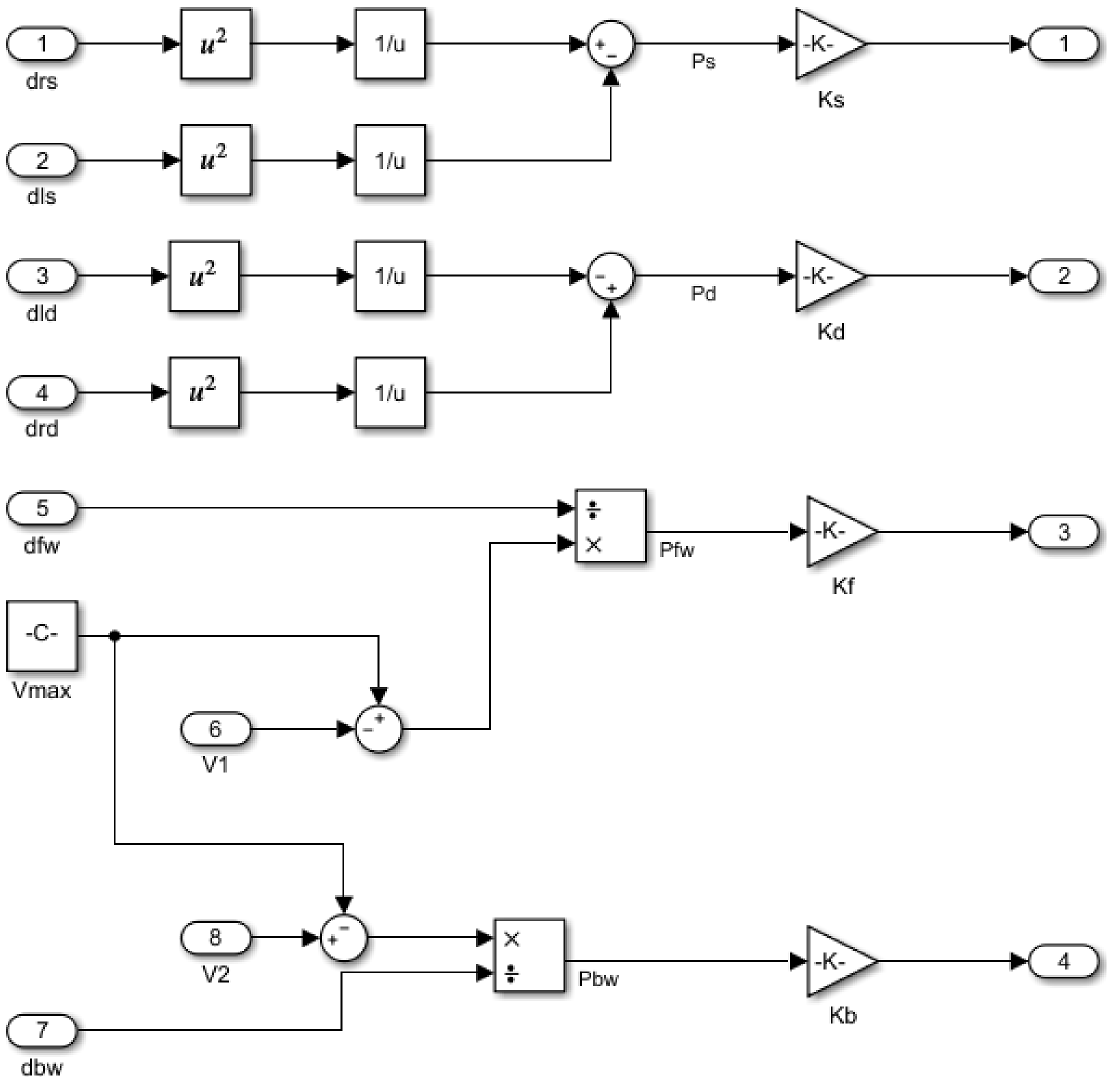

Figura 10: Diagrama de bloques para el control según los potenciales

2.5 Control aplicando regiones de estabilidad

El control de la dinámica vehicular se realiza a través de las denominadas regiones de estabilidad, determinadas por los valores límite de velocidad de guiñada y ángulo de deriva del neumático ($\dot{r} - \beta$), cuya representación se puede apreciar en la Figura 11.

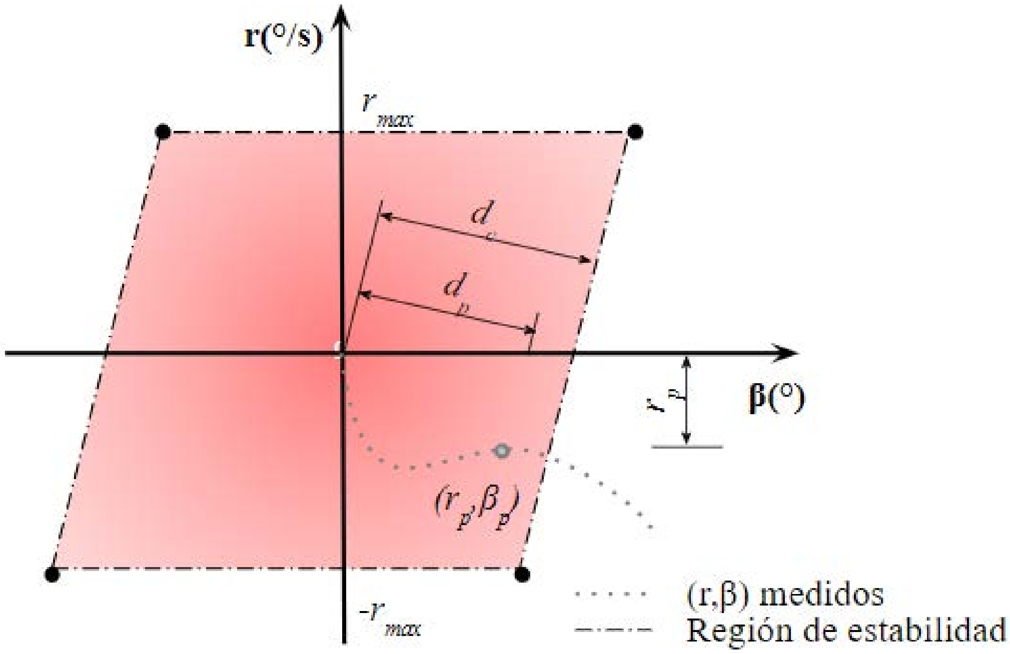

Figura 11: Parámetros para definir la seguridad disponible en cada caso

El uso de estas regiones, en conjunto con el control de la sobreaceleración, evita que el vehículo alcance situaciones comprometidas, como derrapes o pérdida de la dirección en casos más graves (Alonso, 2019).

$$\beta_{demandada}(\%) = d_p/d_c \cdot 100 \quad (6)$$

$$\dot{r}_{demandada}(\%) = r_p/r_{max} \cdot 100 \quad (7)$$

donde:

- d_p – deriva del vehículo parar una condición e instante determinado
- d_c – deriva máximo parar una condición e instante determinado
- r_p – guiñada del vehículo parar una condición e instante determinado
- r_{max} – guiñada máxima

3. RESULTADOS

En el desarrollo de la metodología, se ha considerado un adelantamiento a alta velocidad en una autopista, Figura 12. Para simplificar el caso, se han considerado velocidades constantes de todos los vehículos implicados en la maniobra.

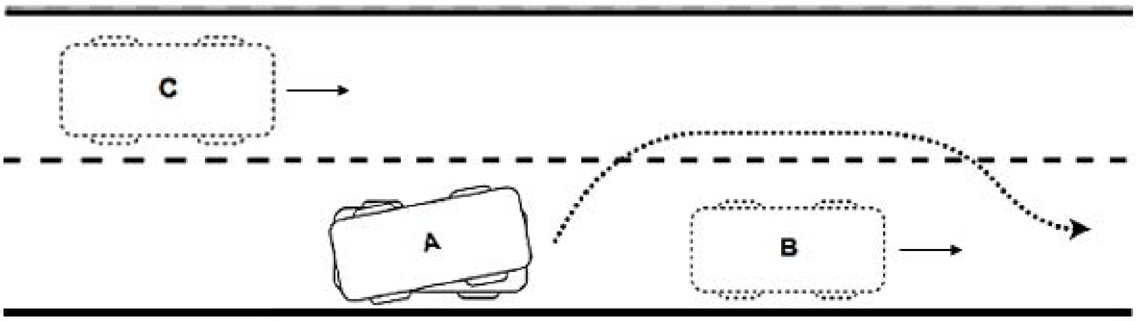

Figura 12: Adelantamiento a alta velocidad

En la Figura 13, se muestran los valores de los potenciales sobre el vehículo, frontal/trasero, laterales y diagonales. Se puede apreciar, que cuando se produce el adelantamiento el potencial frontal cambia de signo, pasa de ser positivo a negativo, también, el efecto en el potencial lateral de la maniobra de cambio de carril.

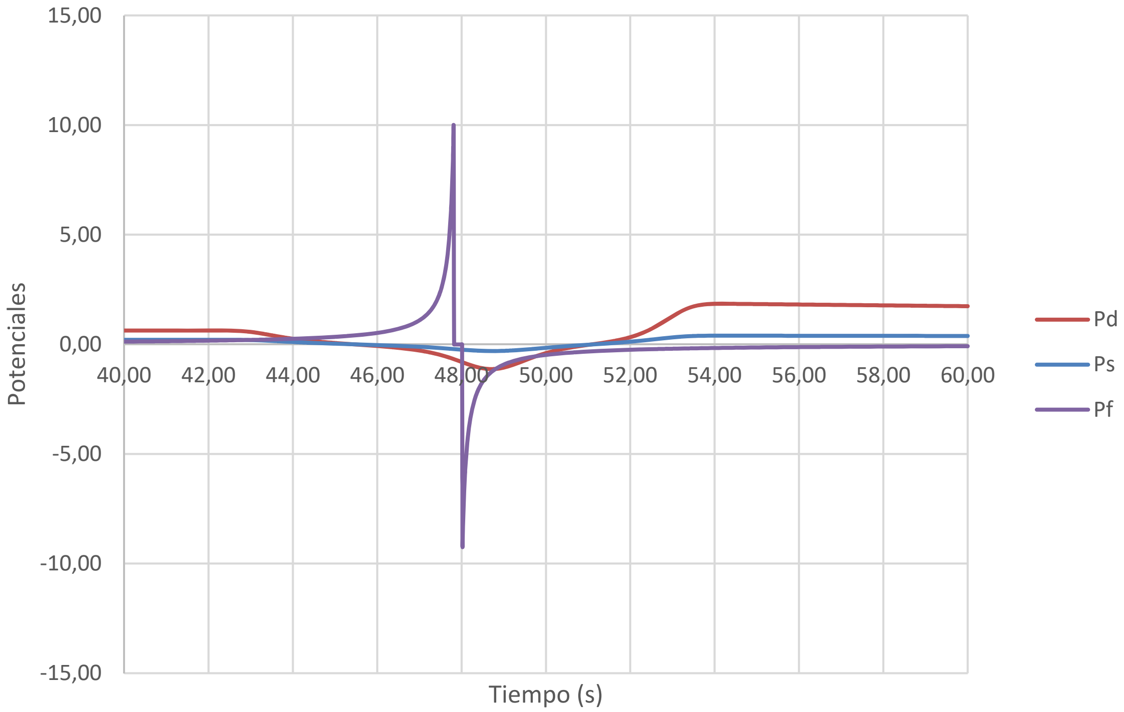

Figura 13: Potenciales sobre el vehículo

Los potenciales, no son indicativos de la seguridad con la que se realiza la maniobra, por lo que es necesario analizar los parámetros que si la determinan. La aceleración lateral y la sobreaceleración representadas en la Figura 14, alcanzan el valor definido como límite para la sobreaceleración, mientras que la aceleración lateral se mantiene por debajo de $1 m/s^2$.

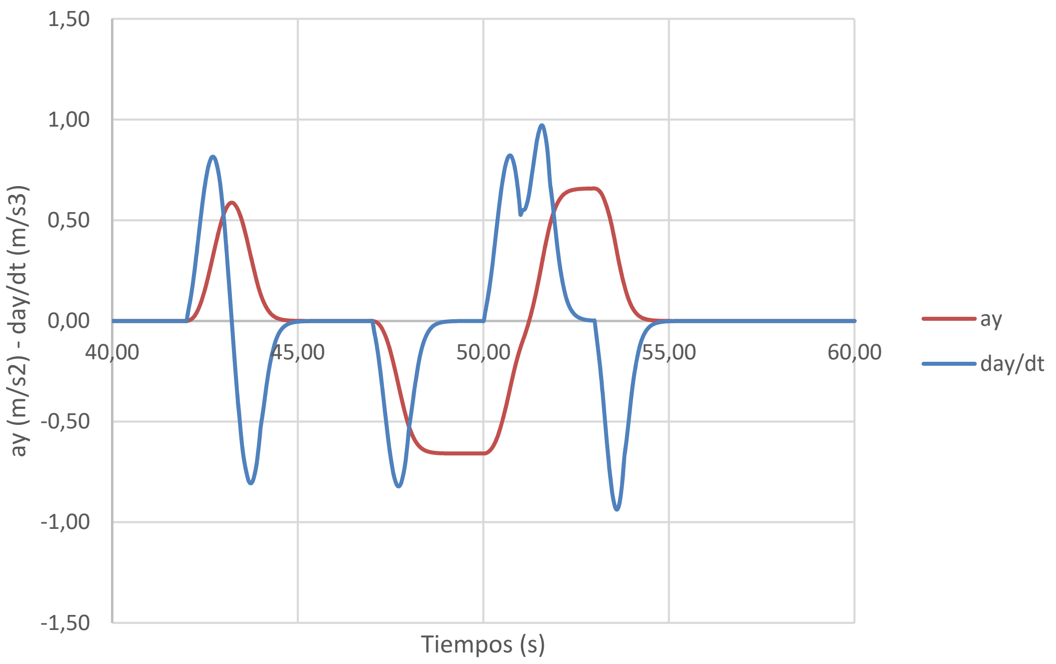

Figura 14: Aceleración y sobreaceleración en la maniobra

En el análisis de la velocidad de guiñada de la Figura 15 se aprecia que los valores obtenidos están muy por debajo del valor límite.

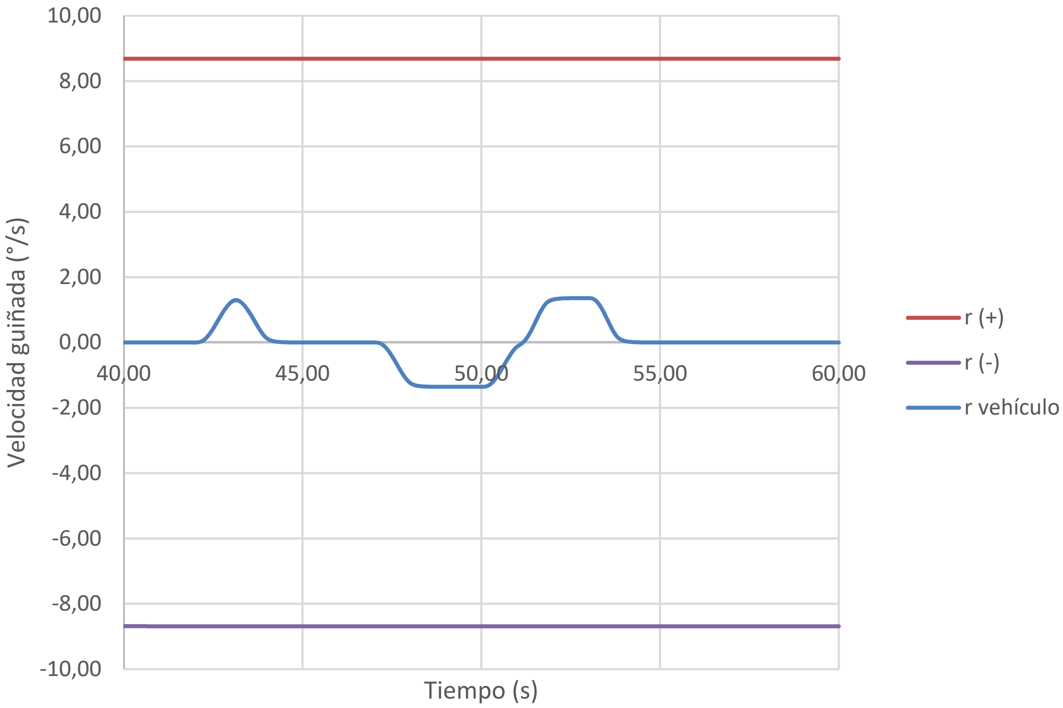

Figura 15: Valor de velocidad de guiñada del vehículo y límites

En el caso del ángulo de deriva que se representa en la Figura 16, ocurre como ocurría en el caso anterior, se tienen valores muy por debajo del límite.

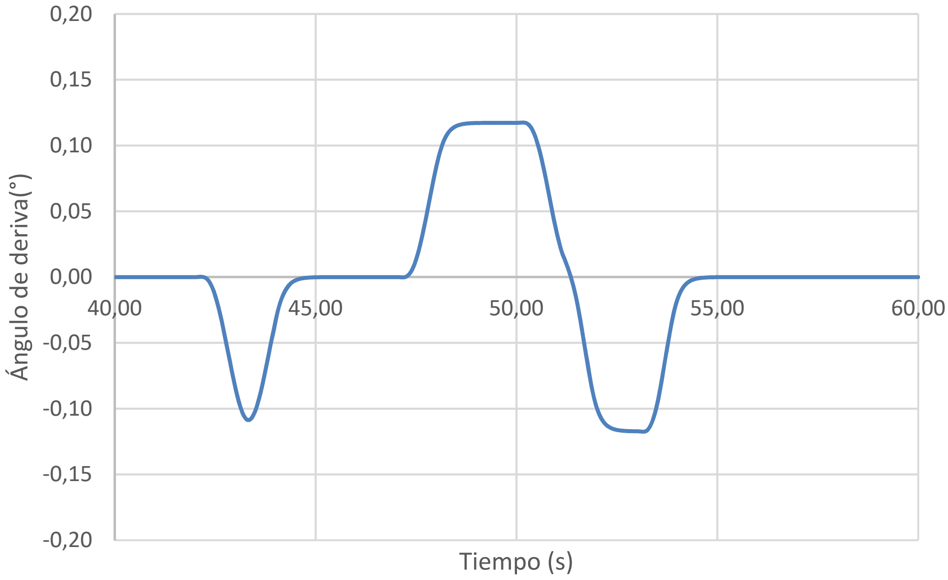

Figura 16: Ángulo de deriva del vehículo y límites

Con estos últimos análisis, se deduce que la maniobra se ha realizado con total seguridad para los conductores.

4. CONCLUSIONES

Se implementa el control para la realización de una maniobra de adelantamiento, en la que prima la seguridad de los pasajeros, ya que se asegura que no se superan los límites que puedan ocasionar lesiones al ser humano.

Los potenciales sobre el vehículo permiten posicionar el vehículo en la carretera y evitar que éste se salga de los límites durante el adelantamiento, cuando vuelve al carril derecho o que colisione con el resto de los vehículos de la vía, ya vayan delante, detrás, o en el carril de la izquierda adelantando, además de guiar al vehículo en todo momento para que la maniobra se realice correctamente.

Las regiones de estabilidad y los límites de sobreaceleración determinan la seguridad con la que se realiza la maniobra, procurando que nunca se sobrepasen los límites del vehículo, atendiendo a cada condición operativa y los límites que los seres humanos somos capaces de soportar.

Al realizarse un adelantamiento progresivo y nada agresivo, se evita el efecto sorpresa sobre el otro conductor y se reduce la posibilidad de accidente. Se controlan los límites de aceleración lateral, que pueden hacer que el vehículo derrape, dando lugar a una situación comprometida incluso para el resto de los usuarios de la vía.

Además, se controla la sobreaceleración que sufren los pasajeros durante la maniobra de adelantamiento mejorando la sensación de confort.

RESUMEN

Las licencias VTC, se definen como vehículos que tienen autorización para "ejercer la actividad de arrendamiento de vehículos con conductor". Su actividad, basada en licencias, es similar a la que desde siempre han empleado los chóferes y las limusinas. Se contrata a través de una aplicación o servicio telemático, sus tarifas no están controladas por la administración y las licencias no son de carácter unipersonal. En España, la regulación de estas licencias es competencia de las comunidades autónomas.

Pese a que la primera aparición de un servicio de estas características en Estados Unidos data de 2009, en la actualidad en Europa se carece de una legislación uniforme en relación con este nuevo modelo peer-to-peer y operan bajo licencias reservadas un servicio de conductor privado cuyos requisitos se alejan de las solicitadas al taxi tradicional para operar. Este nuevo escenario, donde se evidencian las diferencias entre los requisitos y característica del servicio de taxi tradicional ha provocado disconformidad en el sector en España, siendo destacable el caso de Madrid y Barcelona, donde la movilización de los taxistas ha impulsado cambios legislativos.

La cada vez más elevada presencia de estas nuevas plataformas en Andalucía hace necesaria un análisis de la realidad de este servicio en distintos países y ciudades, abarcando su estudio la ordenación del servicio, fiscal o tarifaria y laboral de estas plataformas.
En la comunicación se presentarían:

- Análisis inicial de las diferencias VTC/Taxi
- Legislación existente en materia de taxi y VTC o análogo
- Evaluación de licencias y tarifas en materia de taxi y VTC o análogo
- Análisis comparativo de la información recopilada (Benchmarking)
- Conclusiones y recomendaciones.

1. CONTEXTO

En la actualidad, en España hay 67.089 licencias de taxi y 5.890 de VTC, según datos del Ministerio de Fomento. La normativa reguladora de la actividad desarrollada por el servicio de taxi, establece fuertes restricciones en cuanto al número de licencias, calidad y seguridad en la prestación del servicio, así como en las tarifas a aplicar.

Por el contrario, para las empresas dedicadas a la actividad de arrendamiento con conductor, a nivel estatal, es de aplicación la Ley de Ordenación de los Transportes Terrestres (LOTT), que establece restricciones tanto en el acceso (marca un ratio de una VTC por cada 30 licencias de taxi) como en el ejercicio de la actividad.

Sin embargo, la realidad es que las competencias en esta materia están delegadas en los ayuntamientos, existiendo algunas ciudades donde exceden el límite establecido y colocan el ratio por debajo de lo establecido por la LOTT. Esto es precisamente el origen y causa de la polémica existente y el detonante de los enfrentamientos entre taxistas, conductores de vehículo privados y las administraciones en los últimos tiempos.

3. ANÁLISIS DETALLADO DE ALEMANIA

3.1. Las cifras

Las VTC operan en las tres de las principales ciudades de Alemania, UBER se encuentra en Berlín, Múnich y Düsseldorf, se han establecido otras plataformas como Taxify, pero de manera no continuada.

Actualmente Alemania cuenta con 56.000 licencias de Taxi, 8.161 de ellas en Berlín. No se tienen datos oficiales de número de licencias VTC, debido a que las administraciones no las han hecho públicas, pero se estima que en la capital operan 1.000 licencias de Uber TAXI, estableciendo una ratio aproximada de 1 VTC cada 8 Taxis en la ciudad de Berlín.

3.2. Cómo operan

Uber opera como servicio VTC a través de una app, donde el cliente solicita el servicio previo conocimiento del precio. Esta solicitud se remite a la centralita de la empresa de VTC adscrita a Uber que envía el aviso a los conductores para que realicen el servicio, pues estos deben partir desde la base de la compañía. El cobro se realiza mediante la aplicación.

Respecto a las tarifas son muy similares, si se toma el trayecto desde el Aeropuerto Berlín-Schönefeld hasta el centro de Berlín, la tarifa de UberX va de los 48€ a 55€ y en taxi convencional se mueve entre los 50€ a 56€.

En este caso las VTC están reguladas de manera nacional desde 2016 tras una sentencia de la Audiencia Territorial de Frankfurt que los equipara en gran medida a los taxis, es la normativa más restrictiva de los países europeos en los que opera estas plataformas.

Esta sentencia fundamentaba una serie de prerrogativas para igualar las condiciones del VTC con las del taxi tradicional. Estas se centran en regular el servicio prestado sin incidir en las cuestiones laborales y fiscales.

- Los conductores deben poseer una licencia de transporte de pasajeros para poder prestar servicio en una VTC. Es decir, deben ser conductores profesionales.
- Las empresas que operen con VTC, en consonancia con lo anterior, necesitan de una concesión para el transporte de pasajeros que es regulada por los Estados Federados, similar a las Comunidades Autónomas, que componen Alemania para operar, es decir una autorización para operar como empresa de transporte.
- Esto implica que los, vehículos deben estar dados de alta como vehículos de alquiler y estar asegurados en consecuencia.

El servicio Uber X opera en asociación con empresas de alquiler de vehículos con autorización para el transporte de pasajeros y cuyos conductores tiene la dicha licencia para transportar pasajeros.

La normativa establece como elemento fundamental la precontratación del servicio siendo obligatorio. Esta reserva no realiza directamente al conductor, sino que tiene que ser gestionada por la sede o base de la empresa a la que está adscrito el conductor. Los vehículos deben partir de la base o depósito privado de la empresa. Esto significa que no puede recoger clientes en recorridos de vuelta a la sede. Tienen obligación de volver a la base.

Aun exigiendo el gobierno federal, regulador de las licencias, un registro a las empresas operadoras, la cooperativa de taxistas, Taxi Deutschland, la más grande del país, protesta pues esta condición no es respetada por los conductores de Uber, enlazando unos viajes con otros por lo que piden un endurecimiento de la norma, mayor control y multas.

Del mismo modo, los vehículos están obligados a volver la base o depósito de la empresa a la que pertenecen tras un servicio, evitando de este modo que se mantenga circulando en busca de clientes.

Actualmente Uber opera en el país a través de UberX cuyos servicios se adaptan a la normativa germánica, estando prohibido otros servicios de la compañía como UberPop, que conectaba a particulares que quisieran desplazarse con dueños de vehículos, y UberBlack, la aplicación destinada al contrato de servicios de vehículos de alta gama de la compañía, pues estos no volvían a la base tras el servicio como implica la normativa para vehículos de alquiler con conductor.

3.3. El futuro

A finales de este año, el Ministerio de Transportes alemán ha mostrado su intención de renovar la Ley de Transportes, abriendo la puerta a la coexistencia del servicio de Taxi y VTC. El objetivo principal de esta nueva normativa es adaptar las condiciones marco para el transporte público a las necesidades cambiantes de movilidad de las personas y los nuevos desarrollos tecnológicos.

Algunos puntos del documento de puntos clave del Ministerio de Transportes ya son conocidos; "la mediación digital de los viajes" debe estar sujeta a aprobación, las empresas pueden ofrecer sus propias oportunidades de compartir el viaje a través de aplicaciones si "sustituyen, complementan o consolidan" el clásico servicio regular. Además, las empresas de alquiler de coches tendrían que ofrecer servicios para que varios usuarios pudieran compartir un viaje.

También contempla el servicio directo a pasajeros en la calle, sin precontratación, seguirá siendo un privilegio del sector del taxi. La reforma también prevé que a los municipios se les permite abolir a la obligación de regresar a base impuesta a empresas VTC.

4. CONCLUSIONES

Hay muchas diferencias sobre cómo se hace en los diferentes países de Europa. La incursión de estos servicios se ha realizado en muchos casos bajo figuras normativas en desuso como el alquiler vehículos de transporte con conductor, o limusinas y alquiler de vehículos de lujo, en su mayoría dirigidos a regular un transporte no modal, sino más bien empresarial o “de lujo”. Por lo que en muchos casos la regulación ha llegado tras la puesta en marcha de plataformas como UBER, una vez ya ganado un espacio comercial y modal.

En la mayoría de los países está regulado aunque, por ejemplo, en Rusia, se ha optado por evitado regularizarlo, y en los países escandinavos el servicio se encuentra liberalizado bajo fuertes restricciones. La normativa en su mayoría es estatal aunque en algunos casos como el de Alemania e Italia también delegan cierta competencia a las regiones. Como en España, la normativa existe a nivel municipal en Reino Unido y Rusia.

Las exigencias sobre el operador, la antigüedad de los vehículos y sus condiciones técnicas y otros factores, son muy variadas en todos los casos. Respecto al regreso a las bases es exigida aproximadamente en el 50 % de los países, como el caso descrito de Alemania.

Por último, en la mayoría de los países europeos la pre-contratación no se encuentra regulada, aunque en casos como en Francia y Alemania si se establece su obligatoriedad, pero sin determinar un tiempo previo necesario.

UN NUEVO PARADIGMA DE LA MOVILIDAD: EL AUTOBÚS ELÉCTRICO

RESUMEN

Con respecto al transporte público, uno de los principales pilares de la movilidad urbana actual y futura en nuestras ciudades recae el autobús. Durante los últimos años y con el impulso de las nuevas políticas y leyes, la movilidad eléctrica pública está en auge, gracias al desarrollo tecnológico que ha permitido que la electricidad poco a poco vaya ganando terreno al resto de combustibles.

En efecto, los autobuses eléctricos están llamados a ser una de las principales soluciones de transporte en las ciudades, si bien su implantación está siendo relativamente lenta a excepción de China, donde hoy en día circula el 98% de los autobuses eléctricos del mundo.

Así, son muchas las ciudades que en los últimos años se han interesado por el cambio de su flota y la incorporación de autobuses eléctricos, con el claro objetivo de reducir las emisiones asociadas al transporte urbano. Sin embargo, la transición hacia el mundo eléctrico plantea serias dudas por la inherente novedad de estos nuevos vehículos, los costes de adquisición y mantenimiento, la necesidad de disponer de nuevas infraestructuras de carga, la complejidad técnica de esta nueva tecnología, así como la falta de experiencia con este tipo de autobús.

Bajo este escenario, el presente artículo pretende proporcionar una visión global sobre todos aquellos aspectos que condicionan la transición eléctrica de los autobuses, destacando el gran reto al que se enfrentan las ciudades para desplegar con eficacia amplias flotas de autobuses eléctricos.

1. INTRODUCCIÓN

Durante las últimas décadas, el transporte urbano y metropolitano ha crecido de forma notable, ligado especialmente a la expansión y el crecimiento de las grandes aglomeraciones urbanas. En particular, el crecimiento económico y del empleo en las grandes ciudades supone alrededor del 85% del PIB de la UE, por lo que son el motor del crecimiento económico.

Ahora bien, pese a las mejoras económicas proporcionadas por las ciudades, el bienestar y la calidad del aire han ido disminuyendo de forma drástica, ligado a la dependencia del transporte de los combustibles fósiles. Pese a las mejoras introducidas en los motores de combustión y la aplicación sucesivas normas EURO, el aumento de las emisiones de gases derivados de la combustión en los motores térmicos no ha hecho más que aumentar.

Así pues, en la actualidad en 23 de los 27 países de la UE se superan los estándares de calidad del aire (European Comission, 2016). Con respecto a los autobuses, en Europa son responsables aproximadamente del 0.3% de emisión de Monóxido de Carbono (CO), un 5% de Hidrocarburos (HC), un 9% de Óxidos de Nitrógeno (xNO), un 7.7% de las partículas en suspensión y un 5% de Dióxido de Carbono (CO2).

Si bien en términos generales la contribución de las emisiones de los autobuses urbanos es relativamente reducida, es cierto que es necesario llevar a cabo esfuerzos para mejorar la eficiencia de estos, de la misma forma que están realizando otros vehículos. En particular, las mejoras se fundamentan en tres grandes bloques de medidas: medidas de fomento del cambio modal, el uso racional de los medios de transporte y la renovación de flotas.

En cuanto a las medidas de cambio social y uso racional del vehículo, son numerosas las actuaciones implantadas por las ciudades, con resultados muy diversos. En cuanto a la renovación de flotas, en la actualidad se plantea una gran oportunidad para mejorar la eficiencia: los autobuses eléctricos.

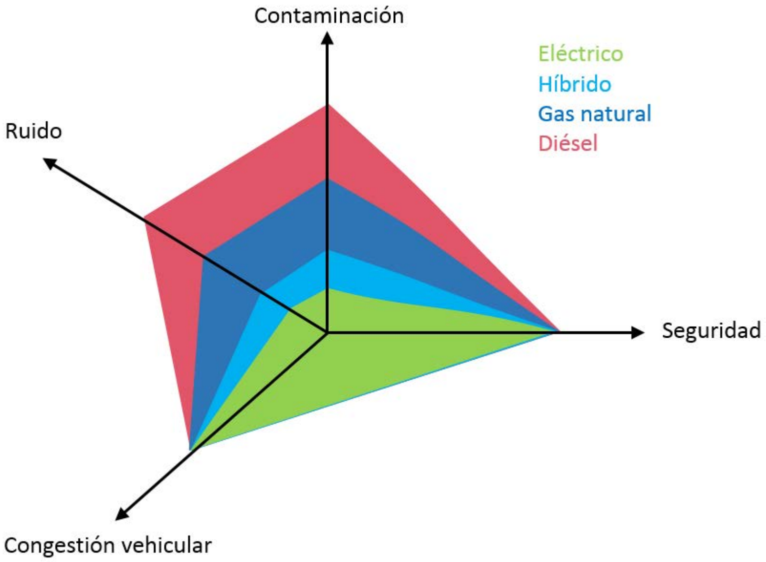

Figura 1: Comparación de los costes externos entre los modelos de buses de transporte público

En efecto, a lo largo del continente europeo son ya muchas las ciudades que están intentando apostar por el estudio, diseño e implantación de líneas de autobuses eléctricos, siendo parte de los programas fomentados por la Agencia Europea de Medio Ambiente.

Por ello, el presente artículo se centra en el estudio de los autobuses eléctricos en cuanto a su viabilidad económica, medioambiental y social que puede tener la utilización de este tipo de autobuses en las ciudades.

2. AUTOBUSES ELÉCTRICOS

En los últimos años la tecnología que sustenta el desarrollo de los autobuses urbanos ha experimentado un cambio notable. En particular, en el año 2019 circularon por las vías urbanas de diferentes ciudades más de 425.000 autobuses eléctricos, de los cuales el 99% está concentrado en diversas ciudades de China. Esto se debe a que, si bien la Unión Europea es una de las regiones punteras en investigación e innovación ecológica, los mayores productores de autobuses eléctricos se encuentran localizados en Asia. No obstante, se trata de un tipo de vehículo que se está adoptando en muchas ciudades europeas, destacando Ámsterdam, Berlín, Milán, o Paris, cuyos objetivos establecen la necesidad de tener toda su flota libre de emisiones para el año 2030.

Si bien existen muchos criterios y condicionantes técnicos, los autobuses eléctricos se caracterizan por ser aquellos vehículos que poseen un funcionamiento 100% eléctrico, al obtener la energía necesaria para realizar su función únicamente a través de motores eléctricos. En la actualidad, tanto los vehículos como las infraestructuras de carga son tecnologías emergentes con un alto grado de diversidad técnica, pero, al mismo tiempo, existe un número limitado de proveedores.

En cuanto a la forma de almacenar la energía, podemos destacar que existen tres grandes sistemas o tecnologías: baterías, catenaria e inducción.

Figura 2: Tecnologías existentes para los autobuses con motores eléctricos

2.1 Baterías

En este tipo de autobuses la energía se encuentra almacenada a bordo por medio de baterías. De esta forma, son la tipología de autobús eléctrico que presenta, a día de hoy, las mayores ventajas para su implantación en las redes de autobús modernas.

Si bien la tecnología de baterías presenta muchas alternativas técnicas, pudiendo clasificarse según el tipo de materiales utilizados y/o los métodos de carga empleados, en este apartado se llevará a cabo una descripción sintetizada con el objetivo de determinar las ventajas e inconvenientes que presentan este tipo de autobuses.

Entrando en materia, los materiales utilizados en las baterías que se instalan en los autobuses eléctricos están formadas, principalmente, por alguno de estos tres elementos: plomo-ácido, níquel y ion-litio. Con respecto a las baterías de plomo (Pb-acid), éstas estas compuestas por cátodo de dióxido de plomo, una placa de plomo como ánodo y un electrolito de ácido sulfúrico diluido. Esta configuración esta contrastada y es barata, siendo posible reciclar la misma al final de su vida útil. Sin embargo, la baja densidad de energía, su elevado peso y los largos tiempos de carga merman sus propiedades.

En cuanto a las baterías de níquel (níquel-cadmio Ni-Cd y níquel-hidruro metálico Ni-MH), poseen una mejor densidad de energía que las de plomo y un mayor número de ciclos de carga. Sin embargo, son poco eficientes en los procesos de carga y descarga y presentan problemas en bajas temperaturas. El impacto ambiental es elevado, por lo que ha llegado a prohibirse las de Ni-Cd.

Por último, la tecnología de baterías que ha facilitado el desarrollo de vehículos eléctricos está basada en el Litio. En este campo existen diferentes modelos, como son las de ion de litio (Li-ion), las de polímero de litio (Li-Po) y las de litio-ferrofosfato (LiFePO4). Este tipo de baterías poseen una alta densidad, poseen un peso ligero y bajo coste, lo que las hace especialmente útiles para su empleo en vehículos como los autobuses. Además, su mayor virtud reside fundamentalmente en la rapidez de carga, pues permite la carga completa en pocos minutos en función del sistema de carga que se emplee.

Tipo de batería	Voltaje nominal (V)	Dens. de energía (Wh/kg)	Poder específico (W/kg)	Ciclo de vida	Coste ($/kWh)	Impacto ambiental
Pb-acid	2.0	35 (baja)	180 (Pesada)	1000	60	Muy elevado
Ni-Cd	1.2	50-80	200	2000	250-300	Muy elevado (cadmio)
Ni-MH	1.2	70-95	200-300	<3000	200-250	Bajo
ZEBRA	2.6	90-120	155	>1200	230-345	Bajo
Li-ion	3.6	118-250	200-430	2000	150	Muy bajo
Li-Po	3.7	130-225	260-450	>1200	150	Muy bajo
LiFePO4	3.2	120	200-4500	>2000	350	Muy bajo
Li-S	2.5	350	-	300	100-150	En desarrollo
Zn-air	1.65	1400	80-140	200	90-120	En desarrollo
Li-air	2.9	1520-2000	-	100	-	En desarrollo

Tabla 1: Resumen de características de baterías para autobuses eléctricos.

Además de los elementos descritos, en la actualidad están desarrollándose otro tipo de baterías con el objetivo de mejorar la carga el rendimiento obtenido. De entre las más destacadas, es posible citar las de litio-azufre (Li-S), las zinc-aire (Zn-air) y las de litio-aire (Li-air). En la Tabla 1 se recogen las principales características de cada una de estas tecnologías.

2.1.1 Métodos de recarga

Tal y como ocurre con otros dispositivos provistos de baterías, tanto la durabilidad como el rendimiento de las mismas está directamente vinculado con la forma en la que se realiza la carga y descarga. Por este motivo, resulta fundamental analizar los procesos de carga realizados actualmente (Young et al., 2013), tal y como se verá en el apartado siguiente.

2.1.2 Autonomía

Una decisión importante y estratégica es la relativa a la autonomía o capacidad de almacenaje de las baterías. En efecto, es fundamental considerar que, para un autobús de 12 m, es posible emplear baterías con un rango de operación de pocos km (unos 50-60 km) hasta baterías con autonomía cercana a los 400-500 km. En realidad, pese a la aparente necesidad de autonomía, la verdadera cuestión se centra no tanto en los kilómetros disponibles con una carga, sino en las oportunidades de carga de la misma a lo largo del itinerario. Este aspecto se debatirá más adelante.

En cuanto a aspectos técnicos, la autonomía de la batería afecta negativamente a la capacidad de los pasajeros, pues a medida que se requiere mayor autonomía aumenta el volumen de la batería, lo que reduce la capacidad para alojar pasajeros, a la vez que aumenta el coste de adquisición y el peso del vehículo. Hay que tener presente que la batería representa, a día de hoy, alrededor del 50% del coste de un autobús eléctrico.

2.2 Catenaria

Este sistema de carga, similar al empleado por los trenes, se basa en el suministro de energía a través de cables suspendidos que se conectan al autobús. Tradicionalmente los vehículos que emplean este tipo de sistema son llamados trolebús. La principal ventaja reside en los costes relativamente reducidos frente al resto de alternativas, pues los componentes y los vehículos son más económicos, además de aligerar el peso de los mismos por no ser necesario el uso de baterías a bordo. Algunos países donde existe este tipo de autobús son: Rusia, República Checa, Eslovaquia, China, Canadá, Ecuador, Argentina, Paraguay, Nueva Zelanda e Italia, entre otros.

Sin embargo, su mayor inconveniente reside en que la ruta es rígida. Si bien es cierto que el uso de una pequeña batería hace que este tipo de autobuses pueda realizar maniobras y pequeños desplazamientos sin el suministro energético proporcionado por los cables. No es tan sencillo modificar un recorrido de forma rápida y sencilla, pues es necesario desplazar los cables que aportan la energía.

Además, existe un cierto impacto visual y una limitación de altura, pues los vehículos que circulan bajo la misma deben respetar un margen de seguridad para evitar problemas.

2.3 Inducción

En cuanto a las tecnologías de inducción, hay que tener presente que los vehículos que usan este sistema poseen baterías, las cuales se cargan mediante la citada inducción. En cierta medida, este sistema únicamente cambia el sistema de carga, pero se sigue manteniendo el dispositivo de almacenaje en el vehículo. La diferencia respecto al sistema convencional de baterías reside, fundamentalmente, en la tecnología y forma en la que se produce la recarga.

En particular, la carga inductiva se lleva a cabo mediante un campo electromagnético generado por unas bobinas situadas en el suelo, capaz de generar un cierto voltaje a otras bobinas alojadas en el autobús y que son las que se encargan de cargar las baterías del vehículo. De esta forma, el proceso de recarga puede ser llevado a cabo en las paradas, en la propia vía por donde circula el vehículo o en depósito.

3. INSTALACIONES DE RECARGA DE BATERÍAS

Analizando las tecnologías de carga existentes, el autobús eléctrico posee 3 opciones claramente diferencias: carga en depósitos, en paradas (de oportunidad) y el cambio de baterías.

Cada una de estas tecnologías tiene distintas implicancias operacionales y requiere una infraestructura particular, lo que resulta en diferencias importantes respecto de la gestión, mantenimiento y operación que habitualmente se lleva a cabo con autobuses convencionales.

En concreto, la programación de horarios, el dimensionamiento de la capacidad de la batería, las estaciones de recarga y los ciclos de conducción deben establecerse en función de las características de los sistemas de recarga establecidos. Así pues, las tecnologías de recarga en depósitos y en paradas parecen ser las tecnologías con mayores beneficios, las cuales se describen a continuación.

3.1 Recarga en depósitos

La terminal de carga está instalada en la cochera donde, en las horas nocturnas donde no hay servicio, los autobuses están conectados a cargadores que recargan las baterías por un periodo e intervalo de tiempo determinado, según el sistema de carga y la batería empleada.

En particular, el tiempo de carga es variable, pudiendo ir desde los 30 minutos hasta las 8-9 horas, pues depende de la capacidad de la batería, el nivel inicial de la misma y la tipología, entre otros aspectos.

En este tipo de modelos los autobuses necesitan instalar unas baterías con gran capacidad, pues es necesario que posean una autonomía suficiente a lo largo del día para cubrir todas las actividades. De lo contrario, pese a que se podría plantear su uso con una menor autonomía, existe el inconveniente de no poder estar circulando durante todas las horas que dura un servicio diario.

A su vez, este tipo de instalaciones requiere un gran espacio y un coste asociado que puede ser importante, así como un complejo sistema de gestión de las baterías.

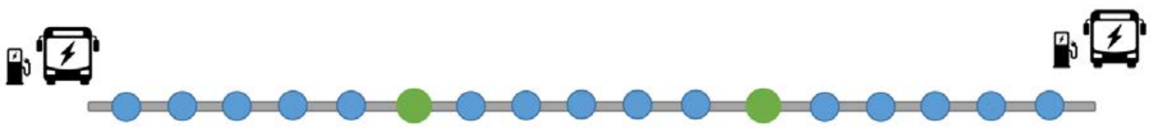

Figura 3: Esquema de recarga en depósitos

3.2 Recarga en paradas

3.2.1 Recarga en cabecera de las paradas

En este caso, los puntos de carga están instalados en tanto en la parada inicial como final de la línea por la que circula el autobús. Este esquema permite una infraestructura de carga mucho más económica respecto a la recarga en paradas, debido a la reducción en el número de cargadores necesarios. A su vez, el proceso de recarga se simplifica puesto que los buses se mantienen en carga durante los tiempos que permanecen en las cabeceras para conceder tiempo de descanso a los conductores, así como también tiempo para regular la línea, en caso de desajuste.

Con este escenario se debe considerar si el tiempo que están los vehículos parados en la cabecera es suficiente para satisfacer la recarga necesaria para mantener la autonomía del autobús a lo largo de su funcionamiento, en función de su consumo eléctrico y de la capacidad de los sistemas de carga considerados.

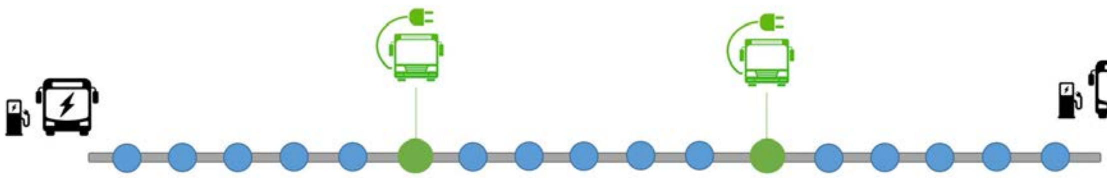

Figura 4: Esquema de recarga en cabecera de paradas

3.2.2 Recarga en paradas intermedias

En este esquema los terminales de carga se localizan en todas las paradas (o gran parte de las mismas) a lo largo del recorrido del autobús. El tiempo de carga es mínimo (tiempo durante subida/bajada de viajeros), por lo que los sistemas de carga deben tener gran capacidad para poder suministrar mucha energía en un corto período de tiempo. Tanto la cantidad de puntos de carga como las necesidades energéticas hacen que este esquema de operación sea de los más costosos frente a las otras alternativas.

Figura 5: Esquema de recarga en paradas intermedias

3.3 Cambio de baterías

Existen varias ciudades chinas donde se han realizado pruebas en estaciones de intercambio de baterías (Beijing, Jinan y Zhengzhou). Para ello los autobuses tienen una capacidad y configuración de batería similar a la de la carga de rápida, pero siendo en este caso reemplazadas por robots que permiten extraer las baterías descargadas y reemplazarlas por baterías cargadas, cuyo proceso implica un tiempo entre los 10 a 20 minutos.

Si bien se han llevado a cabo diferentes pruebas, las estaciones de intercambio de baterías son muy caras, los autobuses deben regresar necesariamente a estas estaciones para efectuar el cambio y los sistemas de intercambio de baterías no están estandarizados, por lo que no parece ser una alternativa que tenga demasiado futuro.

4. CONSUMO ENERGÉTICO

La demanda energética para un autobús eléctrico depende de múltiples factores, como la velocidad, distancia de la ruta, número de pasajeros, temperatura, topografía, calidad de la vía y comportamiento del conductor. En términos generales y según las diferentes pruebas realizadas en distintas ciudades europeas, el consumo para vehículos de 12 m varía entre los 0,7 y 2,8 kWh/km.

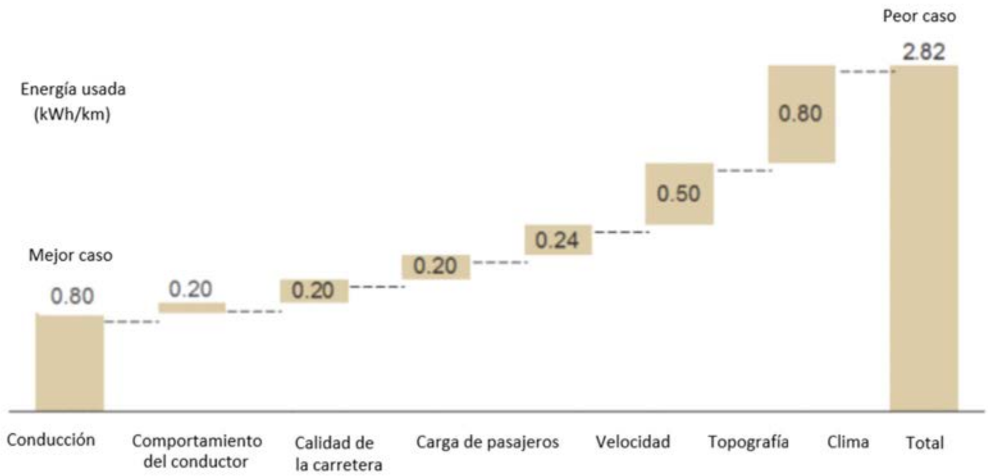

Figura 6: Consumo energético según diferentes aspectos. Fuente: Andersson, M. (2014). Energy storage solutions for electric bus fast charging stations.

En este sentido es importante hacer notar que el rendimiento se hace muy sensible a las condiciones climáticas. Los consumos pueden llegar a ser 50% mayores en temporadas muy cálidas y con alto uso del sistema de aire acondicionado o, por el contrario, en tiempos de mucho frío y un alto uso de calefacción.

Por otro lado, de cara a la explotación hay que tener presente que es altamente recomendable que las baterías funcionen en un rango entre los 15% y el 85% de su capacidad total, con el objetivo de asegurar el buen funcionamiento a lo largo de la vida útil y minimizar la pérdida de la capacidad a medida que aumenta el número de ciclos de carga.

Otro aspecto a considerar son las temperaturas de funcionamiento de las baterías. En efecto, tanto las altas como las bajas temperaturas pueden influenciar tanto el rendimiento como el proceso de carga. En particular, para temperaturas bajas se estima que el rendimiento se reduce alrededor del 10% a 0°C, 20% a -20°C y 25% a -30°C.

Por último, hay que tener presente que los vehículos eléctricos pueden contar con dos tipos de frenado: el mecánico y el eléctrico.

El frenado eléctrico es aquel que se realiza mediante la conexión de una impedancia variable con el generador que está acoplado a la transmisión, obteniendo así una desaceleración paulatina que depende de la velocidad y la posición del pedal de freno. Basa su efecto en actuar como generador cuando el vehículo se encuentra desacelerando, recuperando así la energía cinética desde las ruedas y convirtiéndola en electricidad, mejorando el rendimiento

Por otro lado, sólo para la detención total o para frenados críticos, se utiliza el freno mecánico convencional.

5. ESTRATEGIAS PARA IMPLANTAR LÍNEAS CON AUTOBUSES ELÉCTRICOS

Uno de los grandes retos que enfrenta el uso de autobuses a batería es el montaje y puesta en operación de la infraestructura de recarga de alta potencia necesaria para hacer posible el funcionamiento de una ruta de autobuses electrificada. En este caso abordaremos las particularidades asociadas a una línea de autobús eléctrico con batería, al ser la opción que mayor interés posee en la actualidad.

Es importante hacer notar que los sistemas de transporte masivo que usan energía eléctrica se han de desarrollar simultáneamente con los sistemas de distribución de electricidad. Este aspecto debe ser resuelto para garantizar una adecuada planificación de la expansión y aumento de capacidad de un sistema de transporte, en relación con la generación, distribución y transmisión de energía, minimizando las afectaciones que puedan limitar la capacidad de oferta del servicio de transporte.

Aspectos como la cantidad de estaciones de carga que se necesitan, el número de cargadores, la programación de los períodos de carga para evitar demoras son aspectos a determinar previo a la implantación de este tipo de autobuses.

A su vez, el efecto de una red de autobuses eléctrico en la red de distribución varía según cómo se abastece su demanda, en que puntos de la red, cuando y en qué cantidad se requiere la potencia de abastecimiento, etc. Además, los autobuses eléctricos necesitan transformar la energía eléctrica procedente de la red mediante la conversión de corriente alterna a continua y viceversa, utilizando equipos de electrónica de potencia, rectificadores e inversores.

Otro de los aspectos claves en la explotación de este tipo de autobuses lo constituye la autonomía. En los últimos años, se han reportado en numerosos documentos información sobre el rendimiento de buses híbridos y eléctricos. En efecto, la evaluación de la demanda energética se ha convertido en un requisito previo importante para la planificación y el despliegue de grandes flotas de autobuses eléctricos y la infraestructura de carga requerida.

6. CONCLUSIONES

Los vehículos eléctricos están cobrando una relevancia cada vez más notable en todo el mundo, en gran medida por lo benéficos medioambientales que presentan en cuanto a la reducción de emisiones en las ciudades. En este sentido,

De esta forma, a lo largo del presente artículo se ha puesto de manifiesto los factores y condicionantes respecto a la implantación de líneas de autobús urbano basado en vehículos eléctricos con baterías.

El gran reto al que se enfrentan las ciudades en su transición hacia el mundo eléctrico recae no sólo sobre la infraestructura, sino que debe considerar la forma de operar este nuevo tipo de vehículo, por lo que es necesario explorar las diferentes estrategias de carga para determinar aquella más adecuada según las necesidades de cada ciudad.

En particular, las decisiones que se tomen en los estadios más tempranos dependerá el buen funcionamiento de las futuras líneas urbanas.

Así pues, para garantizar el buen desarrollo e implantación de líneas urbanas eléctricas las ciudades se deben explorar mecanismos innovadores para adquirir y financiar la compra tanto de vehículos como de infraestructuras de carga, así como para garantizar la coordinación de las partes interesadas.

RESUMEN

La introducción de vehículos autónomos (VA) en los próximos años implicará un cambio disruptivo que no sólo va a afectar a la movilidad, sino que podría tener un considerable impacto en las ciudades y el conjunto del territorio.

Los principales efectos esperados se derivan de las oportunidades de regeneración de zonas urbanas previamente asignadas al tráfico y aparcamiento, y su potencial para aumentar la dispersión urbana debido a la mejora de la accesibilidad. En el momento actual estamos en un periodo crítico de transición en el que, para garantizar que su implantación tenga los efectos deseados en las ciudades/territorios, es necesario desarrollar nuevos enfoques de planificación que permitan a las administraciones identificar con suficiente antelación las políticas clave para encajar los nuevos sistemas de transporte y formas de movilidad con la visión que tenemos de las ciudades del futuro.

El objetivo de este artículo es revisar el estado actual de los cambios tecnológicos ligados a los VA, las investigaciones sobre sus implicaciones para el transporte y el desarrollo urbano y, más detalladamente, las recientes aproximaciones de planificación backcasting presentes en la literatura en el marco de los diversos esquemas de construcción de escenarios.

La revisión de estudios que emplean este tipo de planificación, basada en la creación de escenarios ideales y la identificación de medidas y políticas necesarias para alcanzar el futuro deseado, se realiza de manera sistemática mediante una búsqueda de palabras clave en las

principales bases de datos internacionales (WoS, Scopus y Google Scholar), complementada con técnicas de bola de nieve hacia adelante y hacia atrás.

Frente a otros métodos de planificación, la metodología backcasting aplicada a estudios de VA es más novedosa y está comenzando a emplearse con fuerza, si bien solo desde muy recientemente y enfocada sobre todo a su primera fase, consistente en establecer la visión del futuro. Asimismo, los estudios realizados hasta ahora resaltan su carácter más proactivo y más adecuado ante cambios significativos que requieren políticas distintas de las usuales para lograr el escenario de futuro deseado a largo plazo.

1. INTRODUCCIÓN

La introducción de las tecnologías de conducción autónoma es vista como la siguiente revolución que puede producirse tanto en el campo del transporte como en el funcionamiento de las ciudades y los territorios. Históricamente las innovaciones en el campo de la movilidad, del tranvía al coche particular, han tenido un profundo impacto en la forma urbana, permitiendo una extensión de las ciudades más allá de su centro tradicional (Rodríguez, 2020). Por lo tanto, es posible que esta nueva forma de movilidad incentive cambios importantes, tanto en la manera en la que las personas realizan sus desplazamientos cotidianos como en la elección de sus lugares de residencia y trabajo, y que todo ello conlleve importantes transformaciones en la forma urbana.

Los Vehículos Autónomos (VA) no son una hipótesis tecnológica futura, sino que en gran medida son una realidad actual que ya está presente en los *Advanced Driver Assistance Systems* (ADAS) de vehículos convencionales, así como en desarrollos tecnológicamente más complejos como los realizados por empresas como Tesla Inc. o Waymo en Estados Unidos. Los efectos de la automatización y la conectividad del transporte de viajeros y de mercancías pueden ser múltiples, desde impactos más directos en el transporte debidos a incrementos en la capacidad de las infraestructuras o impactos en la reducción de los costes del viaje o en la partición modal de las distintas áreas urbanas, hasta cambios en la estructura y la morfología urbana derivados de nuevas pautas de localización de hogares y empresas o de la reestructuración del espacio físico de las ciudades dedicado al desplazamiento y al estacionamiento de los vehículos (Milakis et al., 2017b).

El hecho de que estos cambios puedan ir en múltiples direcciones y ser muy significativos ha llevado a plantear la necesidad de planificar la implantación de los VA de forma ordenada. Por ello distintos investigadores y expertos han recurrido a métodos de planificación basados en técnicas diversas, entre las que se encuentra, como una de las más destacadas, la metodología conocida como backcasting (Dreborg, 1996). Este método de planificación tiene un fuerte componente normativo, ya que busca definir en primer lugar cuál es el futuro deseado, en este caso del sistema urbano o territorial. Además, la planificación backcasting puede plantear también cuáles serían las políticas más efectivas para alcanzar ese futuro deseado, así como la organización de las mismas en el tiempo, es decir, qué políticas habría que aplicar en las diferentes fases del proceso de planificación (e.g. implementación inicial, consolidación y alcance de la visión deseada).

En el apartado siguiente se revisan las últimas novedades relativas al estado de desarrollo tecnológico de los VA. A continuación, en el apartado 3, se repasan los principales estudios de la literatura especializada sobre los potenciales efectos que estos vehículos podrían tener tanto sobre el transporte como sobre la forma urbana. En el apartado 4 se introducen los enfoques de planificación aplicados a los VA y se analiza especialmente la metodología backcasting, resaltando las fortalezas y debilidades de este tipo de planificación. Finalmente, en el último apartado, se ofrecen las conclusiones obtenidas a partir de los resultados expuestos.

2. ESTADO DEL ARTE SOBRE LA SITUACIÓN ACTUAL DEL DESARROLLO TECNOLÓGICO DE LOS VA

2.1 Desarrollo tecnológico y comercialización

Las primeras predicciones sobre vehículos capaces de conducirse solos se remontan hasta los años 30 del siglo pasado, pero no es hasta principios de los 80 cuando se realizan las primeras investigaciones y experimentos sobre VA (Anderson et al., 2016; Townsend, 2014). Desde ese momento, el grado de automatización en los vehículos ha ido aumentando progresivamente, a medida que han surgido nuevos avances tecnológicos, pero es realmente durante la última década cuando se ha observado una verdadera apuesta por el desarrollo y futura comercialización de los mismos.

En el año 2014, la Sociedad de Ingenieros de Automoción (SAE On-Road Automated Vehicle Standards Committee, 2014) propuso una clasificación sobre los distintos niveles de automatización de los vehículos, denominada J3016, ampliamente aceptada por investigadores, técnicos y fabricantes. En 2018, la SAE actualizó esta clasificación, creando una nueva representación visual para proporcionar nuevos detalles sobre las características de cada uno de los seis niveles de la clasificación. En un primer tramo se encuentran los niveles 0 a 2, en los que el conductor sigue siendo humano, aunque ayudado por sistemas ADAS de asistencia puntual o ante emergencias (nivel 0), de guiado o de control de velocidad de crucero (nivel 1) o de guiado y de control de velocidad de crucero al mismo tiempo (nivel 2). A partir del nivel 3 se produce ya la automatización progresiva en la que el conductor humano no conduce, pero sí puede ser solicitada su intervención en determinadas situaciones (nivel 3), la automatización es completa, aunque sólo en determinados ámbitos y condiciones (nivel 4) y, finalmente, la automatización se produce ya en cualquier tipo de ámbito y condición (nivel 5), incluidas situaciones meteorológicas adversas o entornos urbanos.

En el ámbito de la tecnología de conducción autónoma, tres empresas destacan sobre el resto dado el grado de desarrollo tecnológico y nivel de operación real que han alcanzado. Estas son Waymo (propiedad de Alphabet-Inc./Google), Tesla Inc. y Uber-ATG. Waymo cuenta actualmente con una flota de entre 300 y 400 taxis autónomos operando en varias ciudades del área metropolitana de Phoenix (Arizona) (Hawkins, 2020).

Estos vehículos, que pueden clasificarse en un nivel de automatización según la SAE de entre 3 y 4, pueden ser utilizados por cualquier usuario registrado en su plataforma ofreciendo, por lo tanto, un servicio de taxi autónomo plenamente operativo en condiciones reales, aunque en un área de operación todavía restringida. El sistema requiere que la compañía realice labores de digitalización completa del área en el que van a desplazarse los vehículos mediante tecnología LiDAR. En caso de que surjan dificultades en el desplazamiento de los vehículos, o por la incapacidad de un vehículo para tomar una decisión, un operador humano puede actuar en remoto. La compañía cuenta actualmente con más de 20 millones de millas (32 millones de kilómetros) recorridas en carreteras de EE.UU. (Waymo, 2020).

A diferencia de Waymo, Tesla Inc no actúa como un proveedor de servicios de taxi, sino como un fabricante de vehículos que, entre otras características, tienen capacidad para la conducción autónoma. Los vehículos de Tesla disponen de un sistema para el apoyo a la conducción conocido como Hardware 2 (desde 2016) o Hardware 3 (desde 2019) basado en cámaras, sensores de ultrasonidos y un sistema de radar frontal más económico que el proporcionado por la tecnología de 360 grados de LiDAR. Este sistema permite a los vehículos de Tesla ofrecer ADAS, como el mantenimiento de carril, el control de crucero, al auto-aparcamiento o el reconocimiento automático de las señales de tráfico. El nivel de autonomía alcanzado por los vehículos de Tesla se sitúa entre el 2 y el 3, si bien la compañía asegura que, con la configuración Hardware 3 y nuevas versiones de su software *AutoPilot*, sus vehículos podrán alcanzar los niveles 4 y 5 en pocos años. La compañía ha declarado haber realizado más de 3 billones de millas en las carreteras de EE.UU. mediante el uso de *AutoPilot*, obteniendo información de los usuarios para la mejora del software de Inteligencia Artificial de los vehículos. En materia de seguridad los datos aportados por la empresa registran un accidente por cada 3,45 millones de millas conducidas con *AutoPilot* frente a un accidente cada 1,27 millones de millas en los vehículos conducidos de forma manual y sin medidas de seguridad activas (Tesla Inc, 2020). Sin embargo, hay que tener en cuenta que actualmente el uso del sistema *AutoPilot* de Tesla sólo está autorizado en autopistas, por lo que no es del todo comparable con los datos de conducción manual, ya que estos incluyen también la circulación en carreteras convencionales y en entornos urbanos.

La compañía Uber en su división ATG (*Advanced Technologies Group*) presentó en 2016 su primer servicio de taxis autónomos en el área urbana de Pittsburgh (EE.UU.). El sistema de sensórica de los vehículos Ford estaba basado en 20 cámaras, GPS y un sistema LiDAR (Hook, 2016). En 2017 la compañía empezó a operar en Arizona con nuevos vehículos

Volvo XC90, si bien cada VA sólo estaba autorizado a circular con la presencia de un ingeniero de la empresa en el puesto del conductor como medida de seguridad. Esto no evitó que la compañía tuviera un accidente con un peatón fallecido en 2018. Este y otros factores han provocado que la compañía haya vendido a finales de 2020 su división ATG a la *start-up* Aurora, en la que ha invertido además 400 millones de dólares adicionales (Metz y Conger, 2020).

Aurora no tiene previsto continuar con el desarrollo de taxis autónomos sino de camiones con capacidad autónoma. Por lo tanto, este es uno de los casos más claros de desarrollo tecnológico y comercial en el que la empresa no ha obtenido los resultados esperados por problemas técnicos y legales, por lo que ha preferido la desinversión y reinversión en una compañía externa que le permita acceder a las innovaciones tecnológicas que se vayan produciendo en el campo de la movilidad autónoma, pero asumiendo un menor nivel de riesgo.

2.2 Iniciativas para promover la implantación de VA en España

Aunque a mediados de la pasada década España se sitúo a la vanguardia de los países europeos con la regularización y la realización de una prueba real de conducción autónoma entre Vigo y Madrid (DGT, 2015; Chapela, 2015), el desarrollo tanto tecnológico como legislativo posterior para la implantación de los VA ha sido en general muy escaso, quedando cada vez más alejado de las prácticas internacionales.

Actualmente, España se sitúa en el puesto 22 de 30 del ranking de países que evalúa, mediante un índice global desarrollado por la firma consultora KPMG, la preparación ante la llegada de los VA (KPMG, 2020). Este índice agrupa 28 indicadores en cuatro categorías relativas al desarrollo político y legislativo (puesto 23 de 30), el desarrollo tecnológico y de la innovación (puesto 23), infraestructura (puesto 15) y aceptación del consumidor (puesto 17). Ante esta valoración, el informe recomienda que España incremente el número de iniciativas y pruebas piloto y desarrolle de su ley de movilidad para fomentar la implantación de los VA.

A nivel tecnológico, tanto en Europa como en España se han llevado a cabo proyectos de adecuación de las infraestructuras a la conducción autónoma. Uno de los más relevantes es *C-Roads* (Kernstock, 2019), al que se incorporó España en 2017 invirtiendo 9 millones de euros, junto con 16 países europeos y otros miembros asociados. *C-Roads* pretende acelerar el despliegue de los *C-ITS* (sistemas de transporte inteligente cooperativos) en Europa y en España a partir del desarrollo de múltiples proyectos piloto. En España se han desarrollado 5 de estos proyectos: DGT 3.0 (de escala nacional), SISCOGA Extended (Vigo), Madrid, Cantábrico y Mediterráneo (DGT, 2017). Estos proyectos piloto se centran en el uso de las tecnologías de comunicación Wi-Fi (ITS-G5) y móvil (3G/4G/5G) para la transmisión de información y la coordinación de los vehículos, incluyendo la presencia de VA.

Entre las iniciativas legislativas que se están desarrollando, en julio de 2020 se presentó a consulta pública el anteproyecto de la Ley de Movilidad Sostenible y Financiación del Transporte, que plantea entre sus objetivos de actuación la regulación de la digitalización y automatización del transporte (MITMA, 2020). Así mismo, a finales de 2020 el Gobierno de España firmó un Memorando de Entendimiento con el Gobierno de Francia para mejorar la interoperabilidad y armonizar la normativa entre ambos países en relación a los vehículos autónomos y conectados (Gobierno de España, 2020).

En lo que respecta a la preparación para la llegada de los VA, destaca la falta de actuación de momento desde el ámbito de la planificación regional y urbana, a pesar de las ya numerosas llamadas de atención realizadas desde el ámbito académico (Cohen y Cavoli, 2019; Milakis et al., 2017a; González-González, 2020; Legacy et al., 2018; Nogués et al., 2020; Papa y Ferreira, 2018), hecho que se agrava considerando el horizonte temporal que abarcan dichos planes. Esto es así no solo en el caso de España, sino prácticamente de todos los países, a excepción de algunas alusiones en documentos americanos, principalmente de planificación del transporte (Dupuis et al., 2015; Freemark et al., 2019; Saghir y Sands, 2020). Esto es debido, en gran medida, a la incertidumbre que tienen los decisores políticos sobre el uso y los impactos positivos y negativos que pueden ocasionar tanto en el transporte, como en los usos de suelo y la morfología urbana estos vehículos (Cavoli et al., 2017; Nogués et al., 2020; Saghir y Sands, 2020).

3. EFECTOS DE LA INTRODUCCIÓN DE LOS VA

3.1 Efectos sobre el transporte

El sistema de transporte es el ámbito que se va a ver afectado en primer lugar y de manera más directa y contundente por los VA. Es por ello que la literatura científica se ha centrado en tratar de identificar, valorar y cuantificar estos impactos por encima de otros considerados de segundo o tercer orden (Milakis et al., 2017b). Se prevé que los VA tengan importantes efectos sobre el sistema de transporte que pueden afectar tanto al valor del tiempo de viaje percibido por los usuarios como a las distancias de viaje, así como a la partición modal y a la generación de viajes en general, produciendo potencialmente un gran cambio en cómo los usuarios realizarán sus desplazamientos cotidianos. Dado que los VA aún no están disponibles y no se tienen datos empíricos, los estudios que analizan estos efectos aplican principalmente modelos y simulaciones de tráfico, modelos de elección discreta, generalmente basados en encuestas de preferencias declaradas (PD), así como otras técnicas.

Uno de los efectos más citados y discutidos es si existirá y cuál será la magnitud de un cambio en el valor del tiempo de viaje de los conductores. Si se produce una reducción en el valor del tiempo dentro de los vehículos esto se podría traducir en la posibilidad de que los conductores aceptaran realizar viajes más largos. El estudio de estos potenciales cambios se ha llevado a cabo utilizando diversas técnicas como las encuestas de PD y los modelos de elección discreta (Homem de Almeida Correia et al., 2019; Krueger et al., 2016; Steck et al.

2018) o las técnicas de construcción de escenarios y las estimaciones realizadas por expertos (Milakis et al., 2017a).

Ligado por lo tanto al fenómeno anterior, los estudios generalmente han supuesto que podría producirse un incremento de los kilómetros recorridos por los VA (Soteropoulos et al., 2019). Este tipo de estudios han utilizado modelos de simulación del transporte basados en agentes (Fagnant y Kockelman, 2014) o en actividades (Childress et al., 2015) para ofrecer sus estimaciones.

Especialmente relevante es el hecho de si se considera o no que los VA serán utilizados de forma compartida en el viaje (VAC). En este caso, y si un número significativo de viajes fueran realizados en VAC, si bien los vehículos presentes en la carretera se podrían reducir muy significativamente, el número total de kilómetros recorridos por éstos podría aumentar dada la producción de viajes en vacío y la captación de viajes desde otros modos.

El efecto que los VA y los VAC tendrán sobre otros modos de transporte es por lo tanto un tema abierto y crucial para conocer sus efectos desde el punto de vista de la sostenibilidad.

El método más utilizado para estudiar los posibles cambios en la partición modal ha sido la recolección de datos mediante encuestas de PD que permiten la estimación de modelos con los que simular las cuotas de mercado de los modos tradicionales y de los nuevos modos autónomos en diferentes escenarios. Existe el debate de si los VA, y sobre todo los VAC, pueden ser una gran competencia para el transporte público tradicional y para los modos activos (Ashkrof et al., 2019), algo que podría ser muy negativo desde el punto de vista de la movilidad sostenible e incluso de la salud pública.

Por otro lado, la generación de viajes en coche puede verse afectada por dos efectos contrapuestos. Por un lado, los VA pueden suponer, dada su habilidad para la detección de otros vehículos y el movimiento coordinado, un aumento de la capacidad de las infraestructuras de transporte. Este tipo de efectos de incrementos de capacidad han sido simulados, considerando distintos niveles de penetración de mercado de los VA, mediante modelos de tráfico (Shladover et al., 2012; Liu et al., 2018). Sin embargo, estos aumentos de capacidad, y consiguientes disminuciones en los tiempos de viaje derivados de una menor congestión, podrían ser contrarrestados por una mayor demanda inducida de viajes. Este fenómeno ha sido simulado estimando la elasticidad de la generación de viajes a los cambios en la accesibilidad y calculando cómo podría variar ésta con los nuevos tiempos de viaje más reducidos que implicaría la existencia de los VA (Meyer et al., 2017).

Otro aspecto analizado que podría influir en el tráfico es el relacionado con el aparcamiento. Diversos autores como Fagnant y Kockelman (2014), Martínez y Viegas (2017) y Zhang et al. (2015) han estimado mediante simulación que hasta el 90% de las plazas de aparcamiento en áreas urbanas podrían ser eliminadas si se contara con una oferta suficiente de VAC que eviten tiempos de espera elevados. Pero no sólo se eliminarían, sino que la distribución espacial de los mismos cambiaría. Según Zhang y Guhathakurta (2017) la existencia de tarifas por aparcar en el área urbana central podría cambiar la demanda de los aparcamientos, relocalizándola desde el centro urbano a los barrios residenciales periféricos y especialmente a aquellos con menor nivel de ingresos, donde el precio por aparcar sería gratuito.

Obviamente este sería un efecto problemático, ya que esto podría generar distancias de viaje más largas, mayor congestión y mayor gasto energético.

Millard-Ball (2019) microsimuló también efectos similares, observando que los usuarios podrán hacer que sus vehículos aparquen en localidades más alejadas, o que incluso no aparquen, provocando la generación de más tráfico y congestión a la espera de que su usuario vuelva a querer desplazarse. Además, las políticas de creación de mayor oferta de aparcamiento gratuito en las periferias podrían incrementar aún más este problema. El autor propone en cambio aprovechar la llegada de los VA a las ciudades para introducir una tarificación doble: por utilizar la vía para circular y por distancia de viaje, con el objetivo de internalizar las externalidades generadas por los vehículos.

3.2 Efectos sobre la forma urbana

Los estudios sobre los efectos que podrían tener, directa e indirectamente, los VA en la forma urbana han sido más escasos, si bien comienza a producirse cierto consenso en sus resultados. Estos estudios han usado técnicas como la construcción de escenarios y herramientas de simulación para obtener previsiones realistas de estos efectos, partiendo de supuestos sobre cuáles serán las características predominantes de la movilidad autónoma en el futuro. Los efectos estudiados pueden agruparse en dos grandes bloques (Heinrichs, 2016): cambios en la localización de la población, las actividades urbanas y la atractividad de los distintos vecindarios, y liberación de espacios hasta ahora ocupados en el desplazamiento o estacionamiento de los vehículos.

Como se ha citado en el apartado anterior, los VA pueden tener un fuerte impacto en el valor del tiempo asignado por los usuarios a sus desplazamientos y, por lo tanto, podrían verse incrementadas las longitudes de viaje con el consiguiente aumento de la accesibilidad de barrios o localidades periféricas hasta ahora menos atractivas para residir. Esto ha hecho plantearse a algunos autores que los VA podrían potenciar aún más los procesos de localización dispersa, tanto de la población como de las actividades económicas, especialmente en las ciudades de mayor tamaño (Childress et al., 2015; Soteropoulos et al., 2019). Esto podría ser un problema para la sostenibilidad futura de las áreas urbanas, dadas las implicaciones negativas que tienen los desarrollos urbanos dispersos basados en la movilidad en coche (Hennig et al., 2016).

Una de las primeras aproximaciones a las visiones de los impactos de los VA en los entornos urbanos fue planteada por Townsend (2014). Este autor se basó en la creación de cuatro visiones arquetípicas mediante el método de futuros alternativos: crecimiento o expansión de las tendencias actuales; colapso, en el que las condiciones actuales se deterioran y algunos sistemas críticos fallan; restricción, que limita el crecimiento en función de los recursos; y transformación, un cambio disruptivo que alcance un futuro basado en la innovación. En atención a los impactos esperados en los usos de suelo y el transporte, Townsend apuntó a que la automatización del transporte de viajeros llevaría a una renovada expansión urbana (*sprawl*), y a una consolidación de las llamadas ciudad de borde (*edge city*) en el escenario de crecimiento.

En el escenario de colapso se esperaría un incremento generalizado y desmesurado de la congestión, con un aumento de la movilidad a demanda, y disminución de la vitalidad y espacio de las zonas peatonales. En el caso del escenario de restricción, se podría esperar un sistema basado en autobuses autónomos regionales que consolidaran los suburbios cercanos a los centros urbanos existentes, mientras en el caso del escenario de transformación, los cambios en la propiedad y el auge de los medios digitales y la innovación conllevaría a una densificación de las ciudades, basada en desarrollos residenciales de pequeño tamaño, ciudades con más servicios y actividades, y desplazamientos cortos, en los que la movilidad peatonal y en bicicleta serían protagonistas.

El cambio de los patrones de localización en las áreas urbanas ha sido analizado por otros autores mediante métodos basados en técnicas de simulación para realizar estimaciones. Thakur et al. (2016) utilizaron un modelo de interacción entre el transporte y los usos del suelo (modelo LUTI) para estudiar las implicaciones de los VA en el Gran Melbourne. Esto lo realizaron mediante la simulación de cuatro escenarios en los que se combinaba la reducción del valor del tiempo con la presencia de *ridesharing* (trayectos compartidos). Así, la reducción del valor del tiempo implicó en las simulaciones un incremento claro de las longitudes de viaje y un menor uso del transporte público, con pérdida de población en el centro urbano en favor de localizaciones más periféricas. En cambio, una mayor importancia de la movilidad mediante *ridesharing* tuvo un efecto opuesto, menores kilómetros recorridos por los vehículos y un incremento de la población en el centro urbano. La combinación de los dos efectos al mismo tiempo tuvo efectos similares a este último escenario, pero más moderados. Por lo tanto, parece que los servicios de *ridesharing* podrían compensar los efectos de mayor dispersión urbana y mayor uso del coche de los escenarios con VA de uso privado.

Siguiendo una línea similar a la anterior, Zakharenko (2016) desarrolló un modelo de elección de ubicación basado en la teoría de la economía urbana para una ciudad idealizada bidimensional monocéntrica de forma semicircular, que calibró para una ciudad típica representativa de Estados Unidos. Este modelo asumió que los trabajadores podían elegir entre no desplazarse, desplazarse en vehículos tradicionales y desplazarse en vehículo autónomo teniendo en cuenta los costes fijos, variables y de estacionamiento de cada alternativa. Según los resultados, con la introducción de VA alrededor del 97% de la demanda diaria de estacionamiento se trasladaría a un cinturón de aparcamiento exclusivo en la periferia urbana.

Esto, a su vez, liberaría terrenos para otros usos y tendría un impacto positivo en la densidad de la actividad económica en el centro de la ciudad, impulsando las rentas del suelo. Por otra parte, la reducción de los costes de transporte debido a los VA aumentaría las distancias de viaje y haría que la ciudad expandiera su superficie en más de un 7% y los alquileres de los terrenos disminuyesen aproximadamente un 40% fuera del centro de la ciudad.

Milakis et al. (2017b) consideraron los cambios potenciales en la forma urbana asociados a la introducción de la conducción autónoma como impactos de segundo orden, basándose en el concepto de efecto dominó. Su estudio de revisión, realizado a partir de una búsqueda de la literatura científica en las principales bases de datos internacionales, resalta la escasa atención prestada a este tema. Para estos autores, los VA podrían tener un impacto tanto en la escala espacial macro (regional) como en la micro (local). A nivel regional, la mejora de la accesibilidad general derivada del menor coste del transporte, unida a la mejora de la accesibilidad individual debido a la posibilidad de las personas sin acceso a un automóvil de viajar en VA, podría incidir en la ubicación de la población y actividades incrementando los procesos de periurbanización y el desarrollo de nuevos centros. A nivel local, los VA podría transformar el paisaje urbano. La reducción de la demanda de estacionamiento fuera de la vía pública podría traer cambios en el uso del suelo (desarrollos residenciales, comerciales, espacios verdes, etc.) y en el diseño de los edificios (es decir, carriles de acceso, jardinería), facilitando nuevos desarrollos para usos del suelo más amigables para las personas.

Otros autores como Riggs et al. (2019) han proporcionado evidencia de que la tecnología autónoma puede tener diferentes impactos en distintas áreas de las ciudades como el centro, los suburbios o los bordes rurales. Los autores documentaron un taller realizado en julio de 2017 en el Simposio de vehículos autónomos (AVS 2017), en el que estudiaron los posibles cambios en el entorno construido en dos contextos urbanos diferentes: una ubicación suburbana de tranvía de los años 1920-1930 y una ubicación suburbana de posguerra de los años 1970 más periférica, ambas localizadas en Portland, Oregón, aunque los sitios estaban destinados a representar condiciones típicas en los Estados Unidos. Para evaluar los escenarios utilizaron un método de *charrette*, un proceso participativo en el que los expertos llevan a cabo una serie de diálogos con la comunidad para consensuar soluciones. Los resultados ofrecen información sobre cómo la tecnología autónoma tendría potencialmente diferentes impactos en los usos del suelo, el diseño del espacio público, la densidad urbana, la localización de la población y las actividades según la tipología de espacio urbano. Los resultados también revelan que los VA pueden afectar las decisiones modales de manera diferente según la ubicación, y cómo los responsables de la planificación urbana pueden formular soluciones de diseño y políticas de entorno construido para promover un urbanismo sostenible y habitable.

Otro trabajo interesante es el de Maia y Meyboom (2018), en el que también se analizaron los efectos de los VA en la ciudad a partir de la creación de escenarios posibles formados en base a la metodología de *Scenario learning*. Para ello, plantearon una serie de fases que comienzan con la identificación de los factores y fuerzas principales que pueden guiar la implantación de los VA y su clasificación en atención al nivel de incertidumbre y al nivel de impacto que pueden tener en el proceso. Una vez clasificados los factores se identificaron las relaciones de dependencia entre ellos para posteriormente establecer la construcción de 4 escenarios en función del cruce ortogonal entre los dos conjuntos de factores más relevantes, esto es, más inciertos y con mayor impacto.

En este caso se seleccionaron "regulación y fuerzas del entorno urbano", que distingue entre apoyar el transporte público frente a apoyar los VA y "fuerzas de mercado y de estilo de vida", que distingue entre una adopción rápida (progresivo) y una adopción lenta (conservador) de las nuevas tecnologías. En el caso de regular para apoyar los VA en un contexto progresivo, el principal impacto sería la dispersión urbana, en contraste con la apuesta por el transporte público en un contexto progresivo, que haría menos atractivos los nuevos desarrollos urbanos por su escasez de servicios públicos y liberalizaría espacios en los centros urbanos.

Estos estudios a un nivel macro sobre cambios en la localización de la población y las actividades que podrían ser incentivados por el funcionamiento de los VA, se han complementado con estudios a nivel más micro sobre los impactos en los usos del suelo. El efecto más examinado es la posible liberación de espacios en los centros urbanos debido a cambios en la localización y número de los espacios de aparcamiento. Como se ha comentado anteriormente, las simulaciones realizadas apuntan a una posible eliminación de hasta el 90% de las plazas de aparcamiento en áreas urbanas implicando una cantidad importante de superficie liberada. Duarte y Ratti (2018) llevaron a cabo la revisión de una serie de estudios sobre liberación de espacios destinados a parking, señalando que en ciudades como Melbourne y Los Ángeles las plazas de aparcamiento suponen una superficie equivalente al 76-81% del área del centro urbano. Esto se traduciría en cerca de 567.000 ha. liberadas para 2040 en el conjunto de EE.UU., según un informe de la Asociación del Plan Regional de la región metropolitana de Nueva York (RPA, 2017). Estos espacios podrían reconvertirse, por ejemplo, en zonas verdes, equipamientos o viviendas asequibles.

Además, esta liberación de espacio de estacionamiento podría ser aún mayor gracias a la optimización del mismo, esto es, debido al rediseño de los espacios de aparcamiento que permitiría la automatización. Nourinejad et al. (2018) realizaron estimaciones a este respecto, considerando la reducción del espacio destinado a apertura de puertas, eliminación de pasillos, etc., lo que podría suponer una reducción media de entre un 62% y un 87% del espacio requerido actualmente.

La liberación de espacio ofrece por lo tanto una gran oportunidad para la recualificación de zonas urbanas y la configuración de centros urbanos más densos y con mayores estándares de calidad. Milakis et al. (2017b) también revisan estos aspectos, y señalan que en los espacios previamente asignados al aparcamiento y circulación de los vehículos podrían ejecutarse nuevos desarrollos residenciales, comerciales y recreativos, o bien este espacio extra podría convertirse en carriles para vehículos de transporte público o usos que faciliten la movilidad activa, por ejemplo, espacios verdes, aceras más amplias o carriles bici. El impacto de la optimización del aparcamiento puede ser aún mayor en las zonas céntricas, donde edificios de garajes y plazas de aparcamiento podrían reconvertirse a otros usos, dando lugar a zonas céntricas más dinámicas.

Duarte y Ratti (2018) señalan que los garajes en edificios privados podrían convertirse en usos productivos como el comercio minorista y usos más nobles, desde viviendas sociales a espacios públicos, como los 51 *parklets* creados en San Francisco desde 2010, a los que han seguido muchos otros en todo el mundo. Según Sousa et al. (2018) si el espacio antes destinado a los coches se utilizase para construir carriles bici de calidad, cabría esperar un aumento del uso de la bicicleta, descongestionando las calles y atrayendo a la gente al centro de las ciudades.

Por tanto, los efectos de los VA en el transporte y el desarrollo urbano no van a depender tanto de la tecnología y el nivel de automatización de los vehículos sino sobre todo de la regulación de esta tecnología y de la gobernanza de las ciudades y regiones (Stead y Vaddadi, 2019). Es por ello, que resulta imprescindible definir claramente los objetivos de las ciudades y optar por enfoques de planificación proactivos para lograr los futuros deseados (Cohen y Cavoli, 2019; Legacy et al., 2018; González-González et al., 2020; Papa y Ferreira, 2018).

4. NUEVOS ENFOQUES DE PLANIFICACIÓN

4.1 Técnicas de planificación basadas en escenarios

Dentro del conjunto de técnicas que pueden emplearse en el campo de la planificación urbana y del transporte, la construcción de escenarios es una de las más conocidas, dada la necesidad de construir descripciones de un futuro posible y probable para plantear distintas líneas de actuación en el presente. Börjeson et al. (2006) clasificaron las técnicas de construcción de escenarios en tres grupos principales: predictivas, exploratorias y normativas. Estos tres tipos de técnicas responden a tres posibles preguntas sobre el futuro en un determinado campo de planificación: qué pasará en el futuro, qué podría pasar y cómo llegar a un objetivo deseado. Así, las técnicas predictivas buscan seleccionar el escenario más probable que ocurrirá en el futuro, bien dada la tendencia actual del sistema estudiado (escenario *Business-as-Usual*), bien ante un cambio de política o la ocurrencia de un evento especificado (escenarios *What-if*). Este tipo de predicciones suelen realizarse en el marco de algún tipo de modelo formal que intenta replicar las características fundamentales del funcionamiento y equilibrio del sistema estudiado.

Las técnicas exploratorias en cambio están basadas en la construcción sistemática de escenarios que pueden ocurrir plausiblemente en el futuro, aunque sea incierto si van a producirse realmente. La construcción de escenarios se realiza habitualmente construyendo una matriz estructurada en torno a los principales factores que se considera podrán ser claves en la evolución del sistema en el futuro (Schwartz, 2012). Este tipo de técnica permite que los planificadores tengan en cuenta distintos factores y situaciones que podrían presentarse aceptando la incertidumbre asociada al futuro. Además, los escenarios pueden generarse en función tanto de factores externos, fuera del control de la planificación, como de factores internos, describiendo el rango de las posibles consecuencias que implica actuar sobre elementos estratégicos.

Finalmente, el método de construcción de escenarios de tipo normativo descansa en la idea de alcanzar un objetivo o un conjunto de objetivos deseados. Alcanzar este escenario deseado puede implicar la aplicación de toda una serie de políticas que simplemente ajusten la situación de partida (*preserving scenarios*) o bien, si se considera que el escenario deseado no es alcanzable bajo las circunstancias actuales, de otro conjunto de políticas que contribuyan a cambiar estructuralmente el sistema estudiado (*transforming scenarios*).

Es en este segundo caso en el que se encuadra el enfoque conocido como backcasting o planificación retrospectiva, en el que se diagnostica como necesario un cambio de tendencia en el sistema estudiado que la aplicación de las políticas derivadas del ejercicio de planificación ayudará a alcanzar.

El enfoque backcasting se aplica cada vez más en los estudios de futuro en los campos relacionados con la planificación urbana (Carlsson-Kanyama et al., 2003; Phdungsilp, 2011; Bibri y Krogstie, 2017) y del transporte (Åkerman y Höjer, 2006; Banister et al., 2000; Höjer et al., 2000; Hickman y Banister, 2014; Soria-Lara y Banister, 2017). Esto se debe a que se considera un método especialmente adecuado cuando se esperan cambios disruptivos -aunque no se refieran específicamente a los VA-, que requieren una modificación drástica de las políticas a implementar.

Dentro de la metodología backcasting pueden diferenciarse a su vez distintas formas de aplicación. Según los principales agentes implicados, el contenido de la planificación puede ser establecida por grupos multidisciplinares de investigadores (*think-tank*), por expertos (*expert-led backcasting*) o mediante consultas (*participatory o collaborative backcasting*), ya sea a expertos, grupos de interés y ciudadanos en general (Doyle y Davies, 2013; Robinson et al., 2011).

Si se tiene en cuenta el foco principal del proceso de planificación puede distinguirse, de acuerdo con Wangel (2011), entre la planificación backcasting orientada al objetivo final del escenario deseado (*target-oriented*), la planificación centrada en los medios requeridos para alcanzar ese objetivo (*pathway-oriented*) y la basada en establecer los agentes y grupos de interés que pueden llevar a cabo las acciones identificadas para alcanzar el objetivo (*action-oriented*). Además, según Wangel (2011), de 21 investigaciones backcasting revisadas por el autor, la mayoría fueron *target-oriented* o *pathway-oriented*, mientras que la planificación *action-oriented* ha estado menos presente en la literatura.

En cuanto a su estructura, la metodología backcasting puede descomponerse en una serie de fases. Según los casos de aplicación, algunos autores han aplicado una metodología en tres fases, mientras que otros han utilizado un proceso algo más detallado en cinco fases. Soria-Lara y Banister (2017) han propuesto diferenciar tres fases a la hora de aplicar la planificación backcasting.

La fase de *Visioning* o de definición de la imagen futura deseada, la fase de *Policy Packaging*, de identificación de las políticas y su organización temporal en paquetes de política que pueden conducir a esa imagen deseada, y la fase de *Appraisal* o de evaluación de las políticas para intentar prever su efectividad, aceptación social y potenciales problemas de implementación. Otros autores como Quist et al. (2006) han propuesto en cambio diferenciar cinco fases en la metodología, incluyendo una fase preliminar en la que se establecerían los objetivos de la planificación, y una fase final de monitorización de la aplicación de las políticas que se han derivado del proceso.

4.2 El uso del backcasting en la planificación sobre vehículos autónomos

En este apartado se examina el contenido de los estudios recientes elaborados en el periodo 2000-2020 que emplean enfoques de tipo backcasting en el campo de la movilidad y, más concretamente, de los VA. Los estudios analizados proceden de dos fuentes principales: documentos y publicaciones académicas en revistas científicas, actas de congresos y libros; e informes de organismos públicos. Los estudios se identificaron mediante una búsqueda en la Web of Science (WoS), Scopus y Google Scholar (GS) utilizando combinaciones de la palabra backcasting con las palabras clave: autonomous vehicles, autonomous mobility, automated transport, self-driving car, driverless car y mobility on-demand, complementados con técnicas de bola de nieve hacia adelante y hacia atrás.

En total, se identificaron 15 fuentes bibliográficas que aunaban las palabras seleccionadas. Dado que el objetivo del estudio se centra en la aplicación del backcasting se desecharon 2 referencias que tratan por un lado la revisión bibliográfica de estudios sobre la elaboración de escenarios futuros para analizar los impactos de los VA en los patrones de desarrollo urbano y la forma urbana (Stead y Vaddadi, 2019), y por otro la idoneidad de distintos métodos de planificación para implantar políticas que regulen los VA (Li et al., 2019). Finalmente se seleccionaron 13 fuentes para su examen en el presente estudio (Tabla 1). En la WoS se identificaron 7 documentos, mientras que la búsqueda en GS arrojó resultados en su mayor parte repetidos, encontrándose 5 artículos adicionales. En Scopus se localizaron los mismos documentos que en los buscadores anteriores. Por último, se encontró 1 artículo más mediante la metodología bola de nieve.

Como puede verse en la Tabla 1, la mayor parte de los documentos encontrados, 10 de los 13 (77%), se centran en la primera de las fases del backcasting, el *visioning*, y 5 presentan la segunda de las fases, *policy packaging* and *pathway*, ya sea bien de manera individual bien conjuntamente con el *visioning*. Finalmente, sólo un documento se enfoca específicamente en la fase final de evaluación, *appraisal*. Esta distribución se corresponde además con el desarrollo temporal de los trabajos, apareciendo las últimas fases del backcasting en los documentos más recientes.

Documento	Buscador y palabras clave	Fase de backcasting	Tipo de backcasting
Marchau y van der Heijden (2003)	WoS: B + AT	Visioning	Participatory
Chapin et al. (2016)	Citado por Stead y Vaddadi (2019)	Visioning	Participatory
Vaddadi (2017)	GS: B + AV	Visioning	Think-tank
Papa y Ferreira (2018)	GS: B + ATV	Visioning (critical decisions)	Think-tank
Höltl et al. (2018)	WoS: B + AT	Visioning	Think-tank
Karlsson y Fredriksson (2019)	GS: B + AV	Visioning + Policy packaging	Mixed: Think-tank + Participatory
Dragomanovits et al. (2020)	GS: B + AV	Forecasting+ Backcasting: Policy packaging	Think-tank + Expert-lead

Staricco et al. (2020)	WoS: B + AV GS: B + AV	Visioning + Policy packaging	Mixed: Think-tank + Participatory

Tabla 1: Publicaciones que aplican backcasting para planificar un futuro con vehículos autónomos

* Palabras clave: backcasting (B), autonomous vehicles (AV), autonomous mobility (AM), automated transport (AT), automated vehicles (ATV), self-driving car (S), driverless car (D)

La mayor parte de los estudios de *visioning*, 8 de los 10 (80%), emplearon un backcasting de tipo *think-tank*, es decir, las decisiones fueron tomadas por los propios grupos de investigación. Solo 2 de los casos de esta fase fueron participativos.

En los casos en los que se trata la segunda fase de *policy packaging*, o identificación y organización de las políticas, la mayor parte de los estudios emplea el enfoque participativo (3 de 5). Los estudios de políticas que no utilizaron la participación emplearon una aproximación de tipo *think-tank* o mixta *think-tank* con *expert-lead* (expertos).

Por último, el estudio que realiza la tercera fase de *appraisal* se basa en un proceso participativo *o participatory backcasting*. Es de destacar que todos los estudios que optan por la participación realizan consultas a expertos y grupos de interés, obviando de momento la consulta pública a la ciudadanía.

La primera aportación identificada es la correspondiente a Marchau y van der Heijden (2003). Estos autores realizaron un trabajo pionero de planificación mediante backcasting aplicado al caso de los sistemas de *Automated Vehicle Guidance* (AVG), que se podrían asimilar al concepto más actual de VA, en los que se automatiza la aceleración, el frenado y la dirección de los vehículos. Para ello aplicaron una metodología organizada en tres grandes pasos. En primer lugar, la construcción de diferentes conceptos de AVG utilizando *morphological analysis*.

En segundo lugar, el estudio de las condiciones de implementación de los conceptos de AVG propuestos mediante la aplicación del método Delphi, para lo que recurrieron a 117 expertos de los cuales 40 completaron hasta la tercera ronda de respuestas.

Por último, realizaron una evaluación mediante preferencias declaradas a 485 conductores y poseedores de una flota de coches sobre si los conceptos propuestos podrían ser realmente llevados a cabo. Este proceso permitió a los autores eliminar todos los sistemas de AVG que fueron considerados implausibles, poco prometedores o que no presentaron una aceptación, seleccionando únicamente los que fueron considerados como más viables.

Sin embargo, no es hasta casi 15 años más tarde cuando comienzan realmente a aparecer nuevos estudios e informes que tratan de visualizar y planificar la llegada de los VA. Chapin et al. (2016) se plantearon cómo podría tener que adaptarse el espacio urbano a las nuevas necesidades creadas por los VA.

Para desarrollar su informe realizaron una sesión participativa de *visioning* en Florida sobre los posibles impactos en ámbitos como cambios en los sentidos de las calles, gestión de puntos de subida/bajada de viajeros, cambios en los espacios de aparcamiento, cambios en la señalización, convivencia con los modos activos e incluso posibilidades abiertas para la regeneración urbana.

Para ello se consideraron dos escenarios temporales: uno con una implantación parcial de los VA (2040) y otro con una implantación total (2060). Los resultados obtenidos permitieron a los autores recomendar ciertos pasos para preparar a las ciudades para la implantación de los VA, tales como incorporarlos en el diseño de la red vial, establecer estándares para el tamaño y localización de puntos de subida y bajada de viajeros, identificar oportunidades para el desarrollo de antiguos espacios de aparcamiento y repensar los diseños de las intersecciones de forma que fuesen seguras para los peatones y ciclistas y admitiesen el uso de los VA.

Vaddadi (2017) se realizó una pregunta similar en el desarrollo de su trabajo de máster, en el que propuso distintos escenarios de aplicación a la ciudad de Ámsterdam. Para ello planteó un backcasting que desarrolla dos escenarios con un horizonte de 2040, considerando un alto uso compartido de los VA (*car on demand*) frente a un uso privado individual mayoritario (*luxury driving*).

Estableció entonces 4 fases temporales para aplicar las herramientas o medidas necesarias de planificación y propuso un conjunto de 7 guías de planificación que comprenden la cooperación de las autoridades de transporte público y empresas de desarrollo de los VA, regulación del uso de calzadas y tasas a aparcamientos, incentivos para el desarrollo de la economía compartida y políticas para promover la colaboración público-privada entre otras.

Además de ello, planteó una serie de 6 conceptos o guías de diseño urbano para llevar a cabo los cambios deseados consistentes en espacios flexibles, tecnológicamente amigables, reconversión de los aparcamientos en la calle (batería o línea) como nuevos pequeños espacios verdes o de múltiples actividades (*street parklets*), coexistencia de distintos modos de transporte de manera segura, reordenación de calles y cambio de la finalidad de los actuales grandes aparcamientos en superficie.

Papa y Ferreira (2018) utilizaron la metodología backcasting en una aproximación combinada con la metodología exploratoria para analizar las posibles consecuencias de los VA sobre la accesibilidad. La definición de escenarios futuros, uno optimista y otro pesimista, se realizó mediante la técnica exploratoria mientras el backcasting fue empleado para la identificación de decisiones críticas en relación a las medidas políticas y de planificación a implementar.

Las decisiones críticas encontradas por estos autores hacen alusión al uso compartido de los VA, el apoyo al transporte público, la sostenibilidad ambiental, los sistemas de información de redes, la cooperación autónoma, las políticas de usos de suelo y de aparcamiento, la regulación de tráficos intermodales, el diseño de la red de transporte, la exclusión social o la gestión de datos. Como conclusión del estudio los autores afirmaron que es necesario analizar qué ciudades y regiones pueden ser más vulnerables para la aparición de escenarios futuros no deseados y estudiar cómo evitar estos escenarios, para lo que hacen hincapié en el papel fundamental de la planificación para guiar el proceso de implantación de los VA.

Höltl et al. (2018) utilizaron la metodología backcasting también en el contexto de planificación del transporte, aunque sin tratar específicamente el tema de los vehículos autónomos, sino considerando éstos como uno de los posibles avances tecnológicos en el horizonte temporal contemplado, el 2050. El objetivo de su estudio era definir una hoja de ruta (*pathways*) que permitiera alcanzar la reducción de un 60% en las emisiones de Gases de Efecto Invernadero (GEI) planificadas en el Libro Blanco del Transporte (European Commission, 2011).

Los autores crearon un escenario de referencia y tres escenarios adicionales en los que se cumplía el objetivo de reducción de emisiones en base a dos factores: la velocidad de la transición en el ámbito de la tecnología del automóvil (más rápida o más lenta) y el tipo de posesión de coche (prevalencia de la posesión y uso del coche de forma privada o transición hacía la multimodalidad). De su estudio se deriva que los VA pueden tener un impacto positivo y colaborar, junto con la electrificación de los vehículos y las reducciones de emisiones por kilómetro recorrido, en alcanzar los objetivos fijados de emisiones de GEI para 2050.

Otro estudio relativo a la planificación backcasting del transporte es el realizado por Karlsson y Fredrikson (2019). Este estudio explora la afección de los VA en el transporte de pasajeros en el entorno urbano utilizando entrevistas semi-estructuradas para definir las condiciones del futuro sostenible, las brechas existentes entre la realidad actual y el futuro deseado y las acciones y estrategias que podrían ayudar a alcanzarlo. Entre estas acciones los expertos consultados identificaron como especialmente relevante la creación de incentivos para potenciar los modos de transporte compartidos sobre el uso privado de los VA. Por ello los autores propusieron utilizar la metodología de *Design Thinking* para la creación de una plataforma de taxi compartido que permitiera dar pasos hacia el futuro deseado mediante la reducción de la posesión de coche.

Dragomanovits et al. (2020) presentaron recientemente el primer avance del desarrollo de una herramienta online de toma de decisiones sobre la implantación de los VA con el objetivo de servir de ayuda a técnicos y autoridades municipales, regionales y nacionales. Esta herramienta se estructura en dos módulos, uno de conocimiento previo y otro de estimación. El primero de ellos funcionaría como repositorio en el que se puede consultar bibliografía sobre impactos clasificados en tres grupos principales: impactos directos, impactos sistémicos e impactos más amplios, así como resultados de proyectos aplicados en las ciudades participantes en el proyecto de desarrollo de la herramienta. El segundo módulo se estructura a su vez en un subsistema que sería capaz de realizar estimaciones *forecasting* para diversos escenarios considerando diferentes parámetros de entrada, y otro subsistema backcasting que, a partir de la selección de objetivos políticos, sería capaz de proponer las intervenciones que podrían conducir a una visión deseada.

A partir de 2019 nos encontramos con el trabajo de dos grupos de investigación que tratan las distintas fases del backcasting en publicaciones sucesivas. Por un lado, las publicaciones de González-González et al. (2019, 2020) y Nogués et al. (2020) abordaron las tres fases principales del backcasting, considerando el análisis de los posibles impactos urbanos de los VA para identificar los objetivos a perseguir, las medidas a implementar para guiar la implantación de los VA y su evaluación. La primera de las aportaciones identificó los objetivos de planificación fundamentales que han de perseguir las ciudades del futuro en atención a los principales documentos y agendas internacionales y comparó estos objetivos con los potenciales impactos descritos en la literatura científica.

De este modo se identificaron las oportunidades y amenazas que los VA pueden introducir para alcanzar ciudades atractivas, saludables y sostenibles, ofreciendo una primera aproximación a los objetivos de las políticas de planificación necesarias y a las medidas para alcanzarlos, como la apuesta por la mixticidad de usos, la limitación del acceso a vehículos motorizados en ciertas zonas del centro de las ciudades, y la adopción de sistemas de transporte multimodal, compartido y de gran calidad.

La segunda aportación se centró en la identificación del escenario deseado y las decisiones y medidas de planificación más relevantes para la implantación de los VA en los entornos urbanos. Para ello, se identificaron las dos decisiones estratégicas que sirven de base para la creación de cuatro escenarios de *visioning* futuros: la apuesta por la movilidad compartida y la necesidad de limitar el acceso motorizado a zonas céntricas de la ciudad.

Con el fin de lograr el escenario más favorable los autores establecieron, desde la revisión bibliográfica, una serie de medidas de planificación que se ordenaron y clasificaron en ocho paquetes de políticas (*policy packages*) y tres fases temporales (*policy paths*), desde la actualidad hasta el horizonte temporal de 2050. Estas fases se corresponden con una primera transición segura y compartida, enfocada a la convivencia temporal de los VA y los vehículos convencionales, una segunda fase centrada en la promoción de la movilidad compartida y activa, y una última fase, nombrada reconquista urbana, que aboga por mejorar el entorno urbano redefiniendo los espacios y usos de manera que los ciudadanos vuelvan a ser los protagonistas de la ciudad.

En la última de las aportaciones de este grupo (Nogués et al., 2020) se evaluaron los impactos potenciales de los VA y las políticas/paquetes de políticas que podrían ser más efectivas para alcanzar un escenario de ciudad deseada. Para ello se realizó una encuesta que fue distribuida a un panel de 55 expertos de los ámbitos de la planificación urbana, territorial y del transporte. Los resultados obtenidos mostraron escepticismo sobre los impactos positivos de los VA frente a una mayor confianza en los potenciales efectos negativos, tales como el aumento de los viajes realizados en coche y la dispersión urbana.

De las políticas propuestas, los encuestados consideraron más efectivas para paliar estos efectos y conducir al escenario preferido la potenciación de los modos de movilidad activa y el transporte público, la restricción del acceso de los modos motorizados a las áreas urbanas centrales y el aprovechamiento de los posibles espacios liberados por los vehículos convencionales para otros usos, como la mejora de las zonas verdes y los equipamientos. Además, la mayor parte de los expertos consultados consideraron que los paquetes de política planteados podían ser efectivos o muy efectivos para alcanzar el escenario deseado, a excepción de las medidas para combatir la dispersión. Estos resultados permiten conocer la efectividad de determinadas políticas de cara a futuras actuaciones y ayuda a los responsables de la planificación a establecer medidas para controlar procesos no deseados.

Por otro lado, los trabajos de Staricco et al. (2019, 2020) y Vitale Brovarone et al. (2019) trataron dos de las fases del backcasting participativo en el caso concreto de la ciudad de Turín. Las primeras aportaciones del 2019 relataron la aplicación de la fase de *visioning*, estableciendo tres escenarios en los que se evaluaron los impactos que pueden ocasionar distintas regulaciones de la circulación y el aparcamiento de los VA en la sostenibilidad y habitabilidad de la ciudad. Con la ayuda de un grupo focal formado por 7 expertos y entrevistas a 44 representantes locales (*stakeholders*) se realizó la evaluación y validación de las visiones a 2050 desarrolladas por el equipo de investigación para elegir la más recomendable. El resultado de la consulta fue -a pesar de considerarlo poco verosímil para Italia, pero sí para países nórdicos (Vitale Brovarone et al., 2019)- la recomendación del tercer escenario de fuerte regulación de los VA, en el que se restringe el acceso de VA privados a vías secundarias en zonas residenciales, promoviendo el uso de vehículos compartidos, transporte público, y especialmente los modos activos como prioritarios en estos entornos, y en el que se propone el uso de aparcamientos multinivel cercanos a las principales vías y a las afueras de las zonas residenciales. Uno de los aspectos identificados por los autores como relevantes para estudios futuros fue la escala de análisis, afirmando que sería oportuno analizar entornos metropolitanos más amplios que solamente la ciudad, con el fin de analizar otros impactos como la dispersión urbana, así como el uso de modelos LUTI que simulen las relaciones del sistema de transporte con la localización de las actividades (Staricco et al., 2019).

El documento de 2020 presentó una evaluación de las dos fases de *visioning* y *policy packaging* llevadas a cabo durante la investigación en Turín, identificando los principales retos y puntos críticos encontrados en el proceso. La fase de *policy packaging* se desarrolló, al igual que la de *visioning* explicada anteriormente, utilizando una combinación de metodologías *think-tank* y participativa. Al mismo tiempo que se consultó a los expertos mediante entrevistas sobre la visión más recomendable, se les requirió que identificaran las posibles medidas de planificación para alcanzar esta visión. De esta consulta el equipo de investigación propuso una lista de 18 medidas que fueron posteriormente debatidas en una jornada de trabajo con 8 expertos locales, resultando finalmente un total de 33 acciones clave. Estas acciones se agruparon en atención a seis temas y fueron clasificadas según tres categorías principales: política, tecnología y transformación del espacio urbano, indicando además los principales actores involucrados y la década de implementación.

Uno de los principales retos del proceso, señalado por los participantes del mismo, fue la gran incertidumbre que todavía existe respecto al horizonte temporal de la implantación de los VA, la aparición conjunta de otras innovaciones del transporte, como el transporte aéreo, y de nuevos modelos de explotación del mismo, como los sistemas MaaS y el uso compartido. Esta problemática parece que puede ser reducida con el uso mixto del procedimiento *think-tank* y el participativo, que ayudó a restringir todas las incertidumbres generadas en los participantes. Esta combinación también fue útil para contrarrestar la complicada definición de las fases de implantación de las políticas.

En este mismo contexto, la organización de las medidas de planificación en fases fue más sencilla cuando se referenció a periodos temporales intermedios (Staricco et al., 2020). Otro de los aspectos críticos fue la contextualización de la visión, en lo que respecta a la evolución socioeconómica, territorial y ambiental de la zona, que están muy interrelacionadas entre sí y con el sistema de transporte.

Para resolver este reto el estudio planteó utilizar las condiciones socioeconómicas definidas en un documento de planificación ya aprobado, el plan de transporte de la región. Por último, la voluntad y disponibilidad de los expertos locales a participar en el estudio también condiciona enormemente el procedimiento, así como el escaso o excesivo conocimiento sobre el tema. Para lidiar con esta problemática los investigadores emplearon diversas técnicas que permiten intercambiar estos conocimientos entre los participantes.

5. CONCLUSIONES

En esta ponencia se ha abordado la situación actual del desarrollo tecnológico de los VA y cómo su evolución plantea un escenario en el que estos vehículos podrían estar operativos en las ciudades en un plazo de tiempo relativamente corto. Los avances se están produciendo muy deprisa y los países se esfuerzan por impulsar su implantación, aunque con distinto grado de implicación. Desafortunadamente, España está perdiendo el empuje inicial y corre el riesgo de quedarse rezagada respecto a otros países occidentales.

Se espera que la automatización, según se ha expuesto en apartados anteriores, tenga efectos potenciales diversos y de distinto signo y magnitud, tanto sobre el transporte como sobre la forma urbana. Muchas de las investigaciones tienden a dedicar más atención a los impactos positivos y a escala local; no obstante, los impactos dependerán de la forma en la que los VA sean utilizados, así como de la implementación de políticas clave en materia regulatoria y fiscal, entre otras.

Una cuestión en la que los estudios hacen hincapié es en el papel fundamental de la planificación para encauzar con antelación la llegada de los VA y guiar su proceso de implantación. Sin embargo, fuera de la esfera académica e investigadora no existen todavía planes en la práctica de la planificación.

Desde el ámbito de la investigación, el elevado grado de incertidumbre de los cambios asociados a la conducción autónoma ha llevado a los investigadores, de acuerdo con la literatura académica examinada en esta ponencia, a plantear nuevos enfoques de planificación. En este trabajo se han expuesto los diversos métodos de planificación de escenarios y se han revisado más detalladamente aquellos estudios que se han centrado en la planificación de tipo backcasting, un método de planificación proactivo más novedoso y adecuado ante escenarios disruptivos que requieren cambios drásticos en las políticas para lograr el futuro deseado a largo plazo.

Esta revisión ha partido de una recopilación exhaustiva de artículos científicos en los principales buscadores de información, considerando el periodo 2000-2020, complementada con la técnica de bola de nieve.

Esta búsqueda ha permitido detectar las investigaciones que han utilizado el método de planificación backcasting, así como caracterizar la forma en que la han aplicado, si la han complementado con otros métodos alternativos y qué puntos fuertes y débiles presenta esta línea de investigación en su conjunto.

De la revisión bibliográfica realizada puede señalarse que hasta la fecha se han llevado a cabo escasos estudios sobre este tema, si bien en los últimos años han experimentado un notable crecimiento. La mayor parte de las investigaciones detectadas se han centrado en la fase de definición de la imagen futura deseada, con un menor desarrollo de la fase de propuesta de políticas y de paquetes de política que permitan dar pasos hacía la visión deseada, y una sola aportación en el caso de la fase de evaluación de la efectividad y problemática asociadas a estas políticas.

Respecto a los agentes implicados en el proceso de planificación, en la mayoría de los estudios las decisiones fueron tomadas por los propios investigadores o bien se basaron en la consulta a expertos y grupos de interés.

Dado que las visiones de futuro y las propuestas y evaluación de políticas, especialmente si son realizadas por expertos, pueden no ser lo suficientemente imaginativas, algunos investigadores destacan la necesidad de incorporar también la opinión de los ciudadanos, ya que además de que pueden proporcionar ideas más inesperadas, ayuda a que todos los interesados se pongan de acuerdo sobre las decisiones y pasos a seguir en el proceso.

Finalmente puede concluirse que las metodologías backcasting aplicadas hasta el momento son variadas, no existiendo un procedimiento plenamente consolidado y aceptado. Algunas investigaciones combinan el método backcasting con técnicas de construcción de escenarios y otras técnicas complementarias aplicadas a la planificación.

De cara al futuro se requerirán nuevas investigaciones que combinen la estrategia creada, mediante una planificación de tipo backcasting o mediante otros métodos, con técnicas de evaluación, ya sean basadas en simulación o en conocimiento experto, que permitan realizar estimaciones realistas sobre qué efectos es previsible obtener.

Además, también será necesario el uso de herramientas de monitorización y seguimiento de la estrategia diseñada para determinar de forma continua si se están produciendo los resultados esperados de impulso a ciudades y territorios más deseables y sostenibles.

AGRADECIMIENTOS

La presente investigación se ha desarrollado dentro del proyecto “Formas innovadoras de planificación urbana y del transporte ante los nuevos sistemas de movilidad basados en la conducción autónoma” - AUTONOMOUS, 2020-2023, financiado por el Ministerio de Ciencia e Innovación (MICINN) / ERDF (EU) en el marco del Plan Estatal de Investigación Científica y Técnica y de Innovación 2017-2020 (referencia PID2019-110355RB-I00); así como del proyecto “Movilidad compartida autónoma para las ciudades habitables del mañana” - MOVI-CITY, 2019-2020, desarrollado en el marco de la Convocatoria de la Universidad de Cantabria financiada por la Consejería de Universidades e Investigación, Medio Ambiente y Política Social del Gobierno de Cantabria.

RESUMEN

El cambio climático y el desarrollo sostenible son actualmente materias prioritarias en las agendas de todos los países y organizaciones mundiales. Dado que el transporte -y principalmente el vehículo privado- es uno de los sectores más contaminantes, la mejora de su eficiencia ambiental se ha convertido en un objetivo de máxima relevancia. En esta línea, los avances tecnológicos apuntan hacia nuevos modos entre los cuales el vehículo autónomo (VA) presenta un enorme potencial.

Este artículo hace una revisión de la literatura científica existente sobre los efectos ambientales derivados de la irrupción de los VA. Para ello se utilizan las herramientas Scopus y WoS, estableciendo categorías de búsqueda según los medios físicos que pueden verse afectados (aire, suelo…). La revisión no solamente se centra en las emisiones, el campo más explorado, sino que amplía el foco a los cambios en los usos del suelo y sus implicaciones, y a la contaminación acústica y lumínica, con el objetivo de adquirir una perspectiva más general que la conseguida hasta ahora.

Los artículos analizados presentan enfoques diferentes, aunque principalmente centrados en tres aspectos: consumos y emisiones en diferentes escenarios, hábitos del consumidor frente a las posibilidades de uso e interrelaciones con el resto de sistemas de transporte. Las estrategias y planteamientos para obtener resultados son también heterogéneos. Así, el análisis de emisiones se suele basar en modelos matemáticos con resultados variables, aunque en general se observa que la mayor eficiencia en la conducción favorecida por las comunicaciones vehículo a todo (V2X) conlleva ahorros energéticos y reducción de emisiones, amplificadas si se opta por la movilidad compartida.

No obstante, otros estudios indican que las prioridades de los usuarios pueden llevar a escenarios donde, al maximizarse el beneficio individual, se produzcan efectos ambientales negativos, lo que conduce a la necesidad de establecer una planificación que permita dar pasos hacia el modelo de desarrollo deseado.

1. INTRODUCCIÓN

En 2015 había casi 1.300 millones de vehículos en uso en todo el mundo, de los cuales casi 1.000 millones correspondían a vehículos de pasajeros (OICA, 2020), cifra que puede duplicarse para finales de la década de 2020 o principios de la década de 2030 según los parámetros actuales (Sperling y Gordon, 2009). Esto hace que el vehículo privado (incluyendo todos los tipos: turismos, SUV, pequeñas furgonetas, etc.) suponga aproximadamente el 60% de las emisiones de los gases de efecto invernadero (GEI) dentro del sector del transporte, que es a su vez el mayor contaminante dentro de todos los sectores económicos ya que emite casi 2.000 millones de toneladas de CO_2 equivalente a la atmósfera por año, es decir, casi un 30% de las emisiones totales en el caso de EE.UU. (US Environmental Protection Agency, 2020).

Con el objetivo de alcanzar una economía sin emisiones, el reto de conseguir un sector del transporte sostenible ambientalmente tiene gran importancia en la agenda de la mayoría de las organizaciones nacionales e internacionales. Actualmente, el estudio del transporte sostenible como parte del más amplio concepto de desarrollo sostenible es objeto de gran atención por parte de investigadores y agentes políticos y económicos (Zhao et al., 2020). La UE tiene como objetivo reducir las emisiones del sector del transporte en un 60% para el año 2050 con respecto a datos de 1990 (European Commission, 2011).

En este contexto, el vehículo autónomo muestra un gran potencial gracias a su circulación más eficiente con vehículos más ligeros, seguros y eléctricos, además de favorecer la adopción de la movilidad compartida. Aunque estos potenciales beneficios sean sustanciales, su uso puede generar unos importantes riesgos y desafíos que deben ser gestionados para que tales beneficios sean efectivos (Legacy et al., 2018).Teniendo en cuenta que el 70% de los GEI se emiten desde las ciudades (IEA, 2016), parece evidente que afrontar el objetivo de reducción de emisiones debe considerar la dualidad vehículo privado-ciudad.

La tecnología que permitiría alcanzar el grado de autonomía necesario para influir positivamente en el medio ambiente está todavía en desarrollo. En general, se considera que el máximo beneficio se conseguirá, entre otros factores, con el grado de automatización 5 según el estándar comúnmente aceptado. Este estándar considera 6 niveles, desde la nula automatización (nivel 0) hasta la completa automatización (nivel 5) con la que el vehículo es capaz de operar en cualquier condición ambiental o estado de la infraestructura (SAE, 2018).

Las estimaciones que diferentes autores hacen sobre la disponibilidad de esta tecnología son muy variables, en general alrededor de 2030, considerando que serán necesarios 10 o 20 años más para conseguir un escenario con una mayoría de vehículos autónomos (Milakis et al., 2017a; Hörl et al., 2016). Independientemente de la aceptación de una nueva tecnología por los consumidores, si se considera el ratio de sustitución de la flota de vehículos de pasajeros en la UE-28 del 5,6% (ICCT, 2018), no sería factible un alto grado de presencia de vehículos autónomos (VAs) en las carreteras antes de 25 años.

Algunas proyecciones económicas consideran que el vehículo autónomo y los servicios de movilidad generarán una cifra de negocio de 7 trillones de USD (5,9 billones de euros) para 2050, más que el PIB en 2017 de Japón y Brasil combinados (Lanctot, 2017), lo que supone un importante incentivo para su desarrollo. Incidiendo en su potencial, Greenwald y Kornhauser (2019) proponen una serie de motivos por los que el vehículo autónomo puede suponer una gran oportunidad de mejora para la sociedad: 1,3 millones de víctimas anuales en accidentes en el mundo, 600 billones de horas de conducción al año con una ocupación de asientos muy baja, vehículos detenidos el 96% del tiempo, el estrés que provoca la conducción, las posibilidades comerciales, las posibilidades para complementarse con los servicios de transporte público, etc. En definitiva, la consideración de las calzadas como recursos públicos limitados cuyo uso debe ser optimizado y para lo cual deben ser tenidas en cuenta las preferencias de los usuarios, muchas veces contradictorias, como la decisión antieconómica de mantener el vehículo privado y usar servicios de movilidad bajo demanda (los conocidos en España como Vehículos de Transporte con Conductor o VTC).

Debido a todas estas oportunidades y capacidades para modificar el transporte en el futuro, se está desarrollando una gran cantidad de literatura científica sobre los vehículos autónomos. De hecho, el vehículo autónomo en general es uno de los temas con una mayor atención dentro de la literatura científica hoy en día, con un ritmo de publicación de artículos creciendo por encima del 30% anual cuando la media en la literatura científica está en el entorno del 8-9% (Marçal el al., 2019). Entre toda la literatura que se genera al respecto, los estudios sobre los impactos ambientales, aunque escasos aún, empiezan a tener más presencia por la importancia de la reducción de emisiones a nivel global que podrían implicar.

En general, la literatura científica cuando estudia las repercusiones en el medio ambiente de los vehículos autónomos se centra en el consumo energético y las emisiones de GEI, analizando el vehículo autónomo individualmente, en grupo, como flotas de vehículos o como medio de transporte genérico integrado en el sistema general de transporte. Milakis et al. (2017b) identifican el consumo energético y la polución atmosférica como un efecto de tercer orden en el modelo “ripple effect” adaptado a la conducción autónoma. En ese modelo, los efectos de primer orden serían los producidos sobre el propio tráfico, el coste de viaje y la selección del modo de transporte. En el segundo orden se sitúan los efectos sobre el vehículo en propiedad, los usos del suelo y las infraestructuras.

En el tercer nivel se sitúan los efectos ambientales, la seguridad vial, la economía y la igualdad social y la salud pública. Wadud et al. (2016) identifican una serie de factores con efectos ambientales positivos –eco-driving (conducción eficiente), platooning (agrupación de vehículos circulando en fila), reducción de las congestiones, menor aceleración/frenado, disminución de accidentes, movilidad compartida y ajustes de diseño gracias a los sistemas de seguridad– y negativos –aumento de la velocidad en autopistas, incremento de peso debido a elementos de confort y entretenimiento, reducción del coste del tiempo de viaje que implica más kilómetros recorridos y acceso de nuevos usuarios.

Hay diferentes aproximaciones para estudiar los efectos del transporte en el medio ambiente que se pueden particularizar para el caso concreto de los vehículos autónomos. Taiebat et al. (2018) definen cuatro niveles de estudio: nivel "vehículo": funcionamiento, diseño, electrificación, platooning; nivel "sistema de transporte": coste del viaje, servicios de movilidad, usos, congestión, capacidad; nivel "sistema urbano": implicaciones en las infraestructuras, VAs y sistema de producción de energía, usos del suelo; y nivel "sociedad": cambio en las costumbres de viajar, usos compartidos y cambios en otros sectores. Por otro lado, según Dean et al. (2019) la gran mayoría de estudios se interesan directamente en la eficiencia energética, las emisiones y las implicaciones por kilómetros recorridos por vehículo (VKT) y muestran menor interés en el estudio del ciclo completo de vida o la contaminación acústica.

Los cambios en el uso del suelo, punto que está recibiendo creciente atención en los estudios recientes por los posibles efectos tanto positivos –liberación de espacio urbano– como negativos –dispersión urbana–, tienen gran repercusión ambiental. En ese sentido, Wilson y Chakraborty (2013) agrupan los efectos ambientales de la dispersión urbana, en "aire": pérdida de la calidad del aire, efecto isla de calor, olas de calor extremo; "energía": emisiones; "suelo": pérdida de suelo agrícola, pérdida de terreno natural y de hábitat; "agua": inundaciones, exceso de consumo de agua y restricciones de suministro, equilibrio hidrológico y pérdida del agua de lluvia.

También Bicer y Dincer (2018) identifican siete efectos ambientales derivados de los vehículos a lo largo de su ciclo completo de vida: agotamiento de recursos abióticos, acidificación, eutrofización, calentamiento global, toxicidad en humanos, reducción de la capa de ozono y toxicidad del suelo. Muchos de estos factores no se están teniendo en cuenta en la cuantificación de los impactos medioambientales de la implantación de los vehículos autónomos.

Por el momento no hay muchas revisiones con un punto de vista holístico sobre los impactos ambientales del vehículo autónomo. Sí hay artículos que hacen cierto compendio de la literatura publicada pero dentro de un análisis más amplio del "estado de la cuestión".

Dentro de aquellos que hacen una revisión concreta, Kopelias et al. (2020) analizan dos tipos de estudios desarrollados entre 2008 y 2019: estimaciones en base a propuestas lógicas sobre cómo los VAs y VEs (vehículos eléctricos) modificarán el consumo de combustible y las emisiones, y modelos matemáticos que utilizan distintos datos de entrada para obtener resultados sobre distintos escenarios simulados.

La conclusión es que el medio ambiente se ve afectado directa o indirectamente por 11 factores: vehículos eléctricos/combustibles alternativos; diseño y tamaño del vehículo; platooning; eco-driving; selección de ruta óptima; reducción de las congestiones de tráfico; kilómetros recorridos por vehículo; movilidad bajo demanda o compartida; nivel de penetración en el mercado; uso por población sin posibilidad de conducir y la predisposición del consumidor hacia el modo de transporte.

Autores como F. Liu et al. (2019) también analizan 12 grupos de datos para evaluar consumo y emisiones con alguna ligera variación respecto al anterior ya que, además de agrupar o detallar algunos de los conceptos antes indicados, incorpora otros como el ratio de sustitución de vehículos, la posible circulación a mayor velocidad y la reducción de accidentes.

Como se puede ver, algunos de los factores enumerados dependerán de la aceptación por parte del usuario. En ese sentido, Whittle et al. (2019) integran los resultados de una serie de entrevistas con expertos en transporte junto con un análisis de literatura existente para analizar qué influye en la toma de decisiones de los usuarios, que a su vez tendrá que ver con el nivel de penetración en el mercado del vehículo autónomo y si el vehículo será mayoritariamente usado de manera compartida o no.

Proponen grupos de factores relacionados con la demografía (como el poder adquisitivo), la motivación (la autonomía), los hábitos y las normas sociales y el acceso y la predisposición hacia el transporte público.

Con una visión más general, Martínez-Díaz et al. (2019) proponen un análisis amplio sobre todos los efectos de los VAs aunque no exactamente basado en una revisión sistemática de la literatura existente. En general identifican los mismos factores ya mencionados, como por ejemplo: aspectos tecnológicos, movilidad compartida, demanda, seguridad vial, aceptación social, etc. Sin embargo, mencionan dos aspectos que no aparecen citados anteriormente, el impacto territorial y las consideraciones éticas y legales.

Las implicaciones legales quedarían fuera de los efectos medioambientales de los VAs pero no así el impacto territorial, que puede hacer evolucionar la nueva movilidad hacia un escenario más sostenible o hacia uno opuesto y más contaminante (Nogués et al., 2020).

2. METODOLOGÍA

La revisión de la literatura existente sobre las implicaciones ambientales de la implantación del vehículo autónomo se llevó a cabo a partir de los buscadores Scopus y Web of Science.

Dado que un primer resultado sobre vehículos autónomos arrojó decenas de miles de referencias, fue necesario filtrar la búsqueda mediante palabras clave. Para ello se utilizó un primer bloque de palabras con las que habitualmente se hace referencia al vehículo autónomo en la literatura científica, al que se añadieron una serie de palabras para definir más la búsqueda según los parámetros del estudio. En el cuadro siguiente se incluyen las palabras clave generales utilizadas.

“Automated” OR “Autonomous” OR “Self-driving” OR “Driverless”
AND
Vehicle(s) OR Car(s)

Tabla 1: Palabras clave generales.

La búsqueda se amplió a los términos relacionados con impactos medioambientales en los diferentes medios físicos, incluyendo dos conceptos ambientales que pueden verse afectados por la implantación del vehículo autónomo en sentido positivo o negativo, la contaminación acústica y la contaminación lumínica.

AIRE	“Emissions” OR “Pollution” OR “Global Warming” OR “Greenhouse” OR “Carbon” OR “Air Quality”
SUELO	“Built environment” OR “Land use” OR “Urban form” OR “Territorial Impact”
AGUA	“Water Pollution” OR “Water Contamination” OR “Aquatic Toxicity”, “Water Consumption”
OTROS	“Noise Pollution”, “Light Pollution”

Tabla 2: Palabras clave específicas.

El procedimiento se desarrolló en tres fases. Una primera consistió en la identificación de artículos con las palabras clave indicadas. Se tuvieron en cuenta solamente los artículos publicados en inglés en revistas científicas. Después de identificados, se hizo una revisión para eliminar los artículos duplicados (se realizó la búsqueda con dos herramientas, WoS y Scopus) y aquellos que no correspondían al ámbito de estudio (por ejemplo, vehículos autónomos marinos). Los artículos restantes fueron los que se analizaron en esta investigación, estructurados según los temas de búsqueda.

En algunos casos, para reforzar o completar algún punto de vista, ampliar un análisis o incluir referencias sobre cuestiones aún no suficientemente desarrolladas se recurrió a la técnica “bola de nieve” en un sentido u otro.

3. RESULTADOS

La mayor parte de los resultados obtenidos hacen referencia al impacto medioambiental en general, al nivel de consumo energético o a las emisiones. Sobre el impacto en el uso del suelo comienza a desarrollarse un cuerpo de literatura con varias referencias, pero apenas se refieren a efectos ambientales sino urbanísticos. No se encontraron referencias que identifiquen efectos en el medio acuático como consecuencia de la irrupción del vehículo autónomo y, sin embargo, sí empiezan a analizarse los efectos en la contaminación acústica y lumínica. Finalmente se han seleccionado 90 artículos y se han tenido en cuenta varios más como resultado de las búsquedas según la técnica "bola de nieve".

Palabras clave	Fuentes identificadas	Duplicados/Fuera de tema	Revisión inicial	No representativos	Selección
"Emissions", "Pollution", "Global Warming", "Greenhouse", "Carbon", "Air Quality".	968	812	156	79	77
"Built Environment", "Land Use", "Urban Form", "Territorial Impact"	139	89	50	39	11
"Water Pollution", "Water Contamination", "Aquatic Toxicity", "Water Consumption"	18	18	0	0	0
"Noise Pollution"	16	12	4	3	1
"Light Pollution"	2	1	1	0	1

Tabla 3: Número de referencias seleccionadas.

Por cada medio se identificaron subtemas, siendo más notables estas divisiones en los aspectos más estudiados, como por ejemplo en el caso de las emisiones. Se encontraron análisis con gran cantidad de enfoques, desde el punto de vista operacional de un vehículo en particular y en su interacción con otros vehículos en situaciones de conducción concretas donde la conducción más eficiente y las comunicaciones V2V (vehículo a vehículo) y V2I (vehículo a infraestructura) son determinantes. Igualmente hay estudios a nivel de flota y de servicios de movilidad compartida o bajo demanda, a nivel de ciudad o país, con combustibles convencionales o propulsión eléctrica, etc.

A continuación se exponen los resultados de los efectos producidos en los diferentes medios afectados, cuyo esquema puede verse en la figura 1.

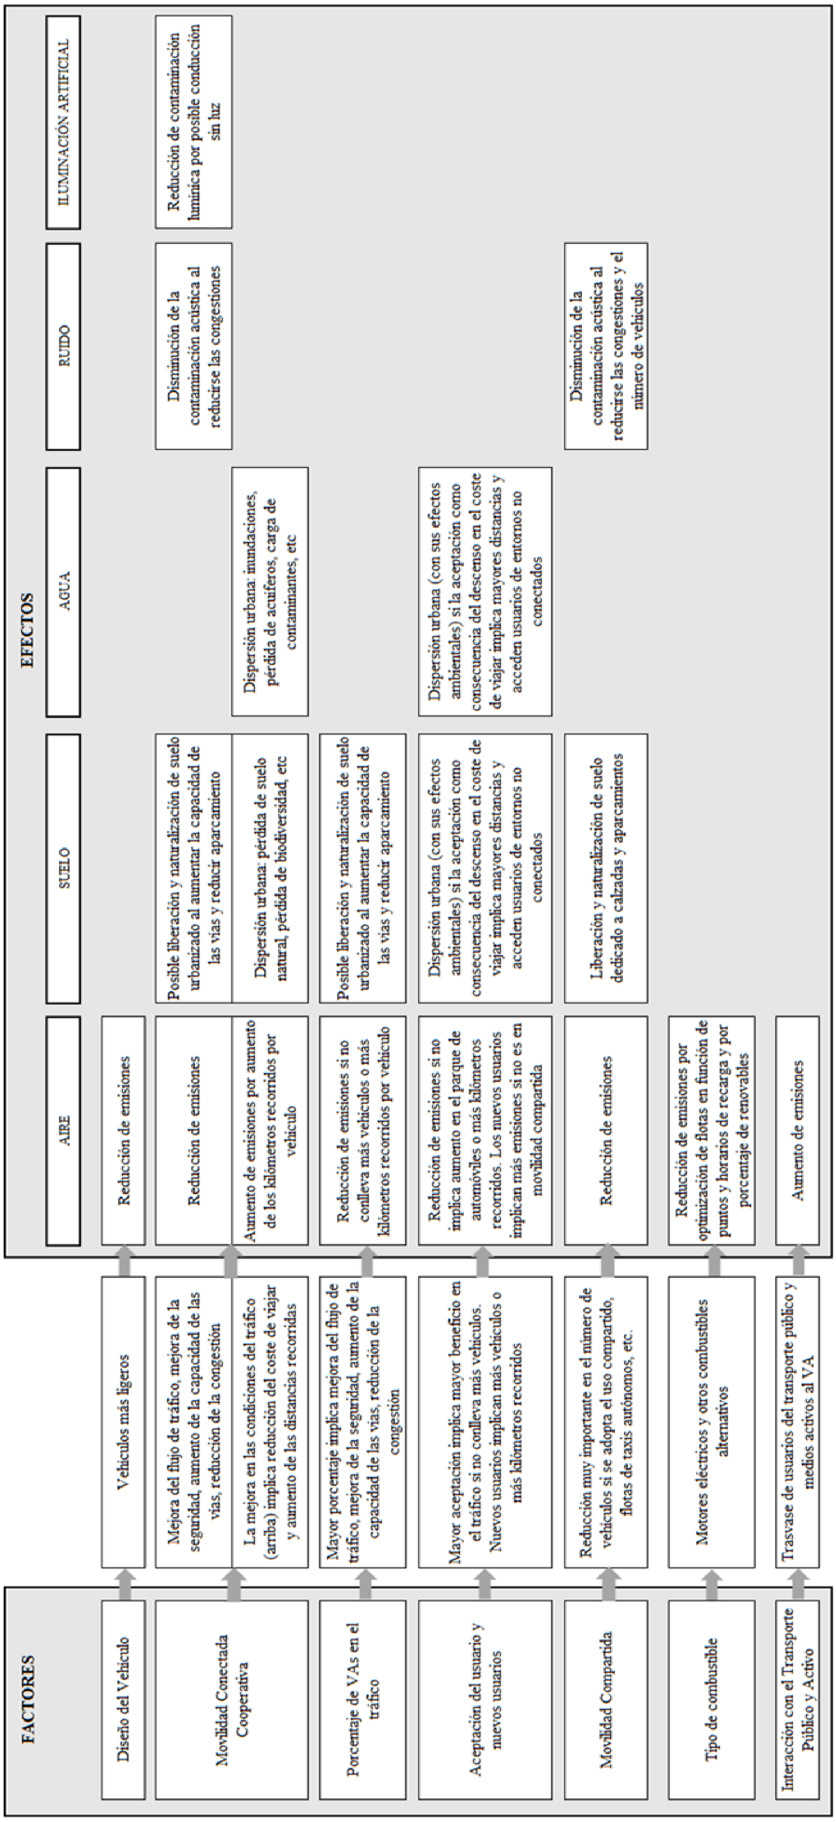

Figura 1: Efectos del vehículo autónomo en el medio ambiente.

3.1 Efectos en la calidad del aire: polución atmosférica, emisiones

3.1.1 Efectos debidos al diseño, los sistemas integrados y la circulación de los VAs

Dentro de las variables que afectan al consumo y a las emisiones del VA, en primer lugar se podrían considerar las derivadas de su propio diseño, de los sistemas de conducción empleados y de los equipos necesarios para el propio vehículo y para sus ocupantes. En ese sentido, C. Zhang et al. (2019) discretizan los consumos energéticos de un vehículo autónomo eléctrico, concluyendo que el 53,4% se consume en acelerar y vencer las resistencias al rozamiento; el 20,7% en pérdidas en el motor incluso con los motores eléctricos más eficientes; el 17,2% se pierde por las baterías y el sistema de recarga; el 3,68% por la climatización (HVAC) y el resto por los sistemas de sensorización, computación, aire acondicionado, etc. En definitiva, toda mejora en la eficiencia en la circulación redundará en menores consumos y por tanto menores emisiones.

Aparte de las mejoras puramente mecánicas (motores, baterías, etc.), gran parte de la eficiencia energética del VA se consigue mediante la mejora general del flujo del tráfico gracias a los sistemas de automatización cooperativa. Z. R. Wang et al. (2020) distinguen 5 diferentes conceptos operacionales cooperativos de los vehículos autónomos conectados (VACs) con beneficios para la seguridad, la movilidad y la sostenibilidad: 1) Control de Crucero Adaptativo Cooperativo (Cooperative Adaptative Cruise Control, CACC) y Platooning; 2) Incorporación Cooperativa en Accesos de Autopistas (Cooperative Merging at Highway On-Ramps); 3) Armonización de Velocidad en Autopistas (Speed Harmonization on Highways); 4) Conducción Eficiente Cooperativa en Intersecciones Señalizadas (Cooperative Eco-driving at Signalized Intersections); 5) Conducción Eficiente Cooperativa en Intersecciones No Señalizadas (Cooperative Eco-driving at Non-Signalized Intersections); clasificando además sus potenciales beneficios ambientales, siendo mayores en el caso 4) seguido del 1) y ya menor en el resto de los conceptos.

Numerosos estudios modelizan los conceptos operacionales antes indicados. Uno de ellos es la mejora del tránsito de los VAs en las intersecciones mediante las conexiones entre vehículos y/o con la propia infraestructura, con evidentes consecuencias medioambientales en cuanto a la reducción de las emisiones al conseguir mayor fluidez de tráfico (Almannaa et al., 2019; Astarita et al., 2019; Bento et al., 2019; Bichiou y Rakha, 2019; Chen y Liu, 2019; Feng et al., 2018; Filocamo et al., 2020; Jiang et al., 2018; Z. Li et al., 2015; Lin et al., 2017; C. Wang et al., 2020; Z. Wang et al., 2020).

Lo mismo ocurre con las rotondas (Cao y Zöldy, 2020), carriles de aceleración/acceso a autopistas (Ding et al., 2020) o circulación general (Xiao et al., 2020), e igualmente, diversos autores proponen mejoras en el flujo del tráfico reduciendo aceleraciones y frenazos mediante límites de velocidad cooperativos u otros sistemas combinados relativos al control de la velocidad (Arefizadeh y Talebpour, 2018; Guo et al., 2020; C. L. Liuet al., 2019; C. S. Miao et al., 2018; Stebbins et al., 2017; Yu y Fan, 2019; X. Zhang et al., 2019).

Además de la optimización de ciertos movimientos y la conducción en general, diversos estudios analizan los efectos de la incorporación a los VAs de varios sistemas de análisis, control y gestión de múltiples parámetros con los que también se obtienen reducciones importantes en el nivel de emisiones (Djavadian et al., 2020; C. R. Lu et al., 2019a; J. Q. Ma et al., 2019; Mahdinia et al., 2020; Phan et al., 2020; Rong et al., 2018; Tu et al., 2019; Zhai et al., 2019)

Independientemente de operaciones concretas o de la aplicación de diferentes sistemas, Stogios et al. (2019) analizan la fluctuación en las emisiones simulando ciertas condiciones de tráfico y en función de cómo se programen los parámetros de conducción.

Otras funciones que se avanzan tienen que ver, por ejemplo, con las posibilidades del aparcamiento en doble fila con estacionamientos dinámicos que, a la vez que aumentan la capacidad de aparcamiento en horas determinadas, reducen las emisiones frente a la opción de circular en vacío hasta un parking (Estepa et al., 2017).

No obstante, algunos estudios alertan sobre la necesidad de considerar el ciclo completo de vida de un vehículo y no centrarse solamente en su fase operativa. Patella et al. (2019a) tienen en cuenta tres fases: producción, uso y final de vida útil. Los resultados indican que, por unidad de vehículo, el autónomo es el que más impacto ambiental genera. Las emisiones correspondientes a la fase de construcción, mantenimiento y fin de vida útil, de media son un 35% superiores a los de un vehículo convencional de combustión interna, un 22% superiores a los de un vehículo híbrido y un 5% superiores a los de un vehículo eléctrico pese a que, en la fase operacional, el vehículo autónomo consigue ahorros del 60%, si bien es cierto que este resultado es muy dependiente del “pool” de generación de energía eléctrica y de las hipótesis consideradas en la fase operativa.

3.1.2 Efectos con tráfico mixto VAs/VCs (vehículos autónomos/vehículos convencionales) y grados de penetración en el mercado de los VAs

La penetración del vehículo autónomo será gradual, por lo que durante un periodo de tiempo considerable lo habitual será la convivencia de vehículos autónomos y vehículos convencionales, conectados o sin conectar en ambos casos, y cuyos tiempos de respuesta ante la información recibida y la toma de decisiones varían enormemente. En experimentos de campo en circuito cerrado, la presencia de VAs, incluso en bajos porcentajes (5%), estabiliza el tráfico y suaviza los intervalos de parada-aceleración consiguiendo reducciones de emisiones del 15% en CO_2 y hasta el 73% en NO_x (Stern et al., 2019). No obstante, en modelizaciones de tráfico real con vehículos con conductor, vehículos autónomos y vehículos autónomos conectados, no siempre la presencia de vehículos autónomos mejora las condiciones del tráfico ya que, si no están interconectados, al considerar parámetros de seguridad y confort en situaciones de alta densidad de tráfico, reducen la velocidad y obligan a bajar la velocidad del resto de vehículos, disminuyendo la capacidad de las vías y generando más congestión (Mattas et al., 2018).

Rafael et al. (2020) estudian el impacto de los VAs en la calidad del aire en una zona urbana con un ratio de penetración del 30%, produciéndose un ligero incremento en emisiones de CO_2 y NO_x como consecuencia de un aumento en la demanda y de aceleraciones después de paradas; sin embargo, en un escenario de vehículos autónomos con un 30% eléctricos se consiguen reducciones en emisiones, variando según la época del año e incluso del día en función de la composición de la generación eléctrica. Simulaciones en entornos urbanos de un vehículo autónomo conectado con propulsión híbrida gestionados mediante modelos predictivos y estrategias “eco-driving” muestran resultados satisfactorios en cuanto a reducción de emisiones (S. Wang et al., 2020)

Se aprecia en diferentes estudios que el ratio de VAs en el tráfico afecta a dos parámetros fundamentales, a su vez relacionados con las emisiones: la capacidad de la vía y el límite de velocidad, de tal manera que es esperable una reducción en las emisiones en la medida que crece la presencia de VAs y por tanto mejora la capacidad de las vías, siempre y cuando esto no conlleve aumentos en los límites de velocidad por encima de un óptimo estimado en 95 km/h (Hwang y Song, 2019).

Igualmente, en una simulación de un tramo de autopista real, con modelos de tráfico relativamente congestionado (entre el 0,7 y el 0,9 de la capacidad de la vía), la introducción de VAs arroja beneficios en cuanto a las emisiones generadas, que disminuyen a medida que aumenta el porcentaje de VAs, pero si se si simula un escenario extremo fuertemente congestionado -3 veces la capacidad de la vía- con el 100% de VAs, aunque mejora el flujo de vehículos, se produce degradación medioambiental como consecuencia de una mayor densidad de tráfico (Li y Wagner, 2019). Es decir, en situaciones de congestión, los VAs conectados aumentan la capacidad de las vías, pero generan más emisiones en términos absolutos (Makridis et al., 2020).

De forma similar, Jin et al. (2020) modelizan un entorno de tráfico mixto concluyendo que el flujo de vehículos mejora con la presencia de VAs, gracias al procesamiento de la información que suministran los vehículos que van por delante. Sin embargo, este flujo se puede desestabilizara medida que aumentan los tiempos de respuesta de los conductores de los vehículos convencionales así que, un aumento del ratio de penetración de vehículos autónomos puede mejorar la eficiencia y hacer descender las emisiones. Sin embargo, el ahorro de combustible, y por tanto el descenso de emisiones de un vehículo concreto, no siempre conlleva ahorros y descenso de emisiones de todo el sistema.

De hecho, la localización de los VAs dentro de la fila de vehículos circulando debe tenerse en cuenta en los análisis y así, si al frente de una hilera de vehículos parte convencionales y parte autónomos se sitúa un vehículo autónomo, todo el grupo puede conseguir hasta un 2% adicional de ahorro de combustible y linealmente reducir las emisiones (C. R. Lu et al., 2019b).

Al igual que está siendo desarrollada la optimización de movimientos en intersecciones con tráfico exclusivamente de VAs, también empiezan a estudiarse las intersecciones con combinaciones de VAs y vehículos parcialmente conectados, consiguiendo, en general, mejorar el rendimiento de la intersección y, por tanto, reduciendo las emisiones (Jiang et al., 2017; Z. Yao et al., 2020; Kamal et al., 2020), aunque con bajos niveles de penetración de VAs conectados las emisiones pueden aumentar debido al comportamiento ineficiente de los vehículos con conductor no conectados (McConky y Rungtan, 2019).

También la implementación de los sistemas ACC (Adaptative Cruise Control) tiene su influencia en entornos de tráfico mixto ya que incluso un grupo de vehículos heterogéneos, parte convencionales y parte autónomos, tiene unos niveles de consumo y de emisiones inferiores a los de un grupo de vehículos convencionales gracias a estos sistemas, incluso mejorando en la medida que el ratio de penetración en el mercado de los VAs es mayor (Huang et al., 2020). F. Ma et al. (2019) incluso proponen mejoras en el consumo energético, y por tanto en las emisiones, respecto a las actuales propuestas de sistemas ACC utilizando estrategias predictivas con modelos no lineales. También Ghiasi et al. (2019) proponen un sistema para armonizar la velocidad entre vehículos autónomos, vehículos conectados pero no autónomos y vehículos con conductor y no conectados, es decir, a todo el flujo de tráfico, y adaptable en tiempo real.

3.1.3 Efectos de la movilidad compartida, vehículos autónomos compartidos (VACs) y otras flotas de VAs

Las tecnologías de la comunicación han supuesto un cambio radical en la movilidad urbana, reduciendo los tiempos de búsqueda de pasajeros en los que habitualmente incurren los servicios de taxi tradicionales. Las plataformas de servicios de movilidad permiten a pasajeros y conductores optimizar oferta y demanda, lo que lleva a disminuir viajes en vacío y, por tanto, consumos y emisiones. Solamente en términos de coste se estiman ahorros de hasta 6.000 USD por familia en EE.UU. utilizando servicios de movilidad compartida en vez de tener vehículo en propiedad (Anderson et al., 2014).

Los investigadores viendo el potencial que presentan este tipo de plataformas para reducir el número de vehículos en circulación, garantizando el mismo nivel de servicio, junto con las posibilidades que presentan los AVs para la mejora del tráfico, han empezado a estudiar los efectos de las flotas de vehículos autónomos (VACs – Vehículo Autónomo Compartido, Autonomous taxis o aTaxis) como posibles opciones de transporte alternativas a los vehículos convencionales.

El procedimiento habitual para estos análisis son las modelizaciones (en general “agent-based”) de entornos urbanos, genéricos o reales (Austin-Texas, Nueva York, Tokio, Lisboa…), con diferentes variables: tamaño de flota, tarifa, tiempos de espera, patrones de distribución, motor eléctrico o convencional, distribución de puntos de recarga, niveles de congestión, tasas por emisiones, etc.

Diferentes resultados indican que un solo vehículo autónomo es capaz de sustituir hasta 11 vehículos convencionales (Fagnan y Kockelman, 2014) o entre 7 y 10 si se tiene en cuenta la relación tiempo de espera/coste del sistema (Iacobucci et al., 2018), con la consiguiente reducción de emisiones, que en el caso de taxis eléctricos autónomos podrían llegar al 87-94% con respecto a los vehículos convencionales con conductor (Greenblat y Saxena, 2015).

Tres modelizaciones desarrolladas tomando como base la ciudad de Austin, Texas (EE.UU.) y sus patrones de transporte, desarrollo urbano, demografía y desplazamientos de vehículos, analizan el desempeño y los efectos de una flota de taxis autónomos en el sistema. Gawron et al. (2019) avanzan reducciones del 60% en emisiones en el periodo 2020-2050 frente a los vehículos convencionales. Este estudio considera los efectos directos e indirectos de los subsistemas de sensorización y computación, eco-driving y conectividad en las intersecciones, kilómetros recorridos en vacío, parking, recarga, mejoras en el diseño, penetración del motor eléctrico, movilidad compartida y tiempo de vida útil, aunque no tiene en cuenta los efectos del "platooning", las congestiones ni el incremento de velocidad en entornos urbanos.

La reducción comentada del 60% se debe principalmente a la electrificación (57%). Es interesante señalar que el modelo avanza posibles reducciones del 87% para 2050 en un escenario de generación eléctrica con el 92% de renovables, incremento de movilidad compartida para reducir los VKT un 22%, una mayor vida útil de los vehículos (hasta 643.738 km) y una serie de mejoras en la eficiencia, diseño y consumo.

J. Liu et al. (2017) estudian los efectos de las tarifas del servicio de taxi autónomo concluyendo que, si las tarifas son suficientemente bajas, se pueden conseguir reducciones en emisiones entre el 16,8 y el 42,7% frente a vehículos convencionales; no obstante, el exceso de millas recorridas por los AV reduce los porcentajes anteriores, aunque sin comprometer el beneficio global según el modelo.

Sin tener en cuenta los efectos de las tarifas, un estudio usando los datos de la flota de taxis de Nueva York (NYC) concluye que cambiando el sistema de taxis tradicional por una flota de taxis autónomos compartidos se pueden mantener los niveles de servicio con un 59% menos de vehículos y reduciendo las emisiones en 725 toneladas de CO_2 al día (Lokhandwala y Cai, 2018).

También modelizando una flota de taxis en Manhattan, en el centro de la ciudad de Nueva York, pero en este caso con taxis autónomos eléctricos compartidos, Bauer et al. (2018) concluyen posibles reducciones de emisiones de hasta el 73% con respecto a la misma flota con motores de combustión interna, considerando la composición actual del suministro eléctrico en Nueva York y estableciendo una determinada infraestructura de recarga de baterías. Los costes y las emisiones además mejoran si las recargas se pueden programar durante el día cuando la energía eléctrica proveniente de la generación solar está operativa.

Sin embargo, H. Zhang et al. (2020), estudiando las necesidades de infraestructura de recarga de una flota de VAs eléctricos en entornos urbanos, concluyen que en la medida que las flotas aumentan en tamaño por encima de un óptimo y aumenta la capacidad de las baterías, las emisiones se incrementan al realizarse más recargas durante la noche cuando la producción eléctrica con renovables desciende. Para que un sistema de taxis autónomos eléctricos conectados y compartidos sea eficiente deben hacerse estimaciones adecuadas de las necesidades de servicio por áreas geográficas y establecer un ratio correcto de vehículos por punto de recarga, pudiendo llegar a reducciones de emisiones del 42% condicionadas sobre todo por factores como la rapidez de carga además del rango de uso y el parque de vehículos (H. Miao et al., 2019)

Calculando el impacto de la sustitución de todos los desplazamientos en vehículo privado y autobuses tradicionales por una flota de taxis autónomos en una ciudad europea de tamaño medio como Lisboa, Martínez y Viegas (2017) también obtienen resultados positivos en cuanto a reducción de emisiones, llegando casi al 40% en el mejor escenario.

Aunque los modelos realizados tomando como ejemplo tramas y datos de ciudades reales, en general avanzan resultados positivos en cuanto a reducción de emisiones, las conclusiones no tienen por qué ser extrapolables a cualquier otra ciudad. En un intento de hacer un análisis más general estableciendo diferentes categorías de ciudades, Oke et al. (2020) concluyen que la introducción de los servicios de movilidad con vehículos autónomos en ciudades con redes importantes de transporte público es contraproducente para la congestión, ya que los usuarios tienden a cambiar del transporte público hacia los VACs; en ciudades grandes muy dependientes del vehículo privado, poco densificadas y con poco desarrollo del transporte público, no parecen tener efecto la penetración de los VACs y, sin embargo, es en ciudades más densas con un uso moderado del transporte público donde la penetración de la movilidad compartida con vehículos autónomos obtiene mejores resultados para reducir la congestión.

Diversos estudios analizan la introducción de tasas contaminantes para fomentar la movilidad compartida. En ese sentido, Jones y Leibowicz (2019) diseñan una serie de escenarios de movilidad compartida con VACs de cuyo análisis concluyen que, incluso con planteamientos sin tasas contaminantes, se consiguen descensos en las emisiones hacia 2035 llegando en 2050 a la mitad de los obtenidos en 2015, pero si se aplican tasas a los gases contaminantes de manera escalonada, se aprecian descensos más pronunciados en las emisiones y mucho antes, llegando a casi cero en 2050. En general, se demuestra que un sistema con una significativa adopción de VACs es menos costoso y genera menos emisiones, incluso si se doblan los VKT con respecto a los vehículos convencionales que sustituyen.

No obstante, algunos modelos analizando exclusivamente los desplazamientos a los lugares de trabajo (commuting) obtienen resultados no tan prometedores desde el punto de vista ambiental.

Si bien con un 20% de taxis autónomos sería posible dar el mismo servicio que toda la flota de vehículos privados dedicados a los viajes de traslado a los centros de trabajo, con una reducción del coste de viaje del 38%, las emisiones de gases de efecto invernadero aumentan un 25% debido principalmente a los recorridos “en vacío” para ir a buscar al siguiente ocupante (M. Lu et al., 2018).

F. Yao et al. (2020) modelizan un escenario híbrido con conductores y vehículos autónomos de servicios de movilidad a gran escala, concluyendo que en la medida en que se van sustituyendo vehículos con conductor por VAs las emisiones descienden llegando hasta reducciones del 12,3%.

3.1.4 Efectos del sistema de transporte conjunto y visiones generales

Una línea de análisis consiste en el estudio de los efectos del coche autónomo considerando su implantación global dentro de un sistema de transporte. Los efectos del vehículo autónomo en el consumo energético y las emisiones no son muy relevantes a pesar de un mayor grado de eficiencia en la conducción, pero donde sí es capaz de producir grandes transformaciones es en el sistema de transporte general, por sus interacciones con otros medios y por su potencial para cambiar ciertos hábitos entre los usuarios. Por ejemplo, hoy en día las emisiones diarias del transporte generadas en una gran área metropolitana como puede ser Toronto, corresponden en un 96% al vehículo privado, mientras que el 4% restante corresponde al transporte público, que sin embargo realiza el 32% de los traslados. Con la introducción del VA, se observa que podrían aumentar los kilómetros recorridos y las emisiones, sin embargo, si el estudio se realiza con VAs eléctricos se pueden conseguir reducciones en las emisiones a nivel regional del 5% (A. Wang et al., 2018).

El modelo generalista de Noussan y Tagliapietra (2020) analiza el efecto de la digitalización sobre la demanda de transporte, el consumo de energía y las emisiones en la UE-28 comparando dos escenarios diferentes, Digitalización Responsable (DR) y Digitalización Egoísta (DE), y dos horizontes temporales, 2030 y 2050. Cada escenario presenta diferentes hipótesis para 4 áreas: movilidad como servicio, movilidad compartida, vehículos autónomos y digitalización en otros sectores (e-commerce, teletrabajo). Se concluye que la demanda total de transporte aumenta y el coche sigue siendo el medio de transporte más utilizado, aunque en 2050 disminuye su uso en el escenario DR a favor del transporte público y bicicleta. En cuanto al consumo energético, el modelo muestra que el consumo general permanece estable hasta 2030, descendiendo en 2050 en el escenario DR hasta un 34% respecto a los valores actuales como consecuencia del efecto combinado de un cambio hacia medios más eficientes y un uso del coche compartido con más pasajeros por vehículo. La tendencia en las emisiones sigue aproximadamente el mismo patrón que el consumo de energía, consiguiendo para 2050 un descenso del 43% respecto a las emisiones de 2015 debido a las mejoras tecnológicas. El escenario DE, en el que la tecnología se usa de manera que se maximice el beneficio individual, muestra un aumento del 7% en el consumo energético para 2050, disminuyendo las emisiones un 8% debido a las mejoras tecnológicas.

En otro modelo generalista, F. Liu et al. (2019) calculan las emisiones de los vehículos de pasajeros en China según la penetración de los VAs teniendo en cuenta una larga serie de factores, como las ventas de vehículos, el ratio de supervivencia, la distancia anual recorrida, consumos y emisiones relacionadas basados en eco-driving, incremento de la velocidad, mejora de la circulación (conectividad e intersecciones), reducción de accidentes, platooning, diseños específicos (optimización del tamaño, menor carga de elementos de seguridad, mayor carga de sensorización, computación, confort y entretenimiento), carga aerodinámica y otros. El modelo no asume cambios muy radicales en cuanto a evolución de la penetración en el mercado y distancias recorridas así que los resultados indican que no se perciben reducciones importantes en cuanto a emisiones hasta 2050, incluso podrían darse incrementos. Solamente a partir de 2045, con unos mejores parámetros de consumo y una mayor penetración de VAs se podrían ver mejoras en la reducción de emisiones a nivel global.

3.2 Efectos en el suelo

El impacto ambiental del vehículo autónomo en el suelo (y por tanto en los hábitats naturales) no está siendo objeto de estudio por el momento, pese a que varios autores ya indican que uno de los posibles efectos indeseados es la agudización de la dispersión urbana, siendo este fenómeno uno de los ya estudiados en la literatura científica desde la perspectiva del vehículo convencional.

Si nos atenemos únicamente al impacto del vehículo autónomo en la forma urbana, sí está recibiendo creciente atención por parte de los investigadores ya que, como se ha dicho, por sus propias características reúne el potencial suficiente como para multiplicar ciertos efectos indeseados o favorecer nuevas, e impensables hasta este momento, posibilidades de uso del suelo. Dentro de los primeros podemos contar con que, al no tener que conducir, los usuarios del vehículo autónomo podrán dedicar el tiempo de viaje a trabajar o a actividades de ocio, haciendo disminuir el coste de viajar y estando más dispuestos a recorrer largas distancias, afectando a la toma de decisiones en cuanto al lugar de residencia o a la localización de las empresas. Por otro lado, las mejoras del flujo del tráfico que avanzan los VAs hacen más fáciles los desplazamientos urbanos y más atractivo el espacio del centro de las ciudades y eso redunda en que, bajo ciertas circunstancias, ganaría atractivo para sus habitantes permanecer en la ciudad y no mudarse a zonas residenciales alejadas.

Un parámetro que definirá, por tanto, la actuación de los usuarios es el valor del tiempo de viaje un indicativo de cuánto está dispuesto a pagar el viajero por disminuir el tiempo que asignan a viajar de carácter subjetivo, y por tanto influenciado por multitud de factores: contexto espacial urbano-suburbano-rural, normas sociales, estatus, forma de vida, etc. En diversos estudios se aprecia que la introducción del vehículo autónomo disminuye el coste de viajar, en mayor o menor medida, pero eso ocurre tanto para usuarios urbanos como para suburbanos y rurales.

Esto, puede implicar diferentes tendencias en la forma urbana, algunas de ellas opuestas: desde un crecimiento suburbial e improbable densificación de los centros urbanos hasta el crecimiento de ambos polos, la periferia y los centros urbanos (Milakis et al., 2018). Gelauff et al. (2019) obtienen que, en un escenario de alta automatización combinado con buenas prestaciones de transporte público en las grandes zonas urbanas de Holanda, la población tiende a aumentar en las grandes metrópolis y sus suburbios, disminuyendo en ciudades más pequeñas y sus suburbios. Zhong et al. (2020) analizando zonas metropolitanas de tamaño medio en EE.UU. concluyen que la reducción del tiempo de viaje es más pronunciada cuando se trata de VAs privados y entre habitantes de zonas suburbanas, llegando al 32%, pero también es importante entre los usuarios urbanos, lo que no redunda en apreciables redistribuciones de población. Moore et al. (2020) igualmente obtienen ahorros en el valor del tiempo de viaje del 30%, pero predicen una expansión urbana horizontal del 68%. Bin-Nun y Binamira (2020) observan que la implantación de los VAs ocasionaría aumentos de población en las zonas más urbanizadas (hasta el 12%) frente a pérdidas de población en las zonas rurales menos densamente pobladas.

Como se puede apreciar en los diferentes estudios, la tendencia hacia la dispersión urbana (sprawl) como consecuencia de la penetración del vehículo autónomo a veces arroja resultados contradictorios. Larson y Zhao (2020), a pesar de que la mayoría de los modelos conducen al sprawl, también analizan esa ambigüedad concluyendo que es producida por la tensión entre la reducción del coste del viaje al trabajo, el incremento de costes por el aumento de la congestión y el aumento de la densidad urbana como consecuencia del nuevo uso residencial de la superficie de parking no necesaria con los VAs.

Si no se adopta el uso compartido y el espacio de parking no se dedica a uso residencial, el modelo resultante es un modelo urbano disperso. Kang y Kim (2019) también observan para Seúl y su área metropolitana un aumento de la superficie suburbana mientras que se densifica el principal centro comercial, perdiendo tierras agrícolas que pasan a uso residencial y con descenso general del suelo dedicado a actividades comerciales.

Por otro lado, varios estudios se centran en otro de los aspectos significativos y positivos: la posibilidad de liberación de espacio urbano actualmente dedicado a vías y aparcamiento. No obstante, se alerta que solamente en combinación con políticas activas adecuadas se podrá desarrollar todo su potencial (González-González et al., 2020).

Así, la reducción del espacio dedicado a aparcamiento puede llegar a ser muy significativa con la adopción de la movilidad compartida (W. Zang et al., 2015). No obstante, algunos estudios reflejan que, al mismo tiempo que se libera espacio de aparcamiento en los centros metropolitanos, los vehículos recorren mayores distancias diarias y se produce un aumento de la superficie dedicada al aparcamiento en la periferia (Harper et al., 2018; W. Zang y Wang, 2020).

Desde el punto de vista ambiental, los anteriores efectos o posibilidades se trasladan a sus repercusiones en el consumo energético y las emisiones de gases de efecto invernadero pero, siendo la agudización de la dispersión urbana una de las posibles consecuencias negativas de la implantación del vehículo autónomo, se hace necesario considerar los efectos contaminantes no solamente en el aire sino en el resto de medios, entre ellos el suelo.

Johnson (2001) resume los impactos que diferentes investigadores identifican en relación con la dispersión y entre ellos, los siguientes afectan al suelo: pérdida de tierras ambientalmente frágiles, espacios abiertos más reducidos, pérdida del atractivo paisajístico, ausencia de vistas del paisaje (montañas), paisaje monótono o inapropiado, pérdida de tierras de cultivo, reducción de la biodiversidad, aumento de la escorrentía y aumento de las inundaciones, pérdida de vegetación nativa y fragmentación de los ecosistemas.

Muchos de los efectos en el suelo son más fácilmente apreciables que medibles y de ahí la dificultad en su estudio. También es evidente que hay impactos cuyos efectos perniciosos no se aprecian hasta que pase un cierto tiempo y además la percepción del riesgo asociado a estos impactos es variable entre diferentes individuos. De ahí quizá que todavía no se encuentren dentro de la literatura científica artículos que aborden el problema de los efectos contaminantes en el suelo como consecuencia de la introducción del vehículo autónomo como medio de transporte de relevancia.

3.3 Efectos en el agua

Los cambios en el uso del suelo son uno de los principales factores que contribuyen a la degradación de la calidad del agua. Como se ha podido ver en el punto anterior, la expansión suburbana es uno de los posibles efectos de la penetración del vehículo autónomo y, por tanto, además de impacto en la calidad del aire y del suelo, tendrá impactos indeseados en la calidad del agua.

La urbanización provoca cambios sustanciales en los sistemas hidrogeológicos ya que, al incrementarse la superficie construida impermeable, aumenta la ocurrencia e intensidad de las inundaciones, disminuye la recarga de acuíferos, elimina los pequeños cursos de agua superficial, altera la permeabilidad del resto del terreno natural y aumenta la carga de contaminantes, a la vez que también aumenta la demanda de agua para la población y sus servicios.Considerando la presencia de nitratos (NO_3-_N), fosfatos (TP) y Escherichia Coli en los cursos naturales de agua, R. Wang et al. (2021) obtienen que los desarrollos urbanos más densos son más efectivos en la reducción de nitratos y fosfatos, aunque pueden tender, dependiendo de la época del año, a aumentar la presencia de E. Coli, pero en general concluyen que la degradación de los flujos naturales de agua es consecuencia del “sprawl”. S. Wang et al. (2019), igualmente, analizando la degradación y disminución de los recursos hídricos como consecuencia de la urbanización suburbana en una megalópolis como Pekín desde la década de los años 90, concluyen que tales niveles pueden comprometer el futuro la sostenibilidad de la ciudad.

Si, como avanzan ciertos estudios, hay relación entre un posible aumento de la expansión urbana de baja densidad y la adopción del AV como medio de transporte masivo, deberían considerarse sus probables graves efectos en el medio acuático más allá de las emisiones generadas. A la vista de los resultados obtenidos en las plataformas WoS y Scopus, no hay por el momento literatura que tenga en cuenta estos efectos.

3.4 Contaminación acústica

La contaminación acústica y la contaminación atmosférica son los dos factores de riesgo más importantes para la salud en los espacios urbanos y son responsables de más del 75% de las enfermedades atribuibles a condicionantes ambientales (Hanninen et al., 2014), siendo el tráfico rodado uno de los mayores emisores de ruido.

Para el análisis de los efectos sobre la salud de la contaminación acústica se suelen emplear los parámetros L_{dn}, nivel día-noche, que es el nivel de sonido equivalente de 24h con los niveles de sonido nocturnos incrementados en 10dB(A) y el L_{den}, nivel día-tarde-noche. La población residente en entornos urbanos en países industrializados está expuesta a niveles L_{dn} por encima de 50dB(A) y hay suficiente evidencia científica que afirma que exposiciones por encima de esos niveles puede inducir disfunción auditiva, hipertensión, cardiopatía isquémica, irritación y alteraciones del sueño (Passchier-Vermeer y Passchier, 2000).

A pesar del potencial del VA para modificar el futuro del transporte y los hábitos de los usuarios, no hay apenas literatura que estudie el impacto que su penetración puede tener en un factor de riesgo para la salud de tal relevancia.

No obstante, algunos primeros estudios, como el realizado por Patella et al. (2019b) analizando los efectos de la penetración del AV en una red de carreteras real (Roma), indican que en un escenario con 100% de presencia de vehículos autónomos las vías urbanas interiores se beneficiarían de descensos en la contaminación acústica al reducirse la congestión, mientras que aumentaría la contaminación en ciertas autopistas de acceso como consecuencia del mayor número de trayectos extra-urbanos.

3.5 Contaminación lumínica

Otro de los contaminantes asociados a los entornos urbanos y las vías de transporte es la luz artificial por la noche. Aunque no se ha desarrollado suficiente evidencia científica sobre sus efectos en la salud, diversos estudios alertan de que, al afectar al comportamiento, el sueño y la melatonina, podría ser un factor de riesgo en desórdenes metabólicos como la obesidad y las enfermedades cardiovasculares, ciertos tipos de cáncer y salud mental (Flies et al., 2019).

Además de en la salud humana, la luz artificial tiene impactos negativos en los ecosistemas (Gaston et al., 2015) y consume una gran cantidad de energía, generando 1900 Mt de CO_2 al año (IEA, 2006).

Al igual que con la contaminación acústica, se ha desarrollado poca literatura en relación con el vehículo autónomo a pesar de que, al no tener conductor, se podría reducir en gran medida la necesidad de luz artificial en ciertos entornos, ya que la iluminación de las calles y de los aparcamientos constituyen el 90% de la iluminación exterior. En ese sentido, Stone et al. (2019) analizan las posibilidades de eliminar iluminación en aparcamientos y autopistas, además de promover un análisis del diseño de los AVs para que sean capaces de circular en la oscuridad en condiciones de seguridad.

3.6 VAs y usuarios: percepción general y compatibilidad con otros medios de transporte

Como se ha podido ver, los efectos ambientales del vehículo autónomo son muy sensibles al grado de penetración, su forma de uso y su interacción con otras formas de transporte. Algunos modelos, teniendo en cuenta los porcentajes de VAs en el conjunto de la flota de vehículos, si son compartidos o no, su impacto en la red de infraestructuras, la posibilidad de viajar “de puerta a puerta”, la reducción del valor del tiempo de viaje y la incorporación de los potenciales usuarios que no conducen, concluyen que, para el horizonte de 2050, los kilómetros por vehículo podrían aumentar un 50%, que el uso del transporte público podría descender un 18% y el uso de los modos activos (andar en bicicleta y a pie) podría bajar un 13% (May et al., 2020). Por tanto, es muy importante conocer la respuesta del usuario hacia esta nueva tecnología y la forma en que considera su uso.

Para analizar estos aspectos, diferentes autores dirigen encuestas y entrevistas con espectros más o menos amplios. Potoglou et al. (2020) analizan las preferencias de los usuarios por los VAs y los combustibles alternativos, identificando y explorando las diferencias entre seis países y sus diferentes segmentos de población. Los resultados indican que, por ejemplo, los participantes japoneses son los que más valoran los avances del VA, quizá por ser una sociedad cuya economía está basada en la alta tecnología o porque anticipan las ventajas que los VAs pueden ofrecer a una población envejecida. Los participantes alemanes, suecos y británicos no tienen esa predisposición positiva y los resultados para EE.UU. varían con respecto a otras encuestas anteriores, indicando actualmente una menor predisposición, quizá derivada de los accidentes ocurridos con VAs. También se encuentran diferencias entre los diversos grupos sociales encuestados resultando, en general, que los más jóvenes están más dispuestos a aceptar altos niveles de autonomía en los vehículos mientras que los que se definen como menos innovadores, menos concienciados ambientalmente y que viven en zonas rurales tienen menor predisposición. Un resultado llamativo se encuentra dentro de los encuestados de Suecia, que pese a autodefinirse como ambientalmente responsables y valorar positivamente los VEs, no consideran interesante el máximo nivel de automatización de los VAs, quizá por un cierto escepticismo sobre los verdaderos beneficios ambientales de los mismos. En este sentido, Müller (2019) incluye en su estudio la actitud del encuestado hacia la protección ambiental y la innovación, concluyendo que una actitud positiva hacia esos factores predispone hacia una mejor aceptación del VE y el uso compartido, pero no necesariamente hacia el VA.

Se observa en ciertos estudios que la penetración en el mercado de los VAs podría cambiar ciertos hábitos actuales relacionados con la movilidad activa y el transporte público, a su vez relacionados con mayores beneficios para la salud y para el medioambiente. Son los segmentos de población más joven los que más utilizan estos medios y a su vez los más dispuestos a adoptar nuevas tecnologías como el VA, lo que puede redundar en un trasvase de usuarios. En este sentido, Booth et al. (2019) han realizado una encuesta con el objetivo de explorar en qué grado son usuarios de modos de transporte activo y en qué medida estarían dispuestos a sustituirlos por VAs. Se concluye que un 48% de los encuestados estarían dispuestos a sustituir el transporte público por un vehículo autónomo, al igual que el 32% de los que usan la bicicleta y el 18% de los que andan.

Blau et al. (2018) han estudiado la influencia de los vehículos autónomos en los usuarios de bicicletas compartiendo las mismas vías, concluyendo que el VA supone un elemento disuasorio para los usuarios de la bicicleta a pesar de presuponer una conducción mucho más segura frente a los vehículos convencionales, por lo que los ciclistas llegan a doblar la preferencia por infraestructuras separadas con respecto a las condiciones actuales. También Latham et al. (2019) se preguntan si la penetración de los VAs desplazarán otros modos de transporte o permitirán una mayor y más igualitaria configuración del espacio urbano. Mediante un experimento con ciclistas haciendo un giro a la derecha en una calle urbana de Carlisle (Reino Unido) con doble sentido de circulación llega a la conclusión de que, pese a las normas formales e informales que regulan una maniobra tan simple, los diferentes usuarios tienen múltiples razonamientos sobre lo que se considera razonable y apropiado. Por ello, y aunque actualmente los VAs se están desarrollando partiendo de calzadas convencionales con tráfico motorizado, deben tener el objetivo de circular en entornos donde se priorice el movimiento y la seguridad de los usuarios no motorizados.

De nuevo respecto a la interacción o desplazamiento que el vehículo autónomo pueda ejercer sobre los modos de transporte activo, y en definitiva sobre la salud pública, Crayton y Meier (2017) identifican que algunas posibilidades beneficiosas desde el punto de vista de la salud pública no lo son tanto desde el punto de vista ambiental si no se regulan correctamente. La capacidad del VA para circular de manera más segura redundaría en menores emisiones al evitar los atascos generados por los accidentes, lo que es positivo, pero el acceso a una movilidad autónoma por parte de población actualmente imposibilitada para conducir implicaría un aumento en los kilómetros recorridos por vehículo y por tanto más emisiones. En definitiva, se percibe como negativo tanto para la salud pública como para el medioambiente un desplazamiento desde medios de transporte activo hacia el vehículo autónomo, por el aumento del sedentarismo y las enfermedades asociadas y por la sustitución de hábitos de movilidad sin emisiones por transporte con cierto grado de emisiones.

El potencial que el vehículo autónomo tiene para conseguir un transporte más sostenible medioambientalmente se basa en que el usuario cambie la preferencia actual hacia el coche privado por un uso compartido con varios usuarios por viaje.

Para comprobar si ese cambio de tendencia es posible, Stoiber et al. (2019) analizan la influencia de varios instrumentos para fomentar el uso del transporte compartido en un escenario de total presencia de VAs. En este caso, un 61% de las respuestas eran favorables a escoger VAs compartidos mientras que el 39% sigue prefiriendo un uso privado. El porcentaje de aceptación de uso compartido es superior a otros estudios anteriores, pero se puede deber a que en este caso no se da la opción de escoger un transporte convencional que no sea autónomo, lo que sugiere que los usuarios están más dispuestos al uso compartido en un escenario de total penetración de VAs al no poder optar por opciones más conocidas.

Dentro de la literatura existente, una forma de análisis consiste en realizar entrevistas a expertos sobre sus puntos de vista acerca de diferentes posibilidades. Lang et al. (2019) conducen una serie de entrevistas cuyos resultados indican que los vehículos eléctricos seguirán creciendo en importancia, pero a pesar de la creciente conciencia ambiental los usuarios no parecen inclinados a otras alternativas como los VA.

Se percibe, no obstante, que los vehículos autónomos tendrán un papel muy importante en el futuro y que es el sector tecnológico con el crecimiento más rápido y un mayor grado de innovación, todo ello estimulado por la competitividad y las alianzas entre empresas. Sin embargo, alcanzar la autonomía completa todavía requerirá un cierto tiempo debido a los costes y a la necesidad de establecer nuevos estándares en la legislación vigente. Adicionalmente, los entrevistados indican que, desde su punto de vista, los usuarios están todavía tratando de averiguar en qué consisten los cambios y sus consecuencias.

También entre los expertos encuestados por Nogués et al. (2020) se aprecia cierto escepticismo sobre los efectos de los VAs -incluso utilizados de modo compartido- en los entornos urbanos, de tal manera que para evitar problemas de sostenibilidad en el futuro se deben implementar políticas activas, como la promoción de los modos de transporte activos, la mejora del transporte público, las restricciones para los vehículos privados en el centro de las ciudades y la promoción de una más compacta y mejor estructurada trama urbana.

4. CONCLUSIONES

Los efectos ambientales de los vehículos autónomos están generando una gran cantidad de estudios con resultados muy dispares y enfoques muy diferentes, aunque principalmente centrados en analizar consumos y emisiones en diferentes escenarios. Para conseguir sus objetivos los investigadores adoptan diferentes estrategias y planteamientos. Si se trata de analizar emisiones se suelen basar en modelos matemáticos con resultados variables y muy dependientes de los parámetros que asumen en la modelización. La mayor eficiencia en la conducción y la posibilidad de la circulación en grupo favorecida por las comunicaciones V2X indican ahorros energéticos y reducción de emisiones, amplificadas si los usuarios optan por la movilidad compartida al conseguir una reducción significativa del parque automovilístico sin pérdidas en los niveles de servicio.

No obstante, otros análisis indican que las prioridades de los usuarios pueden llevar a escenarios donde todos los potenciales beneficios que aporta la tecnología son usados para maximizar el aprovechamiento individual, provocando efectos ambientales negativos con respecto al estándar actual. Igualmente, la tendencia del usuario puede provocar un cambio en el uso del más conveniente transporte activo (uso de la bicicleta, andar) o del transporte público hacia el vehículo autónomo, aún en su modalidad compartida, lo que también tendría efectos contraproducentes en el medio ambiente y a su vez en la salud pública.

Además, ciertos impactos negativos como la dispersión urbana no solamente deben ser estudiados desde el punto de vista del aumento de las emisiones, sino que el efecto negativo se multiplica si se tienen en cuenta la degradación del suelo, el paisaje, los ecosistemas y los recursos de agua natural. Igualmente, nuevas posibilidades que se apuntan, como la posible reducción de la contaminación lumínica, redundarían, por ejemplo, en posibles descensos muy importantes en consumos energéticos y emisiones del sistema global. Es decir, las consecuencias positivas o negativas pueden amplificarse de una manera exponencial si se tiene en cuenta todo el posible espectro ambiental afectado (aire, suelo, agua, ruido, luz artificial, etc.). En este sentido sería importante que futuros estudios tuvieran una visión más amplia en cuanto a los efectos ambientales del vehículo autónomo puesto que potenciales beneficios directos, por ejemplo, en el descenso de las emisiones según un cierto modelo, pueden ser mayores si se aplica la posible reducción de las emisiones por una menor necesidad de iluminación nocturna o la “naturalización” del suelo urbano liberado. También sucede al contrario, modelos que indican incremento de emisiones debido al aumento de vehículos o a las mayores distancias recorridas, pueden ser mucho más perniciosos si se tienen en cuenta las probables degradaciones del suelo, los hábitats naturales y los recursos hídricos como consecuencia de la dispersión urbana.

Muchos de los efectos sobre el suelo y los recursos hídricos naturales son más difíciles de analizar puesto que no son fácilmente evaluables de forma cuantitativa, necesitan plazos más amplios para ser apreciados y además son susceptibles de visiones subjetivas. Sin embargo, las consecuencias de no ser tenidos en cuenta son relevantes por sí mismos y por su interrelación con el resto de los efectos ambientales.

Existe un consenso entre los expertos al considerar que el vehículo autónomo es una tecnología que marcará el devenir del transporte en las próximas décadas, pero hoy en día existen tantas incertidumbres tecnológicas para considerarlo viable en un plazo razonable que el usuario no es capaz de valorar realmente sus potenciales beneficios. Es un hecho que la movilidad está sufriendo una importante transformación con respecto a los usos tradicionales (VEs, VTCs) y que una mayor conciencia medioambiental acelerará este proceso, aunque a día de hoy no parece que ese sea un motivo que favorezca la implantación del VA. La dificultad que supone prever el grado de aceptación y cómo será usada una tecnología tan disruptiva hacen que los resultados de los estudios sean muy variables e incluso antagónicos.

Sin embargo, sí se puede apreciar un cierto pensamiento general por el que el beneficio social óptimo de los sistemas de transporte futuros debe incluir una movilidad autónoma, compartida y complementaria con el resto de medios, y para ello se requiere la motivación de todos los usuarios.

AGRADECIMIENTOS

Esta investigación se ha desarrollado dentro del proyecto “Formas innovadoras de planificación urbana y del transporte ante los nuevos sistemas de movilidad basados en la conducción autónoma” - AUTONOMOUS, 2020-2023, financiado por el Ministerio de Ciencia e Innovación (MICINN) / ERDF (EU) en el marco del Plan Estatal de Investigación Científica y Técnica y de Innovación 2017-2020 (referencia PID2019-110355RB-I00).

ABSTRACT

Sharing mobility is currently one of the most innovative features of metropolitan transportation and is rising along with the development of mobile phones and apps. Riders can rent bicycles, motorcycles, cars or PMVs like mopeds, usually electric, for short-time periods, usually per minute. Vehicle-sharing companies have entered the megalopolis, although the first sharing services were implemented in medium-size cities like Ulm in Germany, Cambridge in the USA or the main Swiss cities.

The purpose of this study was to analyze the current motorcycle sharing systems deployed in Spain based on GIS tools. The research focused on several Spanish cities, the main characteristics of which are representative of the whole country. The study can therefore be useful for companies in the sharing sector interested in introducing the system in cities which do not yet have them, and for government administrations interested in this type of system. Furthermore, this research is a starting point for future comparative studies on Spain and other countries, or electric motorcycle and other e-vehicle-sharing systems.

1. INTRODUCTION AND OBJECTIVE

This study focused on several different Spanish cities. Therefore, its conclusions serve to establish the main characteristics defining *motosharing* systems in this geographic area, and are the starting point for evaluating possible future research that can compare it with the situation in other places. These conclusions may also be of interest to the companies in the sector themselves and also to cities that are considering introducing these services.

The recent growing concern for pollution in large cities and the current trend to urban rezoning promoting more pedestrian spaces (Cervero and Kockelman, 1997; Madanipour, 2019; Plasencia-Lozano, 2014), are generating policies directed at reducing the presence of private vehicles in streets in the city center, especially, polluting vehicles (Mackett, 2001; Tomassetti et al., 2020). Sometimes the number of lanes in the main streets are reduced, causing an increase in the level of service, and thus, an increase in travel time.

It also reduces parking spaces or limits their availability to hybrid or electric vehicles, less used now (Szarata et al., 2017; Yan et al., 2019). This reality can be observed in several countries (Fitzgerald, 2020; Hooi and Pojani, 2020; Mandeli, 2019; Mozos-Blanco et al., 2018).

At the same time, in the last decade, society has been profoundly transformed due to the surge in smartphones and apps. All of this leads to the idea of mobility through per-minute rentals known as sharing, in which the facility offered is supported by mobile devices for geolocation, immediate payment, etc. Thus, companies have started up that offer riders per-minute rental in main cities of electric vehicles such as cars (*carsharing*) (Derikx and van Lierop, 2021; Guirao et al., 2018), bicycles (*bikesharing*) (Barberan and Monzon, 2016; Shaheen et al., 2012) or scooters (Fitt and Curl, 2020; Hardt and Bogenberger, 2019).

One of these options is known as *motosharing* (Spanish common word for describing the sharing of e-mopeds), now available in cities in several different countries, also in Spanish cities (Aguilera-García et al., 2020). The operator distributes a certain number of electric e-mopeds within the area for a rental time rate (usually per minute) which includes the right to the necessary safety equipment and accident insurance.

This is done by downloading the company app and searching for the closest vehicle. All of them have three different modes: (1) Rent, which causes the e-moped to appear as available on the app's map and shows the vehicle battery and autonomy. (2) Ride, which is activated when the rider begins to use it and ends when finished; in general, the rider pays a rate for the use of a e-moped that can reach speeds of 50 km/h, and some companies offer e-mopeds that reach speeds of up to 80 or 100 km/h. In this case, the rider can decide to reach those speeds, but has to pay a higher rate. (3) Repeat, reduced rate the rider can activate after having parked the vehicle to reserve it for further use.

Every company operates in a certain zone and the beginning and end of the journey should be inside that zone, although it may outside it as long as the battery and autonomy allow the vehicle to return to it. The company that offers the service is also responsible for recharging the vehicle and ensuring that all vehicles are in good condition.

The purpose of this study was to analyse the current *motosharing* services in Spain based on defining and determining a series of parameters that help to characterize the service by using QGIS open software for obtaining data.

Therefore, its conclusions serve to establish the main characteristics defining *motosharing* systems in this geographic area, and are the starting point for evaluating possible future research that can compare it with the situation in other places. These conclusions may also be of interest to the companies in the sector themselves and also to cities that are considering introducing these services.

2. METHODOLOGY

The methodology developed is based on finding parameters that characterize *motosharing* services by using two types of data: those related to the service offered by the companies, and those related to the area where the company offers the service (area covered, population density, etc.). The method is carried out in seven steps (Figure 1).

1.	**Sample definition**		Cities with mopeds; Companies in each city
2.	**Parameter definitions**		Number of companies; Prices; Speed; service area…
3.	**Sample characterization**	**Companies**	News on Company web sites; Calls; e-mails; Annual reports
		Cities	2020 census; City council websites; Urban sprawl
4.	**Lab work**		Data processing with QGIS
5.	**Parameter-based results**		Mopeds/km^2; Mopeds/100,000 pop.
6.	**Analysis of results**		
7.	**Conclusions**		

Figure 1: Method description

First, the sample (Spanish cities with a *motosharing* service) was defined. To find them, news items were searched for in local newspapers on this service being started up, increase in the city's fleet, and other published data. Data provided by the Spanish Metropolitan Mobility Observatory [*Observatorio de Movilidad Metropolitana*] were also included.

After finding the cities and the number of companies with permits to operate in each, the data that should be known about them to be able to arrive at the desired conclusions were defined. The following were chosen: number of companies, year *motosharing* began, service price range in each city, maximum e-moped speed, vehicles available, area of the zone covered for starting and ending the ride, population census in the zone, total area of urban sprawl.

Thus, the following parameters can also be determined: number of e-mopeds per 100,000 inhabitants, number of e-mopeds per km^2 and percentage of the total area occupied by urban sprawl of the zone offered for starting and ending the ride.

Once the parameters had been set, the sample was characterized. One part was characterization of the companies, for which their web pages were found and the section on news in some of them showed data of interest on the company's growth over the years (year started up in each city, growth of fleet, etc.); some data were not available on the internet and they had to be contacted or their annual reports searched. The other was the characterization of the zone available for starting and ending the ride. Using QGIS software, the area and population (data from 2020 census) were found for each of them. Finally, the results were analysed, and conclusions reached.

3. RESULTS

3.1. Cities with *motosharing*. Service characteristics.

Ten cities in Spain offer a *motosharing* service: A Coruña, Gijón, Barcelona, Zaragoza, Córdoba, Valencia, Seville, Cádiz, Málaga and Madrid (Table 1).

City	Number of companies	First year of service	Price range [€/min]	Maximum speed offered, combined [km/h]	Companies
Barcelona	5	2013	0.24 – 0.26	80	eCooltra; Yego; Movo; Acciona; Seat MÓ
Madrid	3	2013	0.24 – 0.26	100	eCooltra; Movo; Acciona
Seville	3	2017	0.26 – 0.27	80	Acciona; Muving; Yego
Málaga	2	2017	0.25 – 0.26	80	Acciona; Yego
Cádiz	1	2017	0.27	50	Muving
Valencia	4	2017	0.25 – 0.27	80	eCooltra; Muving; Yego; Acciona
Zaragoza	2	2017	0.26 – 0.27	80	Acciona; Muving
Córdoba	1	2017	0.27	70	Muving
Gijón	1	2019	0.29	50	HiMobility
A Coruña	1	2019	0.24	50	Motiños
Average	2	2016	0.26	72	

Table 1: Number of companies, year started up, prices and speed in each city.

Motosharing services were set up for a time in other cities, but were discontinued as unprofitable, and their vehicles were used to reinforce the fleets in other cities, or to start up a service where there was none yet. Murcia, Alicante, Granada and Palma de Mallorca are in this group.

Other cities have a seasonal *motosharing* service as in Gandía, where a fleet of 200 electric e-mopeds is deployed in the city every summer.

The characteristics and service conditions vary depending on the company that provides them. Some cities (Barcelona, Madrid) have had a satisfactory *motosharing* service for years, which makes the number companies operating in them larger than the Spanish average.

Another example is Valencia, where the service was begun only four years ago, but its popularity has made the number of companies operating in it grow rapidly. Other cities, such as A Coruña and Gijón, have recently begun the service and there is only one company currently operating in them.

3.2. Rates, speed

The highest rate is in the city of Gijón, which has only one company offering the service for 0.29/€/min. In the cities with more companies, the price is not over 0.27€/min, being A Coruña an exception as there is only one company operating for 0.24€/min, the minimum in the country. However, in all the cities, companies have lower rates for their regular customers, offering rides for 0.17-0.19€/min.

The maximum speed riders can reach depends on the model offered by the company. Two points should be emphasized: the users in the three smallest cities, Gijón, Cádiz and A Coruña, have e-mopeds available that can go no faster than 45-50 km/h, while in other cities there is at least one operator offering services with speeds of at least 70 km/h. This may be due to these cities having urban highways. Furthermore, Acciona offers the possibility of reaching 80 or 100 km/h, but at an added cost of 0.03 and 0.09€/min, respectively, over the original rate (Table 1).

Figure 2: Motosharing vehicles. eCooltra, HiMobility, Muving, Yego, Movo, Acciona, Motiños and Seat MO. Source: companies webpages.

3.3. Operating zone

The zone available for starting and ending the ride varies with the operator. The percentage of the urban sprawl occupied by the *motosharing* service zone varies depending on the city, although in all cases is over 40% (Figure 3, Table 2). The minimum is in Seville, where 43.76% of the total urban sprawl is zoned for *motosharing*, and the highest is in Cádiz: 100.81%. This is because the customers, in addition to the city center, can use it at the university campus, outside of the city itself. The mean of the total area is 72.31% of the urban sprawl zoned for *motosharing*.

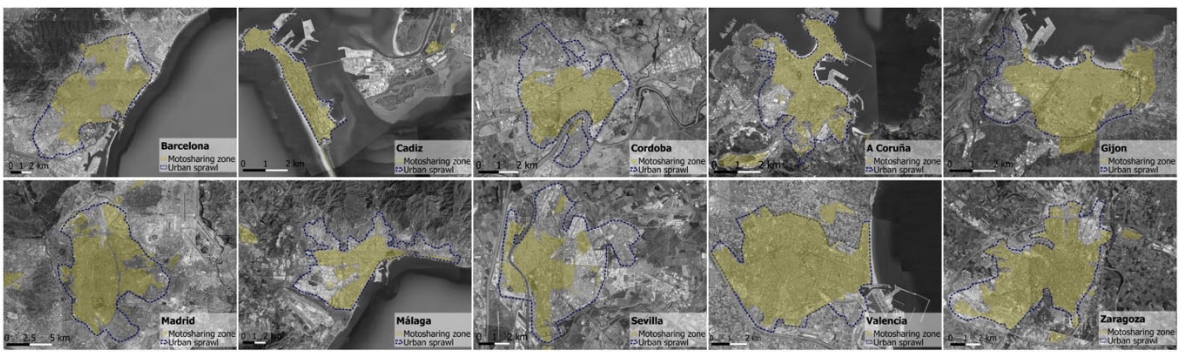

Figure 3: Motosharing operating zones and urban sprawl. Note that urban sprawl does not coincide with the municipal limits, but with homogeneity and continuity of total urbanized or partly residential space.

City	Area urban sprawl [km^2]	Area *motosharing* zone [km^2]	Percent urban area zoned for *motosharing* [%]	Autonomy [km]
Barcelona	67.57	45.06	66.68	80
Madrid	105.92	82.58	77.96	80
Seville	42.86	18.76	43.76	70
Málaga	47.24	23.13	48.95	70
Cádiz	5.37	5.61	104.42	70
Valencia	47.09	36.64	77.80	80
Zaragoza	42.79	37.18	86.88	70
Córdoba	21.44	11.38	53.08	70
Gijón	18.86	16.41	86.99	50
A Coruña	13.56	10.88	80.21	60
Average			72,7	

Table 1: Comparison of areas in different cities in Spain. The area of the *motosharing* zone includes the urban area where there is at least one operator.

3.4. Potential users

The 2020 census was used to calculate the residents in the zones set up by the operators (potential users), and also in the urban sprawl area (Table 3). Potential users have been compared with the total population of each urban area for evaluating the percentage of the population benefited by the service. In this case, the lowest percentage is in Seville, 51.17%, being Málaga the next with 71.55%. On the contrary, Cádiz, Valencia, Zaragoza and Gijón all have motosharing zones affecting over 95% of the population. Concerning the population density in each area, it has been set that the areas served by at least one motosharing company are in the same population density range of 14,455 pop/km^2 to 20,876 pop/km^2, except Barcelona, with a density of 29,152 pop/km^2. These figures are also higher than the population densities observed in the urban sprawl.

City	Urban sprawl population (2020 census)	Potential users [pop]	Percentage city population [%]	City population density [pop/km^2]	Population density in motosharing zone [pop/km^2]
Barcelona	1,725,977	1,313,629	76.11	25,542.27	29,152.89
Madrid	1,990,323	1,611,612	80.97	18,789.43	19,515.77
Seville	545,348	279,067	51.17	12,722.27	14,875.64
Málaga	467,304	334,363	71.55	9,890.53	14,455.82
Cádiz	107,253	106,922	99.44	19,514.88	18,524.42
Valencia	792,527	764,918	96.52	16,828.30	20,876.58
Zaragoza	586,055	575,617	98.22	13,694.92	15,481.90
Córdoba	267,004	201,251	75.37	12,453.42	17,684.62
Gijón	241,227	238,914	99.04	12,787.73	14,559.05
A Coruña	206,200	192,810	93.51	15,202.05	17,721.51
Average			84.19	15,742.58	18,284,82

Table 2: Population and potential users in the cities

3.5. Fleet

The fleet of e-mopeds available was defined by adding up all the companies that operate in each city. The Spanish cites with the most e-mopeds are Madrid (3,620), Barcelona (3,176) and Valencia (1,635). By contrast, Gijón and A Coruña services only offer 50. Analyzing the number of e-mopeds in each city per km^2, and keeping in mind the area zoned for *motosharing*, Barcelona is in first place, with 70 e-mopeds/km^2 followed by Valencia and Madrid with 44 e-mopeds/km^2 (Table 4). Last place is again held by A Coruña and Gijón: 4 and 3 e-mopeds per km^2 respectively.

City	Number of e-mopeds [Units]	E-mopeds/km^2	E-mopeds per 100,000 inhabitants
Barcelona	3,176	70.48	242
Madrid	3,620	43.84	225
Seville	440	23.45	158
Málaga	500	21.62	150
Cádiz	100	17.83	96
Valencia	1,635	44.62	214
Zaragoza	575	15.46	100
Córdoba	115	10.11	57
Gijón	50	3.04	21
A Coruña	50	4.59	26
Average		25,50	128,9

Table 3: Number of e-mopeds, zone for starting and ending rides, and potential users in each city.

The fleet in each city was also compared with the number of potential users in each zone by calculating the number of e-mopeds per 100,000 inhabitants. In this case Barcelona, Madrid and Valencia have over 200 e-mopeds/100,000, while Seville, Málaga and Zaragoza have over 100 e-mopeds/100,000. The rest of the cities have fewer than 100 e-mopeds/100,000, with Gijón and A Coruña at the tail with fewer than 30 e-mopeds/100,000.

4. DISCUSSION

This study analyzed some data related to the existing e-moped sharing systems in Spain (generally denominated motosharing in Spanish) in order to characterize them. Some parameters linked to the companies have been chosen, and also some data from the operating areas have been taken in account. After that, some ratios have emerged linked to the number of vehicles per inhabitant or the number of vehicles per km2.

The motosharing service was shown to be linked to large cities: the six largest cities in Spain were include here, and the seventh (Murcia) and eighth (Palma) at one time had motosharing services. It would be interesting to know the reason why in cities like Las Palmas de Gran Canaria or Bilbao, ninth and tenth in size, still do not have this service, and the reason why middle-sized cities, such as Gijón (15th place) or A Coruña (18th place), do.

It was also observed that the minimum population limit for this type of services is around 250,000 inhabitants. Rates were found to be rather homogeneous, although somewhat more economical in the cities with several operators.

Concerning the speed of e-mopeds, the larger number of operators is also linked to vehicles with higher top speeds. In general, the feeling is that competition between companies contributes to some of them wanting to be differentiated from the rest in this parameter. It has been also observed that cities with a smaller motosharing zone also offered e-mopeds with lower top speeds.

For example, Gijón, Cádiz and A Coruña, are the three cities with the smallest motosharing zone and also those with the lowest top speeds (50 km/h). On the contrary, Madrid, which has the largest zone, offers e-mopeds with top speeds of up to 100 km/h.

Another interesting fact is the percentage of urban sprawl that is covered by the different companies. Furthermore, the presence of more companies in the same city does not ensure wider coverage. One suggestive result is related to the population density in the companies' sharing zones.

This, as demonstrated, is in no case under 14,000 pop/km2. Therefore, it may be inferred that for the service to be profitable in a city, the population density in the sharing zone has to be extremely high. However, this population density is not related to the number of operators in the city.

The reason why the motosharing service is only available in areas where the population density is over 14,000 pop/km2 could be the lack of profitability of the service in areas below this density, so this cipher can be set as the minimum population density which makes attractive a central area for companies. It could be thought that although a city has a very small population, if it is a touristic city, the motosharing service would make sense there, but apparently it does not. In the end, the regular service customers are those who determine its triumph or failure in a city, so that motosharing in a touristic city would only make sense in the high season, as is the case in Palma de Mallorca.

Along this line, it is observed that the sharing zones have a much higher population density than urban sprawl as a whole. However, it is surprising that urban sprawl outside of sharing zones in Barcelona and Madrid have a population density over the 14,000 pop/km2 mentioned above, but the operators have not widened the service offered to the entire sprawl.

In percentage, the difference between the population densities in the sharing zone and the non-sharing zone is considerable in many cities, and shows that operators select the more heavily populated zones as (Table 5).

City	Density in urban sprawl [pop/km^2]	Density in sharing zone [pop/km^2]	Density in non-sharing zone [pop/km^2]	% difference in densities between sharing and non-sharing zones
Barcelona	25,543.54	29,15.89	18,318.44	63%
Madrid	18,790.81	19,515.77	16,22.84	83%
Seville	12,723.94	14,875.64	11,049.00	74%
Málaga	9,892.13	14,455.81	5,513.94	38%
Cádiz	19,514.88	18,524.42	-	-
Valencia	16,830.05	20,876.58	2,642.01	13%
Zaragoza	13,696.07	15,481.90	1,860.61	12%
Córdoba	12,453.54	17,684.62	6,536.08	37%
Gijón	12,790.40	14,559.05	944.08	6%
A Coruña	15,206.49	17,721.51	4,996.27	28%
Average	15,744.18	15,661.12	5,942.59	39%

Table 5: **Comparison of population densities in the urban sprawl and in the sharing zones**

It is worth mentioning that the rates are not related to a significant parameter a priori, the ratio which compares the e-mopeds per 100,000 pop and the *motosharing* zone, which determines the quality of the service offered (Table 6). However, this ratio may be related to the rotation of the e-mopeds, which in turn could be related to the area of the sharing zone: it seems logical that a smaller *motosharing* zone would be paired with a shorter distance to be covered by the ride, and therefore, length of time in use. This ratio was evaluated, and various groups appeared: one group is around 5.01 to 8.42, another in the fork between 1.28 and 2.72, and Cádiz with 17.11. This last is justified because the distance between the city center and the university campus, where it also provides the service, is quite long. The cities with lower ratios could be smaller, or metropolises where public transportation is easily available or transportation alternatives are high. In any case, it would be interesting to find relationships of this type in future research.

City	*Motosharing* zone [km^2]	E-mopeds per 100,000 inhabitants	Ratio
Barcelona	45.06	242	5.37
Madrid	82.58	225	2.72
Seville	18.76	158	8.42
Málaga	23.13	150	6.49
Cádiz	5.61	96	17.11
Valencia	36.64	214	5.84
Zaragoza	37.18	100	2.69
Córdoba	11.38	57	5.01
Gijón	16.41	21	1.28
A Coruña	10.88	26	2.39
Average	28.76	128.9	6.37

Table 6: **Ratio which compares the e-mopeds per 100,000 inhabitants and the *motosharing* zone**

There are some limitations and biases in this study. The data handled are rather reliable and objective, except perhaps the size of the urban sprawl, although there are metropolitan areas where the separation between the urbanized and unurbanized zones is clear, while in others, the definition could be somewhat more subjective. Thus, in Cádiz, it was decided to define the city itself as an island. However, Puerto Real or even San Fernando could have been included. Another question that could vary is the number of e-mopeds the companies offer in a city, as they fit the e-mopeds offered to the needs detected and better or worse reception of the service by citizens.

With a view to future studies of the *motosharing* service in Spanish cities, other factors could be considered in evaluating the service's feasibility, such as traffic inside the city, the percentage of the city that is pedestrianized, the city's motorization rate, the city's shape or alternative services offered, both sharing and public transportation. Another of the factors that could directly affect the use of this service is the climate, as the number rainy days per year or the mean annual temperature could influence users when making the decision to use the service or not. Another possible future study coming out of this one is of those *motosharing* services that have failed in recent times, such as in Murcia, Alicante or Granada, quantifying the parameters determined in this text, and comparing the differences in values of the cities analysed here. Furthermore, this method could be replicated for the study of other e-moped systems in other countries, and for comparing them with the Spanish system. Finally, the ciphers stated here could be used by companies and municipal administrations for planning futures services or for planning urban expansions (it is clear, for example, that low density cities are not interesting for e-mopeds sharing companies).

ACKNOWLEDGEMENTS

This study was carried out in the framework of research project SV-20-GIJÓN-1-21 funded by the IUTA (University of Oviedo and Gijón City Council). The authors wish to recognize the contribution of Dr. Juan Sevilla (University of Oviedo) and Jorge Muriel (Taksee Imbric) for their help during the research.

RESUMEN

La irrupción del virus SARS-CoV-2 y su propagación ha afectado a todos los campos imaginables de la vida. La ciencia no es ajena a ello: la situación derivada plantea desafíos en la obtención de datos. Las tradicionales encuestas in situ, los grupos de discusión y las entrevistas personales se han visto afectados por los nuevos comportamientos sociales y de movilidad, requiriendo introducir cambios en los métodos de obtención de datos.

El proyecto de investigación Travelwell+ – sobre nuevas formas de movilidad, bienestar y espacio público – aplica un enfoque mixto, utilizando métodos cualitativos y cuantitativos de recogida y análisis de información de movilidad de personas. La presente ponencia describe la adaptación del proyecto a las circunstancias de la pandemia, presenta los retos que la situación plantea, explica qué adaptación se ha llevado a cabo en la recogida de datos, y se concluye con una valoración preliminar de los resultados.

1. INTRODUCCIÓN

El 11 de marzo de 2020 la Organización Mundial de la Salud declaró la situación de pandemia por la expansión del virus SARS-CoV 2. La situación de emergencia sanitaria se ha extendido hasta la presente fecha, habiendo introducido cambios notables en la interacción entre personas, en los hábitos de movilidad y, como consecuencia, en las estrategias de obtención de datos para proyectos de investigación como los referidos a la movilidad, que se basan en muchas ocasiones en el contacto directo con los encuestados.

En un contexto de constante cambio en la movilidad urbana, con la aparición de nuevos modos de movilidad y la promoción de políticas de redistribución del espacio público, el proyecto Travelwell+ pretende estudiar los efectos de estos cambios haciendo énfasis en el aspecto psicológico y del bienestar de las personas.

El proyecto Travelwell+ se divide en dos fases, como se especifica en la figura 1. En una primera fase se pretende aportar conocimiento acerca de cómo las nuevas formas de movilidad (servicios de movilidad compartida y vehículos de movilidad personal, VMP) están alterando los patrones de movilidad e influyendo en el bienestar de sus usuarios. La segunda fase pretende estudiar cómo diferentes elementos del entorno urbano afectan al comportamiento y bienestar del usuario. Esta segunda fase pretende centrarse en el estudio de peatones, ciclistas y personas usuarias de VMP.

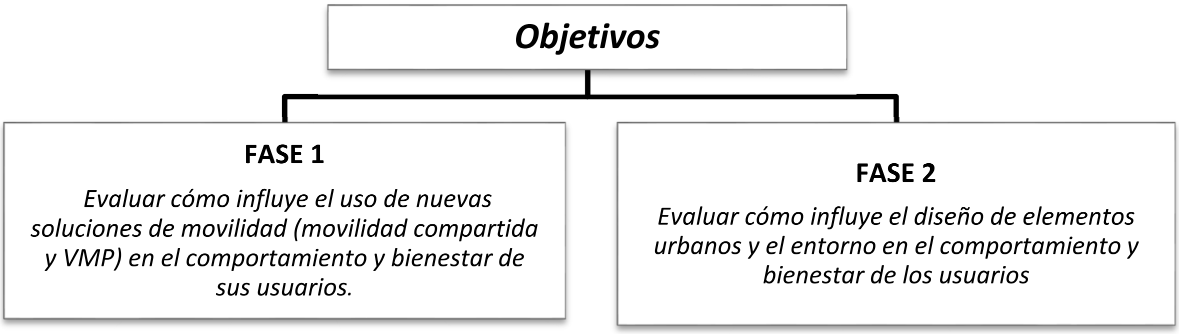

Figura 1: Fases del proyecto Travelwell+

Lejos del enfoque tradicional del estudio del transporte y los hábitos de movilidad según variables como el tiempo o coste mediante el criterio de maximización de la utilidad (Mcfadden, 2000; Ettema, 2010), este proyecto se suma a la creciente preocupación por el estudio de variables psicológicas, especialmente estudiadas en las últimas dos décadas, haciendo énfasis en las nuevas soluciones de movilidad.

Mientras que investigaciones previas (Friman et.al. 2013 o Ruiz et.al 2020) parecen concluir que la mayor satisfacción se alcanza en los desplazamientos a pie y en bicicleta, frente a los menores índices de satisfacción alcanzados en el transporte público, aún queda por analizar la posición que ocuparían los nuevos modos de movilidad: VMP y movilidad compartida como coches o motos. La satisfacción y bienestar con un medio de transporte están estrechamente ligados con las experiencias de los usuarios en ellos, así como con rasgos personales como sus percepciones, hábitos o carácter (Gao et.al. 2017).

Todos ellos pueden ser factores relevantes de la elección modal (Ettema et.al. 2010; Singleton et.al. 2019). El bienestar de una persona se compone de dos: el bienestar hedónico o subjetivo (SWB, de sus siglas en ingles *Subjective Wellbeing*) y el bienestar eudaemónico o psicológico (PWB, de sus siglas en inglés *Psychological Wellbeing*) (de Vos et. al., 2013). El conjunto de teorías sobre el SWB y PWB se ha materializado en una serie de escalas psicométricas que, de forma normalizada, analizan cuantitativamente factores relacionados con el bienestar. En Travelwell+ se complementan estas teorías con la consideración de la Teoría de la Autodeterminación (SDT, de sus siglas en inglés *Self-Determination Theory*) (Deci, 2000).

Una de las subteorías de la misma es la Teoría de las Necesidades Psicológicas Básicas, BPNT (de sus siglas en inglés *Basic Psychological Needs Theory*), que afirma que existen tres vertientes psicológicas innatas, básicas y universales: competencia, autonomía y relación con los demás. Las tres condiciones son esenciales para el bienestar personal, según afirman los autores. Dicha teoría se incorpora, a su vez, en todas las modalidades de recogidas de la información del proyecto Travelwell+.

Esta ponencia se organiza de la siguiente manera. Después de introducir el objeto del proyecto de investigación Travelwell+, a continuación, el apartado 2 presenta los desafíos que la pandemia supone en la obtención de información, tanto respecto a la forma de recopilarla, como respecto a los posibles sesgos que la situación puede inducir en los encuestados.

Se incide, a continuación, en el caso de los grupos de discusión, la fase de la investigación que, por el momento, ha tenido lugar en este contexto. Se realiza un análisis DAFO de los grupos de discusión online en este contexto de pandemia y se concluye en el apartado 3 con unas consideraciones finales.

2. RECOGIDA DE DATOS

El proyecto Travelwell+ se concibe como un proyecto de recogida mixta de información, combinando la información cuantitativa y cualitativa tanto en la fase 1 como en la fase 2, como se describe en la figura 2. Respecto a la información cuantitativa, se prevén en la fase 1 encuestas in situ y en línea que contengan escalas psicométricas que aborden la SWB, PWB y la BPNS (analizando las tres vertientes contenidas en la teoría: autonomía, competencia y relación). Respecto a la información cualitativa, se prevé la realización de grupos de discusión y entrevistas en profundidad en ambas fases.

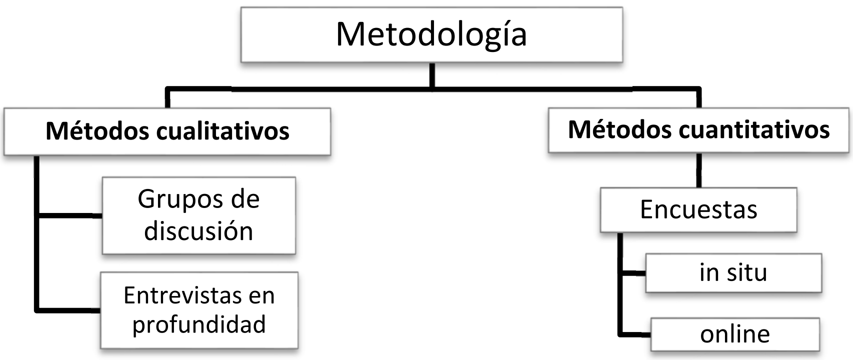

Figura 2: Métodos de obtención de información en el proyecto Travelwell+

Se pretende obtener información preferentemente de la ciudad de València, desde donde se lidera el proyecto, siendo el público empleado para la muestra la población general.

Se pretende, eso sí, obtener una sobrerrepresentación de las cohortes de edad correspondientes con el grupo de *millennials* (nacidos entre 1981 y 1996) y seniors (nacidos antes de 1950). El objetivo es evaluar especialmente en esos grupos de edad la influencia de estos cambios y su flexibilidad o rigidez al cambio de hábitos y las nuevas soluciones de movilidad.

2.1 La influencia de la pandemia en la recogida de información

A la fecha de entrega del presente artículo (abril de 2021), las tareas llevadas a cabo se han circunscrito al desarrollo de pruebas piloto relacionadas con la fase 1, empleando de muestra para ello miembros de la comunidad universitaria de la *Universitat Politècnica de València*, que aceptaron participar sin presentación de incentivo. En diciembre de 2019 se llevaron a cabo las pruebas piloto de las encuestas in situ (ver Ruiz et.al. 2020), antes de la irrupción de la pandemia por SARS-CoV 2. Los primeros grupos de discusión, pertenecientes a la fase 1 del proyecto, se desarrollaron en el mes de marzo de 2021.

La afección de la pandemia no solo se circunscribe a la forma de recogida de la información, sino también a la propia información que los usuarios puedan dar. A las esperadas reticencias al contacto social, cabe esperar que los datos recopilados muestren, al menos en parte, los cambios que la movilidad ha experimentado durante estos meses de pandemia, a saber, un menor índice de movilidad, una mayor reticencia al uso del transporte público y un trasvase de la mayoría de esos usuarios a medios de transporte activos (pie y bicicleta) (sirvan de constatación de esas tendencias los datos diarios de movilidad de la ciudad de València, publicados en su web coronavirus.valencia.es/pages/quadres-de-ciutat).

En el caso de los grupos de discusión, es de esperar que los participantes basen sus intervenciones en la utilidad recordada (Oliver 2017). Las preguntas que se les han formulado a los participantes en los grupos ya celebrados inciden en esa utilidad recordada siguiendo la recomendación de Kanehman y Dolan (2007), que asumen, aplicado al campo de la salud, que es preferible el análisis del bienestar mediante la utilidad experimentada –aquello que el usuario ya ha vivido y recuerda– y no mediante la utilidad esperada, basada en predicciones de los individuos sobre eventos futuros.

Los retos en la recogida de información son diversos y se ven afectados principalmente por las reticencias al contacto en un mismo espacio de personas desconocidas. En el caso de las encuestas in situ, planteadas como encuestas cara a cara en las que un entrevistador realiza preguntas en voz alta y las registra en un dispositivo electrónico, se obtuvo en la prueba piloto (previa a la pandemia) una baja tasa de respuesta, sobre todo, cuando se pretendió captar a usuarios durante sus desplazamientos. Desde marzo de 2020 no se han llevado a cabo nuevas encuestas in situ. Estas se habrán retomado en mayo de 2021 considerando las conclusiones de la evaluación piloto, esto es, priorizando puntos de encuesta en los que se realicen actividades estacionarias –de descanso o tiempo libre–, donde la predisposición a la participación parece mayor que durante los desplazamientos.

Las encuestas se realizarán en puntos al aire libre, respetando las distancias de seguridad y llevando los equipos de protección individual que las autoridades sanitarias recomiendan. Ello nos lleva a pensar que la tasa de respuesta de la gente no será muy diferente a la que puedan dar en circunstancias normales. No obstante, sí que se presenta la duda acerca de cómo conseguir una sobrerrepresentatividad del grupo de edad senior. La disminución de sus desplazamientos y vida social puede dificultar la obtención de datos en esa cohorte de edad.

2.2 Los grupos de discusión, modalidad presencial y online

La gran incógnita se nos presenta en la realización de las entrevistas en profundidad y, sobre todo, en los grupos de discusión. Los grupos de discusión suponen, en el caso de Travelwell+, la reunión de un total de 9 personas (7 participantes, un moderador y un observador) en un espacio que habitualmente es cerrado, ya que al aire libre pueden producirse interferencias y ruido en la grabación y mayores distracciones en los participantes.

Aun guardando las distancias de seguridad, portando mascarilla y tratando de garantizar una buena ventilación del habitáculo, la propia recomendación de las autoridades sanitarias de evitar lugares cerrados, el obligado desplazamiento de los participantes al lugar de reunión, así como su desconocimiento del resto de participantes y de las características del lugar de la reunión, hacen que sea esperable un alto rechazo a la celebración de estos eventos presencialmente. Siendo conscientes de este aspecto, el equipo investigador planteó la posibilidad de realizar los grupos de discusión de forma telemática. El profesorado y alumnado de la UPV ya tenían experiencia a este respecto mediante la plataforma TEAMS, de Microsoft, por lo que se valoró esa opción.

Los grupos de discusión por internet en sus diferentes modalidades (mediante grupos de chat o webcams, generalmente) son una herramienta que permite reunir a participantes que se encuentran geográficamente dispersos, aunque presentan la desventaja de limitar el potencial de participación y depender de las limitaciones tecnológicas (Guest et.al. 2017). En la investigación se trató de analizar previamente qué riesgos podían suponer ambas modalidades. Se entendía que la interacción entre participantes, la dinámica grupal, así como el estudio de la comunicación verbal y no verbal, eran esenciales en el análisis de un grupo de discusión, por lo que la principal amenaza en los grupos online era que estas condiciones se vieran mermadas por la distancia y desapego entre participantes. Por otra parte, más allá de las pruebas piloto, la muestra final se corresponde con la población general de la ciudad de València, a los que no se les presupone un conocimiento de las aplicaciones de videollamada. Los posibles problemas informáticos añaden mayor incertidumbre al correcto funcionamiento de las discusiones. Para los moderadores del grupo de discusión, la modalidad online también era una novedad, para lo cual se empleó, además de la lectura y visualización de diferentes fuentes bibliográficas, la colaboración estrecha de Lidón Mars Aicart, doctora en Psicología e investigadora del proyecto.

Se acordó finalmente la realización de tres grupos de discusión piloto para la fase 1, detallados en la tabla 1. El grupo de discusión se planteó con una duración de 90 minutos y pretendía cubrir los tres elementos básicos de la BPNT: competencia, autonomía y relación. Se organizaba en los bloques temáticos de bienestar (percepciones e interacciones entre usuarios), seguridad, organización de actividades (tiempo, destinos y cadena de desplazamientos), género y elección de ruta.

GRUPOS DE DISCUSIÓN				
FECHA	**MODALIDAD**	**MEDIO DE TRANSPORTE**	**PARTICIPANTES**	**OBJETIVO**
09-03-21	En línea	Bicicletas	Estudiantes	Familiarizarse con la aplicación informática y el control de las dinámicas de grupo telemáticamente. Compañeros de clase con sesgo por amistad previa.
23-03-21	Presencial	Patinetes	Estudiantes	Comprobar dinámicas de grupo de forma presencial en tiempos de pandemia y funcionamiento del guion
30-03-21	En línea	Patinetes	Trabajadores de la universidad	Comprobar dinámicas de grupo de forma telemática y funcionamiento del guion

Tabla 1: Listado de grupos de discusión piloto celebrados

La experiencia adquirida es breve y deben asumirse las limitaciones de muestra y características de los participantes. No obstante, ya pueden apuntarse de forma preliminar aspectos positivos y negativos de los grupos de discusión online, reflejados en la tabla 2.

ANÁLISIS DAFO GRUPOS DE DISCUSIÓN ONLINE	
Debilidades	**Amenazas**
- Carencia de experiencia previa en la conducción de grupos de discusión online	- Mayor incertidumbre acerca del comportamiento de los participantes: dinámica y atención durante el grupo y motivación a participación previamente - Necesidad de equipos informáticos para la correcta grabación (micrófono y cámara) que cada participante debe tener - Desconocimiento de los programas informáticos - Posibles problemas de conexión de los participantes - Comunicación no verbal limitada: reduce la capacidad de control de la discusión, interrupción o reparto de los turnos de palabra
Fortalezas	**Oportunidades**
- Conocimiento y experiencia con aplicaciones para llevar a cabo reuniones telemáticas - Mayor facilidad de grabación de las reuniones	- Predisposición entre la población al uso de herramientas online - Se amplía el abanico de posibles participantes, incluso de diferentes poblaciones (se elimina la necesidad de movilidad) - La pandemia ha supuesto la potenciación de los medios de transporte objeto del análisis. Mayor facilidad de captación de usuarios.

Tabla 2: Celebración de grupos de discusión online. Análisis DAFO

Respecto a las dinámicas de grupo e interacción entre participantes, el grupo presencial tuvo una dinámica muy positiva. Es de mencionar, no obstante, que los estudiantes participantes acuden diariamente a las clases de la universidad y en condiciones parecidas a las del grupo de discusión celebrado. Ello explica, en buena manera, su predisposición a participar. Esa circunstancia no es común a otros grupos de edad, probablemente no tan acostumbrados a reuniones con personas desconocidas bajo las presentes circunstancias, por lo que no es directamente extrapolable. Respecto a los grupos de discusión online, en el celebrado el 30 de marzo la dinámica fue altamente satisfactoria.

Los participantes, trabajadores de la UPV, tenían ya conocimiento de la aplicación y hacían uso habitual de la misma en reuniones internas. Por otra parte, los participantes no tenían amistad previa, y se comprobó la utilidad de una adecuada ronda inicial para ganar confianza y complicidad entre ellos y sentar las bases de una mejor interacción. Se comprobó que es posible entablar una dinámica de grupo adecuada de forma online, aun asumiendo las interferencias y distracciones que a los participantes se les presentan ocasionalmente. Se les pidió, además, tener en todo momento la cámara encendida, lo cual ayudó a involucrarlos en la discusión. La tarea de moderación y control de los tiempos es también compleja. La comunicación no verbal, que en encuentros presenciales juega un papel relevante en el control y reparto de los turnos de palabra, en la modalidad online apenas se advierte por parte de los participantes y obliga al uso de otras técnicas que pueden ser peor percibidas por los participantes.

El incentivo no se planteó en esta prueba piloto, aunque sí se contempla para los grupos definitivos. La tasa de no aparición de los participantes fue considerable (entre un 35-40% de los que en un principio aceptaron). La mayoría o no se excusaron o lo hicieron tras consultas por nuestra parte de última hora. Las causas no parecen estar relacionadas con la situación de pandemia, sino más bien por la ausencia de un incentivo que anime a la participación cuando surgen otros quehaceres de mayor interés a última hora.

Organizativamente, las reuniones telemáticas se han demostrado más sencillas: no es necesaria la reserva de espacios, el desplazamiento de los participantes o la preparación de los dispositivos de grabación, lo cual puede suponer un ahorro de tiempo y dinero tanto a organizadores como a participantes. La grabación mediante la aplicación online es muy sencilla de ejecutar y ofrece buena calidad de audio y vídeo, siempre que los participantes dispongan de cámara y micrófono adecuados, incluso superior a la que podría obtenerse in situ. La no necesidad de desplazamiento abre, a su vez, nuevas posibilidades de recopilación de información más allá de la población en la que se lidera el proyecto. Conocidas las limitaciones en cuanto a servicios de movilidad compartida en València, el equipo del proyecto Travelwell+ se plantea aprovechar esta tesitura para organizar grupos de discusión online con población de la Comunidad de Madrid, donde los servicios de movilidad compartida son más variados y están más extendidos. Se presenta esta situación, por tanto, también como una oportunidad.

3. CONCLUSIONES

La situación derivada de la emergencia sanitaria por SARS-CoV 2 tiene como consecuencia un cambio en los datos y en la forma de obtenerlos. En cuanto a los datos, el cambio en los hábitos de desplazamiento y reparto modal que la situación acarrea deberá ser reflejado y considerado en las investigaciones que tengan lugar durante este contexto. En nuestra investigación puede suponer una oportunidad, ya que el uso de nuevas formas de movilidad personal, como el patinete, parece estar viéndose incrementado. Por otra parte, la toma de datos se ve alterada, especialmente si implica una mayor interacción social, como es el caso de los grupos de discusión.

La investigación Travelwell+, con un enfoque mixto de recogida de datos cuantitativos y cualitativos, ha tenido que adaptarse a esta situación, especialmente en la realización de los grupos de discusión. Aunque los grupos celebrados son escasos en número y se circunscriben a la fase de preparación, se puede concluir que la celebración de los mismos de manera online no supone necesariamente una desventaja en la obtención de resultados. La predisposición de la población a la participación mediante estas tecnologías y las facilidades de organización juegan a favor de esta técnica. Además se eliminan los límites geográficos y surgen nuevas oportunidades de captación de información sin necesidad de movilidad.

El éxito de las dinámicas de grupo recae, aún más si cabe, en los moderadores y su capacidad de animar a la participación y crear el ambiente propicio para ello. Si este se da, la participación no parece verse afectada sobremanera. Entre los desafíos, eso sí, se encuentran la gestión de los turnos de palabra y las estrategias de interrupción a los participantes. Dado que la comunicación no verbal, usual en la modalidad presencial, se ve restringida en la modalidad no presencial, este aspecto se plantea como una dificultad añadida. Como riesgos cabe destacar el posible desconocimiento de las aplicaciones de videollamada, que puede dificultar encuestar a colectivos no acostumbrados a ellas. La logística previa parece más sencilla, aunque son de esperar mayores problemas durante los grupos de discusión (problemas de conexión, interrupciones, problemas de sonido o audio).

AGRADECIMIENTOS

Esta investigación se lleva a cabo gracias a la financiación del proyecto Travelwell+ (PID2019-108843RB-I00) por parte de la Agencia Estatal de Investigación del Ministerio de Ciencia, Innovación y Universidades.

RESUMEN

El bienestar, asociado a los sentimientos de felicidad, emociones positivas o la autorrealización, es un aspecto relacionado con el comportamiento humano que se estudia por los psicólogos sociales desde hace décadas. El bienestar también se aplica en la planificación del transporte como un factor explicativo de las características de la movilidad de las personas.

Esta ponencia presenta en primer lugar, las teorías psicológicas y métodos de estudio más importantes relacionados con el bienestar. Además, se describen las principales escalas de medición del bienestar subjetivo y psicológico, y las variables que se utilizan.

Posteriormente, se revisa su aplicación en el área del transporte; se plasman los resultados más relevantes, obtenidos en algunos estudios de movilidad de personas que incluyen el bienestar, para transporte público, privado y modos activos. Finalmente, se identifican líneas de trabajo futuro, y su importancia.

1. INTRODUCCIÓN

Tradicionalmente se ha estudiado el bienestar desde dos corrientes (Keyes, Ryff y Shmothkin, 2002), la tradición hedónica o el estudio del bienestar subjetivo (SWB, de sus siglas en ingles *Subjective Wellbeing*) y la tradición eudaimónica o el estudio del bienestar psicológico (PWB, de sus siglas en inglés *Psychological Wellbeing*) (De Vos, Schwanen, Van Acker y Witlox, 2013).

El bienestar subjetivo persigue maximizar las experiencias de felicidad y placer, evitando así las que conllevan malestar o dolor. (Ryan y Deci 2001), que consta tanto de elementos afectivos como cognitivos. Este tipo de bienestar se ha medido en numerosos estudios a través de variables como la satisfacción con la vida, el afecto positivo y el afecto negativo (Lucas, Diener y Suh, 1996; Diener 2000).

Por otra parte, el bienestar psicológico estudia la consecución del bienestar a través del desarrollo del potencial humano, del propósito y significado de la vida, el crecimiento personal y el pleno desarrollo de las propias capacidades y potencialidades (Ryan y Deci, 2001). Ryff (1989), sugirió un modelo de bienestar psicológico compuesto por seis dimensiones: la autoaceptación, el crecimiento personal, el propósito vital, la autonomía, el dominio del entorno y el mantenimiento de relaciones positivas.

A partir de esta concepción del bienestar psicológico, se ha desarrollado una teoría evolutiva del bienestar (Ryff y Keyes, 1995; Ryff y Singer, 2001) basada en la búsqueda de la realización del propio potencial. Este tipo de bienestar se ha medido a través de variables como la autoestima, autoeficacia, o la vitalidad subjetiva.

En ocasiones, se habla de estas dos concepciones como si estuvieran en conflicto o fueran contrapuestas, sin embargo, en realidad son complementarias y abordar el bienestar desde ambas hará que las personas alcancen mayor bienestar (Huta, 2015).

Trasladando estos conceptos al área del transporte de personas, Singleton y Clifton (2019) afirman que hay beneficios más allá del simple hecho de alcanzar un destino, de hecho, cuando una persona se traslada de un lugar a otro experimenta una serie de sentimientos y emociones, positivas o negativas, que inciden en la satisfacción de dicho viaje.

Por otro lado, viajar también puede influir en el bienestar gracias a la satisfacción de diversas necesidades, el fortalecimiento de lazos sociales o el alcance de determinadas metas personales.

Sin embargo, las primeras evaluaciones de satisfacción con los viajes, estaban basadas en la teoría de la utilidad, es decir, el análisis de la relación costo-beneficio, restando así importancia a otros aspectos emocionales y psicológicos influyentes como la calidad de vida o el bienestar de las personas, que eran considerados un objetivo secundario (Ettema et al, 2012)

De esta forma, es importante conocer en qué grado, la satisfacción con los viajes diarios contribuye a la satisfacción con la vida y el bienestar emocional; así como, los factores que inciden en la satisfacción de las personas y la forma de medirlos o entender cómo las personas evalúan cognitivamente sus viajes.

Además, establecer diferencias en el bienestar experimentado en diversos modos de transporte. (Redman, Friman, Gärling y Hartig, 2013; Gärling, Ettema, Fors Connolly, Friman y Olsson, 2020).

2. MEDICIÓN DEL BIENESTAR

La evaluación del bienestar, ya sea subjetivo o psicológico, se ha venido realizando a través de diferentes instrumentos o escalas psicométricas. Para la medición del bienestar subjetivo se pueden destacar: la Escala de Satisfacción con la Vida SWLS (del inglés *Satisfaction with Life Scale*) (Diener, Emmons, Larsen y Griffin, 1985), la Escala de Afecto Positivo y Negativo (PANAS, del inglés *Positive and Negative Affect Scale*, Watson, Clark y Tellegen, 1988), la escala de medición de la Intensidad Afectiva de Larsen, (AIM; del inglés *Affect Intensity Measure*, Larsen, 1987); la escala SCAS (*Swedish Core Affect Scale*, Västfjäll y Gärling, 2007) y la Escala de Satisfacción con los Viajes STS. (*Satisfaction with Travel Scale*, Ettema y colaboradores, 2011).

A continuación, se describen algunas de estas escalas utilizadas en los estudios que describe la presente ponencia. En cuanto al bienestar psicológico, se destaca la teoría de necesidades psicológicas básicas BPNT y la escala de medición de la Satisfacción y Frustración de estas Necesidades Psicológicas Básicas, BPNSF.

Diener et al (1985), consideraron que, aunque los individuos pudieran tener diferentes estándares de éxito para cada una de las áreas de su vida, podrían tener al mismo tiempo un criterio global de evaluación de la vida en general, que podía ser evaluado de forma independiente. Por lo tanto, la SWLS consta de cinco ítems que evalúan un juicio global de satisfacción con la vida. La escala de respuesta es de tipo Likert de siete pasos desde “1, completamente en desacuerdo” hasta “7, completamente de acuerdo”.

El inventario PANAS se compone de 20 ítems y consta de dos subescalas, afecto positivo y afecto negativo, con 10 ítems cada una. Los encuestados deben responder siguiendo la consigna de cómo se sintieron durante los pasados días o semanas y la escala de respuesta es de tipo Likert de cinco pasos, desde 1 “nada” a 5 “extremadamente” en la que deben evaluar su estado de ánimo durante ese período de tiempo específico (Watson et al, 1988).

La Escala de Intensidad Afectiva (AIM), desarrollada por Larsen (1987), es un instrumento de medida del constructo unidimensional que describe la intensidad con que se experimentan las emociones (Martínez y Ortiz, 2000). Larsen desarrolla el concepto de intensidad afectiva, para delimitar las diferencias individuales en la intensidad con que las personas experimentan subjetivamente los distintos estados afectivos (Larsen y Diener, 1987). Esta escala está compuesta por 40 ítems en una escala tipo Likert desde “1, nunca” hasta “6, siempre” y los encuestados deben valorar cómo reaccionarían ante las diferentes situaciones que se proponen.

En 2010 Ettema, Gärling, Olsson y Friman propusieron un marco teórico para aplicar el concepto de bienestar en el análisis del comportamiento de los usuarios de transporte. Para ellos el bienestar subjetivo se puede medir a través de la evaluación de la satisfacción con la vida de forma global y la evaluación del bienestar emocional.

Ettema y colaboradores (2011) desarrollaron un instrumento para medir el bienestar subjetivo relacionado con los viajes, la Escala de Satisfacción con el Viaje (STS) que consta de 9 ítems. Esta escala proporciona una medida de la satisfacción general de viajes realizados y está basada en dos dimensiones, cognitiva y afectiva, del bienestar subjetivo, y se refiere al viaje en general y no para cada etapa del mismo. (Ettema et al, 2012).

Los ítems de la STS (Ettema y colaboradores, 2011) que miden el bienestar afectivo se basan en la Escala Sueca de Afecto Central (SCAS; Gärling, 2007) y la Escala de Afecto Central del modelo de Russell (1980; 2003). Según este enfoque, el afecto se compone de dos dimensiones: la activación y la valencia. La activación se refiere al grado de estimulación del individuo, por las señales del entorno, y que fluctúa desde el polo de activación al de desactivación y la valencia se refiere a la evaluación del individuo sobre esos afectos en términos de positivos a negativos. Se parte del principio que la satisfacción con el viaje puede ser una medida de bienestar subjetivo perteneciente a un dominio específico (viaje).

Los 6 ítems que miden el afecto, relacionados con el viaje, se basan en SCAS. (Ettema et al, 2013). Cada ítem, consta de pares adjetivos que representan dimensiones de activación-valencia. Los 3 primeros ítems constan de pares adjetivos que van desde activación negativa a desactivación positiva. Los siguientes 3 ítems van desde desactivación negativa a activación `positiva. Y los 3 últimos ítems son descripciones que van de evaluaciones cognitivas de los viajes negativas a positivas. La escala de respuesta es de tipo Likert de 9 puntos que van de -4 a 4 pasando por cero y la escala se aplica a viajes en general (Ettema et al, 2012).

Con respecto a la corriente eudaimónica o de bienestar psicológico, en sus postulados se encuentra la Teoría de la Autodeterminación, SDT (del inglés *Self Determination Theory*. Esta es una macroteoría de motivación humana, que consta de 6 miniteorías, entre las cuales se destaca Una de estas miniteorías es la de las necesidades psicológicas básicas (BPN, del inglés *Basic Psychological Needs*), Ryan y Deci, 2017; 2019) en ella se plantea que existen 3 necesidades psicológicas básicas y necesarias para el bienestar: autonomía, competencia y relación.

La necesidad de autonomía se refiere al sentimiento de las personas de ser el origen de la propia toma de decisiones o capacidad de escoger las propias acciones y de no ser controladas por otros. La satisfacción de la autonomía conlleva un comportamiento autodeterminado y acorde con la voluntad y los deseos de los individuos, por lo tanto, se genera una sensación de plenitud y placer.

En contraste, cuando las personas sienten que su autonomía es frustrada experimentan que alguien o algo activamente impide que tomen sus propias decisiones y se encuentran en el polo controlado de la conducta por lo que se dan experiencias no placenteras. El término competencia se refiere a la necesidad de los individuos de sentirse eficaces y en control.

De ahí que la satisfacción de la competencia se dará cuando el individuo sienta que puede interactuar de forma eficaz con el ambiente y tiene la capacidad de lograr sus objetivos; por el contrario, la frustración de la competencia se dará cuando el individuo sienta que se le impide ser eficaz y por tanto dude de sus capacidades para interactuar con el ambiente. Por último, la necesidad de relación se refiere a la necesidad inherente del ser humano, como ser social, a ser contactado por otros y tener buenas relaciones con ellos. Así, la satisfacción de esta necesidad consiste en conectar con otros de forma positiva y sentirse unido a ellos; la frustración de esta necesidad se refiere a sentimientos de aislamiento, soledad o no sentir que no se tienen relaciones positivas con los demás (Castro, 2009).

En la teoría de la autodeterminación, un instrumento desarrollado para evaluar la satisfacción de estas necesidades es la escala BPNS, Escala de Necesidades Psicológicas Básicas.

Consiste en 12 ítems, divididos en tres factores compuestos por cuatro ítems por factor para medir la satisfacción de cada una de estas tres necesidades psicológicas básicas: autonomía, competencia y relación. Las respuestas son recogidas en una escala tipo Likert del 1 (totalmente en desacuerdo) al 7 (totalmente de acuerdo). (Nishimura y Suzuki, 2016).

Con respecto a la Escala de satisfacción y frustración de las necesidades psicológicas básicas BPNSFS (Del inglés *Basic Psychological needs Satisfaction and Frustration Scale*, Chen et al, 2015); Está compuesta de 6 factores satisfacción y frustración de las tres necesidades psicológicas básicas postuladas desde la teoría de la autodeterminación, con cuatro ítems en cada factor. La escala de respuesta es de tipo Likert de 5 pasos desde totalmente falso a totalmente verdadero.

3. BIENESTAR Y MOVILIDAD

3.1 Bienestar y transporte público

Ettema y colaboradores en 2011, realizaron un estudio con 155 estudiantes universitarios de la Universidad de Karlstad en Suecia, a quienes por grupos se les pidió que evaluaran cinco escenarios hipotéticos usando el STS que mide bienestar afectivo y cognitivo, la escala de satisfacción con el día (una modificación de la escala SWLS para evaluar un único día) que mide bienestar cognitivo y el SCAS que mide bienestar afectivo. Las diferentes versiones presentadas diferían en el modo de transporte (autobús vs coche), el tiempo de viaje y el acceso a la parada del autobús. En todas ellas los encuestados debían evaluar tres días hipotéticos con tres agendas de actividades determinadas que diferían en la cantidad de actividades que hipotéticamente realizarían en ese día.

Para evaluar las diferencias entre los distintos escenarios hipotéticos, se realizaron análisis de varianza (ANOVA) de medidas repetidas y pruebas *t*, de diferencia de medias. Los resultados concluyeron que tanto el modo de transporte utilizado, como el tiempo de viaje y el acceso a la parada de bus influía sobre el STS y por tanto el bienestar.

En cuanto a los resultados del STS, fueron más bajos para el modo autobús que automóvil; para los viajes en autobús, los encuestados sentían menor bienestar a mayores tiempos de viaje y si era menor el acceso a las paradas de autobús.

Un año más tarde, en 2012, otro estudio realizado por Ettema, Friman, Gärling, Olsson y Fuji pone a prueba la escala STS, el objetivo era evaluar cómo incidía en el bienestar subjetivo, el desarrollo de otras actividades realizadas durante un viaje en transporte público. Se aplicaron cuestionarios a usuarios de transporte público en Suecia que se dirigían hacia el trabajo. A través de análisis de regresión, sus resultados indicaron que las actividades que se realizaban durante el viaje impactaban en la satisfacción del mismo, por ejemplo actividades que implicaran una interacción con otros (ej. hablar con otros pasajeros), tenían efectos más positivos que actividades cuyo fin era el entretenimiento o relajación (ej. escuchar música, o utilizar el teléfono móvil) que por el contrario implicaban una satisfacción con el viaje más baja; se concluyó además que el destino incidía así mismo en la satisfacción con el viaje, ya que encontraron un mayor efecto de las actividades durante el viaje de regreso al hogar que hacia el lugar de trabajo.

Por su parte, Friman, Fujii, Ettema, Gärling y Olsson (2013), realizaron un estudio enfocado en medir el bienestar subjetivo de los usuarios en diferentes modos: transporte público, vehículo privado y modos activos. Aplicaron encuestas STS a muestras aleatorias de residentes de las tres zonas urbanas más grandes de Suecia preguntándoles sobre su viaje de ida al trabajo y de vuelta a sus hogares, posteriormente hicieron análisis factoriales confirmatorios, y pruebas de invarianza sobre las diferentes zonas urbanas y los distintos modos de transporte. Obteniendo como resultado que existían diferencias en el bienestar subjetivo de las personas dependiendo del área en la que viajaran y también del modo de transporte, aquellos que viajaban a pie o en bicicleta sentían mayor satisfacción con el viaje que aquellos que viajaban en otro modo de transporte, además para usuarios de transporte público, la satisfacción con el viaje fue significativamente menor que para usuarios de automóvil y modos activos.

De Vos, Schwanen, Van Acker y Witlox (2015) también realizaron un estudio enfocado en analizar viajes de ocio en diferentes modos de transporte: transporte público, transporte privado y bicicleta, en la ciudad de Gante (Bélgica). Para cada modo de transporte, se calificaron los 9 ítems de la escala STS, y se compararon los promedios de estos valores con las medias de los otros modos combinados, mediante pruebas *t*. La satisfacción del viaje para las evaluaciones tanto afectivas como cognitivas, resultó menor para los viajes de ocio en transporte público que para los otros modos (automóvil y modos activos).

En otro estudio sobre bienestar subjetivo (Friman, Ettema y Olsson, 2017), el objetivo era establecer si la satisfacción con los viajes (diarios, de ocio, escolares y viajes de compras) estaba relacionada con la satisfacción con la vida y el bienestar emocional.

Para ello se aplicó la encuesta STS a una muestra aleatoria de 367 participantes que fue reclutada de tres áreas urbanas en Suecia (Karlstad, Gotemburgo y Estocolmo). Los resultados obtenidos fueron analizados, aplicando la teoría de mínimos cuadrados y modelos de ecuaciones estructurales.

Se reafirmó que, la satisfacción con los viajes diarios influía directamente en el bienestar emocional y directa e indirectamente en la satisfacción con la vida. Los resultados mostraron que los viajes en transporte público eran menos satisfactorios que en automóvil y modos activos.

Más recientemente, Singleton y Clifton (2019) desarrollan mediciones multidimensionales de bienestar tanto subjetivo como psicológico asociados a un viaje. La muestra correspondió a adultos que trabajan y viajan diariamente en el área metropolitana de Portland, Oregón, que se desplazaban, a pie, en bicicleta, automóvil o transporte público; y se aplicaron encuestas on-line. Para la realización de las encuestas, se utilizó el formato corto de PANAS (I-PANAS-SF), el cual ha sido validado psicométricamente (Thompson, 2007).

Para medir aspectos eudaimónicos del bienestar referido a los viajes de ida y vuelta del trabajo crearon diversos ítems basados en otros cuestionarios anteriores que aplicaban a la vida en general. Se realizaron análisis factoriales exploratorios y confirmatorios, para evaluar los diferentes tipos de bienestar; y el trabajo concluye proponiendo una nueva escala de medición de factores que inciden en el bienestar subjetivo y bienestar psicológico.

3.2 Bienestar y transporte privado

En cuanto a las evaluaciones de bienestar para el transporte privado. En el estudio de Ettema et al (2011), se obtuvieron mayores valores de satisfacción con el viaje (usando el cuestionario STS) para los viajes en automóvil, en comparación con los viajes en autobús; al tener este último, aspectos desfavorables como mayores tiempos de viaje y depender mucho del acceso a las paradas.

Ettema, Gärling, Olsson, Friman y Moerdiik (2013) también desarrollaron una investigación para medir la satisfacción con el viaje de una muestra de usuarios de vehículo privado utilizando la escala STS en cuatro autopistas diferentes de Países Bajos. Como resultado demostraron que diversos factores influían sobre la satisfacción con el viaje: la seguridad vial, el nivel de enfado con los otros usuarios de la autopista, cansancio, distraerse con las señales, y falta de capacidad para decidir la velocidad y el carril, así como el propósito del viaje y las propias características del conductor.

Como se ha comentado anteriormente en el trabajo de Friman y colaboradores (2013) a través de la aplicación de la encuesta STS, observaron que la escala global de la satisfacción con el viaje para usuarios de automóvil fue significativamente mayor que para usuarios de transporte público.

En el análisis de De Vos y colaboradores (2015), en el que aplicaron la escala STS, para viajes de ocio en diferentes modos de transporte de la ciudad de Gante (Bélgica); la satisfacción del viaje para las evaluaciones tanto afectivas como cognitivas, resultó mayor para los viajes de ocio en automóvil, que en transporte público.

Friman y colaboradores (2017) en su estudio para determinar la relación entre satisfacción con los viajes y satisfacción con la vida, observaron que la satisfacción con los viajes diarios influía en el bienestar emocional y en la satisfacción con la vida. Los resultados mostraron que los viajes en vehículo privado eran más satisfactorios que en transporte público; debido a las variables como interrupciones en el transporte público por baja capacidad de infraestructura; accesibilidad a aparcamientos de vehículos vs paradas de autobús alejadas, o que el vehículo privado fuera considerado más cómodo que el transporte público. Además de antiguas políticas de vivienda que han favorecido el uso del vehículo privado.

3.3 Bienestar y movilidad activa

Algunos de los estudios anteriormente descritos, además de evaluar el bienestar en el transporte público y el vehículo privado, incluían modos activos como bicicleta o a caminar; en nuestra revisión aparecen otros estudios que se enfocan específicamente en algunas de estas modalidades.

Como se ha descrito anteriormente en Friman y colaboradores (2013), en la medición del bienestar subjetivo experimentado por usuarios de diferentes modos de transporte, los resultados revelaron que, viajar en bicicleta o a pie, era más satisfactorio que viajar en otros modos de transporte público o privado.

Jones, Harms y Heinen (2016) realizaron una investigación enfocada a usuarios de bicicletas eléctricas, de Holanda y Reino Unido, con el fin de determinar su bienestar psicológico, experiencias y percepciones. Esta se centró en 3 aspectos:

- motivos de compra
- percepción del impacto en el comportamiento de viaje
- experiencia del usuario.

Los resultados arrojaron que la principal motivación que tienen las personas para viajar en bicicletas eléctricas es superar viajes largos o complicados o reemplazan viajes personales que normalmente hacían en automóvil.

Los resultados del estudio de Friman et al (2017), confirman la relación entre bienestar y modo de transporte. Para el caso específico de modos activos, los viajes en modos activos son más satisfactorios que en transporte público.

Se destaca también, el estudio realizado en China por Ma y colaboradores (2018), quienes desarrollaron un modelo para determinar los factores que afectaban el bienestar subjetivo de los usuarios de bicicletas compartidas, aplicando encuestas on-line a 908 usuarios, y encontraron que el valor percibido por los usuarios, la influencia social y las características del sistema de bicicletas compartidas son factores importantes que inciden en el bienestar subjetivo de los usuarios; además, el bienestar subjetivo puede verse afectado por factores psicológicos como la realización personal. Concluyendo que el valor hedónico tiene el mayor impacto en el bienestar subjetivo, seguido por el valor social y por el valor utilitario, y por tal razón, los usuarios de bicicletas compartidas valoran más el placer sobre los demás factores. Adicionalmente, ofrecían recomendaciones para los operadores, encaminadas a mejorar el placer de los usuarios, tales como, mejorar aún más el diseño visual de las bicicletas; reforzar la imagen de utilidad, placer y felicidad del servicio, a través de campañas; y aplicar la teoría de la influencia social para atraer más usuarios.

En el estudio de Handy y Thigpen (2019), realizado con estudiantes y empleados de la Universidad de California, se utilizó un modelo de regresión lineal bayesiano. Al evaluarse los resultados de las encuestas, en las que se utilizó una escala de Likert, y se tomó el promedio de la evaluación de 6 aspectos relacionados con sentimientos generales sobre el viaje, resultó que los caminantes estaban más satisfechos seguidos de cerca por los ciclistas.

En el estudio de Burgueño et al (2020) se adapta la versión española de la Escala de Necesidades Psicológicas Básicas en el ejercicio a los desplazamientos activos desde y hacia la escuela, en niños y jóvenes utilizando la escala BPNS, y se considera que la escala para medir la satisfacción de las necesidades básicas psicológicas es el primer instrumento válido para medir las 3 necesidades en los desplazamientos activos desde y hacia la escuela de los jóvenes españoles (a pie y en bicicleta).

4. CONCLUSIONES

El concepto de bienestar en el transporte ha adquirido importancia en las últimas décadas. Se han venido desarrollando y adaptando teorías psicológicas y herramientas de medición, que buscan evaluar de la manera más fiable posible, los componentes afectivos del bienestar, que anteriormente se dejaban de lado, cuando se prestaba más atención a las relaciones costo – beneficio. Se ha demostrado que la satisfacción con los viajes diarios influye en la satisfacción con la vida y en el bienestar emocional; es importante que las políticas públicas se alineen en ese sentido, buscando impactar la calidad de vida de las personas, a través de las mejores experiencias en sus viajes.

La satisfacción y las emociones experimentadas por los usuarios está ligada al modo de viaje, por consiguiente, la implementación de nuevas soluciones de movilidad urbana, afectarán el comportamiento. Se debe estudiar los cambios que se producen, e inciden ya sea positiva o negativamente en el bienestar psicológico y subjetivo de las personas.

Por ejemplo, evaluar el uso de modos de transporte compartidos vs formas convencionales de moverse. Estas nuevas formas de movilidad incluso, han incidido en cambios en el diseño urbano, y aún no se han hecho estudios en cuanto al comportamiento; por ello, es importante, desarrollar investigaciones al respecto. Al realizarse una revisión de literatura, estos estudios son escasos, especialmente, donde se aborden nuevos modos de movilidad, como patinetes o modos compartidos (*carsharing, motosharing*). Por lo tanto, el estudio del bienestar psicológico o eudaimónico, enfocado a analizar estos nuevos modos de movilidad, permitiría obtener conclusiones importantes con respecto a los factores que influyen en el bienestar de los usuarios.

RESUMEN

El uso del patinete eléctrico se está extendiendo cada vez más por distintos países del mundo. Recientemente se han publicado algunos artículos sobre su implantación en algunas ciudades, sobre todo de Estados Unidos. Sin embargo, todavía hay poca investigación sobre aspectos regulatorios. Este trabajo estudia la regulación de esta nueva forma de movilidad en España. Tras analizar la normativa aprobada en las ciudades con más de medio millón de habitantes, se han determinado los factores regulatorios diferenciadores entre ellas. Empleando un análisis clúster, se han establecido grupos de ciudades en función de su similitud normativa. Los resultados obtenidos pueden contribuir a que el uso de esta nueva forma de movilidad sea más eficiente y sostenible.

1. INTRODUCCIÓN

Las políticas de transporte dirigidas a impulsar la sostenibilidad urbana en las ciudades tienen en estos momentos una gran importancia. La División de Transporte Sostenible de la Comisión Económica para Europa considera que apostar por la planificación urbana orientada a la movilidad puede impactar en trece de los diecisiete Objetivos de Desarrollo Sostenible de la Agenda 2030, establecidos por Naciones Unidas. Además, la movilidad sostenible es esencial para cumplir con el Objetivo 11 sobre ciudades y comunidades sostenibles que, dentro de sus metas, establece la de proporcionar acceso a sistemas de transporte seguros, asequibles, accesibles y sostenibles para todos, así como la de mejorar la seguridad vial mediante la ampliación del transporte público.

Desde el año 2017, el patinete eléctrico se ha convertido en una alternativa para moverse por la ciudad, y su uso compartido es cada vez más habitual porque ofrece una alternativa al automóvil privado y reduce la contaminación del aire y el ruido. Se trata de un medio de transporte que sirve para recorrer distancias cortas y se engloba dentro de la micromovilidad.

Sin embargo, la aparición de los patinetes eléctricos en las ciudades no ha estado exenta de problemas. Desde un principio las dificultades más importantes en el desarrollo de esta actividad han estado relacionadas con la convivencia en la acera de peatones y patinetes, así como el su incorrecto estacionamiento.

Todo ello ha dado lugar a un intenso debate sobre la seguridad vial y la protección de los peatones.

En España, la implantación de patinetes eléctricos compartidos está siendo heterogénea, puesto que depende de la política de movilidad de cada Ayuntamiento. Éstos se han visto obligados a aprobar regulaciones específicas sobre esta actividad económica, ya que el vacío legal existente hasta este momento tanto a nivel local como estatal, así como la implantación de empresas para satisfacer una demanda real, han forzado a los Ayuntamientos a aprobar Ordenanzas nuevas que regulen la movilidad o a modificar las vigentes.

El objetivo de este artículo es identificar las tendencias regulatorias del patinete eléctrico en España. Para ello, se analiza la convergencia o divergencia de las decisiones tomadas por los diferentes Ayuntamientos en relación con aspectos clave de la normativa implantada. Para ese fin, se han estudiado las ciudades españolas con una población superior a medio millón de habitantes en 2020 y cuyas Administraciones han establecido medidas regulatorias para los patinetes eléctricos, esto es, Madrid, Barcelona, Valencia, Sevilla, Zaragoza y Málaga.
El análisis realizado permite conocer cuáles son los aspectos regulatorios más importantes en el ámbito del patinete compartido, cuáles son las tendencias normativas que más se han implantado en las ciudades, así como las diferencias más significativas entre unas y otras. Finalmente, se indica por dónde está avanzando la regulación a nivel estatal para homogeneizar la regulación.

Los resultados obtenidos en este trabajo de investigación ayudarán a los Ayuntamientos a generar normativa que regularice el uso del patinete eléctrico compartido de forma homogénea en todo el territorio nacional, promoviendo el uso de nuevas formas de movilidad.

2. LA REGULACIÓN DEL PATINETE EN LAS CIUDADES

El uso del patinete eléctrico compartido como una nueva forma de movilidad se está extendiendo cada vez más a lo largo de distintas ciudades del mundo. Sin embargo, a las empresas operadoras no les está resultando fácil su implantación debido a los vacíos normativos sobre la explotación de este tipo de negocio en unos casos, y a la heterogénea normativa municipal en otros. Son muy escasos los estudios existentes sobre esta cuestión, y los publicados recientemente se centran en ciudades de Estados Unidos (Caspi et al., 2020; Portland Bureau of Transportation, 2018; Wood el al., 2019). Así, NACTO ha elaborado guías de regulación y gestión de la micromovilidad (NACTO, 2018).

En España, el Estado es competente para regular los aspectos básicos en materia de tráfico, circulación y seguridad vial, mientras que los Ayuntamientos gozan de autonomía para regular la ordenación del tráfico de vehículos y personas en las vías urbanas, así como el transporte público de viajeros.

Cada Ayuntamiento, por tanto, es competente en la implantación de medidas que fomenten una movilidad urbana sostenible en su término municipal.

La primera Ordenanza de patinetes eléctricos que se publicó en España corresponde al Ayuntamiento de Barcelona, en junio de 2017, pero en ella no se desarrolló la regulación específica para el alquiler de patinetes. En octubre de 2018, el Ayuntamiento de Madrid publicó su Ordenanza de patinetes eléctricos, desarrollando las especificaciones que deben cumplir las empresas de alquiler de patinetes, y en febrero del año siguiente se otorgaron las primeras licencias. En mayo de 2019 los Ayuntamientos de Valencia y Zaragoza publicaron sus propias Ordenanzas. En Valencia se estableció una política similar a la de Barcelona, en cuanto a no desarrollar en su Ordenanza el servicio de patinetes compartidos. Sin embargo, el Ayuntamiento de Zaragoza sí definió las condiciones en las que se debe operar dicha actividad y otorgó las primeras licencias a empresas de alquiler en mayo de 2019. El Ayuntamiento de Sevilla publicó su Ordenanza de patinetes en octubre de 2019 y en enero de 2021 otorgó las primeras licencias de operación. Por último, la Ordenanza de patinetes eléctricos del Ayuntamiento de Málaga se publicó en agosto de 2019 y, aunque todavía no ha otorgado licencias a empresas de alquiler, desarrolla en su Ordenanza algunos aspectos de esta actividad.

Una vez identificada la regulación en materia de patinetes eléctricos compartidos de las ciudades españolas con más de medio millón de habitantes, se han identificado los aspectos más relevantes de dicha regulación. La Tabla 1 recoge una comparativa entre las ciudades. Para facilitar su presentación, se han agrupado los factores regulatorios en cuatro bloques atendiendo al orden de aparición en normativa:

- acceso al mercado, competencia y distribución en la ciudad
- características técnicas y operacionales
- estacionamiento, circulación y seguridad
- supervisión del servicio.

2.1 Acceso al mercado, competencia y distribución en la ciudad.

Para que las empresas puedan estacionar los patinetes compartidos en zonas de dominio público, se precisa de una autorización demanial o una concesión administrativa otorgada por el Ayuntamiento. A la autorización demanial tienen acceso en cualquier momento todas las empresas que cumplan los requisitos establecidos por dicho Ayuntamiento, mientras que la concesión administrativa se otorga a un número limitado de empresas seleccionadas a través de un procedimiento de concurrencia en un periodo determinado.

Estas dos formas que tienen las empresas de acceder al mercado tienen importantes implicaciones a efectos de limitación de la competencia. Si se accede mediante concesión administrativa, el número de empresas operadoras es más reducido que si se precisa de una autorización demanial.

El Ayuntamiento de Madrid ha optado por autorizar la actividad a todos los operadores económicos que cumplan con una serie de condiciones fijadas previamente; inicialmente se concedieron licencias de operación a 14 empresas de alquiler. Los Ayuntamientos de Sevilla y Zaragoza han otorgado concesiones administrativas para adjudicar la operación a dos empresas en cada uno de sus términos municipales. Por otro lado, los Ayuntamientos de Barcelona, Valencia y Málaga no han dado autorizaciones demaniales ni han otorgado concesiones administrativas.

Tanto las autorizaciones demaniales como las concesiones administrativas son temporales, oscilando su duración entre uno y dos años, con posibilidad de prórroga en algunos casos, como ocurre en Zaragoza. El Ayuntamiento de Madrid optó por las autorizaciones demaniales, no obstante, se reserva la posibilidad de revocarlas en caso de que se saque a concurso público la prestación del servicio mediante concesión administrativa.

Algunas ciudades han establecido un número máximo de patinetes para operar. En Madrid operaron en el año 2020 alrededor de 4.800 patinetes de los 10.000 permitidos. El estricto reparto de vehículos por áreas en la ciudad y la escasa rentabilidad generada ha hecho que algunas de las empresas operadoras del servicio se hayan retirado.

Por su parte, en Sevilla y Zaragoza se ha fijado el límite de patinetes compartidos en 3.000 y 1.700 respectivamente. A diferencia de Madrid, estas dos ciudades exigen en los pliegos de sus concesiones mantener operativas todas las licencias de patinetes otorgadas.

Respecto a la distribución geográfica de los patinetes, tanto Madrid como Zaragoza han establecido unos límites de patinetes de alquiler en cada área concreta de la ciudad. En Madrid, se fijó primero el número máximo de patinetes compartidos autorizables en cada barrio, y posteriormente se concedieron las licencias de forma equitativa en cada barrio a las empresas que solicitaron licencia. Por otro lado, Sevilla tan solo establece en los pliegos de la concesión que los patinetes compartidos se distribuyan de forma equilibrada por la ciudad.

2.2 Características técnicas y operacionales.

La determinación a nivel estatal de las características técnicas y operacionales que deben cumplir los patinetes eléctricos ha ido evolucionando. La aparición de estos vehículos de movilidad personal (VMP) supuso un problema regulatorio para las Administraciones debido a que este tipo de vehículos no venían recogidos en el Reglamento General de Vehículos.

En el año 2016 la Dirección General de Tráfico publicó la Instrucción 16/V-124. Ésta distinguió entre dos tipos de patinetes eléctricos: por un lado, los denominados de tipo A, que son más pequeños y más ligeros; por otro lado, los denominados de tipo B, que son patinetes eléctricos de mayor tamaño. Esta clasificación fue establecida en las Ordenanzas de Madrid, Barcelona, Valencia y Zaragoza.

Con la aprobación del Real Decreto 970/2020, en vigor desde el 2 de enero de 2021, se pone fin al vacío legal en el que se encontraba el patinete eléctrico, incluyéndolo formalmente en el grupo de VMP. Esta norma establece que los patinetes eléctricos no pueden alcanzar una velocidad superior a 25 km/h, no pueden circular por la acera ni zonas peatonales, y no pueden contar con sillín.

La Instrucción 2019/S-149 TV-108 de diciembre de 2019 ya adelantaba que la velocidad máxima de los patinetes eléctricos se fijaría en 25 km/h. De esta forma, las últimas Ordenanzas aprobadas, la de Sevilla y la de Málaga, no establecieron la distinción entre patinetes eléctricos tipo A y tipo B, y fijaron la velocidad máxima de circulación en 25 km/h.

En el Real Decreto 970/2020 también se establece que a partir de los dos años desde que se publique el Manual de Características de los VMP, éstos estarán obligados a disponer de un certificado para la circulación en el que se acredite que dicho vehículo cumple con los requisitos técnicos exigidos por la normativa nacional e internacional, así como de su identificación.

En cuanto a las condiciones operacionales, cabe destacar que tanto Sevilla como Zaragoza establecen restricciones acerca de la recarga de los vehículos. Ambos Ayuntamientos exigen garantizar el uso de toda la flota activa en horario diurno, sin permitir a los operadores subcontratar las actividades de recarga o mantenimiento.

En todas las ciudades se exige que los operadores tengan contratado un seguro de responsabilidad civil ante terceros. En Sevilla y Zaragoza se obliga a que su importe sea superior a 300.000 euros.

2.3 Estacionamiento, circulación y seguridad vial.

El estacionamiento de los patinetes compartidos en Madrid se realiza mediante free floating (aparcamiento libre en la acera), mientras que en Málaga y Sevilla es exclusivamente en base fija (aparcamiento de patinetes en pequeñas áreas establecidas por el Ayuntamiento). Aunque el Ayuntamiento de Málaga todavía no ha otorgado licencias de operación a empresas de alquiler, debido a la proliferación de estos vehículos, han decidido habilitar espacios para el estacionamiento en la vía pública.

Zaragoza ha optado por un sistema mixto, prohibiendo el estacionamiento fuera de las bases fijas en algunas partes del centro, y permitiendo en el resto de la ciudad free floating, aunque recomendando estacionar en bases fijas si existen. Se exige a los operadores establecer mecanismos que premien con incentivos tarifarios a los usuarios cuando estacionen en bases fijas. Además, el Ayuntamiento puede obligar a los operadores a efectuar algunas penalizaciones concretas. Por ejemplo, Málaga exige mantener activa la tarificación si el usuario estaciona fuera de las bases fijas.

En cualquier caso, la responsabilidad por el correcto estacionamiento de los patinetes corresponde a la empresa, sin perjuicio de las sanciones que ésta pueda repercutir a los usuarios.

Las bases fijas pueden disponerse de dos maneras: de uso general o específicas para patinetes. Mientras Zaragoza otorga el uso de estas bases fijas únicamente a vehículos de movilidad compartida, Sevilla reserva al menos un tercio de su capacidad a vehículos privados. Sevilla cuenta con 249 bases fijas con capacidad para 2.650 patinetes eléctricos. Zaragoza cuenta con 38 bases fijas y permite también estacionar en ellas a bicicletas compartidas. Málaga presenta 29 bases fijas a lo largo de la ciudad.

Barcelona y Valencia no permiten a ninguna empresa de alquiler estacionar en dominio público. En algunos casos, las empresas han empleado bases privadas para poder prestar el servicio, por ejemplo, realizando acuerdos con otras empresas que les proporcionen un espacio en sus locales para poder estacionar los patinetes.

En general, el orden de prioridades de estacionamiento de los patinetes es el siguiente: como primera opción se debe hacer uso de estacionamientos específicos para patinetes; la segunda opción es el empleo de reservas de estacionamiento para bicicletas; la tercera opción es hacer uso de la banda de estacionamiento de la calzada; y en último lugar, se permite estacionar en la acera. Es importante resaltar que, aunque la normativa de Barcelona establece que el estacionamiento de los patinetes debe realizarse en los espacios habilitados, en el momento en el que se redactó este artículo el Ayuntamiento no había habilitado ninguno.

Respecto a la circulación de los VMP, el Real Decreto 970/2020 prohíbe de forma general su uso en las aceras. Es habitual que los Ayuntamientos, como el de Málaga, exijan que la circulación se realice por carril bici si éste está disponible. En cuanto a la calzada, los seis Ayuntamientos limitan la circulación de los patinetes eléctricos en carriles de 30 km/h. La diferencia reside en que Barcelona y Málaga permiten circular en cualquier calle de varios carriles por el carril limitado a 30 km/h. Madrid y Valencia permiten circular en calles de varios carriles, pero solo en el caso de estar todos ellos limitados a 30 km/h. Sevilla y Zaragoza sólo permiten circular por calles de un solo carril limitado a 30 km/h. Algunos Ayuntamientos han especificado que la circulación deberá hacerse por la parte central del carril, mientras que Zaragoza tan solo lo recomienda.

En cuanto a las velocidades máximas de circulación, los Ayuntamientos diferencian las siguientes vías: calzada, carril bici, aceras bici y sendas ciclables compartidas con el peatón. Inicialmente, las Ordenanzas de Madrid, Barcelona y Valencia establecieron las velocidades máximas en la calzada según la clasificación de la Instrucción 16/V-124: 20 km/h los patinetes Tipo A y 30 km/h los Tipo B. Posteriormente, con la publicación de la Instrucción 2019/S-149 TV-108, las Ordenanzas de Sevilla, Zaragoza y Málaga ya incluyeron la velocidad máxima en calzada de 25 km/h.

Tan solo en las ciudades que no han desarrollado la regulación de alquiler de patinetes (Barcelona y Valencia) se exige el uso del casco de protección a patinetes de velocidades superiores a 20 km/h.

2.4 Supervisión del servicio.

Los Ayuntamientos han establecido la obligación de que los patinetes de las empresas de alquiler estén identificados. Así, en Sevilla se exige que el VMP sea identificable de forma inequívoca con la documentación, bien con un número de serie o bastidor, o bien mediante la identificación de la marca y el modelo.

Algunos Ayuntamientos han incluido exigencias en cuanto al control remoto que las operadoras de patinetes deben realizar sobre sus vehículos. Málaga exige a los operadores la capacidad de desactivar el vehículo al penetrar en Zonas de Acceso Restringido al Tráfico Rodado. También Sevilla establece este tipo de requerimientos para casos donde el usuario sobrepase los límites de velocidad o estacione en áreas no permitidas.

3. DATOS Y METODOLOGÍA

Una vez seleccionadas las ciudades y recopilada la información regulatoria, se han asociados los factores regulatorios más destacados a variables de tipo cualitativo ordenado y no ordenado. Los factores se clasifican en dos grupos: (a) aspectos que afectan al patinete eléctrico en general y (b) factores que afectan sólo al servicio compartido de patinetes eléctricos (Tabla 2).

Tan solo se incluirán en el análisis los factores regulatorios más destacados que presenten diferencias en alguna de las ciudades. Estos factores son los recogidos en la Tabla 1 y se incluirán como en ella vienen establecidos, salvo la siguiente consideración para extraer mayor información: el factor “Estacionamiento permitido (ordenado por prioridad)” se divide en 3 factores para el análisis clúster, en función de si permite estacionar en calzada, anclado en la acera y en reservas de bicicletas. Todos los factores regulatorios se han considerado cualitativos. Cuando en la Tabla 1 no aparece opción para un factor regulatorio, ello implica que no ha sido recogida en la normativa municipal. Puesto que la Tabla 1 muestra la regulación definida por los Ayuntamientos previa al Real Decreto 970/2020, el análisis clúster incluye los factores “Dimensiones máximas (masa, anchura y longitud)” y “Velocidad máxima en calzada”.

Con el fin de cumplir con el objetivo establecido, se ha realizado un análisis clúster, agrupando las ciudades en función de sus semejanzas. El análisis clúster jerárquico es una técnica estadística multivariante que agrupa elementos tratando de lograr la máxima homogeneidad en cada grupo y la mayor diferencia entre los grupos (Edwards et al, 1965). En este caso los elementos a agrupar son las seis ciudades del caso de estudio, y los factores en función de los cuales se agrupan son cada uno de los factores regulatorios estudiados.

La clasificación se realiza mediante un algoritmo que se basa en la semejanza o diferencia del conjunto de los factores regulatorios comparando los diferentes individuos (Lee et al., 2013). En este estudio se ha medido la semejanza o diferencia de los individuos mediante la distancia de Gower, siendo ésta un valor comprendido entre 0, máximo parecido; y 1, máxima diferencia (Gower, 1967).

$$d(i,j) = (\sum_k \delta_{ijk}\, d_{ijk}) / \sum_k \delta_{ijk} \qquad (1)$$

Donde, i y j, corresponden a los individuos que se comparan; k es el factor de análisis; d_ijk toma el valor de 0 si el factor k de los individuos i y j coinciden, y toma el valor 1 en caso contrario. δ descarta los factores donde los individuos no presentan esa característica. La distancia de Gower entre dos individuos que se establece para cada factor depende de si dicho factor se ha considerado como cualitativo ordenado o no ordenado. En este artículo se han ordenado los factores de una regulación más restrictiva a menos restrictiva. En el caso de factores cualitativos no ordenados, el valor establecido será 0 si ambos individuos coinciden, o 1 en caso contrario. En cambio, para los factores cualitativos ordenados se fijan puntos equidistantes entre 0 y 1 en función del número de opciones del factor, estableciendo la distancia de Gower como la distancia comprendida entre la opción de cada una de las dos ciudades.

Posteriormente, se procede a aplicar el algoritmo de agrupación. Este algoritmo agrupa los individuos (ciudades) por niveles, separando aquellos que más se diferencian del resto (Lee et al., 2013). Cada subgrupo resultante se sitúa en la vertical en función de la diferencia entre los dos individuos más diferentes del subgrupo. Cuanto más parecido hay entre los individuos de un subgrupo, más abajo en el eje vertical aparece. A partir de ese árbol se ha definido el clúster resultado del análisis (Petchey & Gaston, 2007; Akay, & Yüksel, 2018).

Con el objetivo de validar los agrupamientos definidos en el procedimiento anterior, se debe evaluar la bondad de ajuste para evitar la búsqueda de patrones en un dato aleatorio (CHOUIKHI ET AL., 2015). Para evaluar la calidad de los clústeres resultantes se hace uso del índice Dunn, que se estima como la relación entre la mínima separación entre los grupos y el diámetro máximo entre ellos. Se busca que el diámetro de los clústeres sea pequeño y que la distancia entre los clústeres sea grande.

4. RESULTADOS

Se emplea el análisis clúster jerárquico para agrupar a las seis ciudades de estudio en función de la similitud de sus tendencias regulatorias referidas al patinete eléctrico. Se ha establecido previamente que se agruparán las ciudades hasta encontrar los 3 grupos de ciudades con mayor similitud de acuerdo con el óptimo de grupos establecido por la metodología de la silueta media (Rousseeuw, 1987).

El primer análisis clúster compara las seis ciudades en función de los factores del patinete eléctrico en general. Los tres clústeres resultantes son: Málaga; Valencia y Barcelona; Madrid, Zaragoza y Sevilla (Figura 1a).

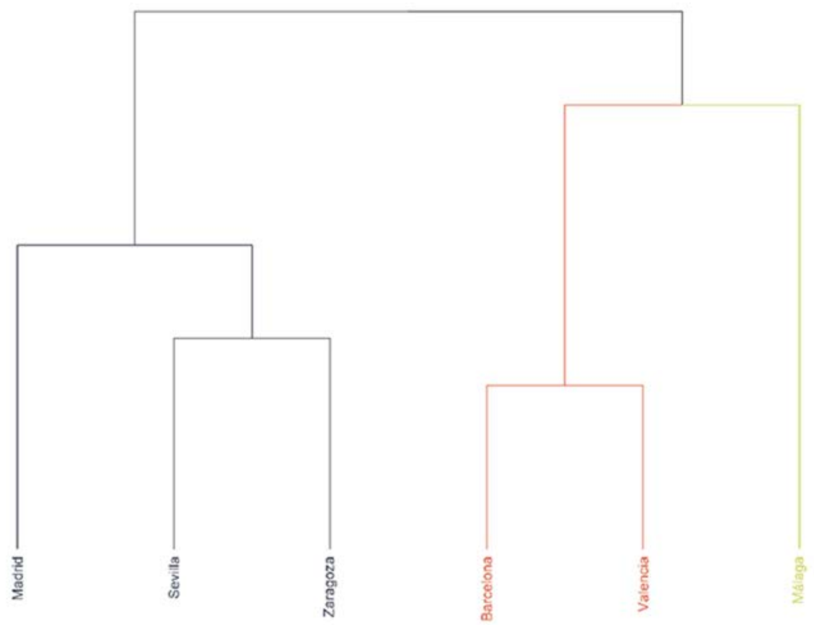

Figura 1a: Patinete eléctrico en general

En este caso, el índice de Dunn resulta un valor de 1,96, lo que significa que los clústeres son compactos y están bien separados de otros clústeres. Málaga forma en solitario el primer clúster, siendo la ciudad que menos se parece al resto en la regulación del patinete en general. La razón se explica en que su Ordenanza ha sido la última en aprobarse, pudiendo estudiar las experiencias en el resto de las ciudades y generar una mezcla de las distintas opciones.El segundo clúster lo forman Valencia y Barcelona. Tan solo se diferencian en algún factor de poca importancia como la velocidad máxima en carriles bici. Esto se puede explicar en que la Ordenanza de Valencias se basó en la de Barcelona.

El último clúster lo forman Madrid, Zaragoza y Sevilla. Son ciudades cuyas Ordenanzas muestran una tendencia a facilitar la circulación en patinete eléctrico. Lo demuestran en varios de los factores en los que coinciden, como son la no obligación en el uso del casco de protección, en permitir estacionar en reservas de bicicletas, o en establecer la circulación del patinete eléctrico por el centro de la calzada. Cabe destacar que dentro de este último clúster Zaragoza y Sevilla acentúan su parecido respecto a Madrid. Esto se debe en parte a que sus Ordenanzas sí fueron establecidas con posterioridad a la Instrucción 2019/S-149 TV-108.

El segundo análisis clúster compara los factores específicos del patinete eléctrico compartido definidos en la Tabla 2. Los tres clústeres resultantes son: Madrid; Sevilla y Zaragoza; Barcelona, Valencia y Málaga (Figura 1b).

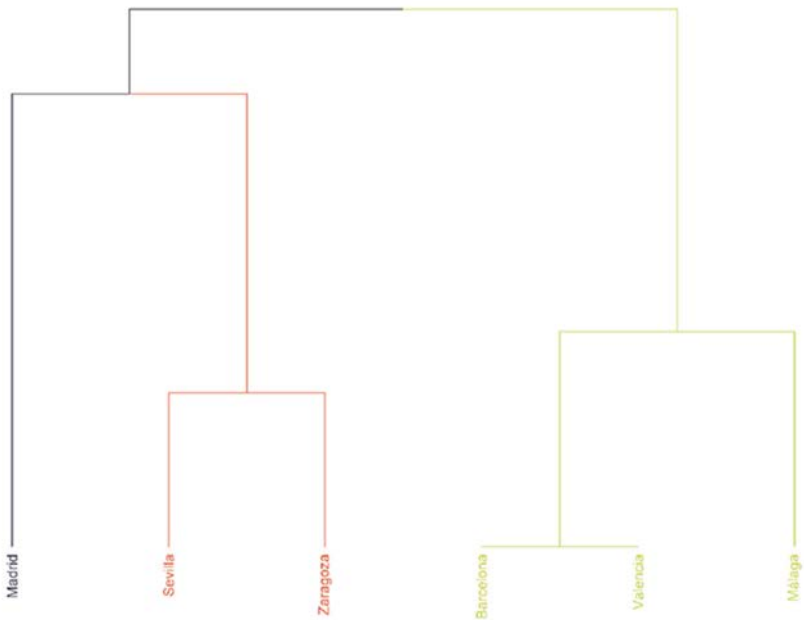

Figura 1b: Patinete eléctrico de uso compartido (alquiler)

En este caso, el índice Dunn tiene un valor de 2,95. Barcelona y Valencia son dos ciudades que casi no han establecido regulación para el patinete de alquiler, por ello no es de extrañar que resulten las dos ciudades más parecidas en este segundo análisis. Málaga completa el primero de los 3 clústeres, aunque manteniendo una cierta diferencia con las dos ciudades anteriores. Esto se debe a que Málaga sí ha adelantado cierta regulación en materia de alquiler de patinetes, como la tipología de alquiler, qué capacidad de control remoto debe tener la empresa de alquiler, y la interacción del usuario con ésta. El segundo clúster está formado por Sevilla y Zaragoza, ciudades muy similares en materia de alquiler de patinetes, donde se optó por restringir la competencia mediante un modelo de concesión administrativa. Por último, Madrid forma en solitario el tercer clúster. Las peculiaridades de Madrid se explican en tanto que fue la primera ciudad en regular y otorgar autorizaciones de alquiler de patinetes.

5. CONCLUSIONES

Ante el incremento de patinetes eléctricos en las ciudades españolas en los últimos cinco años y el vacío legal existente a nivel estatal en cuanto a su uso, los Ayuntamientos se han visto obligados a aprobar Ordenanzas municipales que los regulen.

El resultado es que actualmente existe un abanico de normativas distintas que recogen la voluntad de cada ciudad respecto a su interés en impulsar esta nueva forma de movilidad, y cómo consideran que debe afrontarse. Los factores objeto de regulación más relevantes han sido los requisitos que deben reunir las empresas operadoras de patinetes eléctricos compartidos para prestar su servicio, los requerimientos técnicos y operacionales exigidos a los patinetes, el estacionamiento y la circulación de los mismos, y la supervisión del servicio prestado por las empresas operadoras.

Las primeras ciudades que aprobaron Ordenanzas sobre patinetes eléctricos fueron las de mayor tamaño, Barcelona (2017) y Madrid (2018). En el año 2019 esta nueva forma movilidad compartida se extendió a otros municipios, como son Valencia, Zaragoza, Sevilla y Málaga.

Respecto a la regulación del patinete eléctrico, la normativa de Málaga es la que menos se parece al resto, ya que ha sido la última en aprobarse y esto le ha permitido enriquecerse de las experiencias anteriores. Las normativas de Barcelona y Valencia son similares, puesto que la segunda se basó en la primera. Las normativas de Madrid, Zaragoza y Sevilla muestran una tendencia a facilitar la circulación de los VMP, no obligando a usar casco de protección, permitiendo estacionar en reservas de bicicletas, y permitiendo su circulación por el centro de la calzada.

Respecto a la regulación del patinete eléctrico compartido, se concluye que Barcelona y Valencia no la han regulado. Málaga sí ha regulado algunas cuestiones como la tipología de alquiler, la capacidad de control remoto que debe tener la empresa operadora, y la interacción con el usuario. Zaragoza y Sevilla optaron por restringir la competencia mediante un modelo de concesión administrativa, aunque difieren en cuanto a la duración de las licencias, el número máximo de patinetes, su distribución en la ciudad, y la capacidad de control remoto. Por último, Madrid fue la primera ciudad en regular y otorgar autorizaciones de alquiler de patinetes, estableciendo un sistema de free floating sin limitación en el número de operadores.

Los resultados obtenidos en este trabajo demuestran que, aun cuando se pueden caracterizar grupos de ciudades por su regulación, existen muchas dudas en cuanto al mejor modo de regular esta nueva forma de movilidad compartida. Indudablemente, la regulación debería estar marcada por el logro de objetivos de sostenibilidad y calidad de vida en las ciudades que conduzca a criterios homogéneos.

El desarrollo de nuevas disposiciones normativas más homogéneas debe venir marcado por resultados de futuras investigaciones sobre la eficacia de las medidas normativas adoptadas desde una perspectiva económica, social y medioambiental, que contribuyan a la toma de decisiones de los técnicos y políticos que quieren implantar o mejorar este sistema en las ciudades.

ABSTRACT

Mobility has been massively disrupted by new-generation telecoms and mobile apps, which allow an optimised utilisation of both transport means and infrastructures. When it comes to this kind of mobility, transport authorities and 'traditional' transport planning can only do little. Citizens step in and fill in the gaps at neighbourhood level by co-creating mobility solutions, as they already own or have at their disposal enough assets to work with: private and commercial vehicles, tracking and geo-location capabilities, smart communication devices, a transportation infrastructure grid and so on.

Without additional investment in physical assets for marginal uses of the infrastructure, and without adding more vehicles to the streets, it becomes possible to 'kick start' a new mobility 'metabolism' through collaborative solutions that concatenate several 'sharing' approaches: car-pooling, car-sharing, crowd-parking, bike-sharing, cargo-pooling, data-sharing.

In sum, crowd-sourcing and shared-economy ideas are turbo-charged by new technologies. Such technologies can bridge social capital and citizen power with the valuable aspects of free market economics. In addition, crowd-sourcing mobility solutions seem to make economic sense and bring democratic thinking and environmental conscience. But are they financially sustainable?

1. A NEW MOBILITY PARADIGM?

The idea of sharing things and using them together has worked perfectly well for hundreds of years. In fact, sharing economy ancestors are not Uber or Airbnb. Yet sharing behaviour is being revolutionised and facilitated nowadays by an easy and widespread access to digital information and communication technologies (Papí, 2016).

As a consequence, the shared economy is in the process of evolving into a significant element of the economic cycle -if it is not already-. The idea of sharing things and using them together has worked perfectly well for hundreds of years. All of a sudden, however, it has begun to spawn disruptive business models with spiralling customer numbers and revenues to match (Uber, Airbnb, BlaBlaCar, Deliveroo, etc.)

'Traditional' logistics require centralised planning and thinking; much research has been performed on learning from ant colony and beehive analysis in order to create learning systems. Yet there is a limit on how much we can learn from ants and bees. It is better to design systems to help people interact in better and smarter manner (Papí, 2018). This is the philosophy behind crowd-sourced mobility.

Shared (or collaborative) mobility is arguably the most rapidly growing and evolving sector of the sharing economy. When it comes to this kind of mobility, transport authorities and 'traditional' transport planning can do only little. Citizens step in and fill in gaps where mobility demand is inefficiently met at neighbourhood (or any other) level by co-creating mobility solutions. For example, focus group studies carried out by the ITF show that citizens in Finland's capital Helsinki are specifically looking for services that connect different outer areas of the city with each other (ITF, 2017). In the Irish capital, Dublin, shared services could be useful as feeder services to public transport for residents in suburban areas (ITF, 2018). (Papí, 2016). In this regard, citizens already own enough assets to work with: private and commercial vehicles, tracking and geo-location capabilities, smart communication devices, a transportation infrastructure grid at their disposal, and so on.

Without additional investment in physical assets (obviously in the case of marginal uses of the existing infrastructure, as a widespread commercial roll-out of new solutions would require additional infrastructural investments), and without adding more vehicles to the streets, it seems possible to 'kick start' a new mobility 'metabolism' through sharing and collaborative solutions. These solutions allow changing urban metabolism by concatenating several 'sharing' approaches: car-pooling, car-sharing (car-pooling and car-sharing are often referred indistinctly as 'ride-sharing'), crowd-parking, bike-sharing, cargo-pooling (such as the one proposed by the DynaHUBs project https://www.dynahubs.com) and data-sharing (Such as the traffic data shared by Waze users www.waze.com).

Mobility has been massively disrupted (in a positive manner) by new-generation telecoms and mobile apps, which today are allowing an optimised utilisation of both transport means – public and private – and infrastructures (Papí, 2016). Young professionals living in cities increasingly invest in smartphones to hail a ride rather than in their own set of wheels.

For instance, the International Transport Forum (ITF) has recently stated that both passenger and freight transport demand is set to nearly triple in the next three decades, at the same time highlighting that potential disruptions from within and without could significantly change the transport sector (ITF, 2019). In particular the ITF has examined several disruption scenarios and concluded that:

- A massive uptake of shared mobility could halve vehicle-kilometres travelled in cities and reduce urban transport CO2 by 30% by 2050;
- The combination of shared mobility services, autonomous vehicles, and restrictions on private cars could cut urban transport CO2 by 73%.

Crowd-sourcing and shared-economy ideas are obviously turbo-charged by new technologies. With the proper solutions, such technologies can provide for the European way of bridging social capital and citizen power with the valuable aspects of free market economics. Crowd-sourcing mobility solutions seem to have economic sense and bring democratic thinking and environmental conscience. But are they financially sustainable? (Papí, 2016).

2. LET'S START BY THE BASICS: WHAT DO WE UNDERSTAND AS SHARING ECONOMY?

In 2015 the term 'sharing economy' was introduced into the Oxford English Dictionary. But it seems there is a growing confusion of what the sharing economy actually means. In this context, terms like 'sharing economy', 'peer economy', 'collaborative economy', 'on-demand economy', 'collaborative consumption' are often used interchangeably, though they mean very diverse things.

Today many terms are being used to describe a broad band of start-ups and models that in some way use digital technologies to directly match service and goods providers with customers, bypassing traditional middlemen. The following categorisation (Botsman, 2015) provides much-useful to-the-point definitions:

- Collaborative Economy: An economic system of decentralised networks and marketplaces that unlocks the value of underused assets by matching needs and haves, in ways that bypass traditional middlemen.
- Sharing Economy: An economic system based on sharing underused assets or services, for free or for a fee, directly from individuals.
- Collaborative Consumption: The reinvention of traditional market behaviours — renting, lending, swapping, sharing, bartering, gifting— through technology, taking place in ways and on a scale not possible before the Internet.
- On-Demand Services: Platforms that directly match customer needs with providers to immediately deliver goods and services.

In addition, it is important to highlight the existence of two collaborative economies: one for profit - ridesharing, private accommodation, collaborative food markets, etc. -, which can be considered as an alternative to traditional business models, and one non-for-profit related to barter-like sharing and exchange of goods - home swapping, clothes swapping, services exchange, etc. (Beaumont, 2016).

Another categorisation suggests four categories of activities in the collaborative economy: i) recirculation of goods, ii) increased utilization of durable assets, iii) exchange of services, and iv) sharing of productive assets (Gruszka, 2016; Schor, 2014).

There are authors (Beaumont, 2016) that also connect the rise of the collaborative economy with the economic crisis and the widespread utilization of smartphone applications across the population. Likewise, many of the new sharing and collaborative consumption organisations benefitted from the 2008 economic collapse, which "caused some consumers to lose their homes, cars, and investments and made most everyone more price sensitive" (Belk, 2014).

From a Marxist perspective, collaborative consumption could be viewed as an economic resistance to global capitalism that has born out of its inherent contradictions, signalling a dialectic relationship between capitalism and the sharing economy, which is seen to be more democratic (Rifkin, 2014). Along this line of thought, we could label collaborative consumption as "a form of resistance", a countermovement to the economic violence of the free-market, aimed at self-protection by using the Internet in order to create or engage in alternative to free market-exchange models allowing access to a greater diversity of goods at lower prices (Viba, 2014).

Collaborative consumption can also be labelled as a shift "from a world where we're organised around ownership to one organised around access to assets" (Gansky, 2014). In a way, "the so-called 'sharing economy' has turned traditionally underused assets into competitors to established industries" (Beckmann, 2013). This shift in consumer values from ownership to access is fundamental to understand the on-going emergence of a global network for entrepreneurs, businesses and governments which holds the potential to transform business, consumerism and the way we live.

We can also distinguish between three different constituents in the collaborative economy ecosystem (Sundararajan, 2014):

- Platforms (marketplaces),
- Entrepreneurs (small businesses, micro-entrepreneurs), and
- Consumers.

While the platforms are the person-to-person marketplaces that facilitate the exchange of goods and services between peers, entrepreneurs are the individuals or small businesses that supply goods and services in these marketplaces. In this context, consumers are the individuals who drive demand: buy, rent, consume (both entrepreneurs and consumers are often referred to as ‘peers’). To close the circle, typically the payment from the consumer to the entrepreneur is mediated by the platform, which often charges a commission to one or the other trading party.

From another perspective, we could note five key ingredients to truly collaborative, sharing-driven companies (Botsman, 2015):

- The core business idea involves unlocking the value of unused or under-utilized assets (‘idling capacity’) whether it is for monetary or non-monetary benefits.
- The company should have a clear values-driven mission and be built on meaningful principles including transparency, humanness, and authenticity that inform short and long-term strategic decisions.
- The providers on the supply-side should be valued, respected, and empowered and the companies committed to making the lives of these providers economically and socially better.
- The customers on the demand side of the platforms should benefit from the ability to get goods and services in more efficient ways that mean they pay for access instead of ownership.
- The business should be built on distributed marketplaces or decentralised networks that create a sense of belonging, collective accountability and mutual benefit through the community they build.

Now the issue is to review how the new economic paradigm briefly reviewed above has made its way to mobility and transportation.

3. A DEEPER LOOK INTO COLLABORATIVE MOBILITY

Sharing routine objects seems to make social and economic sense. Such economic sense becomes immediately apparent in the case of automobiles, which are simply left standing instead of being driven for most of the time (Beckmann, 2013).

In recent years, the success story of car-pooling and car-sharing platforms such as BlaBlacar, together with the expansion of transportation network companies (TNC; the TNC acronym designates companies providing transportation services that resort to online platforms (website or mobile apps) to connect passengers with drivers using their personal vehicles. They are also called PHV (Private Hire Vehicles) in the UK. Well-known examples include Uber and Lyft) such as Uber, has marked the onset of a new mode of transport that we could label as 'collaborative transport'.

Beyond the classical motorised individual transport and collective public transport by rail or road, this new transportation option is moving beyond the status of a simple niche demand. A non-exhaustive glance at successful collaborative mobility solutions at the global level brings up platforms as the following:

Uber (www.uber.com) was launched in 2009 as a luxury service providing drivers in black cars to people who needed a ride (https://growthhackers.com/growth-studies/uber. Retrieved on 8 May 2019). A TNC platform, requests and payments are made through the mobile app, and reviews allow building trust between users. Uber is estimated to have 110 million worldwide users (https://www.statista.com/statistics/833743/us-users-ride-sharing-services. Retrieved on 8 May 2019) and has operations in 750+ metropolitan areas worldwide (https://www.uber.com/en-BE/cities. Retrieved on 8 May 2019). Many different services are now available under different brands, including economic options (UberX, Uber XL, UberSelect), premium cars (UberBlack, UberSUV, UberLux), electric cars (Uber Green) and delivery services (UberRush, UberEats). Some Uber services are provided by professional drivers with a TNC licence, while others are provided by peers.

Lyft (www.lyft.com) is a transportation network company (TNC) operating in 600+ cities in the United States and 9 cities in Canada (https://www.lyft.com/driver/cities. Retrieved on 8 May 2019). It develops, markets, and operates the Lyft mobile app, offering car rides, scooters, and a bicycle-sharing system.

Waze (www.waze.com) is an app for smartphones that enables step-by-step navigation and real-time traffic information (RTTI). Traffic information is based on crowd-sourced data regrouping movement data of Waze users (100+ million worldwide) in certain areas as well as their manually supplied additional data such as traffic density, road construction works, or police/radar controls. By utilising this data, Waze detects congestions on the route and suggests alternatives. Waze users can also register themselves as map editors to add missing information and rectify altered design and layout of roads. Additionally, Waze provides traffic data to public entities and broadcasters.

Moovit (www.company.moovit.com) provides an app for smartphones that intends to improve the use of public transportation. Currently it is present in 2,700+ cities in 90 countries and counts on 400+ million users. Users can plan their travel with public transportation and other selected mobility services. Similar to Waze, Moovit relies on crowd-sourced data to add real-time information about delays, cancellations, and other characteristics of individual trains or buses, e.g. crowdedness or cleanliness. Moovit also enables users to register as editors in order to alter or add lines, routes, and timetables.

BlaBlaCar (www.blablacar.com) is an online marketplace for carpooling. Its website and mobile apps connect drivers and passengers willing to travel together between cities and share the cost of the journey. The platform has 70 million users in 2019 and is available in 22 countries (https://thenextweb.com/adobe-fundamentals/2019/02/19/why-french-unicorn-blablacar-still-believes-in-done-is-better-than-perfect/. Retrieved on 7 May 2019).

Zipcar (www.zipcar.com) is the world's leading car-sharing network operating in over 500 cities and towns. Zipcar provides over one million members on-demand access to more than 12,000 vehicles in urban areas and college campuses (https://www.zipcar.com/press/overview. Retrieved on 7 May 2019).

The World Collaborative Mobility Congress (Organised annually by Wocomoco Mobility Academy, a subsidiary of the Touring Club of Switzerland. Flyer downloadable from https://www.wocomoco.org/assets/docs/Publikationen/WOCOMOCO-Brand-Flyer-2014v6_engl-version-webseite.pdf. Retrieved on 22 March 2019) highlighted that "collaborative mobility focuses on sharing journeys, modes of transport and infrastructure. In between collective and individual transport new peer-to-peer based networks are emerging, boosting new types of individual mobility beyond private car-ownership. We are increasingly freeing ourselves from the costly constraints of having to purchase and possess our means of transportation and at the same time are making us independent of large-scale public transport providers to serve our mobility needs. Private bicycle and car sharers, carpooling services, long-distance bus service providers and shared parking providers are as much a part of this new mobility paradigm as the numerous websites and apps where new mobility products and services can be purchased, rented or shared – ranging from cars to public transport tickets to cargo bikes".

A high-level review of the collaborative mobility alternatives listed above (car-pooling, car-sharing, crowd-parking, bike-sharing, plus two additional alternatives suggested by the authors, cargo-pooling and data-sharing) reveals several common features:

- Use is favoured over private ownership (for instance, co-mobility apps launched by cars manufacturers).
- Sharing is often a strategy for investment optimisation (i.e. overhead costs of maintenance minimised in shared fleets).
- Moving is privileged over standing still (i.e. sharing parking reduces costs for parking owners, and at the same time decreases the external costs caused by 'parking search' traffic).
- Pay-per-use is favoured over long-term investment (i.e. the costs of private ownership of a vehicle are passed onto others while the user still enjoys the benefits he sees in possessing a private car).
- Networking and socialisation are preferred over individual ownership (i.e. ride-sharing as a smart form of hitch-hiking and meeting other people).

- A citizen-driven, ‘uncontrolled’ mobility confronting politicians with new challenges (i.e. car-poolers increasing traffic volumes).

Research (Project Consortium TUM Living Lab Connected Mobility, 2016) shows that the attractiveness of the mobility ecosystem depends on a balanced participation (and integration) of service users and services provided. In such a mobility ecosystem, end-users are not only data evaluators as participants but also data sources, as they may contribute to the ecosystem by providing own traveling data and views regarding their mobility preferences. In this context, crowdsourcing in the mobility context often involves:

- Navigation applications, providing the fastest, shortest or nicest driving route from point A to B, or the route with least emissions, to name just a few.
- Intermodal traffic recommendation applications, offering all possible routes from point A to point B providing combinations of different mobility services, such as public transportation, bike sharing or car sharing
- Mobility sharing applications, enabling two or more users to share a ride from point A to B.
- Mapping applications, offering indoor and outdoor maps for special purposes and based on crowd-sourced data.

The availability of Peer-to-Peer (P2P) networks connecting collective and individual transport open new doors, as they apparently free the citizen from the (previously almost-compulsory) private purchase of a mobility tool. In this sense, P2P networks allow people to avoid buying a vehicle of their own and instead hiring a car when they need one; as a consequence, “their mobility is guaranteed without the financial burden of private car ownership” (Beckmann, 2013).

Some authors highlight that collaborative transport benefits from idle, unused transport capacity, therefore offering a low-cost and environmentally friendly mobility with little capital investment in the case of marginal uses of the infrastructure. Taking the example of car-sharing, the potential environmental advantages operate through two channels (Firnkorn and Shaheen, 2015). First, fewer cars have to be produced to satisfy the same overall demand for auto-mobility. Second, with car sharing people use cars more selectively because the marginal costs loom larger than when they own their car (and the fixed costs thus dominate the marginal costs). Along this line, the use of electric or hybrid vehicles in car sharing schemes could have a multiplier effect in terms of these environmental benefits.

This school of thought makes collaborative mobility equivalent to sustainable mobility, highlighting that “it is economically sustainable because it makes better use of existing capacities and requires no additional investments in infrastructures. It is ecologically sustainable because, by making better use of existing capacities, it spares finite resources;

then again, it is socially sustainable because it promotes new forms of communal mobility organisation" (Beckmann, 2013).

To the contrary, other authors challenge the above, as they are indications that shared mobility may not only replace some forms of private travel but may also facilitate other forms of private travel; hence, the net environmental and transport impacts remain contentious (Franckx, 2015).

The authors are of the opinion that the impact of shared mobility on traditional forms of transport has not been studied sufficiently. According to the ITF (ITF, 2019), "bike-sharing and micromobility-sharing may lead to a switch from certain short-distance car trips in some contexts, especially where car use dominates". The IFT further reflects that, in the case of high-quality and cost-effective public transport being available, preliminary findings show that bike-sharing and micromobility-sharing can serve as feeders to public transport, but often replacing walking, while where public transport is infrequent or of low quality, these modes may substitute for public transport.

Today scholars and public policy makers increasingly promote the sustainable mobility paradigm (Banister, 2008) based on 'optimal congestion' and not on 'minimal congestion' (Urry and Lyons, 2005). This is to be achieved through four key objectives: fewer trips, modal shift, distance reduction, and increased efficiency (Cohen, Kietzmann, 2014).

Fewer trips are associated with a reduction in total trips required or taken by a citizen which can be achieved through solutions such as the ability to make online purchases for locally and regionally produced goods and services. Modal shift is the idea of altering the transportation hierarchy from single occupancy vehicles to walking, public, and shared transit alternatives. Through increased densities and better mixed-use development, cities can achieve a reduction in aggregate distances travelled by residents. Finally, increased transport efficiency is associated with reduced environmental impacts of the transportation system through more energy efficient public transportation services and the encouragement of lower footprint personal vehicles (Banister, 2008).

4. COLLABORATIVE MOBILITY: A CHALLENGE TO TRADITIONAL TRANSPORT PLANNING?

Transportation planning is commonly defined as a collaborative process that defines future policies, goals and investments for the mobility of goods and persons in a given territory. Generally speaking, transportation-planning practitioners apply a multi-modal and/or comprehensive approach incorporating the input of public and private stakeholders assessing a range of alternatives and forecasting impacts on the transportation system as a whole.

The second half of the twentieth century saw an increasing sophistication in the methods and techniques associated with transport planning. Increased computer modelling capability, better information technology and improved educational standards all drove up the quality of inputs to planning processes.

Yet we could claim that little change has taken place in the basic transport planning models over the last four decades with the four-stage aggregate model (trip generation, trip distribution, modal split, trip assignment) acting as the bedrock upon transport planning takes place. Since the 1960s transport planners have developed a strong tradition of scientific method for solving urban transport problems, using the classic deductive approach: data collection, defining goals and objectives, and forecasting future demands (Banister, 2002).

Methods and techniques used have been increasingly called in to question in terms of how well they were able to predict long-term futures and help inform policy-making processes (see Timms, 2008 and Næss and Strand, 2012 for lively critiques). Many were associated with practices of ‘predict and provide’ whereby travel demands were predicted using ever more sophisticated models that were then provided for through increased supply (Owens, 1995).

Where mature transport networks exist, the idea of ‘predict and provide’ has been increasingly questioned. Significantly it took no account of the aims of other policy sectors, this at a time when policy integration and sustainability have increasingly become recognised as an important governmental challenge (Te Brommelstreot and Bertolini, 2010). For instance, drawing upon an analysis of 210 projects across 14 countries, Flyvbjerg et al. found that ‘‘forecasters generally do a poor job of estimating the demand for transportation infrastructure projects” (Flyvbjerg et al., 2006: 1).

It therefore seems that current transport demand forecasting and strategic policy-making tools are not sufficient for the change and uncertainty we currently face in the 21st century (Walker et al., 2010, Lyons, Davidson, 2016). On the one hand, physical mobility systems appear ever more crucial in granting individuals and organizations access to the spatially and temporally disjointed resources they need to thrive, or even just to survive. On the other hand, because of a heterogeneous mix of mounting financial and fiscal constraints on infrastructure expansion, and growing awareness of and social resistance to the negative impacts of mobility, the traditional `predict and provide' approach to planning is no longer an option (Bertolini, 2007).

In this context, we could be witnessing an evolution from a rigid transportation ‘monoculture’ that forces people to adapt to the system rather than a flexible, responsive and user-friendly transportation ‘poly-culture’ that can adapt more easily to people and their activities. By transportation monoculture, we refer to inelastic and inflexible systems where there are few mobility options and people must adapt their activities based on the limited mobility options available. In contrast, a transportation polyculture refers to a more robust and flexible transportation system with a wide range of mobility options, involving a wider spectrum of mobility technologies, and in addition requiring a much greater degree of coordination among modes and travellers. In such context, the public sector would have a multifaceted role – not only as a regulator of private transportation and a provider of public transportation, but also a facilitator of shared transportation (Miller, 2011).

Two avenues are of interest here (Vigar, 2017). First, there is increasing recognition in academic circles that disciplinary boundaries often perpetuate approaches not suited to contemporary, complex problems. Inter-disciplinary work is thus often proposed to bring together experts from different disciplines to provide new perspectives. It reflects the idea that innovation frequently arises from interactions outside the immediate policy community. Second, there is increasing attention to involving ‘non-experts’ in such practices, to generate information and ‘co-produce’ solutions. These two elements can be brought together in a ‘trans-disciplinary’ approach, which encompasses experts from across disciplines but also non-experts (Hirsch Hadorn et al., 2008).

The contentious nature of much transport planning in an era of greater citizen activism and less trust in experts also suggest that planning is unlikely to succeed if conducted in a top-down, autocratic way (Vigar, 2017).

In a context where there are opportunities for collecting user preferences at the convergence of three technologies - sensor technologies, geographic information systems, social computing -, collaborative mobility allows participants sharing information and resources, collaborating on solving local and operational transportation challenges (“How do I get to work today?”), and in addition making joint decisions that take the total system costs into considerations (Miller, 2011).

Greater user involvement improves the flow of information, of situated knowledge, to a strategy. And one way of overcoming implementation deficits is by giving people ownership of strategies through participation. The collaborative platforms that ‘match’ services and clients have huge amounts of data available - for instance on accidents, driving patterns, real-time trip data, driver availability. If these data were shared with transportation authorities, this could lead to improvements in the transportation network and the identification of areas that are poorly served by transport services (Franckx, 2015).

Yet at present comparatively little attention is paid to this bottom-up, cooperative approach to transport planning with rather more attention devoted to adjusting demand models for example (Vigar 2017).

The above clearly points out to a principal challenge for transport planners in the years to come: figuring out how to take advantage of the choices of individual transport users in the practice of transport planning and policy development.

5. NEW BUSINESS MODELS FOR THE SHARING ECONOMY

The business model is a broadly discussed concept in academia and practice. It represents a company's money-earning logic (Osterwalder & Pigneur, 2010). Within the architecture of the company, a business model is located between the strategic and operational layer (e.g. Osterwalder, 2004). The meaning of business models underwent strong changes; from a technological to an organisational, and then to a strategic approach (Wirtz, 2011). Still, literature does not agree upon one single understanding.

As noted by Abdelkafi and Makhotin (2013) there are two major streams: an activity-based and a value-based stream. The *activity-based view* describes the business model as the way activities and resources are used to do the business and achieve growth (Baden-Fuller & Morgan, 2010). The *value-based view* defines the business model as a "representation of how a business creates and delivers value, both for the customer and the company" (Johnson, 2010), or as "the way organizations or individuals communicate, create, deliver, and capture value out of a value proposition" (Abdelkafi, 2012).

Staying on the latter perspective, a business model can be defined as a concept describing what value a company proposes to existing and potential customers (*value proposition*), how the business is organized to create the value (*value creation*), with which resources and infrastructure (*value creation infrastructure*), under which circumstances (*value creation conditions*), and how financial value is retained for the company (*value capture*; e.g. Mäkinen & Seppänen, 2007; Johnson, 2010; Osterwalder & Pigneur, 2010; Osterwalder, Pigneur, & Tucci, 2005; Teece, 2010; Zott et al., 2011).

In this sense, a business model defines the product a company provides and the way it interacts with customers and suppliers (Ovans, 2015). It relies on few founding pillars: a superior *value proposition*, a *profit formula* that outlines how to convert value into revenue and the *key resources and processes* to deliver the proposition (Johnson, Christensen, & Kagermann, 2008). These key resources are among others brand, people, technology, partnerships and data (Seiberth & Gruendinger, 2018).

Information technology offers extensive strategic and economic possibilities and decision makers have to consider new technological solutions that re-shape existing business models (Beutel et al, 2014; Teece, 2010). New business model concepts are being explored these days, motivated by the need to describe and analyse new forms of business, such as e-businesses or virtual organizations (Mahadevan, 2000; Timmers, 1998). For instance, today seven in ten of the world's most valuable brands are digital platforms (Seiberth & Gruendinger, 2018).

'E-business' refers to the application of information and communication technologies (ICT) in support of business activities (Beynon-Davies, 2012). The advent of the ICT has caused organisational transformations incorporations and industries (Timmers, 1998; Tapscott et al., 2000; Dubosson-Torbay et al., 2002; Martinez, 2000); in a way, we could say that the concept of a 'business model' has become almost synonymous with e-business and the emergence of the new economy.

Researchers have further created the concept of 'platform business models' to refer to transactions occurring in a two-sided market (Rochet and Tirole, 2003b, 2006) in which various stakeholders can join the platform as part of the supply or demand side (Rochet and Tirole, 2003b; Rochet and Tirole, 2006; Armstrong and Wright, 2007; Evans and Schmalensee, 2008; Rysman, 2009). A two-sided market is an environment established to allow multiple groups such as suppliers and consumers to participate in order to exchange the values that each group desires to obtain through fair 'transactions'. The 'network effect' emerges from these 'transactions' because transactions in two-sided markets create value by facilitating interactions between the different sides (Parker and Van Alstyne, 2005, Eisenmann et al., 2006).

Platforms evolve through the connection and interaction of platform participants as an ecosystem of coexistence that can provide new values and benefits to all participants (Ceccagnoli et al., 2011). And it is at the heart of a business ecosystem that consists of mutually-dependent business communities, producers and consumers, all of which have a complementary and symbiotic relationship with the platform (Evans et al., 2006). Therefore, the nature of platform business models can be characterised by three keywords: 'two-sided market', 'network effect', and 'business ecosystem' (Junic, 2015).

A specific category of platform business models are the ones operating in "sharing economies" of collaborative consumption (Botsman & Rogers, 2010), where people offer and share underutilized resources in creative, new ways. For instance, Airbnb lets people rent out part or all of their homes for short stays, and Uber allows for real-time, location-based ride-sharing. As a consequence, an increasing number of individuals who may not have considered ridesharing or renting a room in private residence as their vacation domicile a few years ago now prefer such sharing models to mainstream alternatives.

Some scholars, however, believe that the 'classical' activity-based and the value-based views presented above do not factor in the resulting complexities when companies deliberately aim for ecological and social value creation beyond financial profits (Schaltegger et al, 2016) and they are therefore increasingly exploring if and how modified and completely new business models can help achieve economic prosperity by either radically reducing negative external effects or creating positive external effects for the natural environment and society (e.g., Boons Montalvo, Quist & Wagner, 2013). Their work has attempted to define the so-called "business models for sustainability" (BMfS), also referred to as "sustainable business models" or "sustainability business models".

The potential sustainability benefits associated with such sharing economies are interesting from an organisational and environmental perspective, but they are not the subject of this research. BMfSs consists of four business model building blocks: a value proposition, supply chain, customer interface, and financial model. Their operationalization of the four elements of a BMfS is provided below (Boons & Lüdeke-Freund, 2013):

1. Value proposition: provides measureable ecological and/or social value in concert with economic value.
2. Supply chain: involves suppliers who take responsibility toward their own as well as the focal company's stakeholders.
3. Customer interface: motivates customers to take responsibility for their consumption as well as for the focal company's stakeholders.
4. Financial model: reflects an appropriate distribution of economic costs and benefits among actors involved in the business model.

The authors consider the BMfSs framework as a viable alternative to start building a taxonomy of the key business models present nowadays in the shared mobility arena.

6. CONCLUSIONS AND THE WAY AHEAD

Only few of the emerging mobile innovations have reached commercial viability backed by real customers, and not just by institutional investors and/or government grants. In short, there seems to be a gap between solutions brought by people and the 'commercial reality'. This gap is like an underwater passage most great innovations fail to cross.

The public perception of shared goods has changed substantially in the past few years. While co-owning properties has been widely accepted for a while (e.g., timeshares), the notion of sharing bikes, cars, or even rides on an on-demand basis is just now starting to gain widespread popularity. The emerging 'sharing economy' is particularly interesting in the context of cities that struggle with population growth and increasing density.

New technologies are enabling the crowd-sourcing of transport data and the emergence of business ideas linked to shared mobility, and this in a society that progressively demands overcoming 'traditional' mobility, at the same requesting i) a flexible and adaptive transport supply with ii) greater respect for environmental considerations.

While sharing vehicles promises to reduce inner-city traffic, congestion, and pollution problems, the associated business models are not without problems themselves.

Many of the collaborative mobility platforms have a hard time finding their way to practical, large-scale exploitation. One of the reasons behind this is that the business model view on this exploitation is lacking. Many of these developments have a technology-push character, where things are developed inside out, with a focus on the concepts and the technologies involved from the very start, and with little attention for actual business deployment at the end of the day. Consequently, a clear, explicit view on commercial exploitation is often missing in these developments. This situation is made worse by the fact that complex mobility scenarios involve a multitude of stakeholders, each of which has its own business interests. Consequently, such business models with a great potential to address mobility and transportation challenges are hardly realised.

Today, TNC (transportation network company) services such as Uber seem to determine their pricing by introducing a reduction to the price of the substitute product (e.g. taxi). At the same time, we can observe that the financial results of this type of companies show losses year after year (for the Uber case: https://techcrunch.com/2019/02/15/uber-reports-3b-in-q4-revenue-rising-operating-losses/?guccounter=1&guce_referrer_us=aHR0cHM6Ly93d3cuZ29vZ2xlLmNvbS8&guce_referrer_cs=PLetZWiCOB-DyCnVQV004A. Retrieved on 18 March 2019), and that their survival strategy seems to be 'burning the cash' received from venture capital investors, with the hope of expelling their competition from the market.

Little research has been conducted on the issue of pricing the new collaborative mobility solutions, and hence this paper proposes calls for further research on the modelling the pricing of collaborative mobility solutions taking into consideration a combination of variables among which we should consider, a priori and for the case of a TNC service, the existing degree of traffic congestion, the cost of living, the cost of fuel, the price of the substitute product (e.g. taxi, public transport) and the recovery of the costs incurred by the vehicle owner (the driver or his employer).

FROM URBAN CONGESTION PRICING TO TRADABLE MOBILITY CREDITS: A REVIEW

Siyu Li
Department of Civil and Environmental Engineering, Universitat Politècnica de Catalunya, Barcelona, Spain
Francesc Robusté
Department of Civil and Environmental Engineering, Universitat Politècnica de Catalunya, Barcelona, Spain

ABSTRACT

Congestion is still a big challenge for urban mobility while vehicle sharing, eCommerce and autonomous vehicles will likely increase the unit veh-km of each vehicle and the density of vehicles moving on the streets. Urban vehicle congestion pricing schemes have been taken as effective solutions to this problem. This paper first reviews the research and application cases of urban congestion pricing through recent years, although with the well-developed theoretical basis and successful practices in Singapore, London, Stockholm, Milan, etc., public acceptance and equity concerns are still the main issues for such policies' implementation. To circumvent this shortcomings of congestion pricing, a scheme of tradable mobility credits is proposed as an alternative. As travellers are distributed mobility credits within a specific urban area, which are allowed to be traded, those with low vehicle-using demands can sell their credits to those with more demands. Therefore with this scheme, people have the incentive to reduce the using of vehicles. This paper reviews the studies on this new urban mobility management strategy and compared it with ordinary congestion pricing schemes. Finally, we conclude the gap and possible directions for future work in this area.

1. INTRODUCTION

Congestion has been the major problem that troubles cities around the world. As a strategy of Transportation System Management, urban congestion pricing (CP) was carried out as the approach to solve it. Since the early introduction by Pigou (1920) and Knight (1924), it has long been taken as the most socially optimal strategy for the allocation of road capacity (Hau, 2005). For road bottlenecks or urban restriction area, vehicles enter or travel within the area will be levied. Especially in recent decades, theories and technologies have been well developed and several cities have practised their urban charge schemes.

However, although there are existences of successful applications, arguments on the implementation of CP schemes never stop. Public acceptance is the main obstacle while the equity problem is often considered the core. Thus, the tradable mobility credits (TMC) scheme is introduced to make up for this shortcoming. It is seen as an alternative to the CP but allow travellers to drive for free with limited quotas. Such schemes of tradable credits or tradable permits are found studies and implementations in various fields like forestry regulation (Tripp & Dudek, 1989), water pollution control (Dales, 1968), automobile emission control (Goddard, 1997; Raux & Marlot, 2005) and the well-known Emission Trading Scheme (ETS) of EU, etc.

Both CP and TMC have gained enough attention, there are still difficulties and unresolved issues. Especially the newer TMC, though theoretical works have been carried out, practical experiences are not seen. This paper aims to present, via a case study of urban congestion pricing and an overview of TMC, valuable insights on the further development of TMC to make it more applicable for future implementation.

The paper is structured as follows. Section 2 reviews the implementation cases of urban congestion pricing in Singapore, London, Stockholm and Milan. Then this part also discusses the arguments on acceptance of CP. Section 3 reviews the development, theory and recent works of TMC schemes. Finally, section 4 concludes the paper and proposes further research direction on this area.

2. URBAN CONGESTION PRICING

The main principle of CP is to charge the externalities that are imposed on other users by a new driver entering the network (Knight, 1924; Pigou, 1920). In this case, the equilibrium will achieve when the charging price is equal to the marginal cost of other users. After decades of development, the research of CP has already been well developed. Detailed reviews on theories and methodologies have been concluded (de Palma & Lindsey, 2011; Tsekeris & Voß, 2009; Yang & Huang, 2005). As a transportation demand management policy, CP leads travellers to change their travel behaviours (including route choice, travel time, mode choice, et al.), reallocate the road to travellers who are willing to pay for the externalities. Besides, CP can raise revenues to fund transport projects like road maintenance and the improvement of public transport. Therefore it is approved by most economists (Lindsey, 2006) to achieve social optimum. With sufficient theoretical support, various CP schemes have been considered or already implemented worldwide.

2.1 Implementation cases

Several urban areas around the world have implemented urban congestion schemes to alleviate congestion in the city centres, including Singapore (1975), several Norwegian cities (Bergen, Oslo, Trondheim, etc.), London (2003), Stockholm (2006), Milan (2012) and Gothenburg (2013). The charging schemes vary among those cities with their unique features. All those practices show efficient consequences on congestion control.

Here, based on literature, we selected Singapore, London, Stockholm and Milan to investigate their CP schemes and impacts.

2.1.1 Singapore

As the first practice, Singapore implemented the Area Licensing Scheme (ALS) in 1975. This is a manual-enforced cordon toll system based on gantries at entry points of Restricted Zone (RZ) of the city centre. Drivers needed to buy licenses in advance to enter and travel within the central area, during morning peak hours from 7:30 to 9:30 am. Then three weeks after the introduction, the morning charging hours were extended to 10:15 am to response to the occurring traffic just after 9:30 am (Fan et al., 1992). And initially, they thought that the restriction of morning peak hours would show a ‘mirror image’ on the evening outbound traffic, so there was not charging for evening peak hours. However, as such image did not materialize, ALS is added to the evening peak from 4:30 pm to 7:30 pm (Phang & Toh, 2004) in 1989. Finally in 1994, in order to make the traffic more even throughout the day, ALS was extended to the inter-peak period (10:15 am to 4:30 pm) but with a lower charging rate. In addition, another Road Pricing Scheme (RPS) was implemented to three expressways.

However, the effect of ALS was far above expectation and was considered to make the road network underutilized (Santos, 2005). After the introduction of ALS, the average speeds within the RZ increased to 36 km/h while the expectation was 20-30 km/h (Phang & Toh, 1997). And the peak-hour traffic flow reduced by 45-50% while the original target of reduction was 20-30% (Phang & Toh, 2004). In that case, McCarthy & Tay (1993) argued that the charging rate of ALS was about 50% above the optimal level. Similar conclusions were made after the implementation of the new Electronic Road Pricing scheme (Li, 1999; Willoughby, 2000).

In 1998, ALS and RPS were replaced by Electronic Road Pricing (ERP). This new system made the charging scheme more convenient for both drivers and the administration department. Drivers do not need to buy various licenses in advance, instead, an In-vehicle Unit (IU) is installed on the windscreen of each vehicle with a stored-value card. With sensors on the gantries at each entrance of RZ and IUs on vehicles, ERP charges vehicles when they pass the gantries. The ERP system based on the rationale of optimal average speeds. The optimal average speed for expressway should be 45-65 km/h while 20-30 km/h for arterial roads. The rates and charges are reviewed every quarter and set in 30-minute blocks which means that the rates can be differentiated regarding the real-time congestion level. That means the charge will be reduced if the average road speeds are higher than the optimal level and vice versa (Goh, 2002; Yap, 2005).

On the other hand, alongside the ALS and ERP, Singapore was also developing its public transit services as the alternative for mobility (Santos, 2005). Commuters shifted from private vehicles to public transport modes. The share of public transport increased from 33% to 69% (Phang & Toh, 2004).

2.1.2 London

Following Singapore and several Norwegian cities, London introduced its Congestion Charge scheme in February 2003. It's a kind of area licensing scheme (Santos & Shaffer, 2004). During weekdays between 7:00 am and 6:30 pm, drivers needed to pay a fee (£5 initially) in advance to travel within the central area delimited by the Inner Ring Road. Once paid, drivers can pass the cordon with unlimited journeys in a single day. Although the heavy goods vehicles were charged three times the normal charge (£15) at the beginning, now the price is the same, regardless of the vehicle types and entry time. Meanwhile, there are exemptions and discounts for several specific kinds of vehicles. For example, vehicles belonging to the residents of the central area enjoy a 90 percent discount. Then in 2007, the Congestion Charge zone was extended, making the total Congestion Charge zone covers 39 km^2. Now the congestion charge has been extended to the entire week, a £15 daily charge is asked from 7:00 am to 10:00 pm to travel within the Congestion Charge zone (except Christmas Day).

Before the implementation of Congestion Charge, traffic within the charging zone was expected to reduce by 20 to 30 percent (TfL, 2003) and average speeds would increase by 10 to 15 percent (Santos, 2008). Several months after, the number of private cars, vans and trucks in the central area dropped by 27 percent (Leape, 2006). In terms of average speeds in central London, it was around 14 km/h in 2002 (TfL, 2003), in comparison with 16 to 17 km/h after the implementation (TfL, 2004).

Alongside the Congestion Charge scheme, London has put investment in public transport sectors, promoting the network, convenience and the level of service (Givoni, 2012; Santos, 2008). This reuse of revenues helped it to increase public acceptance and attracted 50 percent of the former vehicle users to shift to public transportation.

2.1.3 Stockholm

In 2016, Stockholm carried out its CP scheme as a seven-month trial from January to July. It was a time-differentiated charge scheme with the cordon around the inner city of Stockholm. Like ERP of Singapore, charges are made once vehicles pass the border. Then after evaluation of the trial and a referendum, the scheme has been permanently implemented since August 2007.

Vehicles would be levied SEK 10, 15 or 20 (depending on the time of day) when passed the cordon on weekdays from 6:30 am to 18:30 pm. There were not levies in evenings and holidays as well as free for vehicles to cross the charging area through the Essinge Bypass. Meanwhile, around 30% of vehicles were exemptions including buses and alternative-fuel cars (Eliasson, 2008). The target was a reduction of 10 to 15 percent of traffic across the cordon. As a result, compared with the corresponding months of 2005, every month the number of vehicles that passed the border decreased 20 to 30 percent in the trial period (Eliasson et al., 2009).

The most interesting point of Stockholm is the change of public acceptance. Before the trial, only 36 percent of Stockholm citizens were in favour of the CP scheme. Then public acceptance increased gradually after the implementation. Later in September 2006, the referendum showed that 53 percent of voters supported to remain the charging scheme (Borjesson et al., 2012; Eliasson, 2014). However, the oppositions of the citizens live in the suburban areas outside Stockholm did not gained enough consideration.

The revenues collected were dedicated to public transport during the trial. As Menon & Guttikunda (2010) pointed out, like Singapore and London, the success of the implementations of CP in Stockholm is partly attributed to their well-developed public transit systems. Similarly, Kottenhoff & Brundell Freij (2009) pointed out that, the successful implantation of CP in Stockholm is closely linked to the expansion of the public transport system.

2.1.4 Milan

Milan first implemented an urban vehicle charge scheme called Ecopass in 2008. But the difference from other cases is that it was a traffic pollution charge while congestion reduction just a side-goal. The charge was set based on the Euro emission standards. A daily charge was imposed on vehicles enter the traffic restricted zone between 7:30 am and 7:30 pm. The maximum fee was €10 while different levels of discounts were granted to low-emission vehicles and frequent users (Rotaris et al., 2010). This scheme made owners of Euro 0-3 vehicles shift to other low-emission vehicles and led to a substantial increase in motorbikes (Percoco, 2014).

The Ecopass program terminated by the end of 2011 and then, was replaced by a new congestion control scheme (Area C) from January 2012. The new Area C scheme has the same charging zone, technology and time period as former Ecopass. As Area C is a congestion charge instead of a pollution charge, vehicles are imposed the same €5 daily charge regardless of their emission standard. And in order to increase acceptance, residents who live within the area have 40 free entrance per month and need to pay €2 for every extra entrance while commercial vehicles also benefit from discounts (Beria, 2016).

After the implementation of Ecopass, commercial and private traffic showed a reduction of 16.2 percent in 2010, compared to 2007. The daily average emission of PM10 decreased by 25 percent within the area. However, in four years, the environmental-friendly vehicles entering increased by 478 percent and commercial vehicles increased by 1400 percent. Then as the impacts of Area C, traffic volume reduced by 36 percent while PM 10 emission reduced by 27 percent (Martino, 2011).

In terms of the use of revenues collected by the schemes, unlike the Ecopass was criticized for its lack of transparency on the revenue reinvestment, in Area C they reinvested the revenues to improve public transport and sustainable mobility modes (Beria, 2016).

2.1.5 Cases summary

These cases prove the effectiveness of such CP schemes on urban congestion control and the successful result gained the endorsement of citizens. One thing that needs to point out is that, although all four cases of CP schemes charge vehicles at the entrance of charging areas, they are different (Croci, 2016; Gu et al., 2018). Singapore and Stockholm use cordon-based schemes that make charges as long as vehicles pass the borders. London and Milan use the kind of area-licensing scheme or called zonal schemes that collect daily charge that vehicles can enter the area with unlimited times.

These four successful cases have a common feature is that the approach of CP is just one of a basket of policies to manage congestion. Another important point is the investment in alternative transport modes, especially public transport. Kottenhoff & Brundell Freij (2009) concluded that public transport may serve very necessary roles in CP policy package. Sole CP schemes will change the drivers' route and travel time to show the reduction of traffic during peak-hour windows (Santos, 2005) while The development of public transport system can help reduce the use of vehicles and attract the mode shifting. The reinvestment of revenues on public transport can benefit the equity issue as well (Eliasson & Mattsson, 2006). Revenue distribution is considered as one of the auxiliary amendments of CP to deal with inequality and make the policy more acceptable (Tian, 2015).

Furthermore, discounts and exemptions are important. For instance, in London citizens living in the city centre enjoy a 90 percent of discount and in Singapore vehicles with more than three passengers also have a discount. And disabled people are considered exemptions in implementations. Moreover, Gu et al. (2018) stated that, in order to achieve a theoretically efficient pricing scheme, the simplicity of the policies is important. The failure in Edinburgh and the greater Manchester showed people's dislike of complicated mechanisms. The ERP is much more simple than ALS that drivers do not need to buy tickets in advance any more. While in Milan, the replacement of Ecopass by the single-rate Area C helped it to raise public acceptance (Hensher & Li, 2013).

2.2 Public acceptance

However, although with sufficient theoretical studies, urban congestion pricing schemes can only find limited practical applications across the world. The main obstacle to the implementation of CP is public acceptance (Albalate & Bel, 2009; Banister, 2003; Glazer & Niskanen, 2000; Schade & Schlag, 2003). Citizens have long taken the free use of roads for granted. Naturally, it is difficult to gain public acceptance to charge a good which is always for free. Cities including Hong Kong, New York, Edinburg and Manchester are the cases that failed to introduce CP schemes (Albalate & Bel, 2009; Gu et al., 2018). Even in

Stockholm's referendum, they ignored the opposition from suburban areas where residents rely more on vehicles to commute to the urban centre.

On the other hand, equity is greatly concerned by stakeholders (Perera & Thompson, 2020) and is taken as the core of acceptance (Langmyhr, 1997; Viegas, 2001), as this is strongly related to the perception of fairness. People tend to take CP as an extra tax on drivers. And it makes low-income drivers gave the roads to those with higher income or have high value of time (VOT). Meanwhile, if the revenues are not used to improve the public transport system, those low-income drivers would be the victims of CP.

In the context of out-of-pocket charges, low-income drivers and people with reduced mobility are faced with more severe travelling burden and further limitations on the travel options (Gu, et al., 2018; Weinstein & Sciara, 2006). Therefore, in London, Stockholm and Milan there are various discounts for some specific groups. Referring to a review article focusing on public acceptance (Gu. Et al., 2018), it concludes that all of the selected key references mention that in Hong Kong, New York and Edinburg, the design of CP policies ignored the equity problem and therefore the concerns of inequity became the main reason for people's opposition (Larson & Sasanuma, 2010; Pretty, 1988; Ryley & Gjersoe, 2006). Accordingly, a more acceptable and fairer approach is needed.

3. TRADABLE MOBILITY CREDITS

3.1 Early works

In order to tackle the most concerned equity problem of CP, a kind of schemes based on tradable mobility credits are proposed as an alternative (Fiorello, 2010; Gulipalli et al., 2008; Raux, 2004; Zhang et al., 2021). The general concept is simple. Drivers are allocated with a limited amount of mobility credits during a certain period (e.g. one month). When travelling within a charging area or go through a charge cordon, drivers will be charged the credits rather than out-of-pocket monetary. Those who exhaust the credits need to buy from authorities or from other drivers. Tian (2015) described it as a stick-carrot mixed approach while traditional CP was seen as the stick. In this situation, drivers with low VOTs have the incentive to reduce their use of vehicles and get a bonus by selling their surplus credits while those with higher VOTs will pay for the congestion externalities.

In the field of congestion control, mobility credits or mobility rights are not a new concept. Daganzo (1995) proposed a hybrid scheme of rationing and pricing. This scheme can be seen as the allocation of mobility quotas without tradability. Viegas (2001) used the concept of "mobility rights" to deliberate over the quota scheme. He described that, at present, drivers get unlimited quotas of mobility rights to drive and the free allocation of limited quotas could be seen as a reduction of the current situation.

Early research mainly focused on concept development, policy design, qualitative analysis and discuss the potential of implementation and reactions from stakeholders. To tackle congestion externalities, Verhoef et al. (1997) proposed several different types of tradable permits schemes which are based on ownership, distance, fuel consumption or parking, respectively.

Then the idea of TMC is proposed more definitely. Raux (2004) discussed the applications of transferable permits in the field of transport policy. He stated that such transferable permits could be an intermediate solution for congestion problems. Later he further defined the tradable driving rights (TDR) scheme with which that urban inhabitants are allocated certain quotas of driving rights and allowed to trade their unused quotas with those who need excessive trips (Raux, 2007). In parallel, Kockelman & Kalmanje (2005) designed a revenue-neutral credit-based congestion pricing (CBCP) policy. Registered vehicle owners get a monthly monetary allowance of travel credits. Drivers do not need to pay money unless they use out of the credits and those who with unused credits can stock up for next month or exchange for cash. And the further work based on expert surveys gave a more detailed refinement of CBCP policy (Gulipalli et al., 2008). From the user’s point of view, CBCP is a very simple scheme since users only need to interact with the authority. Studies on public acceptance have shown that the simplicity of CP policies is another key factor (Gu et al., 2018), which gains proof from the rejection of Edinburgh and Manchester (Hensher & Li, 2013). Ch’ng (2010) hypothesized a tradable credits system with a two-sided auction market where the price of mobility credits is determined by demand and supply. Based on an experiment of tradable credits auction, he explored that trading in the auction market allows revenues to be returned to drivers who shift to other alternative modes and the equilibrium of utility among both sellers and buyers will be achieved.

In general, the TMC schemes have the features as below:
1) the administration department determines the total amount of credits and allocates them to eligible individuals;
2) the exchange of credits is allowed: individuals that travel less can sell their credits to those who exhaust the credits;
3) like congestion pricing schemes, the charging rates of mobility credits may vary depending on the time, location, route or vehicle type.

3.2 Quantitative studies and development

The idea of such a scheme is simple but deeper works more than conceptual discussions are needed. In the recent decade with the well-developed concepts, investigations started to concentrate more on quantitative studies.

Fiorello et al. (2010) took Genoa as a case study, developed a system dynamic model of Genoa Mobility Rights (GMR) to estimate the impact of TMC on individuals with a sequential procedure. Yang & Wang (2011) introduced a system of tradable travel credits and developed the quantitative analysis as well as modelling of the scheme. They assumed a situation with homogeneous travellers to trade their travel credits in a free and competitive market without the interference of the government. After that, they further investigated the complicated situation of heterogeneous drivers that have different VOTs (Wang et al., 2012). Then more following works contribute to the scenario of heterogeneous users. In order to promote a more equitable TMC scheme, Wu et al. (2012) developed a modelling framework to reckon the impacts of the distribution of credits on travellers with different income and geographic features. He et al. (2013) state that the authority needs to deal with not only individual travellers but also transportation firms (such as logistic companies and transit agencies). They take individual travellers as Wardrop-equilibrium (WE) players while transportation firms as Cournot-Nash (CN) players. The differentiated scheme will allocate different numbers of credits to these kinds of users and also charge them differently. Zhu et al. (2014) assumed travellers with continuously distributed VOTs and established a scheme that can decentralize a given target network flow pattern into a user equilibrium link flow pattern. They stated that a proper credits distribution regulation can make every heterogeneous traveller better off.

In the recent years, the increasing number of articles are seen in this field. Nie & Yin (2013) designed a new TMC scheme that rewards credits to travellers who avoid peak-hour window or choose other alternative modes. Their work assigns that not only the new scheme but even a very simple TMC scheme can achieve substantial efficiency. Miralinaghi & Peeta (2016) proposed a multi-period TMC scheme that travellers are allowed to use or sell the credits in the current period or transfer to future periods. They argue that this scheme can stabilize the price of credits. Xiao et al. (2019) proposed a link-based cyclic tradable credit scheme (CTCS) in which the compensatory credits could be charged from or subsidized to the travellers. In terms of sustainable-oriented transport, Wang et al. (2020) combined the TMC scheme with a link capacity improvement measure and proposed a bi-objective bi-level model to balance economic growth and environmental management.

In addition, the efficiency and effectiveness of TMC for alleviating bottleneck congestion are discussed (Tian et al., 2013; Xiao et al., 2013). Nie (2015) carried out a tradable credit scheme of road bottleneck during the morning peak period. He assumed that vehicles passing the bottleneck within the morning-peak time window would be charged with credits and on the contrary, off-peak travellers would be rewarded with tradable credits.

Meanwhile, as a transportation system management policy, participants' reaction and behaviour are important. Ye & Yang (2013) established a continuous dynamic model to depict travellers' learning behaviour. Bao et al. (2014) adopted a disutility function to study travellers' loss aversion behaviour for credit collection during route choice procedure. Xu & Grant-Muller (2016) captured simulation analysis for a case study of Beijing to appraise the TMC's influence on people's mode choice and travel pattern. Tian et al. (2019), based on an online experiment, studied people's interaction with each other as well as with intelligent virtual agents in the situations of credit trading and route choice. And a more detailed literature review on the behavioural impact of tradable credits is concluded by Dogterom et al. (2017).

And necessarily, in terms of the issue of public acceptance, TMC gains better support from the public. The work by Kockelman and Kalmanje (2005) in Austin, Texas proved TMC as a viable and competitive alternative. Likewise, a survey carried out in the UK revealed the better public acceptance of TMC than CP and participants approved its fairness (Harwatt et al., 2011). Dogterom et al. (2018) investigated the acceptability of a distance-based TMC scheme in the Netherlands and Beijing. They found that TMC gained a much higher acceptance in Beijing in comparison with the Netherlands and attributed it to the worse congestion problem.

3.3 Current problems

TMC is a new congestion management approach and there have not found practical implementations by now. Some issues still need more insights.

The administrative cost is a main issue that researchers concern about for TMC. Authorities need to work on the verification of eligible receivers, allocation of credits, monitoring the use and transaction, etc. Therefore, the administrative cost of TMC scheme will be higher than ordinary CP schemes (Dobes, 1998; Fan & Jiang, 2013; Nie, 2012; Verhoef et al., 1997). Especially the transaction cost is a new matter that needs to be taken into consideration but by now have not gained enough attention. Nie (2012) investigated the effects of transaction cost on auction market and negotiated market respectively. He assumed a brokerage service to assist the transaction procedures and a commission fee is charged. They concluded that the auction market can achieve the desired equilibrium allocation of mobility credits while in negotiated market transaction costs would influence the equilibrium. He et al. (2013) concluded that transaction costs will reduce the trading volume of mobility credits and change the price as well as the travellers' route choices. Zhang et al. (2021) found that transaction cost can lead negative influence on travel disutility for people with low VOT and suggested the imposition of equity constraint in TMC design.

Additionally, TMC is introduced as an alternative to CP. While the distribution of revenues on the development of alternative mobility modes is widely approbated in CP schemes, in TMC there are not enough insights. Revenues could be collected as a commission fee in the free-market schemes or collected directly in the schemes like CBCP. In fact, CBCP may be much convenient for the administration department to redistribute the bonus to drivers and to other transport projects. Authorities need to balance the proportion of revenues that rewarding drivers and investing in transport projects, as well as administrative cost should be considered.

Another issue is that researchers now have not reached a consensus about the credit receivers. In general, we can divide the objects into two groups. One is a more limited group that only referred to drivers or car owners (Ch'ng, 2010; Kockelman & Kalmanje, 2005; Verhoef, 1997). On the contrary, other researchers argue that mobility credits should be allocated to all taxpayers or local inhabitants (Fiorello, 2010; Raux, 2007; Viegas, 2001; Yang & Wang, 2011). A consensus is that credits should be allotted to individuals rather than vehicles. Viegas (2001) pointed out that allotting the credits to vehicles will induce rich drivers to own more cars. It is important to determine the appropriate TMC users which are highly relevant to the quantification of the total amount of credits. If the system adopts a free trade market or the auction scheme for transaction, the trading price will be influenced by the total amount. On the other hand, the number of participants in the system will partly determine the efficiency and cost of administration and trading.

4. CONCLUSIONS

In this article, starting from urban congestion pricing, we have reviewed the successful experience of the implantations in Singapore, London, Stockholm and Milan while the failure cases are also discussed. Sufficient research works and practical cases have shown that public acceptance is the main obstacle for the implementation of CP schemes and the core factor should be equity. Thus, we review the literature on TMC schemes, which was proposed as a fairer congestion management approach to circumvent the shortcoming of CP. Although plentiful conceptual, qualitative and quantitative works have been carried out, there are currently lack of implementation practices of TMC schemes. The TMC presents more complicated management and operation systems than traditional CP schemes. Taking the cases of CP as a reference, future research is recommended to improve TMC schemes more applicable.

First, more specific work can be done in terms of heterogeneous users. The feedbacks of those cases show that commercial, retail and delivery industries enjoy the smooth traffic in urban areas that benefit from the implementation of CP schemes. The abatement of congestion, especially during peak-hour windows, allows the delivery industry to arrange their schedule more flexible. More importantly, while with frequent trips and larger size, urban freight vehicles contribute more to urban congestion. Therefore, in the scenario of heterogeneous users, future works of TMC could draw more attention on urban freight delivery. Setting different regulation of credit consumption that vary from vehicles types to present the externalities caused by freight delivery vehicles.

Secondly, the reuse of revenues on the development of public transport system (Banister, 2003) or active transport modes is essential. As drivers shift from private vehicle to other means of transport like public transport (metro, commuter rail, bus, etc.) and active transport (bicycle, walking and PMDs), the services of these modes should be promoted. Hence, further research can focus on the balance of the bonus enjoyed by individuals and the revenues invested in transport projects.

Besides, researchers could also do further investigation on the allocation process of credits, including more insights on the determination of eligible receivers and the total number of credits. The quantitation of the total amount of credits in the urban area is crucial for the theory's implementation.

PLANIFICACIÓN DEL TRANSPORTE
PLANNING OF TRANSPORT

ANÁLISIS DE EQUIDAD EN LA OFERTA DE TRANSPORTE PÚBLICO MEDIANTE UN MODELO LUTI (LAND-USE AND TRANSPORT INTERACTION). APLICACIÓN AL ÁREA METROPOLITANA DE BUCARAMANGA EN COLOMBIA.

RESUMEN

La planificación y gestión del transporte debe fundamentarse en un conjunto de técnicas que permitan evaluar, de manera integral y dinámica, su funcionamiento en interacción con los usos del suelo. Para concretar esta idea, se plantea el desarrollo y estimación de un modelo LUTI (Land-Use and Transport Interaction), que incorpora cuatro sub-modelos: Transporte (MT), Localización Residencial (MLR), Localización de Actividades Económicas (MLAE) y Modelo de Indicadores de Accesibilidad (MIA). Además, los resultados de este modelo se han evaluado mediante la estimación de distintos indicadores: de equidad horizontal, mediante el uso del Índice de Servicio de Transporte Publico (ISTP), de equidad vertical, mediante el Índice de Necesidad Social del Transporte Publico (INSTP) y de igualdad mediante el coeficiente de Gini. Este modelo se ha aplicado al análisis de equidad espacial ofertada por el Sistema Integrado de Transporte Metrolinea (SITM) en el Área Metropolitana de Bucaramanga (AMB) en Colombia. Los resultados obtenidos ofrecen un cálculo de la equidad en la provisión del servicio de transporte público, considerando tanto la oferta como la necesidad social, entre las distintas zonas del AMB. Esto ha permitido detectar aquellas áreas con mayor necesidad de transporte público y aquellas que, en cambio, experimentan sobre-provisión del servicio.

1. INTRODUCCIÓN

En Colombia, la migración de población desde zonas rurales a las ciudades ha ocasionado un rápido crecimiento de éstas en términos de población, densidad y empleo. Esto ha impulsado un fuerte aumento de la demanda de suelo y, consecuente, de movilidad, una dinámica que ha obligado a implementar de manera urgente una planificación urbana y del transporte más sostenible, es decir, que fomente un crecimiento más equilibrado. Entre las ciudades que experimentan este crecimiento se encuentra el Área Metropolitana de Bucaramanga (AMB) con un desarrollo urbanístico típicamente determinado por los sectores residencial y comercial, mientras que la planificación del crecimiento en infraestructura y servicios de transporte ha sido mucho más lenta. Este proceso ha ido por lo tanto en dirección opuesta a la regla fundamental de sostenibilidad urbana, la cual propone un equilibrio entre los componentes de la movilidad y de uso del suelo (Cordera et al., 2018). La entidad de planificación del AMB ha aplicado distintas políticas para intentar articular transporte y territorio, y atenuar el impacto de la congestión derivada de un uso excesivo del vehículo privado. Dentro de las principales medidas, se implementó un sistema de transporte público tipo Bus Rapid Transit (BRT), denominado Sistema Integrado de Transporte Metrolinea (SITM), para incentivar el modo público frente al uso de transporte individual. Sin embargo, los resultados han sido limitados, gran proporción de usuarios prefieren un elevado tiempo de viaje con mayor confort antes que usar un transporte público, que parece ser cada vez más ineficiente (Ardila, 2019; Pineda, 2017). Por tanto, la falta de planificación y ausencia de técnicas que permitan una evaluación objetiva, han generado hasta ahora soluciones con una efectividad limitada.

En esta ponencia se propone una metodología para la modelización y la evaluación de la equidad espacial del transporte público, considerando la oferta y demanda (Currie, 2010), que ayude a mejorar la planificación del mismo. En el análisis de la oferta se usa el Índice de Servicio de Transporte Publico (ISTP), y en la demanda, el Índice de Necesidad Social del Transporte Publico (INSTP), con el objetivo de obtener una visión clara sobre la equidad en la provisión del servicio. Se entiende además por equidad horizontal, el equilibrio o desequilibrio entre la densidad de población y la oferta de transporte público, y por equidad vertical el nivel de equilibrio o desequilibrio entre la necesidad social y la oferta que provee cada zona del área de estudio. Finalmente, se ha establecido el nivel de disparidad entre oferta y demanda, resaltando las zonas con mayor necesidad de transporte y aquellas donde hay sobre-provisión del servicio. Para una visión global de la equidad y la igualdad en el servicio que provee el SITM, se utiliza el coeficiente de Gini y la curva de Lorenz (Delbosc & Currie, 2011). Este análisis espacial se ha basado en un modelo de interacción entre el transporte y los usos del suelo (modelo LUTI) que, adaptado al AMB, se redefine como AMB-LUTI. Este modelo se ha apoyado en los resultados obtenidos por Cordera et al. (2013), Barrett et al. (2002), John (2005), Salvini & Miller (2005), Strauch et al. (2005), Waddell (2002), Salas et al. (2017) y Guzmán et al. (2017), en este último caso con resultados de carácter más local. En concreto, la metodología interrelaciona los cuatro sub-modelos mediante programación Python, para la representación dinámica y versátil del comportamiento de la movilidad en un día laborable.

2. METODOLOGÍA

Para poder realizar el cálculo de los índices de equidad, se ha partido del desarrollo por etapas de un modelo LUTI, el cual proporcionará los datos de entrada. Este modelo presenta cuatro sub-modelos interrelacionados, procediendo posteriormente a integrar su funcionalidad mediante el lenguaje de programación Python.

2.1 Estructura del Modelo AMB-LUTI

Con el objeto de analizar el SITM, se ha considerado necesario estimar un modelo LUTI (Torrens, 2000) que simule el funcionamiento del sistema urbano. Este modelo debe ser capaz de representar la organización espacial del transporte y de las actividades humanas en el área metropolitana (Lowry, 1964), es decir, reproducir y estimar la movilidad y la localización residencial de la población y de sus actividades económicas. Los modelos LUTI pueden clasificarse en tres grandes grupos según Cordera et al. (2018): de *primera generación* basados en la teoría de la interacción espacial (Wilson, 1970; Andrews, 1953), en técnicas de programación matemática (Herbet & Stevens, 2006; Brotchie et al., 1980) o en matrices de input/output (Leontief, 1966; Echenique, 2011); los de *segunda generación* basados en la teoría de utilidad aleatoria (McFadden, 1974) para la simulación de los usos del suelo (Martínez, 1997; Anas, 1983); los de *tercera generación* basados en modelos desagregados llamados de micro-simulación (Iacono et al., 2007; Castiglione et al., 2015).

El modelo propuesto AMB-LUTI se fundamenta en técnicas tanto de primera como de segunda generación, bajo la premisa de establecer el equilibrio entre los cuatro sub-modelos que lo componen. Es decir, si ocurre un cambio en el uso del suelo, este repercute en el sistema de transporte, generando un nuevo equilibrio y nueva representación del sistema urbano. Este aspecto hace que se interactúe con escenarios hipotéticos mostrando sus posibles efectos. La estructura del modelo AMB-LUTI se puede ver en la Figura 1.

Los cuatro sub-modelos del AMB-LUTI son: modelo de transportes (MT) que funciona con la información proveniente del modelo de localización residencial (MLR) y de actividades económicas (MLAE), generando el equilibrio entre la oferta y demanda de transportes; el MLR que funciona con la información proporcionada por el MT y por el MLAE simulando un patrón de localización residencial de trabajadores por clase socioeconómica; el MLAE que funciona con la información dada por el modelo de accesibilidad (MIA) y MLR, simulando la distribución de las actividades económicas por sector económico; y el MIA que utiliza la información del MT y MLR, y proyecta el nivel de oportunidades que tiene cada zona para acceder al empleo. Además, hay una serie de supuestos del modelo que ayudan a simplificar la simulación, limitando o excluyendo aspectos secundarios difíciles de modelizar (Cordera et al., 2013): la zona de estudio se considera cerrada, es decir, la demanda laboral es satisfecha por la oferta de trabajadores internos al AMB, evitando simular la inmigración y emigración de trabajadores desde zonas colindantes; la ubicación de actividades económicas, como las industrias exportadoras, se considera fija, ya que no depende de la distribución poblacional, ni de la demanda interna de comercio y cuya ubicación está establecida por el Plan de Ordenamiento Territorial (POT); el modelo AMB-LUTI considera la restricción en cuanto a población residente y actividades económicas presentes en cada zona. Si esta capacidad es superada, el modelo reubica estas familias/empresas en su siguiente localización preferida.

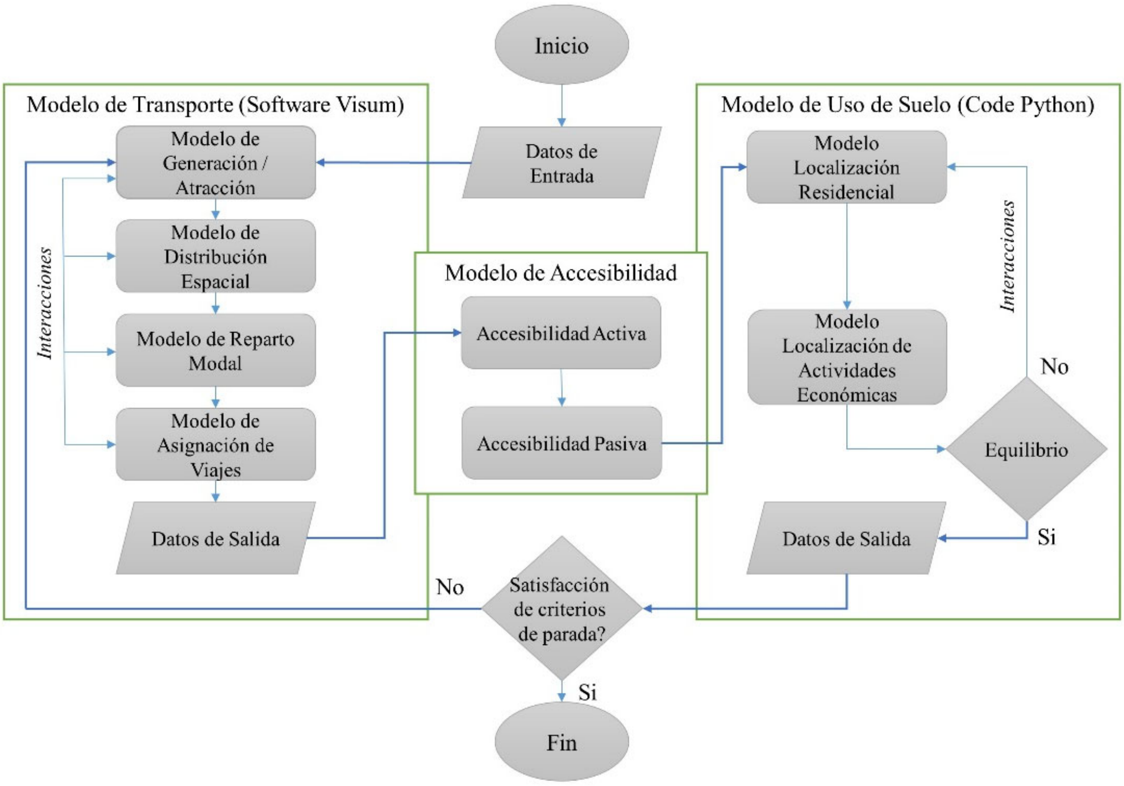

Figura 1:Estructura del modelo AMB-LUTI propuesto

2.1.1 Modelo de Transporte (MT)

El MT utilizado se ha basado en desarrollos anteriores. Tiene carácter estratégico con estructura propia del modelo clásico de 4-etapas (Ortuzar & Willumsen, 2011); *generación-atracción de viajes*, *distribución de viajes*, *elección modal* y *asignación*. La primera etapa está formulada bajo el concepto de ciclo de viaje, es decir, una cadena de viajes con origen en el hogar hacia un destino y respectivo retorno; considerado viaje basado en el hogar (Jovicic & Hansen, 2003). Cada hogar tiene un vector de datos de entrada con características socioeconómicas y elecciones de movilidad realizadas por las personas del hogar. Los viajes son modelizados mediante regresión lineal y posteriormente expandidos por la cantidad de hogares de cada zona. La segunda etapa constituye un modelo de maximización de entropía doblemente acotado basado en la analogía del modelo gravitacional (véase la Ecuación 1).

$$V_{ij} = A_i O_i B_j D_j f(C_{ij}) \qquad (1)$$

donde:

- Vij: viajes entre zonas i y j
- Ai: factor de balanceo en zona i; Oi: viajes originados desde zona i
- Bj: factor de balanceo en zona j
- Dj: viajes atraídos desde zona j
- f(Cij): función de coste entre zonas i y j

La función de coste f(C_{ij}) puede presentar distintas formas, entre ellas la forma combinada (Williams, 1976) de la Ecuación 2. Los costes entre zonas son calculados a partir del coste compuesto (Williams, 1977) mediante la Ecuación 3, el cual es a su vez generado a partir de los costes generalizados por modo de viaje de las Ecuaciones 4 y 5.

$$f\left(C_{ij}\right) = a * K_{ij}^{b} * \exp(-\beta * K_{ij}) \tag{2}$$

$$K_{ij} = 1/-\lambda \cdot ln \sum\nolimits_{n} \exp(-\lambda\left(C_{ij}^{n} + \delta_{ij}^{n}\right)) \tag{3}$$

$$C_{ij}^{Bus} = Coste1 + \theta_{tvp} Tviaje\ percibido \tag{4}$$

$$C_{ij}^{Car} = Coste2 + \theta_{tv}\ Tviaje \tag{5}$$

donde:

- f(Cij): función de coste de tipo combinada;
- Kij: coste compuesto del viaje entre zonas i y j
- a, b y β: parámetros de calibración
- Cnij: coste generalizado entre i y j en el modo n
- λ y δ: parámetros de calibración
- CBus: coste generalizado en transporte público
- Coste1: valor del ticket transformado a minutos
- θtvp: parámetro tiempo de viaje
- Tviaje percibido : tiempo de viaje percibido por usuario
- en vehículo, por trasbordo, entrada, salida y espera.
- CCar: coste generalizado en transporte privado
- Coste2: valor proporcional a la distancia recorrida (min)
- θtv: parámetro tiempo de viaje en transporte privado
- Tviaje: tiempo de viaje dentro del vehículo.

La tercera etapa está basada en la información de cada zona, y es modelo de tipo Logit Multinomial (MNL) que determina la probabilidad de elegir cada modo de transporte. El MNL se genera aceptando que los residuos aleatorios se distribuyen Gumbel independiente e idénticamente distribuidos entre alternativas (IID) (Domencich & McFadden, 1975). Esto permite deducir el modelo dado en la Ecuación 6.

$$P_n = (exp^{(-\lambda(C_n+\delta_n))})/(\sum_m exp^{(-\lambda(C_m+\delta_m))}) \quad (6)$$

donde:

- Pn: probabilidad de elegir un modo de desplazamiento n
- λ: parámetro de escala
- Cn: coste generalizado del modo
- δ: penalidad modal de cada modo.

La cuarta etapa consiste en simular los arcos de red más usados para los desplazamientos generados entre cada par origen-destino, cargándose posteriormente los flujos vehiculares estableciendo las condiciones de tránsito y volumen de pasajeros en las rutas del SITM por zona. Esta asignación es simulada usando el software de transporte Visum.

2.1.2 Modelo de Localización Residencial (MLR)

El MLR se basa en la probabilidad de que un trabajador elija su lugar de residencia dado que trabaja en la zona *d*. La elección se basa en un modelo de elección de zona donde el trabajador maximiza su utilidad de localización. El modelo es probabilístico, permitiendo la evaluación de cada zona de acuerdo a sus atributos socioeconómicos, ambientales e infraestructurales (Hsu & Guo, 2006).

$$P^i_{res-job}(o|d) = (\exp[U^i(o|d)])/(\sum^i_n \exp[U^i(o|d)]) \quad (8)$$

donde:

- Pi : probabilidad de residir en la zona o condicionado a trabajar en la zona d para un usuario de tipo i
- Ui : utilidad sistemática de cada zona o.

La utilidad asumida en cada zona puede descomponerse en dos partes: una sistemática o representativa, medida directamente por el modelador y otra aleatoria cuya distribución se supone Gumbel IID. La utilidad queda definida como:

$$U_i(o|d) = V_i(0|d) + \varepsilon_i(o|d) \quad (9)$$

donde:

- Vi (0|d): atributos cuantitativos de la zona y/o trabajador
- εi (o|d): residuo o utilidad aleatoria.

Dado que la primera hipótesis del modelo supone que el área de estudio es cerrada, es posible calcular el número de trabajadores de estrato *i* que residen en la zona *o* como:

$$W^i(o) = \sum_d P^i_{res-job}(o|d) * Job^i)(d) \quad (10)$$

donde $Job^i(d)$: Número de empleos disponibles en la zona *d* de estrato socioeconómico *i*.

Además, partiendo de la cantidad de trabajadores de estrato *i* residentes en la zona *o*, es posible determinar la población total de dicha zona, aplicando un coeficiente que representa la relación entre población y personas con trabajo.

$$Pop\ (o) = K(o) * \sum_i \sum_d W^i(o) \quad (11)$$

donde K(o): ratio entre población y trabajadores en la zona *o*.

En el MLR, la relación establecida entre la población residente en una zona y los trabajadores presentes en ella, está respaldada por la teoría urbana clásica (Alonso, 1964; Putman, 1979; Simmonds, 1999; Marinez & Donoso, 2001).

2.1.3 Modelo de Localización de Actividades Económicas (MLAE)

La estructura del MLAE es similar al MLR. Partiendo de la teoría de utilidad aleatoria, simula las decisiones de localización de las actividades económicas por medio de elecciones discretas donde se supone que las empresas asignan a cada zona una utilidad y eligen aquella que la maximiza. La probabilidad de localización está dada por la Ecuación 8, usando la Ecuación 9 para el cálculo de la utilidad sistemática. El modelo permite determinar la distribución de empleos por zona y por sectores de actividad según la Ecuación 12.

$$Job_a(d) = P_a(d) * Job_a \quad (12)$$

donde:

- Joba (d): número de empleos ubicados en la zona d pertenecientes al sector económico a;
- Pa (d): probabilidad de localización de empleos de tipo a en la zona d
- Joba: número de empleos totales pertenecientes al sector económico a en el área estudiada.

2.1.4 Modelo de Indicadores de Accesibilidad (MIA)

El MIA es el enlace fundamental en la modelización que relaciona el sistema de transporte y el sistema de usos del suelo. La accesibilidad es la capacidad que tiene un individuo, desde un lugar determinado, de participar en una actividad específica localizada en otro lugar (Hansen, 1959), o bien, la facilidad con la que se puede realizar una determinada actividad desde cualquier ubicación a través del sistema de transportes (Dalvi & Martin, 1976). El indicador de accesibilidad utilizado en este caso es de tipo gravitatorio basado en el concepto de Location–based asccessibility (Geurs & Van Wee, 2004). Además, se han considerado dos indicadores dentro de ese tipo: *accesibilidad activa* (Ecuación 13) u oportunidad potencial para acceder a múltiples actividades desde una zona específica (Cascetta, 2009) y *accesibilidad pasiva* (Ecuación 14), o potencial de oportunidades que tiene una zona de ser alcanzada por la población de diferentes lugares.

$$A(o) = \sum_i [\exp(\alpha_1 * Cost(o, d_i) * Job(d_i)^{\alpha_2}] \quad (13)$$

donde:

- Cost (o, di): coste de viaje entre zona de origen y zona de destino i
- Job(di): número de empleos presentes en la zona de destino i; α1: parámetro de calibración
- α2: parámetro de calibración.

$$A(d) = \sum_i [\exp(\beta_1 * Cost(o_i, d) * Pop(o_i)^{\beta_2}] \quad (14)$$

donde:

- Cost (oi, d): coste de viaje entre la zona de origen y destino
- Pop(oi): población presente en la zona de origen
- β1: parámetro de calibración; β2: parámetro de calibración.

2.2 Evaluación de la equidad en la prestación del servicio de transporte público

La metodología para evaluar la equidad presenta cuatro fases: análisis de oferta del servicio de transporte público, análisis de la demanda potencial del servicio público, índices de disparidad entre oferta y demanda y análisis global.

2.2.1 Análisis de la oferta del servicio de transporte público

La metodología de evaluación más eficiente formulada por Currie (2010) y Delbosc & Currie (2011), hace posible determinar la oferta por medio del ISTP (Rodríguez et al., 2006) basado en la infraestructura (Geurs & Van Wee, 2004). El análisis de la oferta del sistema de transporte público cuantifica el aprovisionamiento en infraestructura y planificación de rutas que tienen las diferentes zonas del área de estudio. Las zonas que presentan un índice bajo mostrarán poca provisión y, si el índice es alto, el nivel de provisión del servicio será elevado.

$$ISTP_n = \sum_{i=1}^{n}(Buffer_{(i)(n)}/Area_n * NS_i) \tag{15}$$

donde:

- Buffer(i)(n): área de influencia de la parada i en la zona n
- Arean: área total de la zona n
- NSi: nivel de servicio de la parada i (numero de servicios que ofrece cada parada en un día laboral).

2.2.2 Análisis de la demanda potencial del servicio de transporte público

El INSTP clasifica las zonas donde se requiere mayor infraestructura o servicios, dada una mayor demanda potencial y un perfil socioeconómico determinado. Puede ser difícil analizar el papel del transporte en la exclusión social en distintos países, ya que la administración no brinda información suficiente sobre las necesidades de demanda insatisfecha (McCray & Brais, 2007), motivo por el cual se utiliza el método propuesto por Currie (2004; 2010), utilizado en múltiples estudios (Camporeale et al., 2019; Ruiz et al., 2016) y que se basa en un modelo multicriterio ponderado con variables socioeconómicas de la zona, a las que se le asigna un peso en función de su relevancia, según reflejen una necesidad social de transporte público mayor.

$$INSTP_z = \sum_{i=1}^{n}(Buffer_{(i)(n)}/Area_n * NS_i) \tag{16}$$

$$VN = (Valor\ variable - Valor\ minimo\ de\ la\ variable)/$$
$$(Valor\ maximo\ de\ la\ variable - Valor\ minimo\ de\ la\ variable) \tag{17}$$

donde:

- Xi: valor normalizado de la variable socioeconómica de la zona i
- Wi: peso asignado a cada variable X
- VN: valor normalizado

2.2.3 Índice de disparidad entre oferta y demanda

El ISTP cuantifica la oferta de transporte público, en términos del número de paradas y frecuencia de rutas, asignando un valor de aprovisionamiento que tiene cada zona. El INSTP cuantifica la necesidad de transporte público que tiene una zona desde la perspectiva de los residentes. La diferencia entre el ISTP y INSTP se denomina Índice de Disparidad entre Oferta y Demanda (IDOD). Este indicador ayuda a detectar las zonas en las que debería ser mejorado el servicio.

$$IDOD_i = INSTP_i - ISTP_1 \quad (18)$$

2.2.4 Análisis global de equidad

A partir de los índices ISTP y INSTP se procede a calcular la equidad horizontal (EH) y vertical (EV) usando las siguientes expresiones (Ruiz et al., 2016):

$$EH_i = DP_i/ISTP_I \quad (19)$$

$$EV_i = INSTP_I/ISTP_i \quad (20)$$

donde:

- EHi: equidad horizontal de la zona i
- EVi: equidad vertical de la zona i
- DPi: densidad poblacional de la zona i.

Las zonas con EH alto corresponden a un mayor equilibrio entre la población de una zona y el servicio en transporte público que dispone. Un valor de EV bajo representa a zonas con elevada necesidad de transporte público y bajo nivel del servicio. Como complemento, se calcula el Coeficiente de Gini (Delbosc & Currie, 2011), obtenido a partir del análisis de proporción de áreas de la Curva de Lorenz (Rodríguez et al., 2016). Este coeficiente refleja la medida de disparidad con valor que oscila entre 0 y 1; donde 0 corresponde a una distribución totalmente igualitaria (igualdad total en la oferta de servicio público) y 1 refleja una disparidad total (una zona tiene toda la oferta y el resto nada). El coeficiente de Gini se calcula mediante la Ecuación 21.

$$G = 1 - \sum_{i=0}^{n}(\sigma Y_{i-1} - \sigma Y_i) + (\sigma X_{i-1} + \sigma X_i) \quad (21)$$

donde:

- σY: porcentaje acumulado de ISTP
- σX: porcentaje acumulado de EH o EV.

3. CALIBRACIÓN DEL MODELO LUTI PARA EL AMB (AMB-LUTI)

3.1 Área de estudio

El AMB se ubica en Santander-Colombia y está conformada por 4 municipios: Bucaramanga (17 zonas), Floridablanca (8 zonas), Girón (3 zonas) y Piedecuesta (3 zonas), estando el área en conjunto dividida en 31 zonas con una población total de 1.160.244 habitantes (Dane, 2019) (véase la Figura 2). Cada zona tiene una red vial interna e información socioeconómica propia. La población se encuentra distribuida de la siguiente manera: Bucaramanga con 543.574 habitantes, Floridablanca 273.817 habitantes, Girón 181.811 habitantes y

Piedecuesta 161.042 habitantes. El AMB tiene además un total de 58.932 comercios que generan 538.671 empleos (DANE).

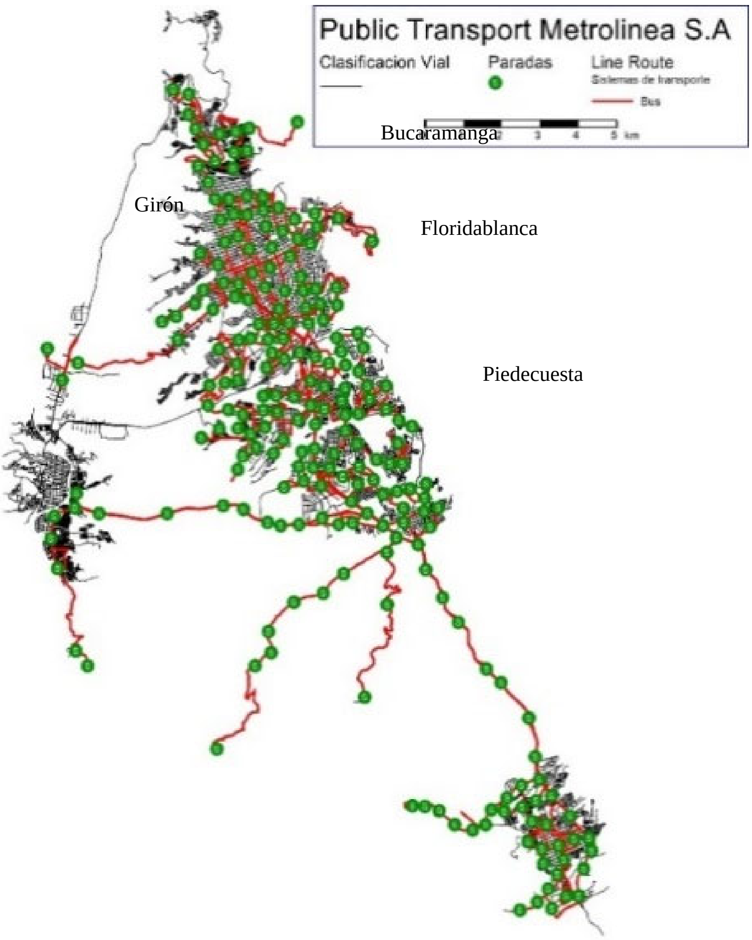

Figura 2: Municipios del AMB y rutas del SITM. **Fuente**: **Metrolínea** (**2019**)

Los datos socioeconómicos, de capacidad vial, tipo de vía y velocidad, son tomados del POT de cada municipio. El SITM es un sistema de autobús tipo BRT que permite viajar por carril segregado en ciertos tramos del viario (Wright & Hook, 2007). Opera de distintas formas, ya que ofrece la posibilidad de construir cada subsistema a la medida aprovechando la infraestructura existente y los vehículos disponibles. Actualmente existen 4 líneas troncales, 10 pre-troncales, 20 alimentadoras y 14 complementarias.

3.2 Calibración del modelo de transporte (MT)

A falta de encuestas de movilidad, los modelos de generación y atracción de viajes se estimaron a partir de una base de datos sobre viajes en día laborable (Manrique, 2016), correlacionada con encuestas domiciliarias de movilidad de la ciudad de Bogotá (Alcaldia de Bogota, 2011) para comprobar su validez. Se formularon los modelos de viajes basados en el hogar (H), que representa el 91,2 % de la movilidad diaria en el área Metropolitana de Bogotá (Guzmán et al., 2015). El modelo de generación se establece con cuatro variables: ingreso *bajo* (1 a 2 salarios mínimos mensual legal vigente smmlv), *bajo-medio* (2 a 4 smmlv), *medio* (4 a 6 smmlv) y *alto* (> 6 smmlv), y la variable *personas por hogar* (P/H). (véase la Tabla 1).

	Modelo de Generación		Modelo de Atracción	
Variable	**Coeficiente**	**p-valor**	**Coeficiente**	**p-valor**
Constante	-0,548	1,39E-06	1,555	0,03123
Ibm/H	0,383	9,23E-20		
Im/H	1,069	8,96E-30		
Ia/H	1,349	1,03E-29		
P/H	1,324	9,81E-30	0,248	0,168143
E/H			1,998	1,03E-38
R^2	0,996		0,998	
R^2 ajustado	0,996		0,998	
F -Test	1869,485		9930,55	

Tabla 1: Estimación de variables y bondad de ajuste en los modelos de generación y atracción de viajes

El modelo de atracción se formula con las variables explicativas *personas por hogar* (P/H) y *empleos por hogar* (E/H). Este último, hace referencia a los empleos en comercios y/o servicios en cada zona. El modelo para distribución de viajes queda establecido en la Ecuación 1 que, a su vez, requiere de la función de coste combinada (Ec. 2), formulada con los parámetros de calibración: a, b y β que se muestran en la tabla 2.

Parámetros de calibración ($\boldsymbol{a}$, b, $\boldsymbol{\beta}$, λ, δ Car, δ Bus)	
a	0,00
b	5,73
β	-0,06
λ	0,007
δ Car	0
δ Bus	208

Tabla 2: Parámetros estimados para la función de coste y para el cálculo del coste compuesto

Estos parámetros representan la distribución de frecuencias de los tiempos de viaje en el AMB. La función de coste del modelo de distribución utiliza el cálculo del coste compuesto (Ec. 3), donde se establece un valor de coste por cada par origen-destino considerando la disponibilidad de transporte privado, de transporte público o de ambos. La Ecuación 3 presenta los paramentos a estimar: λ, δ_{Car} y δ_{Bus}. Los parámetros δ reflejan la penalidad de cada modo, en relación al otro, y son estimados mediante la transformada de Berkson-Theil, con una desutilidad claramente significativa para el transporte público respecto del coche.

En el coste generalizado del transporte privado se utilizó un valor de 426 $ colombianos por kilómetro recorrido con un valor del tiempo de viaje para este modo de 77,80 $ por minuto (Marquez, 2013). Para el coste generalizado del sistema de transporte público se utilizó el coste del viaje de 2.450 $, valor constante en todos los pares origen-destino, dado que, con el valor de un viaje, el usuario puede realizar los trasbordos necesarios mientras se mantenga en el sistema. El valor del tiempo de viaje para este modo se estimó en 55,64 $ por minuto.

3.3 Estimación del MLR y MLAE

El MLR se estimó diferenciando entre residentes con ingreso *bajo* (Ib), *bajo-medio* (Ibm), *medio* (Im) y *alto* (Ia). La utilidad percibida queda especificada con las variables: tiempo de viaje por modo de casa al trabajo considerando congestión y expresado en minutos (JT); accesibilidad activa de la zona (ACA); valor metro cuadrado de viviendas según estrato y características socioeconómicas de la zona (VM2); número de viviendas presentes en la zona (NV); y una variable dummy con valor igual a 1 si la zona tiene un prestigio especial (VP). La estimación de los parámetros de la función de utilidad se realizó mediante máxima verosimilitud (véase Tabla 3); al estar la muestra desagregada a un nivel de elección individual, permite la segmentación de la misma en los cuatro grupos sociales, reduciendo el error de agregación y considerando diferentes variables en la función de utilidad de cada estrato económico. Las personas con ingreso medio fueron el estrato base para el cálculo de los demás parámetros.

	Var.	JT	ACA	VM2	NV	VP	ACP	EMP	RES	CEN	Log (θ)	Log (0)	N

	p-val			0,007			0	0	0	0			

Tabla 3: Parámetros estimados para los MLR y MLAE

El MLR resultó coherente con las hipótesis teóricas. La log-verosimilitud de -8717 es mayor al modelo nulo, de igual forma las variables explicativas obtuvieron signos consistentes con lo esperado; el parámetro de la variable JT presenta signo negativo en personas con ingreso bajo y bajo-medio, con un nivel de confianza del 95%, lo que señala que prefieren residir en zonas cercanas al lugar de trabajo. Dentro de esta misma variable, las personas con ingreso alto presentaron signo positivo en el parámetro, esto se debe a que este tipo de residentes se localizan en zonas claramente alejadas del centro de la ciudad y de los lugares de trabajo.

El parámetro VM2 presenta signo negativo en personas con ingreso bajo y bajo-medio, ya que este grupo reside en zonas con valor metro cuadrado de vivienda menor, en contraste, el signo positivo en personas con ingreso alto refleja la preferencia de vivir en zonas más costosas. Las variables NV y VP son significativas con signo positivo lo cual es coherente, las personas prefieren residir en zonas donde se tiene mayor presencia de viviendas y prestigio. La variable de accesibilidad activa (ACA) no fue significativa, dado que se cuenta con suficientes variables que soportan el modelo de localización (JT), esta variable no se incluye en el modelo final. Para el MLAE las actividades se dividieron en tres tipos: comercial, de servicio e industrial. La actividad industrial se considera como básica en el presente modelo y su localización es fija. La utilidad sistemática del modelo ha quedado especificada como una combinación lineal de los atributos: accesibilidad pasiva (ACP) de la zona en función del tiempo de viaje y de la localización de la población (Ec. 14); empleos presentes en la zona (EMP); residentes presentes en la zona (RES); y una variable dummy que representa si la zona pertenece al centro urbano (CEN). La estimación se realizó por el método de máxima verosimilitud, obteniendo resultados coherentes con las hipótesis teóricas. Se formularon dos modelos distintos, uno para las actividades comerciales y otro para los servicios. Ambos modelos presentaron una log-verosimilitud mayor a la del modelo nulo. En las actividades de tipo comercial, las variables EMP, RES y CEN presentaron parámetros positivos y significativos, a un nivel de confianza del 95 %, excepto para la variable ACP cuyo parámetro fue significativo a un nivel de confianza del 90 %, aunque, dada su importancia teórica y papel como variable de política, se decidió mantener en el modelo. El precio del metro cuadrado de bienes inmobiliarios en la zona tuvo signo negativo, es decir, la mayoría de los propietarios de comercios prefieren localizar su negocio en zonas de menor coste. En el modelo para las actividades económicas de servicios, todos sus parámetros fueron significativos, incluida la accesibilidad pasiva. La variable VM2 presentó un parámetro positivo lo que significa que, para este tipo de negocio, la localización es influenciada por zonas con residentes de alto ingreso, lo que es coherente con lo observado. La variable CEN presento en ambos casos el parámetro con el mayor peso. Esta calibración, aunque no se aplica directamente en el análisis de equidad de la situación actual, permitiría realizar este análisis en distintos escenarios de planificación.

3.4 Calibración del modelo de accesibilidad (MIA)

La estimación de los parámetros de los modelos de accesibilidad activa y pasiva se realizó linealizando las Ecuaciones 13 y 14, mediante una transformación logarítmica, y posteriormente utilizando mínimos cuadrados. Este proceso exige el uso de una variable dependiente asumida como variable proxy de accesibilidad. Se tomaron los datos del MT del año base 2019 (viajes producidos y atraídos) de cada zona, que tienen relación directa con la accesibilidad activa y pasiva, donde a mayor cantidad viajes el valor de accesibilidad es mayor. La accesibilidad activa y pasiva quedan formuladas bajo las variables coste (tiempo de viaje entre zonas considerando congestión), empleos y población de cada zona. Los resultados se resumen en la Tabla 4.

	Accesibilidad Activa		**Accesibilidad Pasiva**	
Variable	**β**	**P-Valor**	**β**	**P-Valor**
Ln_Job/Ln_Pop	0,98	0,000	0,87	0,000
Cost	-0,015	0,000	-0,017	0,000
R^2	0,97		0,97	

Tabla 4: Parámetros establecidos para los modelos de accesibilidad

La calibración del parámetro coste presentó un signo negativo en ambos casos, con un mayor valor en el caso de la accesibilidad pasiva, hecho que es coherente con la teoría, ya que los viajes relacionados con el trabajo muestran de media una menor impedancia.

4. RESULTADOS SOBRE LA EQUIDAD EN EL TRANSPORTE

El análisis de la oferta de transporte se realizó con la información digitalizada mediante el software Visum y codificación proveniente de Metrolínea considerando: paradas y rutas (977 paradas y 44 rutas de servicio); nivel de servicio en cada parada, número de rutas y frecuencia en día laborable; y evaluación del ISTP por zona con un área de influencia concéntrica de 300 metros desde cada parada. Los valores finales son normalizados en una escala entre 0 y 100 con el objeto de ser comparados con los índices de demanda potencial. El análisis de demanda se realizó por medio del índice INSTP desarrollando un análisis Multi-criterio para la ponderación mediante el método de jerarquías analíticas (AHP) (Saaty, 1995).

Así, se compararon por pares las variables: tasa de trabajadores, tasa de población de recursos bajos, tasa de actividades económicas y valor de accesibilidad al empleo en la zona. La valoración fue realizada por un equipo de seis expertos mediante la plantilla de evaluación AHP propuesta por Goepel (2013) obteniéndose unas ponderaciones para la población de ingreso bajo de 49,8 %, para la accesibilidad al empleo de 21,9 %, para la tasa de trabajadores de 20,2 % y para la tasa de actividades económicas del 8 %. Los valores son normalizados para poder ser comparados con los índices de oferta (véase la Tabla 5).

Zona	INSTP	ISTP	IDOD	Zona	INSTP	ISTP	IDOD
1	80,91	15,94	64,97	**17**	35,66	10,40	25,26

Tabla 5: Índices del nivel de oferta de transporte público (ISTP), necesidad de transporte público (INSTP) y disparidad oferta-demanda (IDOD)

En el caso de la accesibilidad al empleo y tasa de actividades económicas se utilizó un valor inverso, para reflejar que, a mayor valor menor necesidad de transporte público, es decir, las zonas con más comercio y más accesibilidad al empleo tienen una menor necesidad de transporte público para que su población acceda a esas oportunidades.

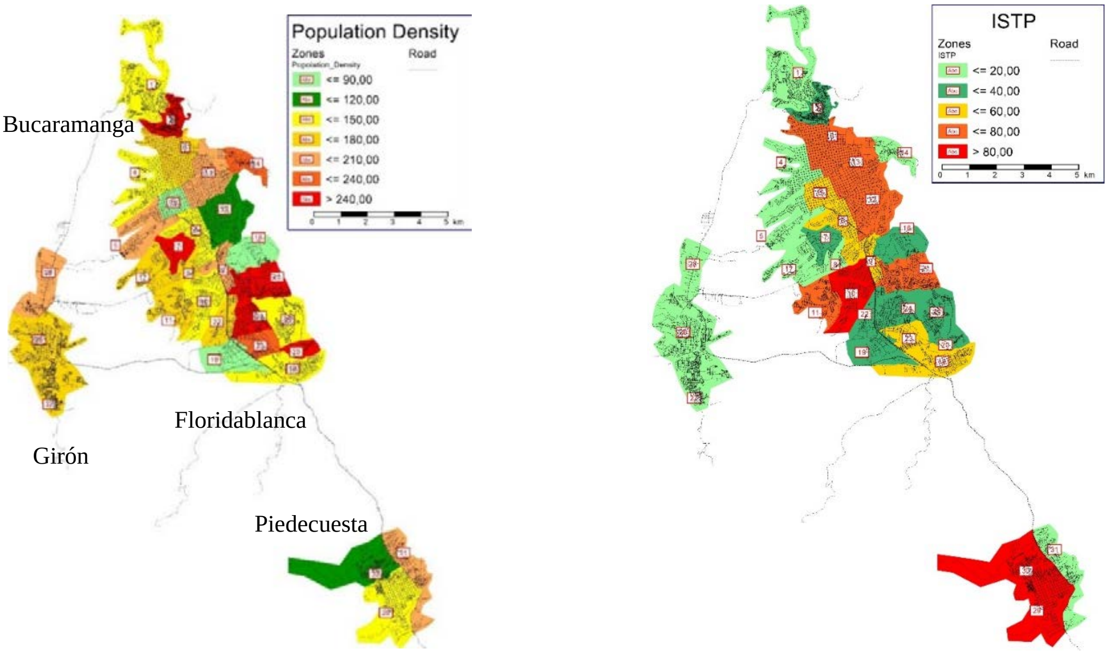

Figura 4: Distribución espacial de la densidad poblacional e indicador ISTP

La figura 4 muestra la distribución de población en el AMB. Destacan las zonas Ciudadela, Nororiental, Morrorico, Caldas Reposo, Valencia, Bucarica y Lagos como las más pobladas, con uso netamente residencial y población de ingreso bajo. Las zonas más comerciales son Centro, Cabecera del Llano, La Concordia, Cañaveral y casco antiguo de Piedecuesta, presentando menos densidad de población, lo que implica que las personas en general residen lejos de su lugar de trabajo. El índice ISTP permite, por su parte, identificar zonas con mayor oferta de servicio: San Francisco, Oriental, Cabecera del Llano y Provenza, en el centro del municipio Bucaramanga. En cambio, las zonas Caldas Reposo en Floridablanca, las zonas centro y norte de Piedecuesta, junto al municipio Girón, lucen totalmente excluidas del servicio, es decir, sin infraestructura óptima que satisfaga la demanda de viajes.

En contraste, se puede observar sobre-provisión de oferta de transporte público en zonas de uso comercial favoreciendo el desplazamiento con fines laborales. Los resultados del modelo muestran que las tres zonas de Girón con indicador bajo de ISTP, aunque pertenece al AMB, están desconectadas del sistema de transporte público. En cuanto a las zonas con mayor necesidad de transporte en el municipio Floridablanca, estas son: Caldas, Reposo y la Cumbre. De igual forma, el municipio de Piedecuesta presenta gran necesidad al presentar un proceso de expansión urbana sin que el servicio se haya adecuado. El indicador de disparidad oferta-demanda, IDOD, muestra que las zonas con valor negativo tienen una oferta de servicio muchísimo mayor a la necesidad estimada.

En cambio, cuanto mayor sea este indicador significa que la provisión de infraestructura y frecuencia de rutas es insuficiente para satisfacer la necesidad estimada (véase la Figura 5).

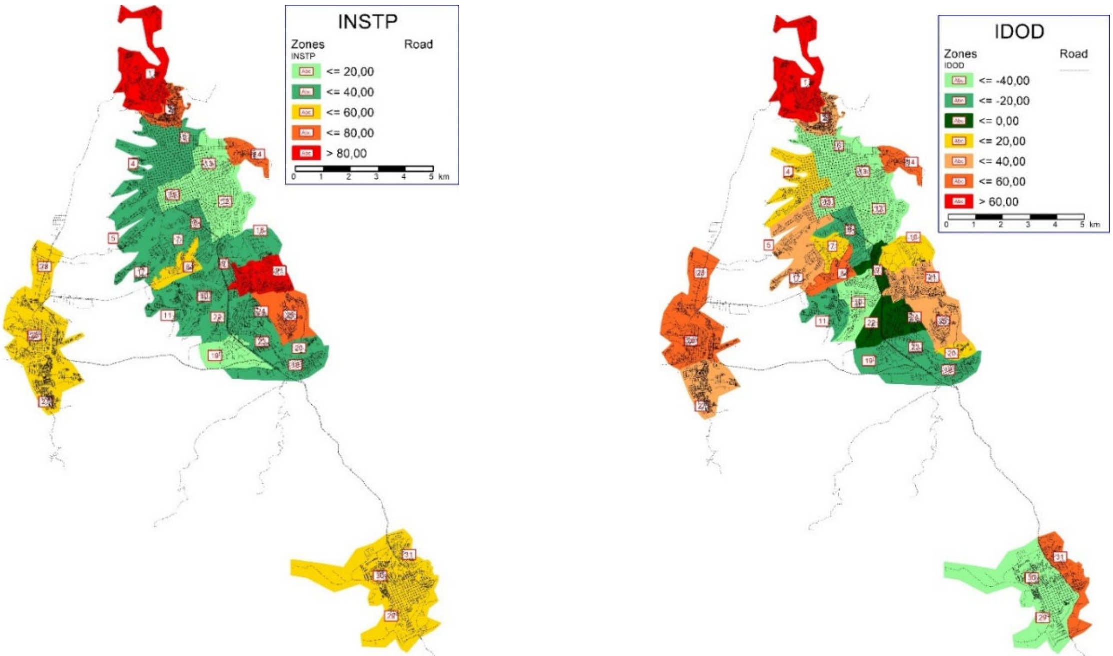

Figura 5: Distribución espacial de los índices INSTP e IDOD

En Bucaramanga, las zonas con indicador negativo son las de uso comercial: San Francisco, Oriental, Cabecera del Llano y Centro. Estas zonas presentan un sobre-aprovisionamiento de infraestructura y servicio justificable, aunque no puede tener más residentes ni población de bajos recursos, ya que presentan en promedio, el 40 % de todos los empleos del AMB. Las áreas residenciales que tienen aprovisionamiento extra en este municipio son: Concordia, Provenza y Sur. Las demás zonas periféricas tienen indicadores positivos lo que señala que podría ser necesario aumentar la infraestructura y la planificación de nuevos servicios en esas zonas. El municipio de Floridablanca es el segundo más grande en términos de área y población, todas sus áreas tienen residentes de bajos recursos y presentan un valor positivo en su indicador IDOD, estas son: Caldas Reposo, La Cumbre y Bucarica, lo que señala que el sistema de transporte público de esta área presenta cierto aislamiento. En el municipio Girón el índice revela la necesidad de una mayor oferta del servicio de transporte público en todas sus zonas pues sus indicadores de IDOD son los más altos en el AMB, es decir, es el municipio peor servido. El municipio de Piedecuesta, a pesar de estar más alejado del centro del AMB, tiene un índice elevado de servicio en relación a la demanda pues sus indicadores en dos zonas de tres son negativos.

En general el sistema de transporte satisface el desplazamiento hacia cuatro zonas: San Francisco, Oriental, Cabecera del Llano y Centro, mientras que el sistema no facilita una movilidad transversal, y en caso de permitirse, implica un desplazamiento que toma mucho tiempo y varios trasbordos, lo que causa desequilibrio en el acceso a los equipamientos y servicios, potenciando el uso de vehículo privado para este tipo de movilidad. El modelo de rutas establecido como Periferia–Centro de Bucaramanga–Periferia, no contempla un municipio como Floridablanca, donde hay zonas con alta densidad de comercio. Este análisis permite ver que el sistema de transporte público contribuye a la consolidación de áreas urbanas periféricas aisladas del conjunto urbano central, debido a que se encuentran conectadas por una sola ruta de servicio troncal. Por su parte, la equidad horizontal, formulada a partir de la densidad de población e ISTP, arrojan resultados de disparidad muy alta dentro del AMB. Las zonas con valor mayor corresponden a áreas con mucha población y servicio ineficiente de transporte público, destacando en Bucaramanga: Norte, Nororiental, Occidental, Morrorico, García Rovira, Mutis y Sur. Todas las zonas ubicadas en la periferia y con residentes de bajo ingreso del municipio Girón tienen valores muy altos en comparación a las demás zonas, señalando una falta de servicios de transporte público. En Piedecuesta solo una de sus tres zonas presenta un servicio ineficiente y el mayor equilibrio de equidad horizontal se da en el centro de los municipios de Bucaramanga y Floridablanca, donde se tiene exceso de servicio e infraestructura frente a su baja densidad demográfica. Es importante resaltar que el SITM tiene en estas áreas varias rutas troncales con carril exclusivo que cruza la ciudad de extremo a extremo, desde Bucaramanga hasta Piedecuesta. Además, el resto de las rutas, ya sean alimentadoras o complementarias, deben como mínimo realizar una parada en las estaciones, lo que ayuda a aumentar el nivel de aprovisionamiento del servicio. En general, ocho zonas se destacan en la equidad horizontal: Morrorico, García Rovira, Mutis, Sur Occidente, Girón Norte, Casco Antiguo Girón, Girón Sur y Piedecuesta Oriente (véase la Figura 6).

La equidad vertical, evaluada por medio del ISTP e INSTP, refleja la relación entre oferta y necesidad de todas las zonas consolidadas, donde zonas con un alto valor corresponden a áreas con alta necesidad de transporte público y bajo nivel de servicio. Es importante resaltar, el desajuste que tiene Girón en todos los indicadores evaluados resultando el área más perjudicada por falta de servicio. Si evaluamos al municipio de Bucaramanga y Floridablanca como una sola entidad (dada su cercanía) podemos deducir que hay ocho zonas que presentan alta densidad de población y muy bajo nivel de servicio de transporte público, en comparación con el resto, siendo estas: Norte, Nororiental, Morrorico, García Rovira, Mutis, Sur Occidente, Caldas Reposo y La Cumbre, siendo nuevamente las zonas con residentes de ingreso bajo las más perjudicadas. El SITM tiene por lo tanto un efecto muy poco positivo en zonas con población de bajo ingreso, como puede verse en todos los indicadores, incluso cuando existe una gran concentración de población. Además, el actual sistema de transporte no contempla las zonas en las periferias de los municipios de Bucaramanga y Floridablanca, ya que cuanto más alejada está la zona de su eje troncal, peor es el servicio de transporte ofrecido. Estas condiciones hacen que estas zonas, en su mayoría con población de bajos ingresos, presenten peores condiciones de acceso al empleo, lo que deteriora aún más sus oportunidades. Además, en zonas de mayores ingresos, la falta de oferta de transporte público incentiva el uso del vehículo privado.

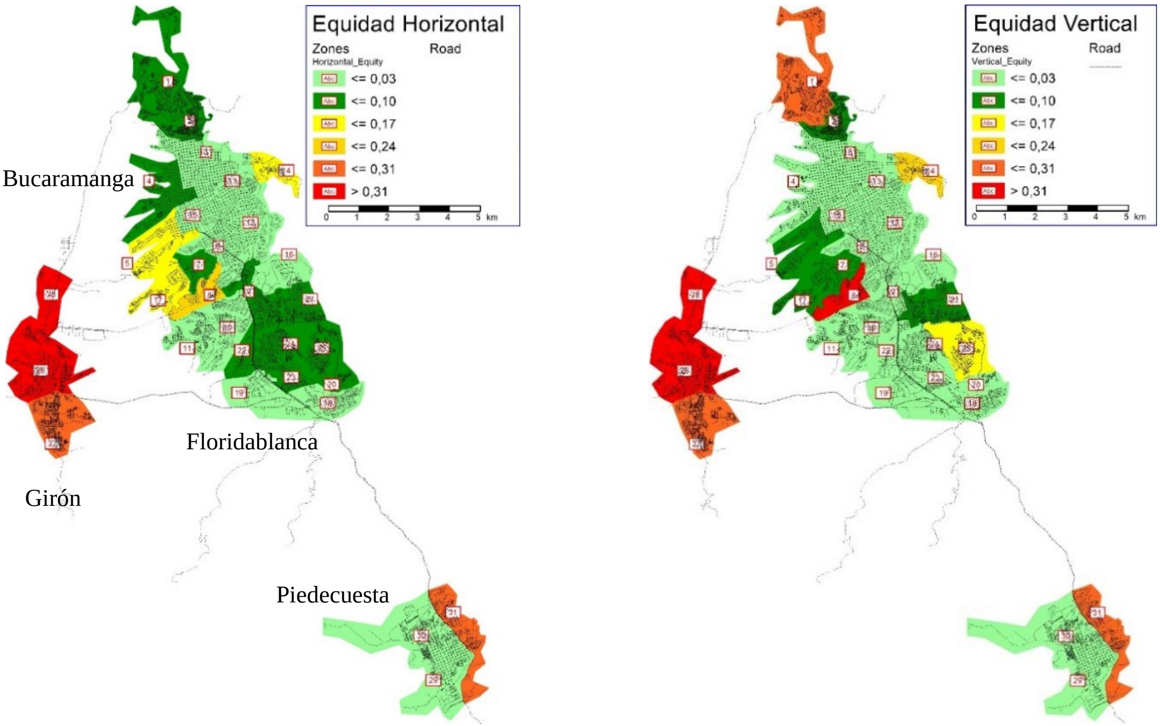

Figura 6: Distribución espacial Equidad Horizontal y Equidad Vertical por zona

Evaluando la equidad horizontal y vertical y la igualdad en la distribución por medio de la curva de Lorenz y coeficiente de Gini, se comprueba que la disparidad entre oferta y necesidad del servicio de transporte público es notable. Las curvas mostradas en la Figura 7 señalan el alejamiento notorio de la situación de igualdad total, tanto según la densidad de población de los residentes en cada zona como en la necesidad social de transporte público estimada.

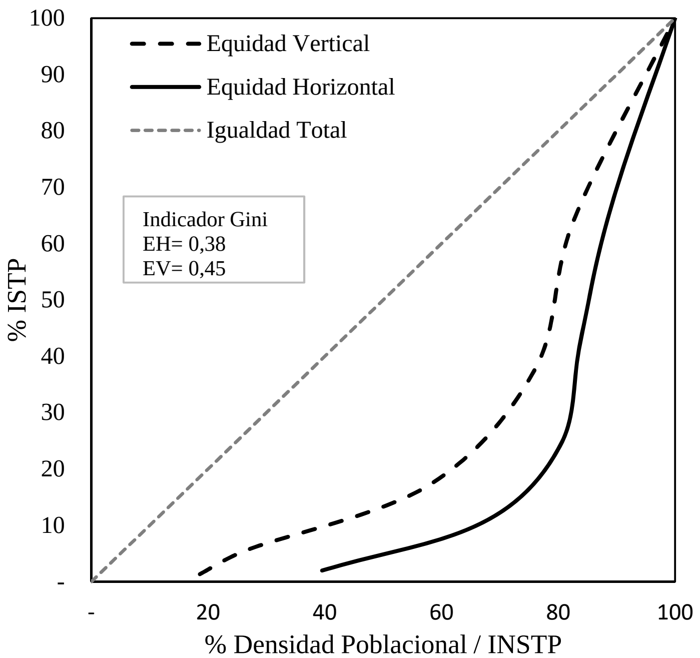

Figura 7: Curvas de Lorenz a partir de índice de equidad horizontal y vertical

El coeficiente de Gini muestra un valor menor de disparidad en equidad horizontal (0,38) evaluado a partir de la densidad poblacional versus el nivel de servicio del transporte público, comparado con la equidad vertical (de 0,45) determinada mediante los índices ISTP e INSTP. Los valores de estos indicadores son diferentes a cero, lo que representa una falta de equilibrio entre la necesidad y oferta del transporte público, tanto en cuantía como en características socioeconómicas.

5. CONCLUSIONES, DISCUSIÓN Y LIMITACIONES

En esta ponencia se ha realizado un análisis de la equidad espacial ofertada por el SITM en el AMB – Colombia. Para ello se ha estimado el desequilibrio existente entre la necesidad social y los servicios ofertados de transporte público mediante los Índices ISTP y INSTP. Además, se ha calculado el coeficiente de Gini a partir de datos proporcionados por el modelo de interacción entre el transporte y usos del suelo AMB-LUTI. Este modelo ha permitido obtener los datos sobre la oferta de transporte público y la demanda potencial en las distintas zonas, basándose en el software de transporte Visum y código propio programado en el lenguaje Python.

El AMB constituye un área urbana en desarrollo donde el sistema de transporte publico presenta debilidades, pudiéndose equiparar a otros territorios metropolitanos similares, afectados por el desarrollo rápido y desorganizado de los usos del suelo y la falta de información para imponer una planificación del transporte más efectiva. Entre estas debilidades se encuentra la de una estructura de la red de transporte público basada en una sola ruta troncal de la que se benefician sólo las zonas centrales de los municipios, constituyendo un sistema rígido que no facilita la movilidad transversal. La falta de interconexión entre los cuatro municipios de Bucaramanga, Floridablanca, Girón y Piedecuesta ocasiona una baja equidad en la oferta del transporte público e indica la necesidad de reestructurar el sistema. Esta reestructuración debería basarse en medidas como: colocar rutas de servicio en función de la densidad poblacional, tener en cuenta las zonas con crecimiento demográfico y urbanístico, relocalizar las paradas en función de las zonas en aras de poder brindar un servicio más equitativo evitando el sobre-aprovisionamiento en algunas áreas, planificar las frecuencias en función de la necesidad de servicio público de las diferentes zonas y adaptar la infraestructura para satisfacer la demanda de movilidad entre municipios, no solo hacia y desde Bucaramanga. En virtud de la dificultad para realizar estos cambios por los costes elevados que pueda representar, es aconsejable disponer de una metodología que permita simular distintos escenarios, incorporando cambios leves que faciliten poco a poco la adecuación de la oferta a la demanda como medida más viable e inmediata a corto plazo.

El AMB presenta por lo tanto desequilibrios notables en la prestación de servicio del SITM, al no facilitar un acceso adecuado al empleo desde todas las áreas. Se puede observar gran dependencia de ciertas rutas del centro urbano comercial, sin contemplar los nuevos centros urbanos que se están desarrollando en la actualidad. Así, en algunos municipios el servicio de transporte público se está quedando obsoleto, no se está adaptando a las modificaciones rápidas de los usos del suelo, y los ciudadanos están migrando paulatinamente de forma progresiva hacia un uso más intenso de transportación individual que implica no solo al vehículo particular sino también al uso de la motocicleta como modo de desplazamiento cotidiano.

La metodología propuesta constituye un avance en este sentido, como integración de técnicas de análisis de datos geográficos y socioeconómicos que permitan evaluar la equidad en el servicio de transporte público en Áreas Metropolitanas. La interrelación de los sub-modelos de transporte, localización residencial, localización de actividades económicas e indicadores de accesibilidad permite tener disponible un modelo útil a la hora de medir los efectos dinámicos de cambios que se ejecuten en el sistema de transporte. Las técnicas de medición de equidad, tanto horizontal como vertical, permiten además una evaluación más completa de estos cambios en términos de impacto social.

El modelo AMB-LUTI presenta ciertas limitaciones que es importante mencionar de cara a trabajos ulteriores. La falta de información desagregada del estrato social por zona afecta el uso del modelo cuando se desee dar información a ese nivel de detalle, dado que se utilizaron valores totales para el AMB. No obstante, los resultados obtenidos fueron buenos, ya que el modelo permite una interpretación global de las condiciones de movilidad existente en día laborable en toda el Área Metropolitana. La metodología implementada, la cual combina el análisis de equidad del servicio de transporte público y el modelo LUTI, puede ser una herramienta útil para evaluar distintos escenarios de planificación en otras áreas de estudio.

ABSTRACT

Combinatorial optimization problems abound in the field of airline planning. Aircraft and passengers fly on networks made up of flights and airports. To schedule aircraft, assignments of fleet types to flights and of aircraft to routes must be determined. The former is known as the fleet assignment problem while the latter is known as the aircraft routing problem in the literature. Aircraft routing is typically addressed as a feasibility problem, the solution to which is required for the construction of crew schedules. All these issues are typically resolved 4 to 6 months before the day of operations. As a result, there is little information available about each aircraft's operational status when making such decisions. The tail assignment problem, which has received little attention in the literature, is solved when additional information about operational conditions is revealed, with the goal of determining each aircraft's route for the day of operations while accounting for the originally planned aircraft routes and crew schedules. As a result, it is a problem that must be resolved closer to the day of operations. We propose a mathematical programming approach based on sequencing that captures all operational constraints and maintenance requirements while minimizing operational costs and schedule changes relative to original plans. The computational experiments are based on realistic cases drawn from a Spanish airline with over 1000 flights and over 100 aircraft.

1. INTRODUCTION

Tail assignment is the step in the airline planning process in which specific aircraft (tails) are assigned to flights on a specific schedule. This task is completed a few days before the operation and is subject to several constraints. Firstly, and foremost, all maintenance activities must be ensured. Secondly, information that becomes available following fleet assignment and aircraft routing should be considered. Finally, all operational constraints must be adhered to. The availability of information is the reason for performing tail assignment in the operational horizon. Little to no information about the maintenance needs of each tail is known months or weeks before the day of operations; therefore, generic maintenance opportunities are only considered in the aircraft routing problem. Also, as late adjustments in the schedule occur, the series of flights to be flown by the same tails (line-of-flights) can be modified; certain flights can be cancelled, and others can be added immediately before the service.

The aircraft routing problem has been studied for decades and described in a variety of ways (Barnhart et al., 1998). The following is a generally accepted term. Given the assignment of fleet types to flights, the aircraft routing involves deciding the sequence of flights, i.e., line-of-flights, to be flown by each aircraft and ensuring that each flight is flown exactly once, each aircraft visits maintenance stations at regular intervals, and the solution uses only available aircraft of each type (Desaulniers et al., 1997). It should be noted that it is standard practice to produce flight sequences for aircraft quite early in the planning phase. This early decision is essential to provide input data to the crew planning process and to prepare long-term maintenance, not considering individual constraints but generic maintenance constraints. Then, as the day of operations approaches, the aircraft must be assigned to flight sequences. However, on average, only 80–85 percent of the sequences can be used in actual operations (Liang et al., 2015). This is due to the quality and level of detail of knowledge available about aircraft operational status when solving the aircraft routing, which, on average, is insufficient.

Consequently, the tail assignment problem is addressed very close to the day of operations. Here, all individual operational and maintenance constraints are considered. The problem is solved for a time horizon, which usually spans several days, and provides fully operational assignments of aircraft (tails) to sequences of flights. In practice, the input sequences of flights, which are determined in the aircraft maintenance routing problem, are usually not all suitable for satisfying operational constraints on the day of operations and they must be updated (Liang et al., 2015). Some variants of this problem have been developed in response to different airline business practices and involving planning horizons from months to days (Maher et al., 2018; Grönkvist, 2005; Gabteni and Grönkvist, 2009).

Because of the different approaches to the problem in the literature and real practice, there is not a widely accepted objective function. For example, the aircraft routing problem is not universally recognized as an optimization problem. Many authors have defined it as a feasibility problem, and others have attempted to maximize same-aircraft connections for passengers or to minimize expected delays (Lan et al., 2006). Also, it is common practice for airlines addressing the problem to consider it to be a feasibility problem (Grönkvist, 2005).

A mathematical model, which minimizes constraints violations and conflicts among others, and a solution strategy are proposed to find optimal solutions to real-world large-scale tail assignment problem instances in a short amount of time. The mathematical formulation presented here is based on the one developed for the crew scheduling problem, and it is capable of capturing all of the operational requirements for problem instances as given by our airline partners, including apron-related requirements. Existing methods in the literature fail to capture such a level of detail. Attempts to achieve this while still providing good quality solutions have failed. A rolling horizon approach is used to solve large-scale instances and achieve feasible solutions, in which the model is solved in many smaller sub-models. This approach is useful for finding a viable solution to a problem in a limited amount of time. The obtained solution is then fed into a heuristic-based method, which allows us to empirically demonstrate optimal solutions to the overall model. Computational studies based on data from Vueling Airlines, one of Spain's major airlines, are presented. The model's solutions outperform the airline's solutions, according to empirical proof. Besides, as evidence of the presented approach's effectiveness, a decision support tool was developed and given to the airline. This tool, which is based on the methods described in this report, is now being used in real-world operations.

2. PROBLEM DESCRIPTION

A time-directed graph represents the airline network, with nodes representing tasks such as flights and maintenance duties, and arcs representing relations between tasks. An origin airport, a departure time, a destination airport, and an arrival time define tasks. One tail must be assigned to each task. The remainder of this section introduces rotations, maintenance duties, the guidelines to be followed when assigning tails, and the goals to be pursued.

2.1 Rotations

A rotation is a series of flights performed by the same tail on the same day. A Line of Work (LoW) is a series of rotations to be performed by the same tail over a set period of time, usually several days. It should be noted that rotations and LoWs are results of the aircraft routing problem, which is solved after flight schedules and fleet assignments are determined. Rotations and the fleet allocated to them are the key inputs in tail assignment, and they should be kept as consistent as possible when allocating tails to tasks because crew schedules are dependent on them.

However, if planned rotations become infeasible, for example, due to tail operational conditions, the tail assignment must update them such that the flight schedule remains feasible. When allocating tails to rotations, the maintenance requirements of the tails must be considered, or else assignments will be infeasible. Swaps are used to help or make it easier to meet those requirements. A swap is the recombination of sections of two rotations with different bases, allowing the tails assigned to them to switch bases. Some rules, such as those requiring space-time compatibility, must be followed by swaps. Furthermore, their effect on crews must be minimal, so only a limited collection of all the potential swaps is allowed, as defined when the aircraft routing problem is solved and following the airline's criteria.

2.2 Maintenance duties

Maintenance entails arranging the repair of identified issues, removing objects after a certain amount of flight hours or calendar time, correcting previously found defects (e.g., pilot or crew reports, line inspection, items postponed from previous maintenance), and conducting scheduled maintenance. On an aircraft, various types of maintenance duties must be performed, which may or may not be planned ahead of time. Scheduled duties are identified in advance since they must be completed on a regular basis, while others are the product of operations, typically following equipment failures. They can be classified based on their frequency: flight line inspections are carried out on a regular basis, overnight checks (also known as "daily checks") are small checks conducted every two days during the night, A checks are light checks that are performed every few hundred flying hours, B checks are light checks that are performed every few months, C checks are heavy checks that are performed every 2 years, and D checks are heavy checks that are performed every 6–10 years. The aim of these checks is to perform both routine and non-routine aircraft maintenance. It should be noted that some maintenance checks (hereafter referred to as maintenance tasks) are more flexible than others when conducting tail assignment. Since the tail assignment planning horizon features several calendar days, flight line checks and overnight checks are thoroughly considered. The remaining checks are also fully considered, but are well established prior to operations.

2.3 Allocation rules

Several rules govern the assignment of tails to tasks. They can be classified as hard or soft requirements. Any hard requisite must always be met, while soft ones may be related to market considerations, such as a preference for particular tails due to capacity or efficiency, and may be violated, but, if violated, have a negative effect on the solution efficiency. The number of current rules is usually enormous, and they are complicated, making this problem difficult for planners to solve. They can be general or global rules, but they can also be fleet, aircraft, or airport specific (Grönkvist, 2005).

The following is an example of a hard constraint. Owing to noise restrictions, a specific tail cannot operate at a specific airport at certain times. And an example of a soft constraint follows. Because of its maximum takeoff weight, an aircraft type has limited performance at a specific airport. It will fly from that airport if the tail is not at its maximum weight.

2.4 Objectives

The tail assignment problem can have several objectives. In reality, they can change as the revealed information develops as the day of operations approaches. The primary goal in the early stages is viability, while in the later stages, meeting optimization requirements becomes more important. The following are some of the most important key performance indicators to be minimized: soft restriction violations, fleet changes, swap use, prolonged idle periods, fuel costs, and apron conflicts. Simultaneous departures of neighbouring aircraft on the apron or ramps may cause conflicts and delays. They could need the same airport services at the same time. As a result, they should be kept to a minimum.

3. MATHEMATICAL MODEL

We propose an Integer Linear Programming (ILP) model. Its mathematical formulation is built on a framework in which the tasks to be assigned are nodes and the relations between them are arcs. Mathematically, we consider one type of node (we treat all tasks the same, regardless of their nature) and one type of arc. The model's employed sets, parameters, and variables are described next. The mathematical formulation is then explained.

3.1 Sets

- F is the set of tasks to be covered in the given time-horizon. Tasks are indexed by i and j.
- $FF \subseteq F$ is the subset of tasks which are flights.
- $FSM \subseteq F$ is the subset of tasks which are soft maintenance tasks. They can be postponed if necessary, to improve schedule performance. If they are postponed, they must be rescheduled.
- $FHM \subseteq F$ is the subset of tasks which are hard maintenance tasks. They cannot be postponed.
- $F_i^+ (F_i^-) \subseteq F$ is the set of tasks which may follow (precede) task i in a line of work.
- P is the set of fleet types.
- $P_i \subseteq P$ is the set of fleet types compatible with task i.
- T is the set of tails.
- $T_i^F \subseteq T$ is the set of tails compatible with task i.
- $T_p^P \subseteq T$ is the set of tails belonging to fleet type p.
- $F_t^T \subseteq F$ is the set of tasks which may be assigned to tail t.
- $FA_t \subseteq F$ is the set of tasks which may be the first task in a line of work assigned to tail t.
- C is the set of conflict events. Each conflict event is characterized by a combination of 10-minute time periods and a collection of adjacent parking spots. A possible conflict is identified at each conflict event by combinations of flights scheduled to depart within the predefined time periods and tails located in adjacent parking spots. It should be noted that there is a possible conflict with each flight for which there are other flight departures within a 10-minute time span beginning with the flight's departure.

3.2 Parameters

- c_t^i is a penalty for operating flight i with tail t. This cost accounts for soft operating restrictions.
- b_1^i is the cost of not covering flight i.
- b_2^i is the cost of not covering soft-maintenance task i. Recall that some maintenance tasks, which do not feature urgent, strictly needed, or important repairs or checks may be postponed.
- $\kappa_t^{i,j}$ is a penalty for each combination of tail t and consecutive tasks i and j.
- λ^c is a penalty for each excess conflict at conflict event c.
- μ_i is the change penalty for not operating flight i using the originally planned fleet type.
- $\widehat{w}_i^p$ is 1 flight i was originally scheduled to be operated by fleet type p, and 0 otherwise.
- $\nu_{i,j}$ is the change penalty for not operating tasks i and j consecutively using the originally planned line of work (where task j follows task i in the line of work).
- $\hat{u}_{i,j}$ is 1 flight i was originally scheduled to precede task j, and 0 otherwise.

3.3 Variables

- $x_i^t \in \{0,1\}$ is 1 if tail t is assigned to task i, and is 0 otherwise.
- $y_{i,j}^t \in \{0,1\}$ is 1 if tail t is assigned to consecutive tasks i and j in a line of work, and is 0 otherwise.
- $w_i^p \in \{0,1\}$ is 1 if fleet type p is assigned to task i, and is 0 otherwise.
- $a_i^t \in \{0,1\}$ is 1 if tail t starts a line of work whose first task is i, and is 0 otherwise.
- $s_i \in \{0,1\}$ is 1 if task i is not covered, and is 0 otherwise.
- $u_{i,j} \in \{0,1\}$ is 1 if tasks i and j are consecutive in a line of work, and is 0 otherwise.
- $o_c \in \mathbb{R}^+$ is the number of conflicts in excess of the maximum number of allowed conflicts at conflict event c.

3.4 Objective function

$$z = \sum_{i\in FF}\sum_{t\in T_i^F} c_t^i x_i^t + \sum_{i\in FF} b_1^i s_i + \sum_{i\in FSM} b_2^i s_i + \sum_{i\in F}\sum_{j\in F_i^+}\sum_{t\in T_i^F\cap T_j^F} \kappa_t^{i,j} y_{i,j}^t + \sum_{c\in C}\lambda^c o_c + \sum_{i\in FF}\sum_{p\in P_i}\mu_i\left|w_i^p - \widehat{w}_i^p\right| + \sum_{i\in F}\sum_{j\in F_i^+}\nu_{i,j}\left|u_{i,j} - \hat{u}_{i,j}\right| \quad (1)$$

The objective function in (1) has a total of seven terms in the following order. Penalties for unsuitable task-tail combinations, costs for not covering flights, costs for not covering soft-maintenance duties, penalties for any task link, and penalties for any conflict over the maximum allowed number. The objective function's last two terms penalize deviations from the originally intended schedule. The first penalizes deviations from the initial fleet type assignment. The second penalizes deviations from the initial line of work.

3.5 Task covering constraints

$$\sum_{p \in P_i} w_i^p + s_i = 1 \qquad \forall i \in F \tag{2}$$

$$\sum_{t \in T_p^P \cap T_i^F} x_i^t = w_i^p \qquad \forall i \in F, p \in P \tag{3}$$

Constraints (2) state that each task is assigned to one fleet type or it remains unassigned. According to constraints (3), if a task is assigned a fleet type, it must also be assigned a tail that belongs to that fleet type and is compatible with the tail.

3.6 Line-of-work constraints

$$\sum_{i \in FA_t} a_i^t \leq 1 \qquad \forall t \in T \tag{4}$$

$$u_{i,j} = \sum_{t \in T_i^F \cap T_j^F} y_{i,j}^t \qquad \forall i \in F, j \in F_i^+ \tag{5}$$

Constraints (4) are constraints on line of work initialization. They assign the first task in the line of work to each tail. Constraints (5) define task lines in terms of succession regardless of the allocated tail.

3.7 Task sequencing constraints

$$\sum_{i \in F_j^- \cap F_t^T} y_{i,j}^t + a_j^t = x_j^t \qquad \forall j \in F, t \in T_j^F \tag{6}$$

$$\sum_{j \in F_i^+ \cap F_t^T} y_{i,j}^t \leq x_i^t \qquad \forall i \in F, t \in T_i^F \tag{7}$$

Task sequencing restrictions are constraints (6) and (7). Constraints (6) are backward sequencing constraints; for each task in a line of work to be allocated to a compatible tail, it must be preceded by another task, unless it is the first task in the line of work. Constraints (7) are forward sequencing constraints; there can be up to one successor for each task in a line of work to be allocated to a compatible tail.

3.8 Other constraints

Owing to space constraints, other constraints are not directly shown here. Seating capacity on each cabin type must be equal to or greater than the number of confirmed reservations. Constraints to ensure that operational restrictions are not broken. Constraints preventing night flights from taking place on two consecutive nights. Constraints stating that no tail can fly consecutive nights in order to ensure that every tail rests overnight at least once every two days. Constraints restricting the number of tails that can be used for each day's schedule to the number that are available. Constraints to ensure that hard maintenance and regular maintenance activities are allocated to the appropriate tail. Constraints stating that daily maintenance duties are conducted at every airport where possible for the tails that need it. Constraints on the number of conflicts that may occur, limiting the number of conflicts exceeding the airline's overall allowable.

4. COMPUTATIONAL EXPERIMENTS

We assessed the model's success using case studies based on real-world examples from Vueling Airlines. The information was given by the airline and represents its operations in Europe in 2019. The data set includes operational schedule details, operating expenses, passenger demand values, the BCN airport apron layout, maintenance capacities, and the available fleet from October 6 to October 10, 2019. The air network features 173 airports spread across Europe, as well as those in Asia and Africa. On a typical day, approximately 700 flights operate throughout the network. Three fleet types were available in this case study: a fleet of A-319s with 141 seats per plane, a fleet of A-320s with 171 seats per plane, and a fleet of A-321s with 200 seats per plane. A series of case studies was suggested to evaluate the model and solution methods for real-world instances. All of the case studies were set in the same time period but had different planning horizons ranging from one to five days. This essentially means that the problem size was different with each case study. The tests were performed on an Intel NUC machine equipped with an Intel Core i7-8559U @ 2.70GHz processor and 2x16GB SO-DIMM DDR4 2400 MHz RAM, running Windows 10 Pro. The models were written in Python 3.7.3 and solved with the commercial solver IBM ILOG CPLEX 12.9.0. Many of the instances tested were either solved to perfection or ran for less than 24 hours.

Table 1 displays the mathematical model size for each of the case studies, with each row representing a different case study. Table 1 also indicates how many flights, maintenance duties, and tails are available in each case study. The number of (discrete) variables, constraints, and nonzero elements were given as model sizes.

No. of days	Flights	Maintenance tasks	Tails	Variables	Constraints	Non-zero elements
1	682	59	127	117,217	120,342	352,884
2	1,376	77	127	454,550	242,922	1,150,661
3	1,999	86	127	998,446	352,142	2,347,908
4	2,626	95	127	1,729,013	464,960	3,925,464
5	3,279	100	127	2,731,427	581,291	6,048,599

Table 1: Model size for different case studies.

We began by solving all of the case studies using the branch-and-cut and heuristics approaches given by the commercial solver IBM ILOG CPLEX 12.9.0. Table 2 displays these findings. It contains a case study for each row, which is defined by the number of days in the planning horizon, the number of flights, the number of maintenance duties, and the number of tails. Table 2 also displays the lower bound (L.B.), incumbent solution (I.S.), optimality gap (O.G.), and computational time in seconds for each case study (T.). The lower bound is equal to the solver's highest bound. The incumbent solution is the best solution discovered. The optimality gap is the relative gap between the incumbent solution and the lower bound. The computational time is the amount of time the solver spent running. Except for the case study involving 5 days, all of the case studies were solved to optimality; however, as the problem size grew, the computational time increased exponentially, implying that this solution strategy was unable to produce solutions within a reasonable time if the timeframe to be solved was longer than a few days.

No. of days	Flights	Maintenance tasks	L.B.	I.S.	O.G. (%)	T. (s)
1	682	59	193.050	193.050	0.00	1.05
2	1,376	77	333.025	333.025	0.00	7.88
3	1,999	86	451.525	451.525	0.00	1,200.27
4	2,626	95	599.350	599.350	0.00	47,312.28
5	3,279	100	728.100	18,690.100	2,466.96	86,403.72

Table 2: Solutions of all the case studies using the branch-and-cut and heuristics approach

To efficiently solve the problem, we created and implemented an algorithm based on rolling horizon methods (Sethi and Sorger, 1991) to obtain solutions. The Rolling Horizon Algorithm (RHA) is a technique for solving mixed 0-1 deterministic optimization problems that is based on rolling horizon methods. It involves solving a series of integer programming subproblems in which the variables are partitioned into three subsets. The values of the variables in the first subset are fixed to previous solution values, the 0-1 variables in the second subset are held free, and the values of the variables in the third subset are fixed to 0. However, the RHA cannot prove optimality. A particular approach should be taken to demonstrate it. To that end, the solution can be used as an initial solution for another approach and the whole problem solved. While exact methods should be used to ensure optimality, we have empirically discovered that feeding the CPLEX "solution polishing" heuristic with the initial solution obtained by the RHA provides the optimal solution. Table 3 displays the solutions obtained for the case studies with planning horizons of 4 and 5 days. The obtained incumbent solutions are equal to the respective lower bounds in Table 2, indicating that they are optimal. Furthermore, computational times are significantly reduced.

No. of days	Flights	Maintenance tasks	I.S.	O.G. (%)	T. (s)
4	2,626	95	599.350	0.00	279.50
5	3,279	100	728.100	0.00	407.42

Table 3: RHA solution for the case studies featuring planning horizons of 4 and 5 days

To determine the quality of the model's solutions, they were compared to the actual solutions implemented by the airline. In this comparison, three major performance indices were examined: the number of unassigned tasks (U.), which were either flights or maintenance tasks, the number of hard constraint violations (H.V.), and the number of soft constraint violations (S.V.). Table 4 shows the comparison, which is made the day before the day of operations, when schedules are ready to be implemented. The case study is described in the first column of Table 5. The other two main columns, Model and Airline, display the key performance indices for the mathematical model's and the airline's solutions, respectively. Note that the solutions provided by the model never violate hard restrictions. Moreover, the number of soft restriction violations is significantly reduced.

	Model			Airline		
No. of days	U.	S.V.	H.V.	U.	S.V.	H.V.
1	0	26	0	0	42	3
2	0	56	0	0	90	7
3	0	80	0	0	126	18
4	0	95	0	0	171	27
5	0	119	0	0	224	35

Table 4: Comparison of the model solutions with those used by the airline

Maintenance operations scheduling in airlines is a difficult and complex issue. Maintenance plans are usually prepared in practice based on the expertise of maintenance operators. However, this method is typically time consuming and can result in subpar solutions. Many industries, including the airline industry, are designing better maintenance plans in order to maximize asset availability and performance (Deng et al., 2020). Predictive maintenance techniques predict when maintenance should be done. It saves money over preventive maintenance since tasks are only done when they are required. The aim of predictive maintenance is to make it simple to schedule corrective maintenance in order to avoid unexpected failures. Two additional studies were carried out to demonstrate the possible benefits of using a holistic predictive maintenance method. For the two tests, a 5-day planning horizon was selected. In the first experiment, there is insufficient knowledge on maintenance duties for the entire planning horizon, which means that some of them are revealed as time passes. The aim of this environment is to mimic the airline's current operating model, in which a near-perfect predictive maintenance method is currently unavailable. In the second experiment, maintenance duties feature full or perfect details, implying that a perfect predictive maintenance tool is usable. In the first experiment, the mathematical model was solved every day, which means the model must be solved 5 times. The number of disclosed maintenance duties varied for each run of the model, implying that the schedule is not static. It should be noted that the model's 5 runs were also embedded in a rolling horizon approach. In the second experiment, the knowledge was perfect, so the five days could be solved in a single execution. Table 5 shows the results. The first column lists the main performance indicators (KPIs), the second the solution to the first experiment, i.e., the imperfect information scenario, and the third the solution to the second experiment, i.e., the perfect information scenario. The value of the objective function for the incumbent solution (I.S.) in the second row of the table, the number of unassigned tasks (U.) in the third row, and the number of violations of soft constraints (S.V.) in the last row of the table were used to compare the two scenarios. The findings of the perfect information scenario clearly outperform those of the imperfect information scenario.

KPI	Imperfect information scenario	Perfect information scenario
I.S.	1,655.975	1,072.450
U.	6	0
S.V.	125	119

Table 5: Results for the imperfect and perfect information scenarios

4. CONCLUSIONS

We took a novel approach to the tail assignment issue in airlines. The method we devised gathers a broad range of data and offers a basis for generating optimal proposals rather than just feasible solutions. Among the specifics considered are all applicable aircraft maintenance constraints and flight activity requirements. Furthermore, possible conflicts during aircraft taxi operations in aprons are considered, so that departures are optimally planned to prevent multiple aircraft from departing the same place at the same time. We were able to solve real-world instances in short computational times while proving the optimality of the given solutions using the methodology we devised. The algorithms we created to solve the problem are divided into two stages. Firstly, a feasible solution is found using the rolling horizon process. Secondly, a heuristic-based approach improves the feasible solution obtained. We presented the findings of several computational experiments conducted using data from Vueling Airlines, a major Spanish airline.

ABSTRACT

Mobility in major European capitals is not yet sustainable. The need to respond to the ongoing changes in public transportation demand, operationalize safety norms of social distancing, and reach carbon neutrality are prompting cities to reassess public transport systems. Cross-mode synergies in multimodal transport systems can be explored (including convenience, reliability, cost, speed and predictability) to foment public and active modes of mobility. In this context, multimodal traffic pattern analysis can unravel cross-mode vulnerabilities, a possibility that is finally rising with the sensorization of cities, integration of ticketing systems, and consolidation of traffic data sources and their situational context.

This work introduces a methodology for the analysis of spatiotemporal indices of multimodality against available situational context, aiding specialists to find vulnerabilities on the public transportation network. Traffic generation poles, large-scale public events, and weather records are the considered sources of situational context. We discuss the role of context-aware multimodality indices to understand demand and its emerging changes, assess cross-modal transfers and preferences, and support cross-mode route and schedule planning. This work further discusses the relevance of multimodal pattern discovery to offer data-centric views ensuring: fully transparent decisions to the citizens; and an objective coordination between carriers, municipalities and authorities. Lisbon is further introduced in this work as a reference case study for context-aware multimodal mobility.

1. INTRODUCTION

Worldwide, city municipalities are establishing efforts to collect urban data in order to gain more comprehensive views of the ongoing changes to city traffic dynamics. The undertaken initiatives are particularly relevant in face of pandemic-driven shifts to traffic demand and private car ownership, city reforms, the need to enforce safety norms, and the rising advocacy towards active modes of transportation. In particular, the Lisbon City Council has established relevant initiatives to this end: city traffic sensorization, consolidation of relevant sources of urban data on its Intelligent Management Platform , the integration of automated fare collection systems and tariffs along the public transport system, and entry requirements for carriers operating in the Lisbon metropolitan area. These initiatives offer unique opportunities for multimodal pattern analysis – encompassing road, railway and inlands waterways modes, as well as active modes such as walking and cycling – and cross-carrier coordination. Still, the inherent nature of multimodal traffic data – heterogeneous, massive in size, rich in spatiotemporal dynamics, subjected to variable aspects, and dependent on context factors – together with the increasing disruptive changes in urban traffic poses challenges to data-centric multimodal decisions.

This work proposes a methodology for a preliminary assessment of multimodal synergies in demanding urban areas of a city using multimodality indices estimated from available traffic data. Context-aware corrections are proposed in the presence of information associated with large-scale public events and available weather conditions. These contextual factors can account for meaningful variations to the level and distribution of traffic demand across transportation modes. A spatiotemporal analysis of multimodality indices is conducted for the city of Lisbon using three major modes of public transportation: bus (CARRIS), subway (METRO) and cycling (GIRA). In addition, we further extend this methodology to relate the gathered knowledge against additional sources of situational context, including traffic attraction-generation poles.

This paper aims at bridging the existing gap on the integrative analysis of multimodal traffic data and its situational urban context. A discussion on the relevance of cross-modal pattern analysis for the articulation between operators, and alignment of the public transport supply with the self-actualizing city dynamics are further provided.

This work is anchored in the pioneer research and innovation ILU project (DSAIPA/DS/0111/2018), a project that joins the Lisbon City Council and national research institutes to bridge ongoing research on urban mobility with recent advances on artificial intelligence.

The manuscript is organized as follows. Section 2 provides essential background. Section 3 introduces a novel methodology for the context-aware assessment of multimodality indices from heterogeneous traffic data. Section 4 gathers results of its application on the Lisbon city. Final remarks and major implications are then synthesized.

2. BACKGROUND

Multimodality is generally defined as the use of more than one transport mode to complete a trip within a certain period. In contrast, monomodality commonly refers to the exclusive use of one mode of transport (Nobis, 2007). Multimodality is a subfield of a broader body of research focused on intrapersonal variability of travel behaviour, comprising temporal, spatial, purpose and modal dimensions (Buehler and Hamre, 2016). Nobis (2007) emphasizes the fact that the general definition of multimodality must entail a time frame, possibly going beyond end-to-end trips to further encompass a week period. The longer the period, the higher the probability for multimodal transport use.

2.1. Opportunities and challenges in Lisbon

The Intelligent Management Platform of Lisbon City (PGIL) was publicly launched in 2017 to meet various policy and planning goals at the operational level. In this context, advancing towards sustainable and multimodal mobility in Lisbon is understood as a policy opportunity while it offers multiple research challenges around the interdisciplinary triaxial lens: data science and statistics – urban mobility planning – artificial intelligence. Using the available big data from various heterogeneous sources of traffic data across public transport operators, the following research challenges have been addressed so far:

- processing and consolidation of raw sources of urban data across public transport operators, and their multimodal descriptive and predictive analysis to support mobility planning decisions at the city level
- discovery of emerging spatiotemporal traffic patterns, while accounting for the stochastic nature of mobility dynamics (Neves et al., 2020, 2021).
- inference of dynamic and multimodal origin-destination (OD) matrices sensitive to missing boarding validations and monthly patterns of circulation (Cerqueira et al., 2020)
- incorporation of contextual data (weather, public events, traffic incidents, etc.) to enhance traffic data analysis and its integrative learning potential for future behaviour inferences (Leite et al., 2020; Cerqueira et al., 2020)
- exploratory policy framework of multimodality indices to measure social equity regarding users’ multimodality options in the city (Lemonde et al., 2020)
- development of the ILU app, namely, to enable visualization of large-scale and heterogeneous data and to enhance specific data-centric views of the relevant information while accounting for each operator/city specificities and both cross-modal or unimodal user-centric perspectives.

The implementation of this set of urban analytics tools within the PGIL platform, managed by the city Council, is expected to support urban mobility planning, giving priority for public transport options and the integration of active travel modes (walking, shared public bicycles) with bus and/or metro/subway. Moreover, the full scalability and online nature of the devised tools can be enriched by targeting other dimensions of the city dynamics in the post-pandemic era.

3. METHODOLOGY

The assessment of multimodal urban transportation is a key issue in modern transport research, and the proposed solutions must handle the massive, heterogeneous, spatiotemporal, context-dependent and incomplete nature of traffic data. In this section, a sequence of procedures (Figure 1) is proposed for context-aware multimodal analytics.

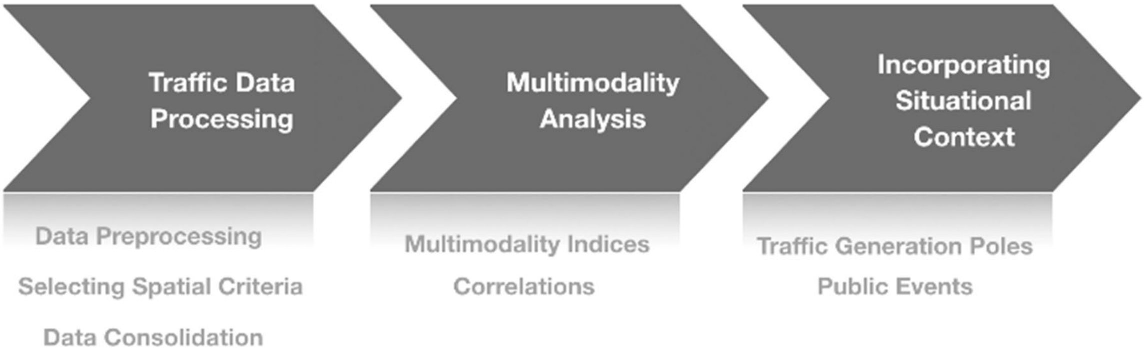

Figure 1: Public transportation multimodality analysis process

3.1. Traffic data processing

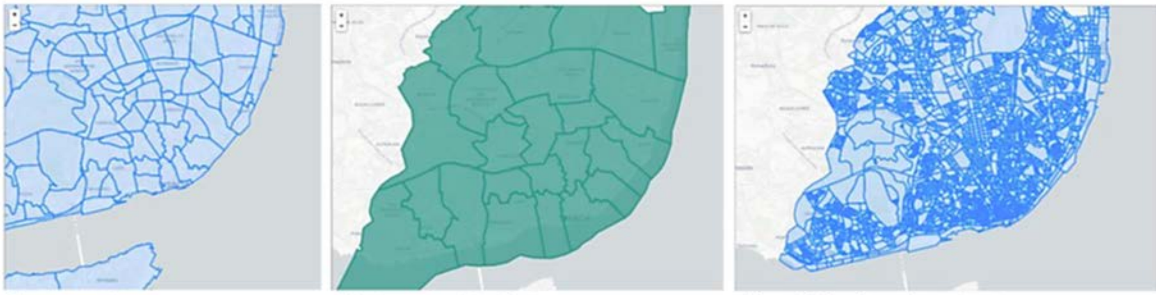
Raw traffic data from different sources can come in different formats and structures, being essential to start by preprocessing the collected data, where noise and inconsistencies are removed and high multiplicity of data sources are integrated within a single repository. The consolidation step was accomplished in this work using a multi-dimensional schema to allow for an effective and efficient cross-modal retrieval of trip records from specific users, operators, geographies and time periods. To this end, shared dimensions between sources were identified, including user, carrier, spatial and temporal dimensions.

Given the massive size of urban data, proper indexation of spatial, temporal and modal information was pursued for efficient data retrieval (Mamoulis et al., 2004). Efficient slicing, dicing and drilling query facilities were further made available. Unnecessary memory inefficiencies were further avoided by, for example, decoupling stations, vehicle or card details from the validation records. In addition, data cleaning procedures were applied to ensure the absence of duplicates and gross errors, and estimate missing entries using alight stop inference methods (Cerqueira et al., 2020). Finally, updating routines were applied for the automatic extraction, transformation and storage of continuously arriving trip records.

Given the presence of consolidated trip records, the user can select among pre-established spatial and temporal granularities for the subsequent multimodal traffic data analyzes. In terms of spatial specifications, two main possibilities are made available. One of them is to customly specify the target geographical region of interest (i.e. using a polygon or circular marking). The other is to select predefined regions.

The following zoning maps are considered for the Lisbon Metropolitan Area (Figure 2):

- traffic analysis zones (TAZ): geographical unit used in transportation planning models to assess socio-economic indicators
- administrative zones: coarsest geographical unit for the city, ranging from municipalities to parishes, depending on the geographical organization of the target city; and
- sections: finest geographical unit, comprising small districts and neighbourhoods.



a) TAZ zoning b) City municipalities c) Neighborhood sectioning

Figure 2: Zoning: geographical decomposition of the Lisbon city at different granularities

Two major types of temporal constraints can be placed. First, calendrical constraints – such as day of the week (e.g. Mondays), weekdays, holidays or on/off-academic period calendars – can be specified to segment the available traffic data. Second, time intervals (e.g. on/off-peak hour intervals) or a fixed time granularity (e.g. 15 minute) can be optionally placed to guide traffic data description and prediction.

Once these constraints are fixed, multi-dimensional querying can be automatically derived to produce the consolidated data. Given consolidated traffic data from cross-mode carriers, data mappings are generally further applied to transform the queried data into more conducive data structures (Mamoulis et al., 2004). Illustrating, spatiotemporal data structures can be mapped into georeferenced multivariate time series structures to facilitate subsequent mining tasks.

These time structures can be aggregated at different granularities and barycenter averaging further applied. Correlation between time series from different modes can also support the understanding of multimodal synergies. Linear correlation coefficients (e.g. Pearson's, Spearman's, Kendall's) and detrended cross-correlation analysis for correlating non-stationary time series can be considered to this end (Podobnik and Stanley, 2008).

3.2. Multimodality Data Analysis

Spatial multimodality indices support the analysis of multimodal transport usage in specific urban areas using inequality measures to assess available and enacted options by citizens

(Lemonde et al., 2020). An inequality measure is a function that describes a distribution of ‘income’ in a way that allows direct and objective comparisons across multiple distributions (Cowell, 2011). Although inequality measures are usually used in socio-economics studies, they can by extended to transportation by reformulating their core properties (Diana and Pirra, 2016):

- Weak Principle of Transfers: considering two travel modes with I and Iδ intensities of use. If the intensity of the most used mode decreases and the other increases in same degree $I<2\delta$, then multimodality increases;
- Scale Independence: if the frequency of use of each mode changes by the same proportion, the multimoda-lity index should remain the same;
- Principle of Population: the multimodality index should remain the same for any replication of the modes with their corresponding intensities of use.

The choice of a suitable index for multimodality analysis will depend on the context of the problem. The Gini coefficient is a summary statistic of the Lorenz curve and is usually used as a measure of inequality in a population. Diana and Pirra (2016) translated the usual formulation of the index to the context of multimodal transportation,

$$Gini = 2/\mathrm{n} \cdot (\textstyle\sum_{i=1}^{n} i \cdot f_i)/(\sum_{i=1}^{n} f_i) - (n+1)/(\mathrm{n}) \tag{1}$$

where f_i is the intensity of use of ith transport mode and n the total number of modes. Another possible measure is the Herfindahl–Hirschman index, a typical measure of market concentration to determine market competitiveness,

$$\mathrm{HH}_m = 1/\mathrm{m} \cdot (\mathrm{n} \cdot \textstyle\sum_{i=1}^{n} (f_i - \bar{f})^2)/((\sum_{i=1}^{n} f_i)^2) + 1) \tag{2}$$

where m corresponds to the effective number of used modes (Diana and Pirra, 2016). Both indices range from zero, corresponding to an equal usage of all modes, up to a maximum of one, which refers to monomodality in the presence of an infinite population of modes.

3.3. Incorporating Situational Context

The analysis of multimodality indices can be enriched with the presence of situational context. A major constituent element of such context is ornament information, specially traffic generation poles (Figure 3), including commercial areas, employment centers such as business parks and enterprises, and collective equipment like hospitals, schools and stadiums, that generate or attract a significant volume of vehicle trips, either from contributors, visitors or providers (IMTT, 2011). The combined analysis of these traffic poles locations against the computed multimodality indices, as well as station-route maps, provides a comprehensive and dynamic way of assessing causal factors pertaining to the spatiotemporal distribution of traffic along the city.

Additionally, the surveyed indices can be revised to further measure how the volume of passengers generated and attracted by nearby poles are being currently satisfied by the co-located modes of public transport.

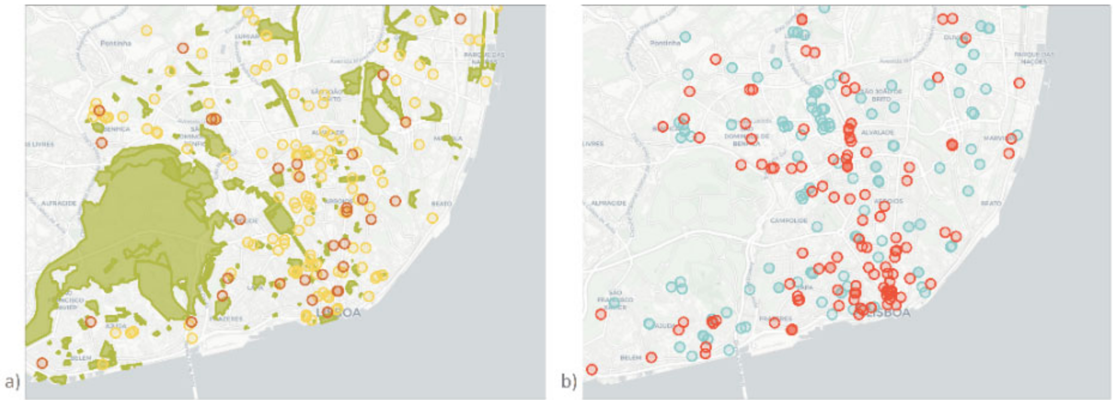


Figure 3: Some traffic generation poles: a) large commercial poles and parks; b) healthcare poles in red and educational poles in blue.

In addition, weather factors and public events can further impact traffic demand and modal choices (e.g. decreased cycling activity under rainy weather conditions). Two major strategies for context-sensitive analysis are suggested to this end. First, data can be segmented according to the available situational context followed by context-specific inference of multimodality patterns (Cerqueira et al., 2020). Second, and in alternative, the context can be directly accommodated in the indices by capturing correlations with the context and using these correlations as correction factors to adjust traffic demand.

4. LISBON'S CASE STUDY

Three public transport modes were considered for this study – bus-and-tram, subway and cycling modes. The bus mode, operated by CARRIS, and the subway mode, operated by METRO, are the two most used public transport modes and their stations offer a good spatial coverage within the Municipality of Lisbon. The stations of GIRA, the biking sharing system, however, can only be found in the center axis of the city and in the neighborhood of Parque das Nações (Figure 4); and the validations during the week are significantly lower than the other modes (Figure 5).

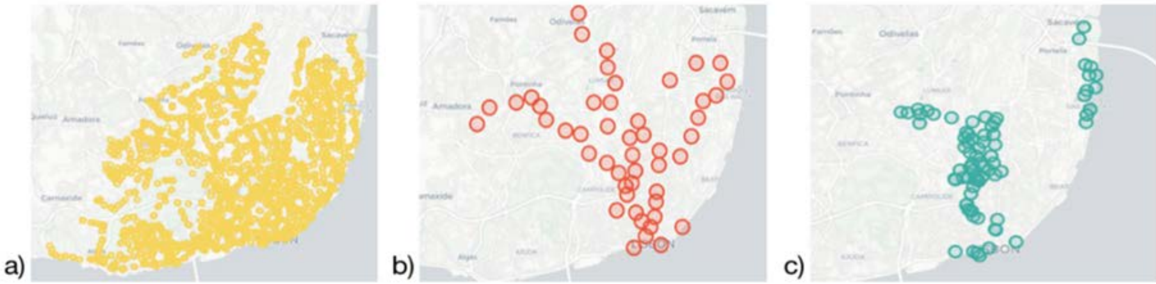

Figure 4: Lisbon's stations location: a) CARRIS, b) METRO, c) GIRA.

Smart card technology was used to gather public transport traffic data. For the bus transportation, as smart card data only monitors entries, estimators are necessary to infer exit validations from vehicle-to-vehicle transfers, daily pendular movements and circulation patterns across days. In this context, multimodal circulation views were considered to capture cross-mode transfers and thus increase the success of the alight stop inference task (Figure 6).

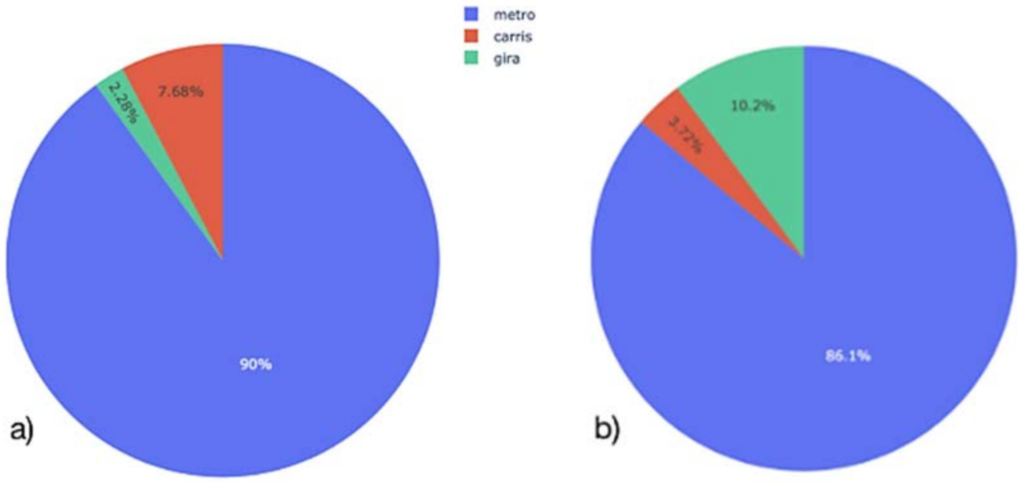

Figure 5: Weekly mode share distribution of TAZ nº 66 (Entrecampos): a) week days, b) weekends.

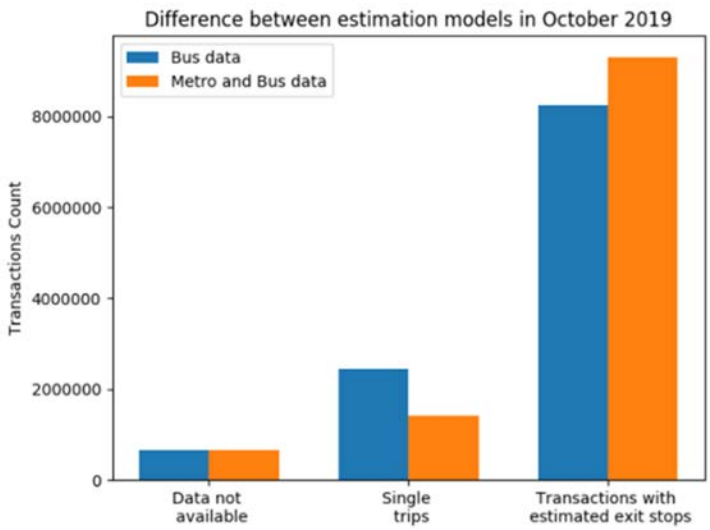

Figure 6: Multimodal alight stop inference success for CARRIS data in October 2019

Traffic Analysis Zones (TAZ) were selected in this study as the spatial granularity criteria (Figure 7). This form of spatial modelling is derived from trip generation densities processed by delineation algorithms that use the peaks of densities as the centre of a zone (Martínez et al., 2009). Subsequently, the public traffic demand is estimated (section 3.1) by retrieving the volume of validations from the stations and stops of the chosen transport modes per zone.

Figure 8 shows the daily volume of validations in TAZ nº66. Figure 9 provides a complementary view of the demand distribution per mode and TAZ.

Figure 7: TAZs of Lisbon Municipality: a) all TAZs, b) TAZs with all modes (subway, bus, bike).

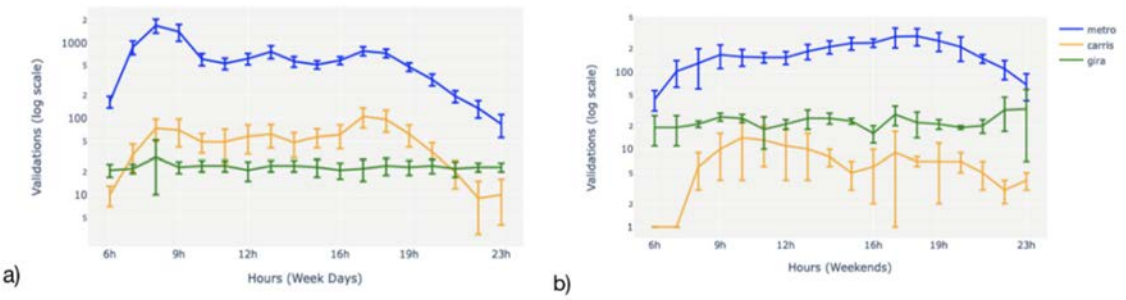

Figure 8: Daily volume and variation of validations in TAZ nº66: a) week days, b) weekends

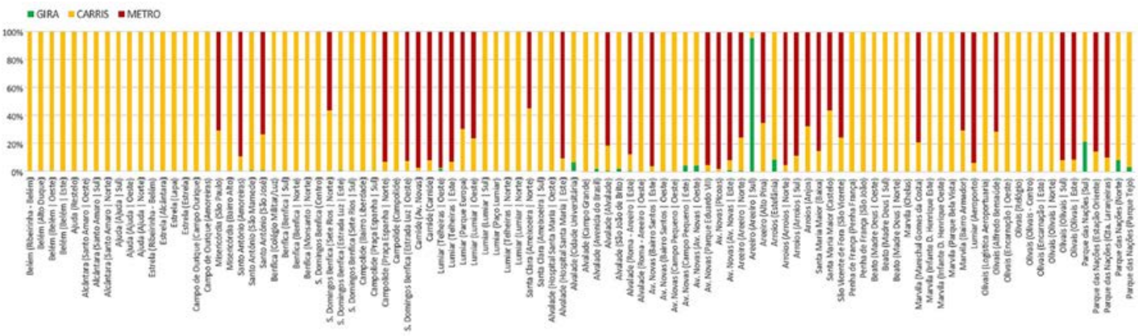

Figure 9: Distribution of demand per transport mode in 2019.

Correction factors corresponding to weather variables (Figure 10) and public events were applied by respectively removing correlation factors on mode-specific demand and replacing demand observed during the spatiotemporal footprint of an event by the average demand on a comparable time period

Figure 10: Correction factors produced by the Pearson correlation between weather data and observed check-ins/outs at GIRA's bike stations for 2 hours intervals (7/1/2019 to 28/2/2019).

The public traffic demand from each zone can be correlated with computed spatial multimodality indices, to further detect vulnerabilities in the public transport system of a particular zone. Figure 11 displays four TAZ maps of Lisbon coloured with the values of the Gini index and Herfindahl–Hirschman index respectively at different hours.

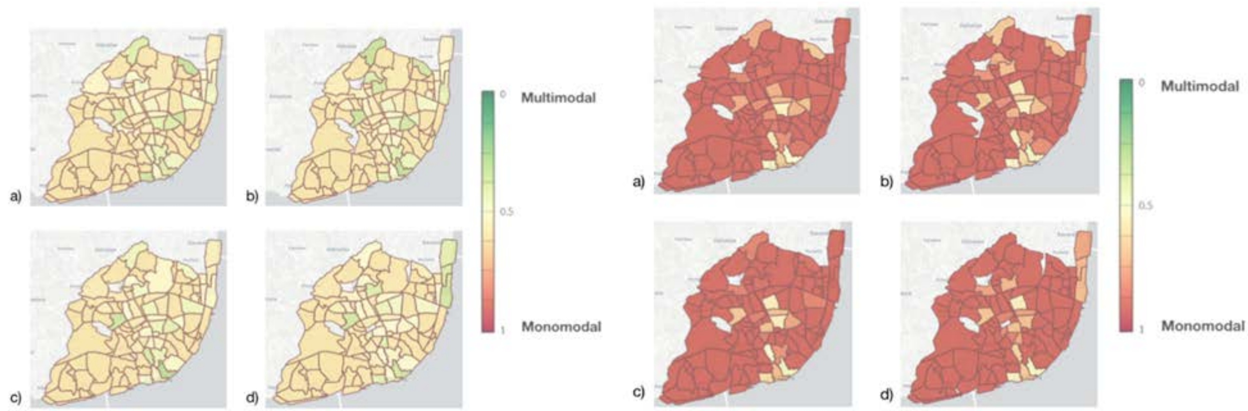

Figure 11: Gini index (left) and HH index (right) on week days: a) 8h, b) 12h, c) 17h, d) 21h.

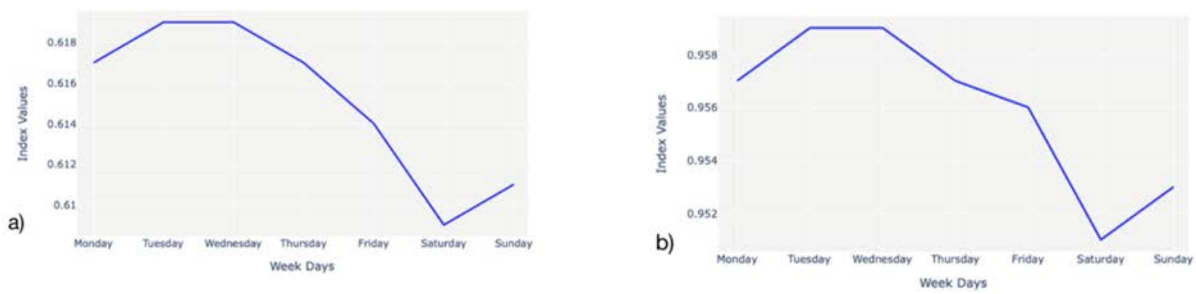

Figure 12: Weekly multimodality index variation: a) Gini, b) HH.

The spatiotemporal analysis of the indices provides an exploratory policy framework to measure social equity regarding the available multimodality options along the zones of an urban region. In the context of the Lisbon case, the TAZs with higher degree of multimodality generally correspond to zones that contain all targeted modes - bus, subway and cycling (Figure 7) - and encompass a large number of traffic generation poles (Figure 3). Considering the Gini index, a few TAZs contain all selected modes yet yield a medium index value (around 0.5). This occurs due to heavy subway usage patterns (scale dependence property). Herfindahl–Hirschman index (HH) results are similar to Gini indices, with the exception that HH is more sensitive to the number of used modes (population property), justifying the red coloring on most TAZs. The variation along a week is coherent for both indices (Figure 12), with a subtle multimodality increase in weekends moved by an increased cycling demand and decreased subway demand.

5. CONCLUDING REMARKS

This work introduced a methodology that offers a solid ground for multimodal traffic data analytics, including a means for the consolidation and efficient retrieval of heterogeneous sources of trip record data; the possibility to estimate missing validations at the entry or exit of stations and vehicles; and the accommodation of correction factors to discount the impact that a given situational context can have on circulation patterns.

We provide preliminary empirical evidence for the relevance of the proposed methodology to aid the calculus of multimodality indices for an initial characterization of mobility restrictions and social equity aspects.

We are currently extending the proposed methodology to accommodate more advanced descriptive and predictive analytics of multimodal traffic, including the discovery of emerging multimodal patterns, inference of origin-destination matrices, and modeling of inter-mode dependencies to assist context-aware predictors of public traffic demand.

These contributions are expected to assist the municipality of Lisbon and comparable cities in moving towards urban mobility plans closely aligned with the real traffic dynamics as objectively given by trip record data, therefore:

- supporting the transparency of urban mobility planning decisions to the citizen
- offering a solid ground for coordination efforts among municipalities and public transport operators
- promoting the continued alignment of the public transport network with the ongoing city transformations, thus ensuring that the public transport system responds to emerging multimodal traffic vulnerabilities, a growing need given the transformations and changing regulations observed in a pandemic context.

ABSTRACT

Cost-benefit analysis (CBA) is the most widely used tool for appraisal of transportation infrastructure projects, but there isn't generalize guidelines about its implementation, there can be found different approaches that suit the perspectives of each evaluating entity. This document, it shows three different guidelines that used in practice for transportation infrastructure projects, in which there are some different costs and benefits considered informing decision makers about the project appraisal. The costs and benefits with market values have been the predominant ones in the CBA, but there is a transition to use without market values, however, there are no generalized methodologies, so more research will be needed.

1. INTRODUCTION

The constant growing world population causes a greater demand for transport infrastructure that are pressured by the increase in users, causing the need for improvements or new infrastructure projects, the problem is limited financial resources (Jones et al., 2014).

Efficient transport infrastructures are essential for the proper financial and social functioning, helping to increase productive capacity and promoting development; their economic impact can be transformative, in particular for those with a low income level (Feick & Roche, 2013; Younis, 2014).

In the last decades, studies have been carried out on the social impact of having access to mobility, with topics such as the role of transport in social exclusion, the importance of accessibility, the interface between social capital and transport, the effect of transport on human well-being and how it influence the actions of decision makers in a region (Lowe et al., 2018).

Transport infrastructures are key in ensuring the accessibility of passengers and goods, helping to shorten distances and time. The other side of the coin is the negative effects such as the investment, becoming physical barriers, the congestion and noise. Active planning minimize negative externalities and enables the shift towards a sustainable transport infrastructure, which is necessary to steer development in a better direction (Banister, 2011; Koglin & Rye, 2014; Meunier et al., 2014).

Countries invest in transport projects as new infrastructure, upgrade, maintenance or repairs to the transport network. The common denominator among these types of projects is that they are the outcome of public sector decision-making at different levels of government and, sometimes, at the international level. Despite the important technical and economic dimension, investments in transport infrastructure may represent partial political statements of objectives, prioritization of financing and target users (Berechman, 2009).

The ability to choose the best projects according to transportation needs, relies on the quality of data used, the tools for its evaluation and choose the correct variables that lead to guidelines for solving public management problems of decision making (Broniewicz & Ogrodnik, 2020).

The term transportation project evaluation is used to describe the formal procedure for determine the net social benefit of different transport project alternatives that may be of different nature, objectives, costs and benefits (Berechman, 2009). To get an idea about whether planning is heading towards a correct development, different tools and models help to analyze transportation projects in order to estimate their benefits in monetary terms (Laird & Venables, 2017), there is an increase interest in knowing the benefits of a more social nature (Johansson et al., 2017).

Within the European context, the most used tool for the evaluation of transport projects is the Cost Benefit Analysis (CBA), in which it is very clear the variables to be used when it comes to direct impacts that are easily translated into monetary terms, but not much with indirect impacts where there are no market values available. The Multicriteria Analysis (MCA) is an alternative that can use variables without market value, is being used to a greater extent as a complement, or as a comparison in the evaluation of projects with the CBA (Bristow & Nellthorp, 2000).

This document intends to show the costs and benefits taken into consideration in three different contexts, making known the actuality of centralized guidelines of the CBA for transport infrastructure projects, as it is the most used tool to evaluate projects and thus know possible areas of opportunity for improvement or updating.

2. EUROPEAN CONTEXT

The transport infrastructure for the European Union (EU) is essential since it is a single market, so it must have a solid transport network that links its members, without it the internal market would be affected. For this reason, all levels of government have addressed the resolution of the dilemma that exists between policies that promote economic growth and consequently the generation of more transportation infrastructure projects and environmental policies that require reducing environmental impact (Villa et al., 2020).

The global economic recession has affected investment in transport infrastructure since 2008, the percentage of the Gross Domestic Product (GDP) allocated to infrastructure projects is at the bottom, that remember the limited resources despite current transportation needs (OECD, 2019).

Investments have focused on improving the quality of transport, accessibility, mobility and safety, while covering the demand (European Commission, 2014). Despite limited resources and the need to allocate them in the best way, it has been shown that project evaluation tools have had little relevance during the decision-making process and are often seem as tedious obstacles to get the investment required for the project (European Parliament, 2019). Another problem is the enthusiasm in the CBA, the evaluator may be too optimistic about key parameters of the project, causing the projected benefits to be less or impossible to meet (ECA, 2018).

Table 1: Type of analysis by country in road project appraisal. Ref: Adapted from (Odgaard et al., 2005)

The role of the tools for project evaluation is inform to decision makers about relevant data, in this way it will be possible to prioritize projects from the same program, choose the best solution alternative for a problem, know the social benefits of the project and above all choose if it is the right time to make the investment.

The most common tool of evaluation in the EU member states are the CBA and MCA, in some cases the CBA is complemented with the MCA to get a quantitative or qualitative evaluation to include other impacts that are not monetized for technical reasons or policies (Bristow & Nellthorp, 2000).

In 25 European countries, table 1, the most used types of analysis for the evaluation of road transport projects are: CBA, MCA, Quantitative Measures (QM), Qualitative Evaluations (QA) and Not Available (NA) (Odgaard et al., 2005):

Transportation contributes to economic growth that enables a global market, but it also gives rise to externalities, some of which can be expressed in monetary terms. External costs (externalities) are the effects imposed on society, in contrast to benefits, not assumed by the users of the infrastructure and, therefore, not considered in the decision-making process. Internalizing these costs means making such effects part of the decision-making process, using market-based instruments is considered an effective way of limiting the negative side effects of transportation (European Commission, 2019).

(Odgaard et al., 2005) mentions certain effects that are used within the European scope being;

- Infrastructure costs: construction costs, system operation and maintenance costs.
- Benefits for the user: time savings in passenger transport, vehicle-operating costs, benefits for freight traffic.
- Externalities: security, noise, air pollution (local - regional), climate change.
- Also; user charges, revenue and construction disruptions.

According to (Odgaard et al., 2005) in 25 European countries the CBA is used to a greater extent according to the type of element to be evaluated, which is complemented with another type of analysis. Table 2, shows the distribution of analysis used in the countries of the study, it can be seen that the countries mostly use the CBA for purely convertible effects to monetary terms:

Effects	CBA	MCA	QM	QA	NA
Construction Cost	25	4	1	1	0
Disruption from construction	10	1	0	6	11
System operating cost and maintenance	24	4	2	2	0
Passenger transport saving	24	4	3	2	0
User charges and revenues	17	1	1	3	6
Vehicle operating costs	23	4	1	0	2
Benefits to goods traffic	17	2	1	1	8
Safety	24	4	3	1	0
Noise	13	3	7	8	3
Air Pollution - Local/Regional	14	2	5	7	3
Climate change	8	1	3	7	10

Table 1: Type of analysis by effect. Ref: Adapted from (Odgaard et al., 2005)

In 2016, total external costs in EU countries amounted to €726 billion and congestion costs to €271 billion with a total of €987 billion, representing 6.6% of GDP. Road transport is the mode with the highest impact on external costs, accounting for 83%, when including aviation and maritime modes; 97.5%, when excluding them. Considering accidents, congestion, climate change, air pollution, environmental damage and noise (European Commission, 2019).

3. COST-BENEFIT ANALYSIS

CBA is a technique developed in the field of economics, mathematics, statistics, and operations research, which seeks to provide guidance to decision-makers on the formulation of public policies (Nilsson et al., 2008).

The CBA was the first formal economic evaluation method to be applied to potential projects with the impetus of selecting more rational investments that represent better value for money. The CBA through indicators shows a comparative description of the potential costs and benefits of the project, indicating its economic contribution to society, as well as to the project's investors. Currently, during the analysis not only the cash flow is considered but also the economic, environmental and social impacts, both positive (benefit) and negative (costs), quantified in monetary terms adjusted for the present value of money (Dimitriou et al., 2016).

The CBA is the dominant method in the economic evaluation of projects since the 1970s (Macharis & Bernardini, 2015). Despite its wide use, there is still no universal standard CBA model, each organization or country defines its own specific requirements for evaluation, although with similar criteria (Vickerman, 2017).

The methodological advantages of using the CBA are; it carries the improvement of the evaluation since out under the same scenarios and impacts. Decision makers have more complete information to appraise the projects according to its effects, however, it should be taken into consideration that the information might be incomplete or of poor quality, which may cause the decision taken not to be the best one. The CBA can be a good discussion platform for those involved in economic research, design and planning of infrastructure, improving the quality of information for decision-making, helping to support final decisions. Among the negative points, the CBA lacks transparency for the final reports to society, as well as its difficulty to worth environmental impacts without market value. Although it may seem to have few negative points, the area of work is controversial and of great economic impact (Annema et al., 2007).

4. REVIEW OF CBA GUIDELINES

This section provides the costs and benefits that are included in the CBA guidelines by government agencies for the evaluation of transport projects, as a tool to support decision making in road projects, which are: CBA Guide for EC, United States (US) and New Zealand (NZ) investment projects.

4.1 The CBA Guide for transport investment projects of the EC

The CBA Guide of Investment Projects (CBA Guide) for transport projects for the EU aims to provide guidance on the common rules for the European-wide use of the BCA for large projects, referring to works, with a total cost of more than 50 million Euros. Having the intention to ensure; the improvement in the movement of people and goods in order to obtain better accessibility, mobility and safety, improving the quality and safety of infrastructures; better linkage between EU member states, promoting the single market and meeting transport demand, developing transport infrastructures and improving transport services; promote national or regional economic development by investing in newly created, extended or linked infrastructures (European Commission, 2014).

4.2 The U.S Department of Transportation's CBA Guide for Investment Projects.

The application of the CBA in highway projects is to ensure that funding is directed to projects that contribute to the economic growth of the users and the nation as a whole. Through an efficient transportation system, requiring repairs, expansions and modernizing aging facilities but also new projects to ensure that they continue to meet the needs of the population and the marketplace. (USDOT, 2018).

4.3 The N.Z. Transportation Agency's CBA Guide.

The purpose of applying CBA to highway projects is to establish a quality transportation system that promotes the well-being and livability of society through new, upgrade or extension of road projects. The CBA should identify economic effects (including social and environmental) in decision-making, whether or not it can be quantified, establishing consistency, transparency and compatibility between activities to help assess their economic efficiency (NZ Transport Agency, 2020a).

	EC	US	NZ
Transport mode	General	Road	Road
Discount rate (%)	3 - 5	7	4
Economic performance indicators	VAN, B/C, ERR	VAN, B/C	VAN, B/C
Decision indicator	VAN	VAN, B/C	B/C
Time horizon (years)	Up to 30	Upgrade: 20 New project: 30	Up to 40
Risk assessment	Sensitivity (Monte Carlo)	Sensitivity (Monte Carlo)	Sensitivity (Monte Carlo)

Table 2: Guideline’s summary. Ref: Own elaboration with data from (European Commission, 2014; NZ Treasury, 2015; USDOT, 2018)

4.4 Review of stages in the application of the CBA

The reviewed guidelines have a similar structure, although they differ in the number of steps in which their application is applied, it can be divided into 3 stages:

- Determination of the project: Describes the context of the project, establish the objectives, introduce the alternatives and define the base case for measure the incremental cost and benefits.
- Identification of costs and benefits: Costs and benefits are identified with/without market prices, usually divided into financial and economic analysis, discounted over the analysis time horizon to obtain the project's performance indicators.
- Analysis of results and report: The results are analyzed and the alternatives ranked. A report is prepared showing the results of the CBA in which the project's performance indicators are shown, as well as the data used to obtain them.

4.5 Financial analysis

4.5.1 Investment Costs

- EC: It is recommended to present both total project cost and unit value, infrastructures should be shown separately to allow comparative assessment and include all works necessary for their operation, land cost (property) and environmental protection costs (European Commission, 2014).
- US: The capital cost of a project is the sum of the monetary resources required to carry out the project, including, direct construction costs, capital costs, planning costs, project design, environmental reviews, land acquisition, utility relocation, or transactions to secure financing (USDOT, 2018).
- NZ: These are the costs required for the planning, analysis and delivery of the transportation infrastructure. Costs include any contingencies in the estimation of infrastructure costs, which may cause a cost overrun (NZ Transport Agency, 2015).

4.5.2 Operation and Maintenance costs

- EC: Operation and maintenance (O&M) cost can be grouped into the following categories; infrastructure operation, service operation, service management, routine maintenance and periodic maintenance. In the financial analysis, they are estimated in on-project and off-project scenarios (European Commission, 2014).
- US and NZ: Transportation facilities require continuous O&M to provide adequate service, maintain assets in operating condition and its costs should be included throughout the analysis period and should be directly related to the proposed project service plan (NZ Transport Agency, 2015; USDOT, 2018).

4.5.3 Revenue projections

- EC: Revenue projection are the product of the charges applied to users for access to the infrastructure, which are estimated based on: traffic volume forecast, projection of changes in the tariff system, pricing policy, traffic forecast for each projection of the tariff system and subsidy projection. In case the operating cost is not fully covered, the gap must be filled with other sources to avoid service closure (European Commission, 2014).
- US: Revenues from user charges (tolls, taxes, etc.) for the right to access transportation infrastructure, are an important source for public agencies to finance the operation of the infrastructure. These revenues cannot be considered "benefits" of the infrastructure, taking them would mean a double counting of the benefits, since the user chooses to pay for greater security, less travel time or operating costs (Lawrence et al., 2014).
- NZ: A comparison of the costs incurred in the transport infrastructure with the revenue is made to determine the financial viability of the project. The existing gap, if any, is determined by testing the funding gap values until the sum of the present value of the net annual cash flows is zero (Wallis et al., 2013).

4.6 Economic analysis

4.6.1 Travel time

- EC: Travel time savings can be derived from the construction of new or improvement of existing transport infrastructure, tell apart between work and non-work travel time estimation (European Commission, 2014).
- US: Estimated travel time savings will depend on engineering calculations and their effects on the operations of the improved infrastructure and the local area transportation network. These improvements can reduce travel time for drivers and passengers, including both in-vehicle time and waiting time (USDOT, 2018).
- NZ: Productivity and utilization of the network are related to the efficient use of the land transport network, seeking to optimize it instead of maximizing its use. The monetization of network productivity is measured through changes in travel time and financial costs of transport use (NZ Transport Agency, 2020a).

4.6.2 Vehicle operating costs

- EC: Vehicle operating costs are defined as costs borne by vehicle owners to operate vehicles, including fuel consumption, lubricant consumption, tire deterioration, repair and maintenance costs (European Commission, 2014).
- US: Operating cost savings commonly result from improved transportation infrastructure projects, resulting in lower fuel consumption and other operating costs (USDOT, 2018).

4.6.3 Accidents

- EC: Transport activities involve a risk to users of suffering an accident, because of mechanical failure or, more commonly, due to the influence of human error (European Commission, 2014).
- US: Transportation infrastructure improvements help to reduce the likelihood of death, injury, and property damage by reducing the number of crashes and / or their severity (USDOT, 2018).
- NZ: There are three variables, the first is the "social cost of death and serious injury" which includes the cost to the user, the cost to the health system and the costs of delay in the network. It considers loss of life, production, incapacitation, legal costs and property damage. In accidents, not only the user is impacted, but also the family and friends who may be affected by the accident. The second is "System safety", which focuses on investment aimed at improving system safety. The third is "Perception of safety and security", physical attributes such as lighting, safety cameras and speed controls that enhance the feeling of safety (NZ Transport Agency, 2020a).

4.6.4 Noise

- EC: Noise pollution can be defined as "unwanted external sound that has negative effects on human health". Noise emissions have a local impact, relating the magnitude of the effect to the location of the infrastructure, vibrations affect the quality of life and the productions of certain goods (European Commission, 2014).
- US: Noise pollution is caused by high levels of ambient sound that cause annoyance, distraction, or harm to people and animals. The US Department of Transportation doesn’t have a reliable means of estimating the public value of noise reductions (USDOT, 2018).
- NZ: Noise and vibration have significant effects on human health, mainly with sleep disruption and stress. Humans are sensitive to vibration and noise, which can come from the construction, operation, maintenance and use of land transport infrastructure (NZ Transport Agency, 2020a).

4.6.5 Air pollution

- EC: Transport investments can significantly affect air quality, reducing or increasing the level of pollutant emissions, having harmful effects on health, causing damage to infrastructure and impacts on nature (European Commission, 2014).
- US: The economic damages caused by exposure to air pollution are borne by society rather than by travelers and transportation operators that generate those emissions. Transportation projects can reduce overall fuel consumption and thus can produce climate and other environmental benefits (USDOT, 2018).
- NZ: The effects of air emissions from road transport that impact human health are monetized by assigning a cost to each tonne of pollutant as a proxy for the harm caused to people exposed to air pollutants (NZ Transport Agency, 2020a).

4.6.6 Climate change

- EC: Economic cost of positive or negative variations in Greenhouse Gas (GHG) emissions, the main emissions are carbon dioxide (CO2), nitrous oxide (N2O) and methane (CH4). These emissions contribute to global warming, therefore, it has a global impact and the related cost does not depend on the location of the investment (European Commission, 2014).
- US: GHG emissions have long-lasting even intergenerational impacts, unlike all other benefit categories (USDOT, 2018).
- NZ: Road transport is the largest contributor to emissions, the number of vehicles emitting GHGs emissions should be identified, get their fuel consumption and thus emissions can be monetized (NZ Transport Agency, 2020a).

4.6.7 Benefits to existing and additional users

- US: The main benefits of a project will arise in the "market" that the project would improve, with its users experiencing them directly. Users attracted by the improvement are willing to pay less for use it than the original users (USDOT, 2018).
- NZ: User experience can include comfort, simplicity, convenience, crowding, travel time and network condition (NZ Transport Agency, 2020a).

4.6.8 Loss of emergency services.

- US: Transportation projects can help to reduce the frequency of emergency service delays, generating benefits by reducing damages caused by delay (USDOT, 2018).

4.6.9 Modal diversion

- US: Improvements in transportation infrastructure or services may attract additional users of alternative routes or modes of transportation, it is challenging to capture the impacts of such modal shift within CBA and should be carefully examined to ensure that such benefits are correctly calculated within the analysis (USDOT, 2018).

- NZ: It is critical to know the variables that may encourage or discourage a user from selecting a transport mode. The user assigns a value to options, i.e., the value to individuals or groups of knowing about or having transport mode options available, even if they are not used (NZ Transport Agency, 2020a).

4.6.10 Work zone impacts

- US: A common example of "downsides" associated with transportation projects is impacts during construction or maintenance activities, such as delay due to traffic, increased insecurity, and vehicle operating costs (USDOT, 2018).

4.6.11 Agglomeration economies

- US: Transportation infrastructure improves connections between communities, people and businesses by reshaping the economic space of a region. The economic theory of agglomeration suggests that firms and households enjoy positive benefits from the spatial concentration of economic activity. These benefits can stem from a more efficient exchange of information and ideas, access to larger and more specialized workforce (USDOT, 2018).
- NZ: Changes in productivity result from of agglomeration, where scale and spatial concentration enables an increase of productivity by enabling a better learning, bonding and economic exchange (NZ Transport Agency, 2020a).

4.6.12 State of good repair

- US: These are the project benefits while replacing, repairing, or improving existing transportation assets to bring them to a state of good repair. These are generally captured by cost and benefit factors, such as maintenance, asset repair costs, improved safety, improved reliability, and service or facility quality (USDOT, 2018).

4.6.13 Resilience

- US: Incorporating resilience benefits requires an understanding of the expected frequency of each stressful event and its economic impacts on infrastructure (USDOT, 2018).
- NZ: These are system vulnerabilities and redundancies, are about reducing the risk of exclusion of communities from social and economic opportunities due to system disruptions. These may also relate to the preparation of solutions to ensure that the economic and social needs of communities are met (NZ Transport Agency, 2020a).

4.6.14 Quality of Life

- US: Transportation projects can provide benefits that improve quality of life but are difficult to monetize; these can be as varied as improved pedestrian connectivity, increased accessibility to remote communities, and other localized amenities. Quantifiable data on impacts should be provided, focusing on the changes expected to be generated by the transportation improvement project itself (USDOT, 2018).

- NZ: The impact of transport mode on physical and mental health is related to users' transport mode choice which is associated with the adoption of active modes (NZ Transport Agency, 2020a).

4.6.15 Increased in property values.

- US: Transportation projects improvements can increase the accessibility or improve the attractiveness of land parcels near infrastructure, resulting in increased land values (USDOT, 2018).
- NZ: The role of the transportation system is enabling and maintaining the normal functions of a community, with others or areas of the same community that due to a lack of transportation infrastructure may suffer a disconnection with the rest of the community (NZ Transport Agency, 2020a).

4.6.16 System reliability

- NZ: Comprises the user being able to have on a similar travel experience on the transport system each time with the same travel conditions (NZ Transport Agency, 2020a).

4.6.17 Employment

- NZ: An important impact of transport infrastructure is job creation, not referring to the direct or indirect employment produced by its construction. New or improved infrastructure can make it easier for people to get to work faster and can reduce the discouragement effects on workers by reducing travel times, which increases worker performance (NZ Transport Agency, 2020a).

4.6.18 Imperfect competition

- NZ: As transportation infrastructure improves, output increases in sectors where there may be differences between the price of the product and its marginal cost. Conventional CBA assumes economic sectors operate in perfect competition, where the prices are equal to its marginal costs. However, since there is a margin between price and cost, there is a gap between gross hourly labor costs and the market value of what is produced in that hour (NZ Transport Agency, 2020a).

4.6.19 Regional economic development

- NZ: There is an increase in gross domestic product or gross national income and a change in demand for goods and services (NZ Transport Agency, 2020a).

4.6.20 Water pollution

- EC: Pollution of water bodies occurs by discharging pollutants directly or indirectly without adequate treatment, affecting seriously the water quality, biodiversity and society (European Commission, 2014).

- NZ: Transport infrastructures during their life cycle can have a major impact on water flow and its quality, having short or long term effects, impacting the natural or artificial environment (NZ Transport Agency, 2020a).

4.6.21 Impact on soil and biodiversity

- EC: The presence of chemicals or soil disturbance due to industrial activity or improper waste disposal has long-term social and economic effects on society (European Commission, 2014).
- NZ: Biodiversity is fundamental to the existence of life, as people, animals and other organisms depend on it. Natural resources underpin the economic and social area of our society, during the different stages of the life cycle of transport infrastructures impact biodiversity (NZ Transport Agency, 2020a).

4.6.22 Resource Efficiency

- NZ: Sustainable use of resources, materials and reduction of environmental damage can be achieved by minimizing waste by using green energy and monitoring the carbon footprint generated (NZ Transport Agency, 2020a).

4.6.23 Access to opportunities

- NZ: Transport can function as an enabler and integrator of land use, focusing on the importance of destinations, services and activities that can be equitably accessed to enable economic and community participation (NZ Transport Agency, 2020a).

4.6.24 Heritage and cultural values

- NZ: Cultural values can be closely related to heritage values, the former are physical and can be expressed in monetary terms, the latter are based on perceptions and are not so easily expressed in monetary terms. Cultural values are considered both tangible and intangible benefits. The historic environment is important for health and well-being, playing an important role in urban development and in generating economic activity (NZ Transport Agency, 2020a).

4.6.25 Impact on landscape

- EC: This is the loss of recreational or aesthetic value and not only for rural environments, also there may be urban areas that may be affected (European Commission, 2014).
- NZ: The relationship between people and landscape can be explained as a reflection on their relationship (NZ Transport Agency, 2020b).

4.6.26 Urban landscape

- NZ: It is the constant changes in the urban environment, its form and character that generate an identity (NZ Transport Agency, 2020b).

Table 3: Cost and Benefits in CBA Guidelines. Ref: Own elaboration with data from (European Commission, 2014; NZ Transport Agency, 2020a; USDOT, 2018)

5. CONCLUSIONS

During the evaluation of projects in the part of the economic analysis may be have difficulties in valuing variables (without market values) that can be easily identified. Despite the difficulties there has been significant progress in integrating them into the economic analysis process of the CBA, there are no methodologies for its analysis but given the importance of these variables to be considered in transportation infrastructure projects, future research still needs to be done in the area. Improvements in the CBA and its evaluation guidelines contribute to better informed decisions and investment, hence the importance to interpret these terms into more useful terms for decision makers.

Table 4 shows the costs and benefits of the guidelines reviewed. The EC, US and NZ columns represent the guidelines by country and the Methodology column represents the existence of guidelines to analyze the cost or benefit by country. In the European case, the costs and benefits have market values, or are easily converted, to avoid the calculation having multiple methodologies that may hinder the evaluation in the possible case of needing EC resources to finance the project. In the U.S. case, some costs and benefits without market value are mentioned, encouraging the evaluator to use their own method with caution and relying on projects carried out previously. The New Zealand case has a greater consideration of non-market value costs and benefits, which they intend to integrate in their CBA, encouraging the evaluator to develop their own method for the time being, but mentioning that a centralized methodology will be provided in future editions of the manuals.

The guidelines reviewed have a similar structure in the application of the CBA, so it can be said that are guidelines with a classic CBA core, differing in the types of costs and benefits taken into account. An important consideration is the update of the guides, NZ (2020) and US (2018), while the last update of the CBA Guide is from 2014 with the experience gained in the previous policies goals, it is expected that there will be a next update that studying at great length the impacts of difficult monetization, given the beginning of the new stage of the EC cohesion policies.

RESUMEN

Las políticas de transporte para mejorar la calidad del aire se aplican cada vez más en los centros urbanos de todo el mundo. A pesar de que la eficacia de estas políticas se encuentra notablemente afectada por una fuerte controversia social, no se ha aprovechado en su totalidad el rol que pueden desempeñar los stakeholders a la hora de identificar posibles impactos así como potenciales estrategias de implementación. Esta investigación ha permitido la evaluación por parte de stakeholders de un conjunto de medidas de transporte para mejorar la calidad del aire. La ciudad de Madrid (España), donde existe una clara intención de reducir el tráfico en su zona centro, ha servido como caso de estudio. Stakeholders locales participaron en una serie de entrevistas semiestructuradas y en un workshop final de manera presencial para evaluar impactos potenciales, aceptabilidad y viabilidad de ocho medidas de transporte. Los resultados muestran dos grupos diferenciados: por un lado, participantes de instituciones públicos y movilidad sostenible; y por otro lado, participantes con relación con el comercio, logística y servicios de movilidad compartida. La mayor dificultad a la hora de encontrar un consenso se estableció en tres medidas de transporte:

- restricciones por número de matrícula
- cobros por tipo de motor
- desarrollo de infraestructura peatonal y ciclista.

Este artículo describe el proceso metodológico, indicando la utilidad de la participación de los stakeholders en el proceso de creación de políticas y concluye con una discusión sobre la aceptabilidad de las medidas de transporte en el contexto local de Madrid.

1. INTRODUCCIÓN

La fuerte relación entre el transporte y la vida diaria de las ciudades requiere de un enfoque más amplio en el planeamiento del transporte. De esta manera, se deben conectar lugares y actividades espacialmente dispersas y, a su vez, encontrar formas de reducir los impactos ambientales del transporte (Bertolini, 2017). En el largo plazo, está aumentando el consenso sobre la necesidad de integrar políticas para conseguir el transporte futuro deseado a nivel ciudad (compactación urbana, tecnologías verdes, etc.) (Hickman, Saxena, Banister, & Ashiru, 2012; Soria-Lara & Banister, 2008). A corto plazo, la implementación de medidas de transporte específicas para mejorar la calidad del aire (Transporte Policies for improving Air Quality, TPAQ) en el centro de las ciudades está ganando importancia en las últimas décadas. Estas TPAQ están fundamentalmente enfocadas a reducir el tráfico motorizado, si bien su tipología y características varían en función de las peculiaridades de la ciudad, sus normas culturas y sus objetivos específicos (Kelly et al., 2011; Polichetti, 2017; Ramos, Cantillo, Arellana, & Sarmiento, 2017; Wen & Bai, 2017). Ejemplos de TPAQs los encontramos en las restricciones por número de matrícula, las cargas por tipo de motor, la promoción de la movilidad compartida, las restricciones temporales de tráfico, etc.

La controversia social ocasionada por estas TPAQs es normalmente alta, afectando a su aceptabilidad y a su viabilidad. Sin embargo, las investigaciones previas han prestado limitada atención a estudiar la influencia de los stakeholders en los procesos ex ante de evaluación de impactos y aceptabilidad de dichas medidas. La mayoría de estudios han sido dirigidos a analizar ex ante y ex post los efectos de una única medida o un reducido número de ellas frente a objetivos ambientales, económicos y sociales (Mohan, Tiwari, Goel, & Lahkar, 2017; Moncada, Bocarejo, & Escobar, 2018; Pucher & Buehler, 2008; Szarata, Nosal, Duda-Wiertel, & Franek, 2017; Zhang, Chen, Wang, Huang, & Wang, 2017). El reto que debe afrontar la planificación del transporte se basa en la aparición de enfoques colaborativos basados fundamentalmente en la participación e interacción de los stakeholders (Le Pira, Marcucci, et al., 2017). Esto significa una reorientación que busque el consenso a través de la discusión entre stakeholders y ámbitos profesionales (Willson, 2001). Cascetta, Carteni, Pagliara, and Montanino (2015) señalan tres acciones clave para activar este cambio en el campo del planeamiento del transporte:

- identificación y modelización de impactos relevantes para stakeholders y responsables políticos
- procesamiento y presentación de los resultados obtenidos para los no expertos
- y uso de métodos mixtos (cualitativos y cuantitativos) para involucrar al máximo rango de stakeholders. Esta situación es de especial interés cuando se implementan políticas controvertidas, por lo que los TPAQs en el centro de las ciudades son un buen ejemplo de ello.

Sobre la base de estas cuestiones, se ha identificado una brecha de conocimiento en los estudios académicas sobre la evaluación de los efectos de las medidas de transporte para mejorar la calidad del aire en los centros de las ciudades y la participación de stakeholders. La resolución de esta brecha de colaboración puede ayudar a implementar de una manera más viable y efectiva diversas políticas de actuación.

Así, las TPAQ pueden ver aumentada su credibilidad como parte de un objetivo colectivo donde diferentes actores de la sociedad pueden deliberar y exponer sus puntos de vista sobre la viabilidad, aceptabilidad y efectividad, promoviendo un proceso de decisión más inclusivo e igualitario.

Este artículo presenta un marco de evaluación colaborativa para evaluar ex ante un total de ocho TPAQs (restricciones por tipo de motor; restricciones por número de matrícula; restricciones por límite de velocidad; cargas a vehículos por tipo de motor; desarrollo de infraestructura peatonal y ciclista; ayudas económicas para la renovación de la flota de vehículos; promoción de la movilidad compartida; y desarrollo de infraestructura de transporte público). La evaluación ex ante abarca los impactos potenciales derivadas de la implementación de los TPAQs (tanto de manera general como de manera específica para sectores concretos), su aceptabilidad, y posibles estrategias de implementación para incrementar su efectividad y viabilidad.

La ciudad de Madrid (España), donde existe una clara intención gubernamental de restringir el tráfico motorizado en la zona centro, ha sido utilizada como caso de estudio. El marco de enfoque colaborativo ha sido designado de acuerdo a tres aspectos innovadores:

- un proceso bottom-up, en el cual los stakeholders determinar tanto los impactos relevantes que pueden originarse por la aplicación de las medidas en el centro de la ciudad de Madrid como estrategias potenciales de implementación para incrementar su aceptabilidad, viabilidad y efectividad
- un proceso colaborativo en dos etapas, que comienza con entrevistas semiestructuradas y finaliza con un espacio de diálogo abierto llevado a cabo en un workshop final
- un proceso de aprendizaje, donde los participantes se conocen de manera presencial, promoviendo la transparencia y el conocimiento de las visiones colectivas sobre las TPAQs.

El equipo investigador ha actuado como director y observador en este proceso colaborativo, tomando distancia cuando ha sido necesario para facilitar el intercambio de opiniones e identificar los resultados de la investigación. El proceso ha contado con la participación de un total de 28 stakeholders locales de diferentes sectores afectados por la implementación de las TPAQs en la ciudad.

El capítulo 2 revisa la literatura previa relacionada con esta investigación. El capítulo 3 describe la ciudad de Madrid como caso de estudio. El capítulo 4 detalla el diseño de la investigación mientras que el capítulo 5 muestra los principales resultados obtenidos. Finalmente, el capítulo 6 cierra el artículo con las principales discusiones y observaciones finales.

2. REVISIÓN DE LITERATURA: EVALUACIÓN DE TPAQs

La adopción de un proceso de participación bottom-up para diseñar y evaluar políticas de transporte ha experimentado un rápido crecimiento durante las últimas décadas, encontrando ejemplos relacionados con el uso de la planificación de escenarios en el ámbito del transporte (Soria-Lara & Banister, 2017), el proceso de financiación de infraestructuras urbanas de transporte (Roukouni, Macharis, Basbas, Stephanis, & Mintsis, 2018) y la selección de las medidas políticas más adecuadas para la sostenibilidad (Hickman et al., 2012). Sin embargo, se ha dedicado escasa atención a evaluar TPAQs bajo escenarios colaborativos.

Para analizar esta brecha teórico-práctica de conocimiento, se ha realizado una revisión de literatura utilizando la base de datos de Scopus. Las palabras clave utilizadas durante la búsqueda han sido: políticas de calidad de aire, políticas de restricciones de tráfico y zonas de bajas emisiones. Esta revisión ha resultado en un creciente número de estudios en los últimos años centrados en llevar a cabo evaluaciones ex ante y ex post sobre efectos de TPAQs en la calidad del aire, el cambio de flota y el espacio público entre otros (Fatima & Moridpour, 2016; Invernizzi et al., 2011; Lu, 2016; Wang, Shao, Wang, & Sun, 2010; Xu & Ma, 2012). No obstante, la evaluación de impactos potenciales de dichas TPAQs a partir de la participación de stakeholders ha sido un tema fuera de los ámbitos de estudio frecuentes.

Un grupo relevante de los estudios consultados desarrolla evaluaciones ex post sobre efectos de las TPAQs ocurridos varios años después de su implementación. Estos estudios detallan principalmente impactos específicos de las medidas frente a los objetivos ambientales, económicos y sociales. Por ejemplo, Chowdhury et al. (2017) evalúa los impactos de las restricciones por número de matrícula sobre las concentraciones de $PM_{2.5}$ en la ciudad de Delhi (India). Jia, Zhang, He, and Li (2017) proponen un modelo teórico, basado en una encuesta, para estudiar la aceptación de los commuters y sus comportamientos frente a las restricciones por matrícula en Tianjin (China). La afección de las restricciones de tráfico sobre la concentración de PM_{10} en ciertas franjas horarias en Nápoles ha sido analizado por Polichetti (2017). Liu, Yan, and Dong (2016) han conducido una investigación diseñada para comparar y analizar los efectos sombre el cambio en los patrones de viaje generados por las políticas de restricción de coches en Beijing (China). Un último ejemplo lo podemos encontrar en el estudio de Kelly et al. (2011), quien evalúa la efectividad de la zona de bajas emisiones de Londres sobre la disminución de la concentración de contaminantes en la ciudad.

Un segundo grupo de estudios se centran en implementar evaluaciones ex ante para anticipar posibles efectos de la implementación de TPAQs. Los estudios consultados se basan en modelar y simular dichos efectos futuros de acuerdo a características socioeconómicas y variables de comportamiento de viaje. Tal y como se ha comentado, la participación de stakeholders en este grupo de estudios es muy limitada. Por ejemplo, Ramos et al. (2017) modela los efectos de sustituir las restricciones actuales por número de matrícula en Medellín (Colombia) por políticas de cobro ambiental. Zhang et al. (2017) trata de anticipar como las restricciones en Beijing (China) pueden impulsar un cambio modal desde los vehículos privados al sistema de metro. Wen and Bai (2017) usan un modelo dinámico para simular variaciones en el consumo de energía urbana y en los kilómetros recorridos por la población a través de la comparación entre diferentes TPAQs: restricciones por número de matrícula, restricciones por un sistema aleatorio y desarrollo de la infraestructura de transporte público. Otro ejemplo se puede encontrar en el estudio de Hanna, Kreindler, and Olken (2017), quienes simulan hasta qué punto las políticas de vehículos de alta ocupación podrían impulsar una reducción de la congestión del tráfico urbano en Yakarta (Indonesia).

En resumen, y a diferencia del conjunto de estudios mostrados anteriormente, este artículo proporciona una evaluación ex ante sobre los impactos potenciales, aceptabilidad y estrategias de implementación de varias TPAQs en el contexto de la ciudad de Madrid, usando una metodología colaborativa bottom-up que involucra a múltiples stakeholders de la ciudad.

3. CASO DE ESTUDIO: LA CIUDAD DE MADRID (ESPAÑA)

La ciudad de Madrid se encuentra en el centro geográfico de España. Su área metropolitana cuenta con aproximadamente cinco millones de habitantes en un área de 2.000 km^2. Dicho área metropolitana está formado por 27 municipios, siendo la ciudad de Madrid su centro. Desde los años 90, la población alrededor de la ciudad de Madrid ha iniciado un proceso de expansión geográfica, generando efectos relevantes en el transporte. Por ejemplo, el ratio de posesión de coches en Madrid (690 coches por cada 1.000 habitantes) es superior que la media española (500 coches por cada 1.000 habitantes). La mencionada suburbanización de residencia y empleo, así como el incremento de vehículos, ha originado nuevas tendencias de transporte. De hecho, de acuerdo con la encuesta de movilidad de Madrid, el número de viajes motorizados ha incrementado un 46% desde 1996 a 2014, con un incremento del 50% en la posesión de vehículos propios por vivienda, mientras que la población ha incrementado únicamente un 29% en el mismo periodo.

La red de carreteras de acceso a la ciudad de Madrid es muy amplia, con 10 autopistas (4 de ellas de peaje) conectando la ciudad de Madrid con los municipios del área metropolitana. Además, hay que destacar los cuatro cinturones que rodean la ciudad de Madrid (M-30, M-40, M-45 y M-50) siendo los dos primeros, por su carácter de anillo (interior M-30 y exterior M-40), los más importantes. El anillo interior, de 32 km de longitud, es utilizado mayoritariamente por vehículos de pasajeros mientras que el anillo exterior, de 64 km de longitud, tiene un gran porcentaje de tráfico pesado. Ambos presentan problemas de congestión durante las horas punta.

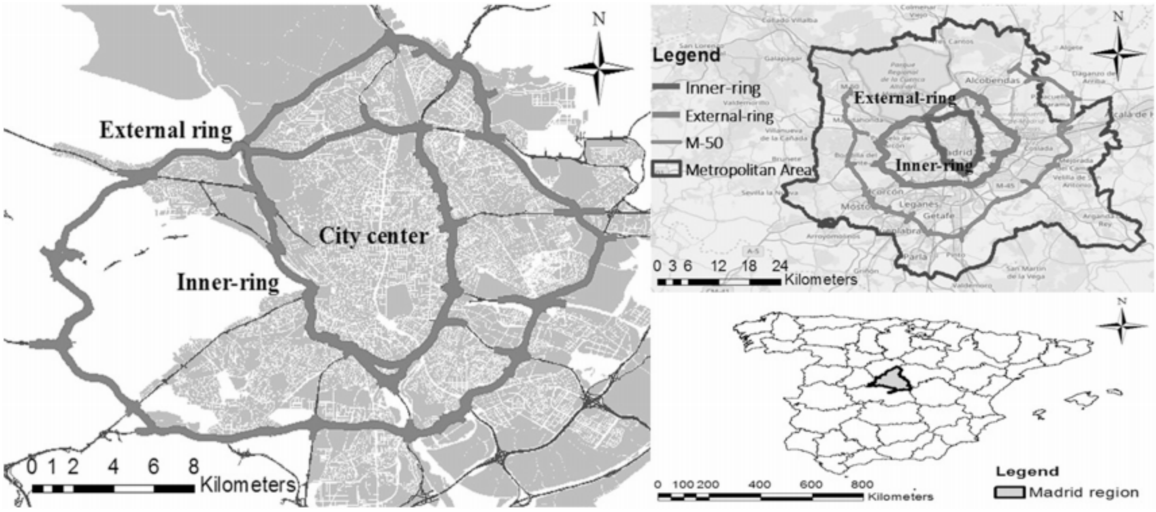

Figura 1: Localización del caso de estudio

La expansión de la población y el empleo ha provocado un aumento del uso del coche por parte de los viajeros que se dirigen desde municipios exteriores hacia el centro de la ciudad de Madrid. Hay aproximadamente 2 millones de viajeros diarios en el anillo interior. Esto ha generado efectos negativos en el medioambiente, especialmente en las emisiones de gases de efecto invernadero y en la emisión de contaminantes como NOx y PM. En algunos episodios, normalmente durante el otoño y el invierno, el anillo interior de Madrid ha superado los umbrales de salud establecidos por la Unión Europea.

Para solucionar este problema de salud pública, el gobierno local de Madrid ha implementado recientemente el Plan de Calidad del Aire “Plan A”, destinado a la mejora de la calidad del aire en el centro de la ciudad. Este Plan incluye un conjunto de TPAQs para reducir la congestión de tráfico en el anillo interior de Madrid.

A pesar de que el Plan A ha sido aprobado, la mayoría de sus políticas continúa bajo discusión debido a una alta controversia social. De hecho, se espera que la mayoría de sus políticas se modifiquen en los próximos años.

Bajo este contexto, es oportuno y conveniente llevar a cabo una evaluación ex ante involucrando a stakeholders en la evaluación de impactos potenciales de las TPAQs implementadas en el centro de la ciudad de Madrid (incluyendo impactos generales e impactos específicos para sectores particulares), en la aceptabilidad de las medidas y en las estrategias de implementación. De esta manera, la ciudad de Madrid es un excelente lugar para realizar esta investigación.

4. DISEÑO DE LA INVESTIGACIÓN: MARCO DE EVALUACIÓN COLABORATIVA

Para conseguir el principal objetivo del artículo, la evaluación ex ante de ocho TPAQs en la ciudad de Madrid a partir de la participación de stakeholders, se ha diseñado e implementado un enfoque de evaluación colaborativa en tres fases secuenciales:

- Identificación de TPAQs
- Entrevistas semi-estructuradas
- Espacio de diálogo abierto.

4.1 Fase 1: Identificación de TPAQs

El equipo investigador llevó a cabo una revisión de TPAQs basado en dos aspectos clave:

- TPAQs previamente implementados en otras ciudades del mundo (Méjico, Londres, Beijing, etc.) con diferentes niveles de efectividad, viabilidad y aceptación social
- TPAQs en línea con los objetivos locales de Madrid para mejorar la calidad del aire.

La revisión incluyó tanto estudios académicos como trabajos profesionales disponibles para su análisis. El proceso concluyó con un total de 43 referencias. Dichas referencias fueron analizadas en profundidad por medio de un análisis de contenido (Bryman, 2012), destilando tanto TPAQs previamente implementados en otros contextos como potencialmente aplicables en la ciudad de Madrid. Una descripción detallada del trabajo realizado analizando múltiples TPAQs en todo el mundo se presenta en Vassallo, Bueno, Ortega, Soria, & Tarriño (2018).

Se resalta que el objetivo de este estudio no es evaluar las TPAQs específicas implementadas por el mencionado PLAN A en Madrid, sino evaluar un mayor número de TPAQs potenciales alineadas y diseñadas de acuerdo a los objetivos de Madrid en cuanto a la calidad del aire. Así, las TPAQs seleccionadas pueden coincidir con algunas de las medidas incorporadas en el Plan A. Las 8 TPAQs seleccionadas para el estudio fueron (Tabla 1):

- restricciones por tipo de motor
- restricciones por número de matrícula
- restricciones del límite de velocidad
- cobros a vehículos de motor
- desarrollo de infraestructura peatonal y ciclista
- ayudas para el cambio en la flota de vehículos
- promoción de la movilidad compartida
- desarrollo de infraestructura pública de transporte.

Los stakeholders también fueron estimulados para añadir TPAQs durante el proceso participativo si lo consideraban necesario. Sin embargo, no fue propuesto ningún TPAQ adicional.

TPAQ	Descripción
Restricciones por tipo de motor	Restricción total a vehículos diésel y vehículos antiguos en el anillo interior de Madrid en 2020 afectando a vehículos de pasajeros y mercancías.
Restricciones por número de matrícula	Restricciones totales a vehículos según su número de matrícula (par o impar) en el anillo interior de Madrid afectando a vehículos de pasajeros y mercancías.
Restricciones del límite de velocidad	Reducción del límite de velocidad de 50 a 30 km/h en el anillo interior de Madrid y de 90 a 70 km/h en el anillo exterior afectando a vehículos de pasajeros y mercancías.
Cobros a vehículos de motor	Cobro variable a los vehículos en función de afección al medioambiente por su tipo de motor y en función de la congestión en la red del anillo interior de Madrid, afectando a vehículos de pasajeros y mercancías.
Desarrollo de infraestructura peatonal y ciclista	Desarrollo de infraestructura peatonal y ciclista adicional en el anillo interior de Madrid a costa de espacio actual dedicado al tráfico motorizado.
Ayudas para el cambio en la flota de vehículos	Subsidios locales y regionales para sustituir vehículos privados diésel y antiguos por vehículos con nuevas tecnologías tanto en vehículos de pasajeros como de mercancías. Estas ayudas provienen de impuestos a la ciudadanía.
Promoción de la movilidad compartida	Los vehículos de alta ocupación tienen preferencia para acceder al anillo interior de Madrid. En el caso del transporte de mercancías, se promueve un sistema colaborativo entre compañías para facilitar el reparto.
Desarrollo de infraestructura pública de transporte	Desarrollar infraestructura de transporte público en el anillo interior de Madrid a costa de espacio actual dedicado al tráfico motorizado.

Tabla 1: Descripción de las TPAQs seleccionadas

4.2 Fase 2: Entrevistas semiestructuradas

Un total de 28 stakeholders fueron seleccionados para participar, consiguiendo una matriz de expertos que asegura la retroalimentación de todos los actores clave potencialmente afectados por las TPAQs en la ciudad de Madrid. Entre estos sectores se encuentran los siguientes: instituciones públicas, sector de mercancías, comerciantes, ambientalistas, asociaciones de transporte público, autoridades de transporte, operadores de transporte público, asociaciones de taxi, etc. La lista completa de perfiles se presenta en el Apéndice 1.

Los participantes fueron entrevistados individualmente por el equipo investigador a través de entrevistas semiestructuradas, donde el entrevistador dispone de una serie de cuestiones generales que se formulaban con libertad para obtener aspectos más detallados ante respuestas significativas (Bryman, 2012). El trabajo empírico fue completado durante otoño de 2017.

Después de clarificar el rol de los entrevistados en el sector transporte (posición, intereses generales, etc.) cada entrevista semiestructurada constaba de cuatro bloques diferentes relativos a las ocho TPAQs previamente mencionadas. Para cada medida, los participantes fueron preguntados sobre sus opiniones en:

- impactos generales producidos por la TPAQ (ambientales, económicos o sociales)
- impactos específicos producidos por la TPAQ en su sector profesional
- aceptabilidad de cada TPAQ dentro del sector del entrevistado
- estrategias de implementación para conseguir una mayor aceptabilidad de dicha TPAQ (temporalidad, etc.).

Los stakeholders fueron animados a expresar libremente sus ideas y opiniones así como a añadir cualquier aspecto no incluido en la entrevista semiestructurada. Cada entrevista tuvo una duración aproximada de 40’-60’. La mayoría de encuestas fue realizada de manera presencial y, excepcionalmente, por teléfono. Todas las encuestas fueron guardadas para su posterior análisis.

Las entrevistas fueron analizadas mediante un proceso sistemático de transcripción individual, incluyendo codificación y varias rondas de interpretación de los códigos asociados con las ocho TPAQs de estudio. Se consiguieron un total de 1287 visiones independientes durante dicho proceso. Estas ideas fueron agrupadas en 540 códigos de acuerdo a los diferentes bloques de la entrevista semiestructurada:

- impactos generales
- impactos específicos por sectores
- aceptabilidad
- estrategias de implementación.

Por ejemplo, varias opiniones con un mensaje similar (reducción de contaminantes, aire más limpio) fueron agrupadas bajo el mismo código (mejora de la calidad del aire). El objetivo de esta fase metodológica fue obtener opiniones adicionales sobre los impactos de las TPAQs. Por lo tanto, los resultados obtenidos en esta etapa muestran percepcionesque son, por definición, subjetivas. Se creó una base de datos final para comparar las opiniones de las partes interesadas, incluyendo estadísticas descriptivas sobre consenso o desacuerdo con los distintos temas en función de la frecuencia y el contenido de las respuestas de las partes interesadas.

4.3 Fase 3: Espacio de diálogo abierto

El espacio de diálogo abierto se llevó a cabo mediante un workshop donde los participantes se conocieron en persona. Se centró especialmente en aquellas TPAQs donde existían discrepancias entre las opiniones recogidas por los participantes. De esta manera, se focalizó en la discusión de posibles estrategias de implementación que pudieran incrementar la aceptabilidad y viabilidad de los TPAQs analizados.

Los 28 stakeholders fueron invitados al workshop si bien finalmente 15 de ellos asistieron al mismo (Apéndice 2). El objetivo era la creación de un espacio donde los participantes tuvieran la oportunidad de conocer al resto, relacionarse y aprender de la visión de los demás. La posibilidad de escuchar diferentes valoraciones podría modular discursos y permitir incrementar las oportunidades de buscar soluciones en beneficio de todos. El workshop fue estructurado en dos partes:

- Parte 1: El equipo investigador presentó un resumen de los resultados obtenidos durante las entrevistas individuales. Esto facilitó la generación de nuevas visiones y reacciones por parte de los stakeholders. La duración de la primera parte fue de 25'. Se dedicó especial atención a aquellas TPAQs donde predominaba falta de consenso entre los participantes, explicando que dichas medidas constituirían el cuerpo del debate en la segunda y principal parte del workshop.
- Parte 2: Se centró exclusivamente en aquellas TPAQs con bajo consenso entre los stakeholders según los datos obtenidos de las entrevistas. Para cada TPAQ, el equipo investigador mostró tres posibles estrategias de implementación y los stakeholders debían elegir una de ellas mediante un voto anónimo. No se permitía la abstención. Seguidamente, los stakeholders debían responder si estaban o no de acuerdo con cada una de las tres estrategias de implementación mostradas por el equipo investigador, activando tres nuevas rondas de votación anónimas por cada TPAQ. Una vez realizado el recuento, se mostraron los resultados agregados y los stakeholders fueron animados a tener una discusión abierta sobre los resultados de la votación para alcanzar un consenso sobre la estrategia de implementación más poderosa para aumentar la aceptabilidad y la viabilidad de cada TPAQ. Tras ello, los participantes fueron estimulados a proponer nuevas estrategias de implementación si lo consideraban necesario. La duración de esta parte fue de aproximadamente 40' para cada TPAQ a discutir.

El equipo investigador, integrado por un total de 5 miembros, no tomó parte activa en el workshop, actuando 2 de ellos como moderadores y 3 de ellos como observadores. Los observadores tomaron notas durante el workshop, e cual también fue grabado para futuras consultas.

5. RESULTADOS

Este capítulo presenta los resultados obtenidos durante el marco de evaluación colaborativa, destacando el éxito conseguido mediante consenso entre los participantes sobre los posibles impactos de las TPAQs (tanto genéricos como específicos para sectores concretos), la aceptabilidad y las posibles estrategias de aplicación.

5.1 Resultados de las entrevistas semiestructuradas

Durante las entrevistas semiestructuradas, fueron registradas en la base de datos un total de 1287 visiones de los participantes referentes a los diferentes aspectos de la misma. Estos puntos de vista cubrían las ocho TPAQs incluidas en la investigación y fueron clasificados en los cuatro principales bloques de la encuesta:

- impactos generales
- impactos específicos
- nivel de aceptabilidad
- estrategias de implementación.

Posteriormente, se clasificaron en 540 códigos tras varias fases de codificación, agrupando puntos de vista similares bajo el mismo código. Las TPAQs que originaron un mayor número de opiniones fueron las restricciones por tipo de motor y el desarrollo de infraestructura peatonal y ciclista, mientras que las TPAQs con el menor número de códigos fueron las restricciones al límite de velocidad y las cargas a los vehículos de motor. Las disidencias se observaron fundamentalmente en las restricciones por número de matrícula, las cargas a los vehículos de motor y el desarrollo de la infraestructura peatonal y ciclista. Por esta razón, las tres TPAQs mencionadas fueron posteriormente incluidas en el espacio de diálogo abierto.

5.1.1 Identificación de impactos generales

El primer bloque de las entrevistas semiestructuras se centraba en la percepción de los stakeholders sobre la capacidad de las TPAQs de conseguir una mejora de la calidad del aire. De manera general, se observó un alto nivel de acuerdo entre los participantes en cuanto a la alta capacidad de la mayoría de las TPAQs para mejor la calidad del aire en el anillo interior de Madrid, con la excepción de las restricciones por límite de velocidad. De hecho, se considera que esta medida puede generar el efecto contrario y las emisiones podrían ser mayores tras su implementación.

El impacto de las ocho TPAQs en la congestión urbana de tráfico fue un tema frecuente de discusión entre los participantes. No existe un consenso sobre cuáles de las TPAQs resultarían efectivas para conseguir este objetivo. Si bien hubo consenso en la reducción de la congestión del tráfico si se aplicaban restricciones por tipo de motor y tasas a los vehículos de motor, se encontraron divergencias cuando se trataba de restricciones por número de matrícula, desarrollo de infraestructuras peatonales y ciclistas, y subvenciones para cambiar el parque de vehículos. En estos casos, los participantes del sector público afirmaron que los tres TPAQs mencionados contribuirían a reducir la congestión del tráfico en el centro de Madrid, pero los participantes del sector privado, específicamente los comerciantes, los taxistas y el sector de las mercancías, señalaron que estas medidas podrían incluso empeorar los niveles de congestión. Estos stakeholders también creían que las restricciones por número de matrícula aumentarían el ratio de posesión de vehículos privados, mientras que el desarrollo de infraestructura para peatones y ciclistas implicaría un número similar de vehículos circulando por calles de baja capacidad, lo que aumentaría la congestión urbana.

Finalmente, el impacto de las TPAQs en las desigualdades sociales fue otro tema recurrente entre los encuestados. En particular, se encontró un alto nivel de desacuerdo en las respuestas otorgadas sobre las restricciones por número de matrícula, los cobros a vehículos motorizados y el desarrollo de infraestructura peatonal y ciclista. Los participantes de instituciones públicas y los operadores de transporte indicaron que las restricciones por número de matrícula y el cobro de tasas podrían afectar enormemente a familias con bajos ingresos. Sin embargo, para los comerciantes, taxistas y sector de mercancías, el desarrollo peatonal y ciclista provocaría mayores desigualdades sociales ya que muchas personas se verían impedidas de participar en actividades diarias como consecuencia de las restricciones al coche.

5.1.2 Identificación de impactos específicos para cada sector

El segundo bloque de las entrevistas semiestructuras se focalizó en los impactos específicos generados por las TPAQs en cada uno de los sectores de trabajo. Los stakeholders estuvieron de acuerdo en el impacto neutro o positivo de dos TPAQs: restricciones al límite de velocidad y ayudas para renovar la flota de vehículos. Sin embargo, se encontró un alto nivel de desacuerdo en el resto de medidas de estudio.

Por un lado, los operadores públicos de transporte y los responsables políticos coincidían en que dichas TPAQs propiciaban una reducción del uso del coche en el centro de la ciudad de Madrid, originando impactos positivos en sus respectivos sectores. Por otro lado, comerciantes, taxistas y trabajadores del sector de mercancías observaban impactos negativos para sus respectivos sectores. Consideraban que disminuiría su competitividad y que aumentaría las desigualdades entre grandes y pequeñas compañías. La controversia fue particularmente notable en las restricciones por número de matrícula, apoyadas fuertemente por los responsables políticos y rechazadas por el sector del transporte; los cobros a vehículos de motor, secundado por los operadores de transporte público y con el resto de participantes en contra; y el desarrollo de infraestructura peatonal y ciclista, apoyado enormemente por responsables políticos, operadores de transporte público y ambientalistas, mientras que el resto de sectores rechazaban dicha medida.

5.1.3 Nivel de aceptabilidad de TPAQs

El tercer bloque de las entrevistas semiestructuradas analizó los niveles de aceptabilidad de las TPAQs de estudio para cada sector (Figuras 5 y 6). En el caso de las restricciones por tipo de motor, el 60% de los stakeholders declararon una alta y muy alta aceptabilidad para sus sectores, mientras que un 17% indicó una aceptabilidad neutra. Sin embargo, las restricciones por número de matrícula encontraron un alto nivel de disidencia. El sector transporte de mercancías se posicionaba totalmente en contra de esta medida, mientras que los operadores de transporte público, responsables políticas y ambientalistas apoyaban la implementación de la misma. Un caso similar ocurrió con las tasas a los vehículos de motor, donde el nivel de discrepancia fue muy alto. Un 50% de los stakeholders señalaron una aceptabilidad alta o muy alta ara esta medida, principalmente desde instituciones públicas y operadores de transporte. No obstante, un 33% indicó una aceptabilidad baja o muy baja, principalmente desde el sector del transporte de mercancías y los ambientalistas.

En cuanto a las restricciones al límite de velocidad, el 42% de los entrevistados señaló una alta o muy alta aceptabilidad (principalmente responsables políticos y ambientalistas) y un 46% declaró una aceptabilidad neutra. El desarrollo de infraestructura peatonal y ciclista mostró un alto nivel de discrepancia en cuanto a su aceptabilidad. Un 50% (incluyendo instituciones públicas, sector tecnológico, operadores de transporte y sector de la movilidad compartida) indicó una aceptabilidad alta o muy alta; frente a un 33% que señaló una aceptabilidad baja o muy baja en sus respectivos sectores, principalmente desde el sector de mercancías, comerciantes y taxistas. Para el resto de medidas, los niveles de aceptabilidad fueron similares. La mayoría de stakeholders indicaron una aceptabilidad neutra o alta para sus respectivos sectores.

5.1.4 Identificación de estrategias potenciales de implementación

El cuarto bloque de la entrevista consistió en la discusión de estrategias potenciales de implementación que podrían incrementar la aceptabilidad, viabilidad y efectividad de cada TPAQ. Se consiguió un alto nivel de consenso en cinco TPAQs:

- restricciones por tipo de motor, basadas en una progresiva implementación en el tiempo que diese suficiente tiempo a viajeros y empresas para renovar su flota de vehículos
- restricciones al límite de velocidad, a través de un programa de desarrollo educativo y conciencia social para conductores
- ayudas para la renovación de la flota de vehículos, resaltando la necesidad de comenzar con los sectores de población de menores ingresos
- promoción de la movilidad compartida, considerando la necesidad de un marco legal que garantizase la libre competencia en el sector
- y desarrollo de infraestructura de transporte público, estableciendo un balance adecuado en el diseño de calles entre el espacio otorgado al transporte público y el espacio dedicado al resto de modos.

Sin embargo, no se encontró consenso en la aplicación de las restricciones por tipo de matrícula, los cargos a los vehículos de motor y el desarrollo de infraestructura peatonal y ciclista. Este es otra de las razones para que fueran las tres TPAQs incluidas en el espacio de diálogo abierto.

5.2 Resultados del espacio de diálogo abierto

Como consecuencia de la falta de consenso entre los participantes durante la fase de entrevistas, se incluyeron tres TPAQs en el workshop: restricciones por número de matrícula, tasas a los vehículos motorizados y desarrollo de infraestructura peatonal y ciclista. En este apartado se resumen los principales resultados obtenidos en esta fase, incluyendo una descripción detallada de los debates en torno a las tres TPAQs mencionadas.

Las restricciones por número de matrícula fueron la primera medida analizada durante el workshop. Una vez que los participantes fueron informados sobre los resultados agregados obtenidos en las entrevistas, el equipo investigador planteó tres estrategias de implementación:

- Opción A: Implementación temporal afectando tanto a vehículos de pasajeros como de mercancías (a excepción del transporte público), exclusivamente en periodos donde la concentración de contaminantes fuera superior a los umbrales de salud establecidos por la normativa.
- Opción B: Implementación permanente de la media con excepciones para transporte de mercancías, alta ocupación y transporte público.
- Opción C: Implementación permanente de esta medida únicamente en horas punta, tanto para vehículos de transporte de pasajeros como de mercancías (a excepción del transporte público).

Tras la primera ronda de votación, la opción B fue apoyada por el 53% de los participantes, seguida de la opción A (40%) y la opción C (7%). La opción B fue principalmente seleccionada por participantes del sector transporte de mercancías, movilidad compartida, comerciantes y operadores de transporte. La opción A fue la elegida por ambientalistas y empresas de movilidad sostenible. Finalmente, la opción C fue apoyada por stakeholders del gobierno local.

La segunda ronda de votación tenía el objetivo de captar el acuerdo o desacuerdo de cada agente con cada una de las tres estrategias de implementación. Los resultados mostraron que la mayoría de los votantes se mostraban contrarios a la opción A (73%), la cual tenía sus votos favorables en agentes ambientalistas. Un hecho similar ocurría con la opción C, apoyada únicamente por un participante proveniente del gobierno local de Madrid. Sin embargo, un 60% de los stakeholders (representando al sector transporte de mercancías, movilidad compartida, comerciantes y operadores de transporte) se mostraban de acuerdo con la opción B.

Los resultados agregados fueron mostrados a todos los participantes antes de iniciarse una ronda de debate. En esta parte del workshop, se incluyeron 11 nuevos códigos en la base de datos asociada a esta TPAQ. Durante la discusión, los agentes del sector de mercancías y los operadores de transporte mostraron la necesidad de establecer excepciones para sus respectivos sectores si esta TPAQ se implementaba. Por su parte, los ambientalistas alertaron de que estas excepciones podían generar desigualdades que hicieran menos efectiva la medida en el largo plazo. Tras escuchar diversas opiniones, el agente del gobierno local que había elegido la opción C acabó cambiando su punto de vista y admitiendo esta medida únicamente como política temporal en periodos de superación de los límites de salud establecidos por la normativa. Stakeholders del sector transportes, comerciantes y operadores de transporte declararon admisible una implementación temporal de la medida, teniendo en cuenta la baja posibilidad de que se llevase finalmente a cabo.

En resumen, se consiguió un acuerdo final en la mayoría de participantes sobre la conveniencia de la opción A como estrategia de implementación para mejorar la aceptabilidad y viabilidad de esta TPAQ en Madrid.

Las tasas a los vehículos de motor fueron la segunda TPAQ analizada durante el workshop. Una vez que los participantes fueron informados sobre los resultados agregados obtenidos durante las entrevistas, se presentaron las tres estrategias de implementación a debatir:

- Opción A: Implementación permanente de tasas dentro del anillo interior de Madrid, afectando de igual manera a todos los vehículos motorizados a excepción de los sistemas de transporte público.
- Opción B: Implementación permanente de tasas dentro del anillo exterior de Madrid, con excepciones para transporte de mercancías, taxistas, vehículos de movilidad compartida y transporte público.
- Opción C: Implementación permanente de cargas en horas punta dentro del anillo externo de Madrid, afectando a todos los modos de transporte con la excepción del transporte público.

La primera ronda de votación mostró una preferencia mayoritaria por la opción B (80%), seguida muy de lejos por la opción C (13%) y la opción A (7%). La opción B fue seleccionada por agentes del sector mercancías, comerciantes, taxistas y empresas de movilidad compartida porque sus vehículos estaban exentos. Sin embargo, la opción C fue elegida por stakeholders del gobierno local de Madrid y pequeñas compañías centradas en la movilidad sostenible.

La ronda de votaciones siguiente mostró un amplio rechazo a la opción A (73%) y un resultado similar para la opción C. En cambio, un 60% de los participantes se mostraron de acuerdo con la opción B, representando en su mayoría al sector de mercancías, movilidad compartida, comerciantes y operadores de transporte.

Una vez que los resultados agregados fueron expuestos a todos los participantes, se abrió el turno de debate, en el que se introdujeron 10 nuevos códigos referidos a esta TPAQ. Esta medida tuvo menor controversia en comparación con las restricciones por número de matrícula. Se observó unanimidad entre los participantes en el rechazo de las cargas a vehículos de motor, con un porcentaje bajo de aceptación en las tres estrategias de implementación planteadas. El principal argumento fue que provocaría un incremento en la desigualdad social si fuese implementada. No obstante, sectores como el transporte de mercancías y los comerciantes mostraron conformidad con esta medida si se tenían en cuenta las particularidades del sector transporte durante su implementación. De esta manera, no quedó establecida cuál podría ser la mejor estrategia de implementación para aumentar la aceptabilidad y viabilidad de esta medida.

La última TPAQ estudiada durante el workshop fue el desarrollo de infraestructura peatonal y ciclista. Las tres estrategias planteadas, tras informar a los participantes de los resultados agregados durante las entrevistas, fueron las siguientes:

- opción A: Reducir el número de carriles en las calles de varios carriles para ampliar la infraestructura para peatones y ciclistas de forma homogénea en barrios del anillo interior de Madrid.
- Opción B: Establecer una restricción total del tráfico en algunas calles seleccionadas con alta actividad comercial para construir una infraestructura para caminar y andar en bicicleta que cubra todo el espacio de tráfico. El resto de las calles permanecerían como estaban.
- Opción C: Establecer una restricción total del tráfico en las calles secundarias, implementar una infraestructura para caminar y andar en bicicleta que cubra todo el tráfico espacio de tráfico en esas calles, con excepción de los residentes, que podrían acceder a sus garajes utilizando vehículos motorizados.

La primera ronda de votación mostró igualdad de preferencias entre las opciones A y C, con un 40% de votos para cada una de ellas, mientras que la opción B fue seleccionada por el 20% de los agentes. La opción A fue elegida principalmente por los operadores de transporte de mercancías, comerciantes y el sector de la movilidad compartida, quienes creen que una restricción total al tráfico podría dañar seriamente a sus sectores. La opción C fue indicada en su mayoría por instituciones públicas y operadores de infraestructuras. La opción B fue apoyada exclusivamente por ambientalistas.

La segunda ronda de votación mostró un 60% de apoyo favorable a la opción A, incluyendo representantes de instituciones públicas, servicios de movilidad sostenible y ambientalistas). La opción C fue apoyada por el 53% de los encuestados, incluyendo de nuevo agentes de instituciones públicas y ambientalistas. Sin embargo, la opción B fue rechazada por el 53% de los stakeholders, entre los que se encontraban comerciantes, movilidad compartida y sector de transporte de mercancías. Se debe mencionar que los agentes representantes del

Ayuntamiento de Madrid apoyaron las tres estrategias de implementación mostradas por el equipo investigador. En su opinión, "recuperar las plazas de tráfico para hacer las ciudades más caminar era esencial para alcanzar resultados sostenibles a nivel de la ciudad".

La fase de debate abierto sobre la medida, en la que fueron incluidos 25 nuevos códigos en la base de datos, mostró dos grupos diferenciados. Por un lado, los participantes que consideraban un gran problema para su sector la sustitución de plazas de tráfico por áreas para movilidad no motorizada: transporte de mercancías, comerciantes, servicios de movilidad compartida y operadores de infraestructura. Por otro lado, los stakeholders de instituciones públicas, movilidad sostenible y ambientalistas se mostraban de acuerdo con la idea de reducir las áreas de tráfico por movilidad no motorizada. No obstante, algunos de los agentes de instituciones públicas indicaron que las tres estrategias de implementación planteadas eran muy radicales para tener un mínimo nivel de aceptabilidad en la sociedad. De esta manera, tras escuchar las opiniones del resto de grupos, los representantes del Ayuntamiento local de Madrid (que previamente habían apoyado las tres estrategias propuestas) cambiaron su opinión e indicaron su rechazo sobre todas ellas. Estas estrategias se consideraron finalmente con un bajo nivel de viabilidad y fiabilidad para la ciudad de Madrid. Finalmente, no se pudo llegar a un consenso tras el debate sobre qué estrategias de aplicación aumentarían la aceptabilidad de este TPAQ.

6. CONCLUSIONES

Este trabajo ha desarrollado y testado un novedoso enfoque de colaboración para evaluar ex ante la implementación de TPAQs en el centro de las ciudades a través de la participación de stakeholders. Un total de ocho TPAQs fueron estudiadas y comparadas en el contexto de la ciudad de Madrid:

- restricciones por tipo de motor
- restricciones por número de matrícula
- restricciones del límite de velocidad
- cobros a vehículos de motor
- desarrollo de infraestructura peatonal y ciclista
- ayudas para el cambio en la flota de vehículos
- promoción de la movilidad compartida
- desarrollo de infraestructura pública de transporte.

Los resultados de la investigación arrojan luz sobre la mejor manera de implementar TPAQs para alcanzar los mayores niveles de aceptabilidad desde los diferentes actores de la sociedad. El análisis muestra que todos los stakeholders están concienciados en la adopción de medidas políticas para mejorar la calidad del aire en las ciudades, pero tienden a oponerse a aquellas políticas que afectan directamente al tráfico motorizado de vehículos. El método colaborativo demuestra que un diálogo abierto y activo entre stakeholders clave puede sur una manera útil de encontrar inteligentes estrategias de implementación que son efectivas ambientalmente y aceptables para la mayoría de los grupos afectados.

Las principales conclusiones del artículo son las siguientes:

- TPAQs en el caso de estudio: la ciudad de Madrid constituye una ciudad adecuada en tiempo para llevar a cabo esta investigación Las autoridades locales están involucradas activamente en la formulación de políticas para mejorar la calidad del aire en el centro de la ciudad. Un ejemplo de esto es la implementación del Plan A, que recopila un número relevante de medidas destinadas a reducir el tráfico de vehículos y las emisiones de transporte. Mientras los niveles de controversia en la población respecto al mencionado plan siguen aumentando, se ha prestado limitada atención a implementar escenarios colaborativos que promuevan la participación de stakeholders en el diseño de políticas. En este sentido, el estudio proporciona una base para diseñar estrategias de implementación basada en consensos entre stakeholders que podría incrementar el nivel de aceptabilidad de algunas medidas incluidas en el planeamiento local de Madrid. Este es el caso de las restricciones por número de matrícula, que se aceptan únicamente en episodios temporales de alta contaminación y el desarrollo de infraestructuras peatonales y ciclistas, que se considera preferible realizarlo en calles secundarias frente a las calles principales. Otra contribución ha sido la identificación de TPAQs con un alto consenso, como la promoción de la movilidad compartida; y el acuerdo general sobre el rechazo a las cargas por tipo de motor.
- Existen dos grupos de opinión diferenciados en el contexto de Madrid: como se indicó previamente, el consenso general ha sido conseguido satisfactoriamente en 5 TPAQs, mientras que los puntos divergentes fueron fácilmente identificados en las restricciones por número de matrícula, las cargas por tipo de motor y el desarrollo de infraestructura peatonal y ciclista. Los impactos potenciales más discutidos fueron la mejora de la calidad del aire, la reducción de la congestión urbana y la generación de desigualdades sociales. A pesar de que todos los grupos mostraron su apoyo a la necesidad de implementar políticas de transporte para mejorar la calidad del aire en los centros de las ciudades, se ocasionaron altos niveles de desacuerdo entre dos grupos. Por un lado, responsables políticos, operadores de transporte público y ambientalistas. Por otro lado, conductores de taxi, comerciantes y operadores de transporte de mercancías. Se debe tener en consideración tanto el transporte de pasajeros como el transporte de mercancías.
- Participación de stakeholders y activación del proceso de aprendizaje: la inclusión de stakeholders en la evaluación ex ante de TPAQs ha probado ser una forma eficiente de integrar múltiples puntos de vista en el proceso de formulación de políticas, generando un consenso base para asegurar una mayor efectividad y aceptabilidad de las TPAQs. Esta idea es considerada un punto crucial cuando para la implementación de políticas con una alta controversia social (Mohan et al., 2017;

Moncada et al., 2018; Pucher & Buehler, 2008), obteniendo un proceso más democrático. Otro punto relevante ha sido el proceso de aprendizaje estructurado en fases secuenciales donde los participantes han podido conocer los resultados globales obtenidos en las entrevistas, aprender de ellos y aprender de otros agentes mediante su interacción cara a cara. Esto ha facilitado la modificación y modulación de sus opiniones. En concreto, el encuentro llevado a cabo en el workshop ha contribuido a alcanzar cierto nivel de consenso en cuanto a potenciales estrategias de implementación para las restricciones por número de matrícula y las cargas a vehículos por tipo de motor. Esto ha sido posible gracias a que stakeholders relacionados con instituciones públicas han cambiado su punto de vista al escuchar el razonamiento de otros grupos de actores.

- Necesidad de combinar enfoques cualitativos y cuantitativos. Frente a la evaluación basada en la modelización y los enfoques plenamente cuantitativos, se apuesta por la necesidad de utilizar también un enfoque cualitativo. De esta manera, se espera capturar en mejor medida cómo la efectividad de las TPAQs puede verse afectada por un bajo nivel de aceptabilidad social, normas culturales y hábitos individuales.
- El marco de evaluación colaborativa y otras técnicas de apoyo a la decisión. Combinr el enfoque bottom-up desarrollado en esta investigación con otras técnicas conocidas (EIA, Análisis Coste-Beneficio, Análisis multicriterio, etc.) constituye un futuro desafío. En este sentido, los resultados obtenidos pueden ser una aportación para dichas técnicas de evaluación tradicionales (Cascetta et al. 2015), anticipando potenciales conflictos entre actores así como su posible interés de considerar estrategias para reducir los impactos esperados de las TPAQs. La experiencia en Madrid indica que la evaluación bottom-up debe ser diseñada para cada caso particular. Los factores que influyen en el proceso participativo de diseño incluyen el tiempo, coste, tradiciones culturales, la predisposición a la participación y otros factores.

Por último, cabe mencionar que en esta investigación se ha desarrollado un conjunto de nuevos fundamentos de evaluación, más democráticos, colaborativos y basados en la participación ascendente. Un reto importante es también cómo integrar finalmente estos enfoques de evaluación en los procesos de planificación institucional, que tradicionalmente son más tecnocráticos y se limitan a pequeños grupos de deliberación.

ABSTRACT

While the role of ageing population is considered crucial for Sustainable Development Goal at city level, limited attention has been paid to study the walking accessibility level of this population group to retail activity. Moreover, one missing element is the analysis of the ageing population willingness to reach retail activity on foot, which is here seen as a key point to generate friendly, liveable, and decarbonised urban environments. The city of Granada (Spain) is taken as spatial laboratory for the research. For this city, the planning of ageing population mobility in the mid-term seems to be challenging. First, a questionnaire regarding the willingness of ageing population to walk to daily, weekly, and incidental retail locations was conducted, including the identification of the main barriers to cover those distances on foot. Data were collected between January 2018 and January 2019. Second, a detailed description of the main existing problems to access to different types of retail activities be explored and compared, distilling findings for urban diagnosis. This research provides a strong basis for policy-making formulation, which can be orientated towards making cities more inclusive, liveable, and sustainable. Its findings can facilitate the identification and mapping of locations where ageing population groups can be under risk of walking accessibility disadvantage.

1. INTRODUCTION

It is widely believed that accessibility planning can be a powerful tool to effectively link transport and land use planning, two disciplines traditionally rooted in separated realms (Bertolini, 2017; van Wee & Handy, 2016). In this sense, the accessibility planning approach has gained prominence between academics, professionals, and institutions to become a key aspect in achieving sustainable planning outcomes at city and regional levels (Arranz-López et al., 2017; Geurs & van Wee, 2004; van Wee, 2016). Moreover, accessibility to major opportunities has been even recognised as a human right (United Nations, 2014), as it is one of the crucial factors that enable the participation of individuals in social life (Kenyon et al., 2003; Lucas et al., 2016).

Accessibility is usually seen as the relationship between the availability of opportunities in a given location and the transportation supply to reach them (Bocarejo S. & Oviedo H., 2012), being traditionally applied as an absolute concept affecting equally to the full spectrum of population. However, accessibility is conditioned by contingencies such as cultural norms, physical environment, and personal characteristics (Morency et al., 2011). In other words, different individuals display varying levels of willingness to travel to reach opportunities (Morency et al., 2011; Moniruzzaman, Paez, Nurul Habib, & Morency, 2013). Limited attention has been paid to how accessibility levels vary between population groups (Chang & Liao, 2011; Chia et al., 2016; Páez, et al., 2010), and the study of walking accessibility variations between seniors is a significant case in point (Böcker, van Amen, & Helbich, 2017; Negron-Poblete, Séguin, & Apparicio, 2016; Cao, Mokhtarian, & Handy, 2010; Hess, 2012).

A more in-depth understanding on how the senior population can reach major locations on foot is crucial for policy-making at local level (Givoni and Banister, 2013; Vale et al., 2015). That has triggered a growing number of studies focused on the accessibility levels of seniors (Páez et al., 2010; Páez et al., 2013). It has been reported how within the senior population exists significant differences regarding its travel behaviour and its capacity to access to certain locations (Hildebrand, 2003; Rahaf and Hensher, 2003).

Nevertheless, the senior population is frequently analysed as a homogenous group to be compared with other socio-economic groups. It is also known that the willingness of the senior population to reach retail locations on foot significantly diverges from the rest of population groups (Arranz-López et al., 2018; Negron-Poblete et al., 2016). It is evidenced that at least 1/3 of daily travels between the senior population is on foot (Paez et al., 2013). However, studies on walking accessibility focused on the senior population are limited.

To bridge the abovementioned gaps, this paper aims at exploring if and to what extent walking accessibility to retail activities is similar for different socio-economic groups among the senior population. The empirical focus will be the city of Granada in Spain, as it is a city with a high ageing population rate and where retail locations are widely dispersed across the city reducing distances between population and destinations. A questionnaire regarding the willingness to reach daily, weekly, and incidental retail locations on foot was elaborated and disseminated in the case study among population older than 55 years old. Then, a K-modes clustering method was implemented distinguishing four socio-economic groups among seniors (the “non-motorized seniors”; the “motorized seniors”; the “older seniors”; the “younger seniors”), followed by a statistical comparison of time-willingness decay functions to reach retail locations on foot for each identified cluster. Finally, walking accessibility to retail activity was estimated and mapped by using a gravity-based model.

The remainder of the paper is organized as follows: Section 2 reviews previous studies on accessibility to major destinations among the senior population. Section 3 presents the case study, while Section 4 shows the research design. Section 5 summarizes the main obtained findings. Finally, Section 6 closes the paper with some concluding remarks, including reflections on future research lines.

2. ACCESSIBILITY STUDIES ON THE SENIOR POPULATION

The strong ageing population trends in developed countries have facilitated a growing concern regarding travel patterns associated to seniors and its accessibility levels to major locations. Most of the consulted studies in the field are based on comparing motorised accessibility standards between seniors and other socio-economic groups. For example, Ricciardi et al., (2015) explored the accessibility levels to public transport systems in the context of Perth (Australia) between seniors, low-income people, people without car availability, and the rest of population. The authors showed how the biggest accessibility differences were focused on the group of seniors, who had the lowest accessibility levels to public transport systems. Similarity, Delbosc & Currie (2011) also analysed the access to bus system stops in Melbourne (Australia), finding that the low-income people had the lowest accessibility levels followed by the senior population. Páez et al., (2013) demonstrated that the likelihood to access to major destinations by car was higher for the senior population in comparison with other population groups in the city of Montreal (Canada). Also in Montreal, Páez et al., (2010) evidenced how the accessibility of seniors to health care facilities was significantly lower in suburban areas than in the city centre compared with other population groups in the same location.

Less attention has been traditionally paid to compare non-motorised accessibility levels between seniors and other groups. In that way, Arranz-López et al. (2018) demonstrated significant differences between seniors and the rest of population regarding their time-willingness to reach retail by walking and cycling in the city of Zaragoza (Spain). Generally, seniors were more willing to cover distance on foot to most of retail types, while the rest of population preferred taking motorised modes. On the contrary, Chia et al. (2016) showed that seniors walked shorter distances than younger people to reach public transport systems in Brisbane (Australia), affecting to its accessibility levels. Lord et al. (2011) also found that seniors from Brisbane had more difficulties to participate in the social life of its community when the access to car was limited, signalling the need for increasing non-motorised levels among seniors in comparison with other population groups. While most of accessibility studies identified seniors as a genuine group, it is almost unexplored how those accessibility standards can vary within this group and its consequences for policy-making.

3. THE CITY OF GRANADA IN SPAIN

Granada is a medium-size city (232.770 inhabitants) located in the southern Spain (Figure 1). The city shows a strong increase of the senior population during the last decades. Specifically, the demographic cohorts of people over 55 years old have experienced an increase of 20.000 individuals in 20 years, supposing a total of 34.5% of the population in 2020 (INE, 2020). The spatial distribution of seniors across the case study is not homogenous. The neighbourhoods with the highest rate of seniors (greater than 35%) are historical places, located in the city centre. Conversely, peripheral neighbourhoods have experienced a positive population growth in recent years, predominating young and active-age population.

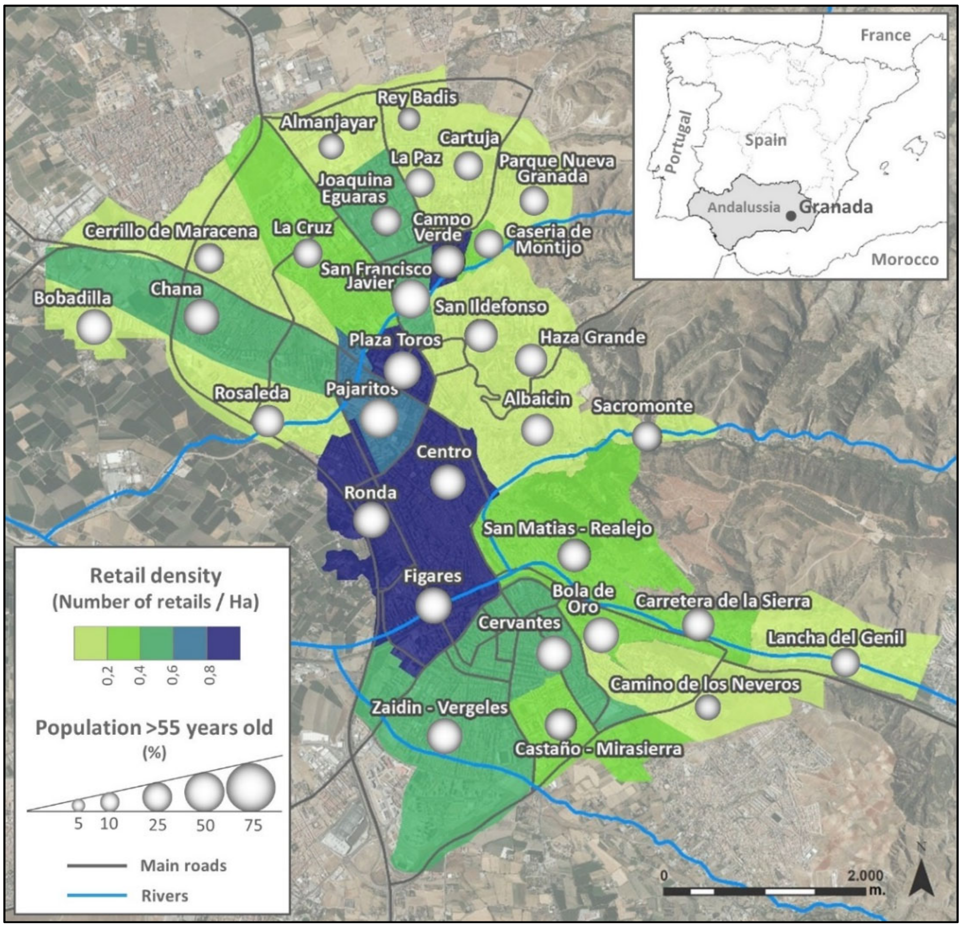

Figure 1: The city of Granada

Regarding transportation issues, short distances between population and destinations predominate across the city, providing with a good local environment to foster non-motorised transport modes. Non-motorized trips represent a total of 54% of local movements (PMUS, 2013). However, the rate of motorised trips has been drastically increased to approx. 80%, especially when trips take place between Granada and surrounding municipalities (The Metropolitan Area of Granada), where the main shopping centres are located. Shopping trips are almost a total of 38% of all local trips (PMUS, 2013). The density of retail activity decreases from the city centre to the periphery, where the new residential neighbourhoods located. Consequently, an important number of motorised shopping trips are originated from those neighbourhoods in the periphery to the city centre or to the surrounding shopping centres.

4. RESEARCH DESIGN

This research followed a three-stage approach (Figure 2):

- data gathering
- clustering analysis of seniors and comparison of its time-willingness decay functions
- calculating and mapping relative walking accessibility.

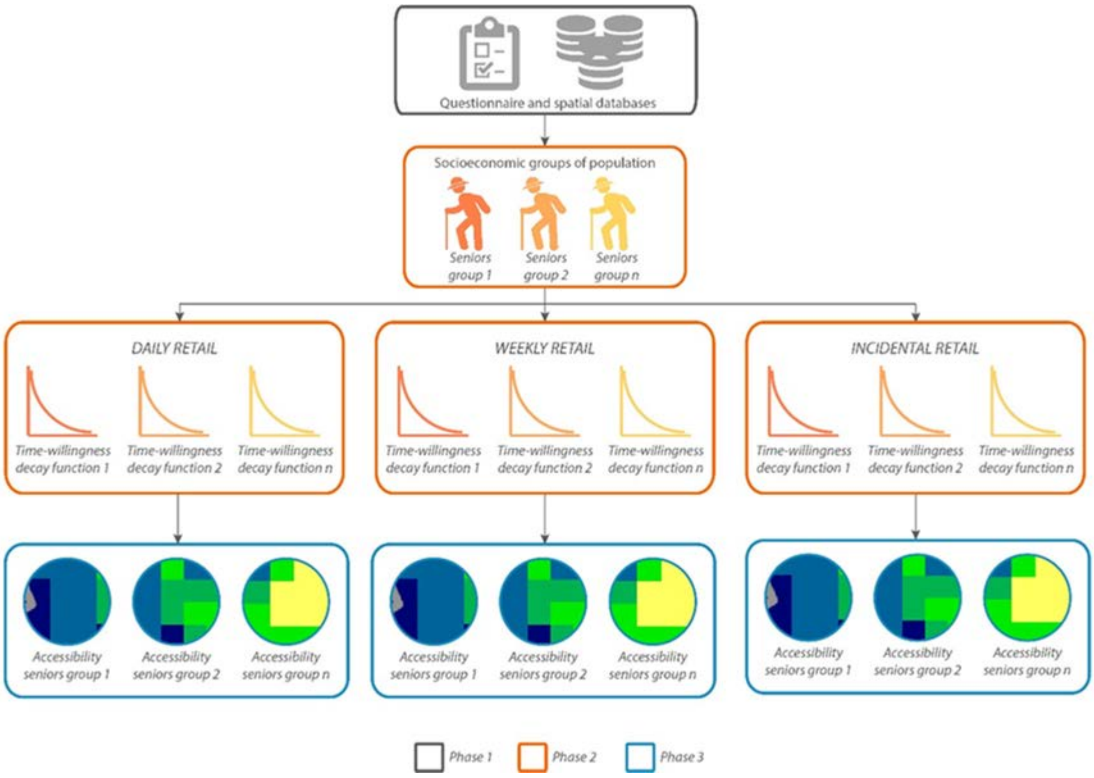

Figure 2: Methodological scheme

4.1. Data gathering

The main data source for this study was a questionnaire addressed to population over 55 years old. A total of 171 questionnaires were via face-to-face conducted visiting to the public active participation centres for seniors. Such centres were distributed equally across the city of Granada with a total of 6 centres, and all of them were visited during the fieldwork. The questionnaire was also disseminated online, obtaining a total of 31 responses. Totally, 202 valid questionnaires were collected, representing a 95% confidence interval with a bias of 5% in the context of the case study. Face-to-face interviews were especially relevant since the target population of study was seniors, who had limited access to online resources and a high rate of digital divide.

The questionnaire was structured in two blocks. The first block consisted of questions focused on demographic and socio-economic characteristics of the target group, such as gender, age, neighbourhood, household size, living alone, monthly household income, household car availability, educational level, and employment status. The second block of the questionnaire asked to seniors for their time-willingness to reach daily, weekly, and incidental retail locations on foot. Daily retail included food store, butcher, charcuterie, greengrocers, bakery, fishmonger, supermarket, and kiosk. Weekly retail included bazar, drugstore, perfumery, pharmacy, DIY store, copy shop, tobacconist, herbalist, houseware store, stationer's shop, hairdresser's, barbershop, clothing store and shoe store. Finally, incidental retail included travel agency, car/motorcycle/bicycle rental, pet shop, comic store, car dealership, sports shop, electronic/informatics shop, florist, garden store, jewellery, toy store, bookshop, furniture store, music store, optics, orthopaedics, gift shop, souvenirs, and videogame store. An example of question was: "*Independently of the neighbourhood where you are currently living, how much time are you willing to spend to reach daily/weekly/incidental retail stores on foot?"*.

Additionally, spatial databases required to calculate accessibility indicators were both collected and manually digitised. A grid from the European Environment Agency was used as a spatial basis to represent accessibility values. Furthermore, a street network from the Spanish National Centre of Geographic Information was used to calculate the distance between origins and destinations. On the other hand, retail locations were manually digitised from a databased developed by the Andalusia Regional Government, and cross-checked with Google Maps and Open Street Maps, yielding a total of 2,929 retail locations.

4.2 Clustering analysis of seniors and comparison of distance-decay functions

Clustering techniques were employed to group seniors into homogeneous socio-economic groups of population. Those groups were the basis for both analysing time-willingness decay functions and conducting accessibility analysis. A k-modes algorithm was used due to the categorical nature of the data involved. During the process, special attention was paid to the choice of the variables that would characterise those population groups as well as the optimal number of clusters.

Regarding the choice of the variables for the clustering process, it was calculated Pearson correlation coefficients at $p<0.05$ level between socio-demographic variables to assess the relationships between them, being the most correlated variables discarded. It was noticed that age, monthly household income, household car availability, and living alone were the less correlated variables, and therefore, the most suitable for the clustering process.

On the other hand, the choice of the optimal number of clusters was based on the gap-statistic method, which compares for different numbers of clusters the total intra-cluster variance observed and it finds the value with which the cluster structure obtained is as far as possible from a random uniform distribution. An error bar analysis with a confident interval of 95% was carried out to check the suitability of the clusters to the sample. This has allowed a correct definition of the socioeconomic groups based on the representative variables.

Time-willingness decay functions to reach daily, weekly, and incidental retail were empirically obtained for each socio-economic cluster from the questionnaire, being a total of 12 walking time-willingness decay functions. The mentioned functions were statistically compared to identify time-willingness thresholds between the socio-economic clusters by using the following process:

- The first step consisted of the simultaneous comparison of the absolute values of time-willingness between clusters. To address this step, the non-parametric Kruskal-Wallis test was used. Significant differences at $p<0.05$ level indicated that at least one socio-economic cluster had its time-willingness decay function significantly different to other clusters for any time-willingness slot.
- If no significant differences were found during the first step, the second step consisted of the simultaneous comparison of the percentile values of time-willingness between clusters. This allowed the identification of statistical differences between clusters within a specific time-willingness slot.
- Finally, the non-parametric Mann-Whitney U test was used to analyse pairs of time-willingness decay functions for those cases where differences at $p<0.05$ level were obtained for the Kruskal-Wallis test during steps one or two.

4.3 Calculating and mapping relative accessibility

Relative accessibility to retail locations for each socio-economic group was calculated by using a gravity-based model (Equation 1), meaning that access indicators are based on the distance between origins and destinations, weighted by both the availability of retail stores at the destination and the time-willingness decay functions of each cluster. Accessibility was calculated for daily, weekly, and incidental retail.

$$GA_i = \Sigma_{j \neq i} E_j e^{-\beta X_{ij}} \quad (1)$$

where A_i is the accessibility for zone i; E_j is the number of stores at destination j; X_{ij} is the distance, along a street network, between origins and destinations, and β is the parameter of the time-willingness decay function.

5. RESULTS

5.1 Clustering and distance-decay analysis

The population sample included a higher number of women (56%) than men, and the average age of the respondents was 69 years old. A total of 79% of individuals reported to be retired, while 83% of participants indicated that they had some type of motorized vehicle. The most common monthly family income was between 1000-2000 €, while at least a total of 20% of the respondents declared to live alone (mostly women). Regarding transport modes choices, 88% of seniors stated to go to daily retail stores on foot. However, that ratio was lower for reaching both weekly (66%) and incidental retail destinations (44%).

From the described sample, a total of four socio-economic groups were identified by using the K-modes algorithm and according to the following variables: age, motorized vehicle availability at home, monthly household income, and whether seniors lived alone or did not (Figure 3). Cluster#1 was labelled as “the non-motorised seniors”, including people between 65-75 years old, most of them had not vehicle availability at home, their average monthly household income was around €1000-2000, and mostly they did not live alone. Cluster#2 was called “the motorised seniors”. That is population who were 65-75 years old, with motorised vehicle availability (usually car), with a high monthly household income between €3000-5000, and who usually did not live alone. Cluster#3 were nominated as “older seniors”. Their ages were over 75 years old, without motorised vehicle availability at home, with a low monthly household income (<€1000), and most of them were living alone. Cluster#4 were labelled as “younger seniors”. Their age range was 55-65 years old, with availability of a motorised vehicle at home, medium-high monthly household income (€2000-3000), and rarely lived alone.

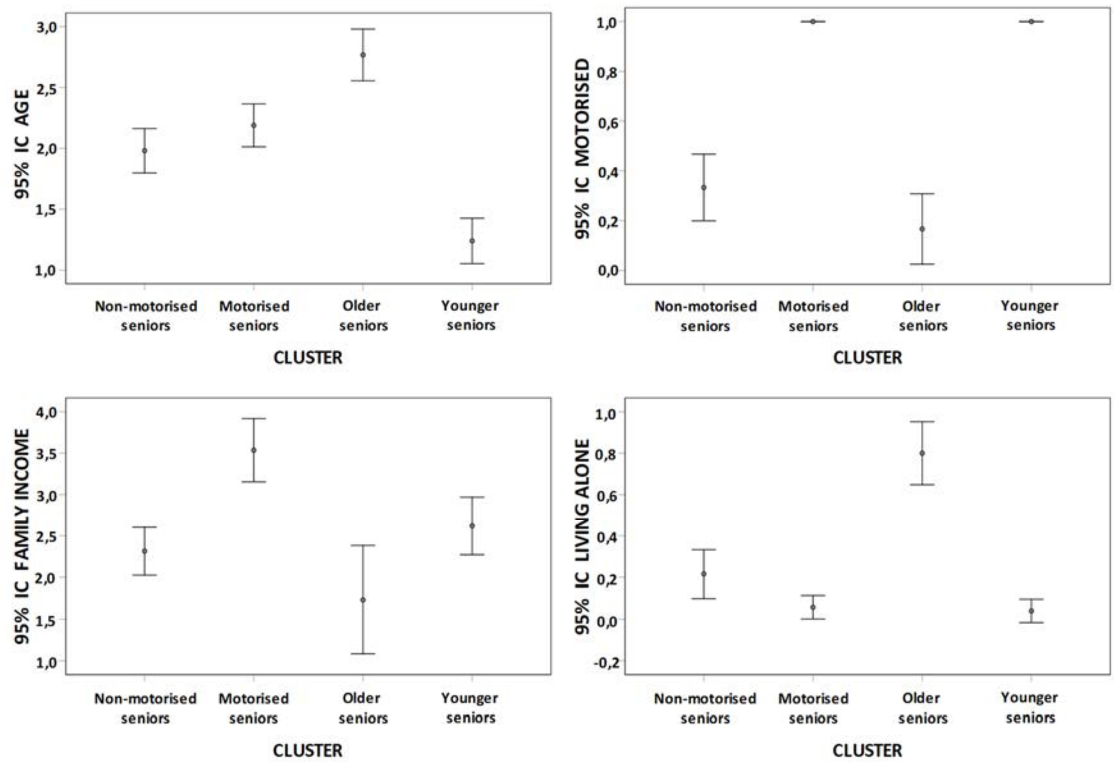

Figure 3: 95% IC error bars by cluster and socio-economic variable

For each socio-economic group, the time-willingness decay functions for walking to daily, weekly and incidental retail were empirically obtained by using the questionnaire described in the methodological section. When analysed the absolute values of the time-willingness decay functions with the Kruskal-Wallis test, significant differences at p-level 0.05 were not found to any type of retail (daily, weekly, and incidental). That meant that there were no differences when the full range of time-willingness decay function was studied. Accordingly, percentiles of time-willingness for walking were then analysed by using again the Kruskal-Wallis test. That would facilitate the identification of significant time-willingness differences for specific time-slots. For both daily and incidental retail significant differences were not found for any particular time-slot (Figure 4a and Figure 4c).

In the case of daily retail, it was seen that the time-willingness decay functions were very similar between the four population clusters. In all cases, participants were not willing to walk more than 15 minutes to reach daily retail locations, as it was generally assumed that daily retail should be located very close to residential areas in the case study. The need for daily retail proximity was especially relevant for the group of “non-motorised seniors” (C#1), since 94% of them are only willing to walk 10 minutes. Most of respondents from the four socio-economic clusters declared that they usually reached daily retail on foot. All clusters preferred local small stores followed by medium-sized stores (e.g., supermarkets) for daily retail. It was also signalled how seniors felt more confident buying in retail stores located in their own neighbourhood and knowing the shopkeeper. No differences between socio-economic clusters were seen in that respect.

For the incidental retail, differences were not found for any particular time-slot. Most of people from the different socio-economic groups stated to be willing to walk until 30 minutes to reach incidental retail destinations. Those average time-willingness were higher than the rest of the retail types because of the infrequent use those stores. Some differences were seen according to the modal choice to reach retail between the clusters. On the one hand, the "non-motorised seniors" (C#1) and the "older seniors" (C#3) opted for reaching incidental retail on foot and by using the public transport, as individuals from those groups tended to go to small and medium stores highly dispersed around the city. On the other hand, the "motorised-seniors" (C#2) and the "younger seniors" (C#4) preferred using the private vehicle to reach bigger shopping centres where incidental retail was mainly concentrated in one single place. Nevertheless, the average to walk to incidental retail were similar between groups of seniors, independently of the mentioned differences regarding modal choice preferences.

The analysis of time-willingness by percentiles showed significant differences for weekly retail. Results showed statistical differences in the time-willingness slots between 20 to 30 minutes, as well as for the 60 minutes (Figure 4b). It indicates that at least one socio-economic cluster had a walking time-willingness decay function significantly different from the other clusters within those time-willingness slots. The results for the Mann-Whitney test, used to identify significant differences between pairs of time-willingness decay functions for weekly retail, shown that the time-willingness decay function for "the younger seniors" (C#4) was significantly different from the other clusters for the 20 to 30 min slot (Figure 4b). This is especially relevant if we consider that 40% of the sample revealed that its willingness to walk to weekly retail was within that 20 to 30 min slot. On the other hand, for the 60 min slot, the distance-decay function for "the motorised seniors" (C#2) is significantly different from the rest of the clusters (Figure 4b). The "younger seniors" (C#4) had one of the lowest willingness to walk to the weekly retail. In particular, the percentage of people included in C#4, who were willing to walk more than 20 minutes to reach the weekly retail is very small compared to the rest of the groups. This suggests that, if weekly retail is located at a distance that takes more than 20 minutes to walk, there would be high probability that the "younger seniors" opted for motorised transport modes. The previous can be explained by the characteristics of the "younger seniors", who are mostly workers with family responsibilities, so they could have major temporary restrictions in comparison with the rest of senior groups. In addition, the "younger seniors" declared to go more often to weekly retail than the rest of the groups, which increases the need for establishing policies that facilitate the non-motorised access of the "young-seniors" to the weekly retail.

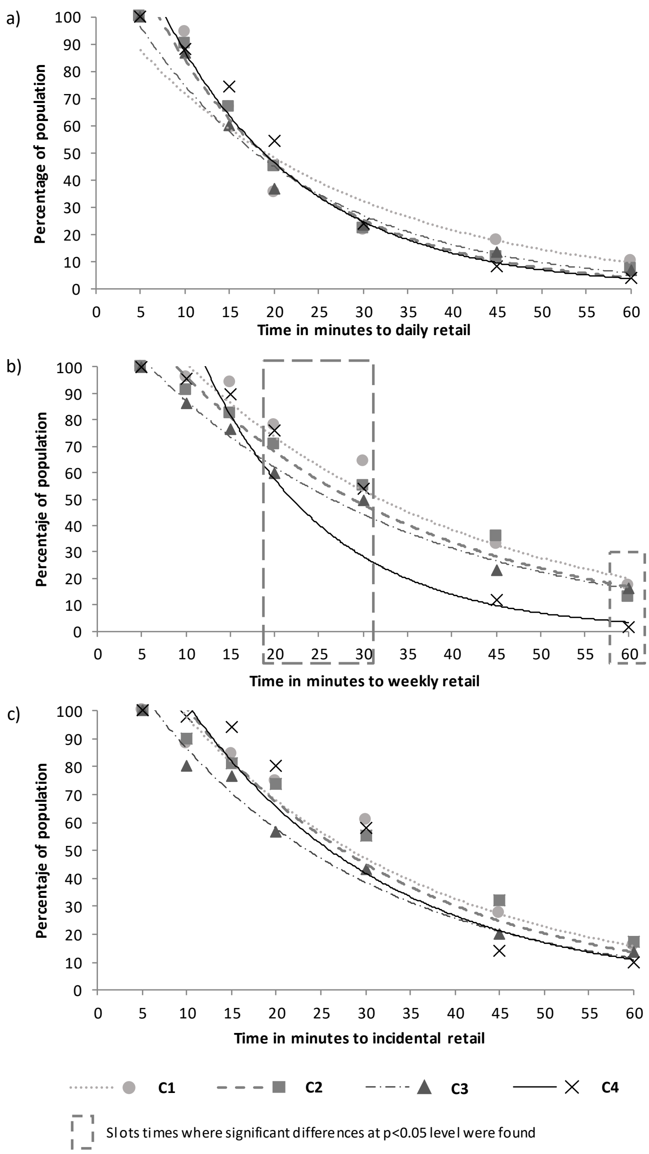

Figure 4: Time-willingness decay functions for daily (a), weekly (b), and incidental (c) retail.

5.2 Mapping relative accessibility

A gravity-based model was used to spatially show the accessibility to weekly retail, as statistical differences were found for this type of retail (Figure 5).

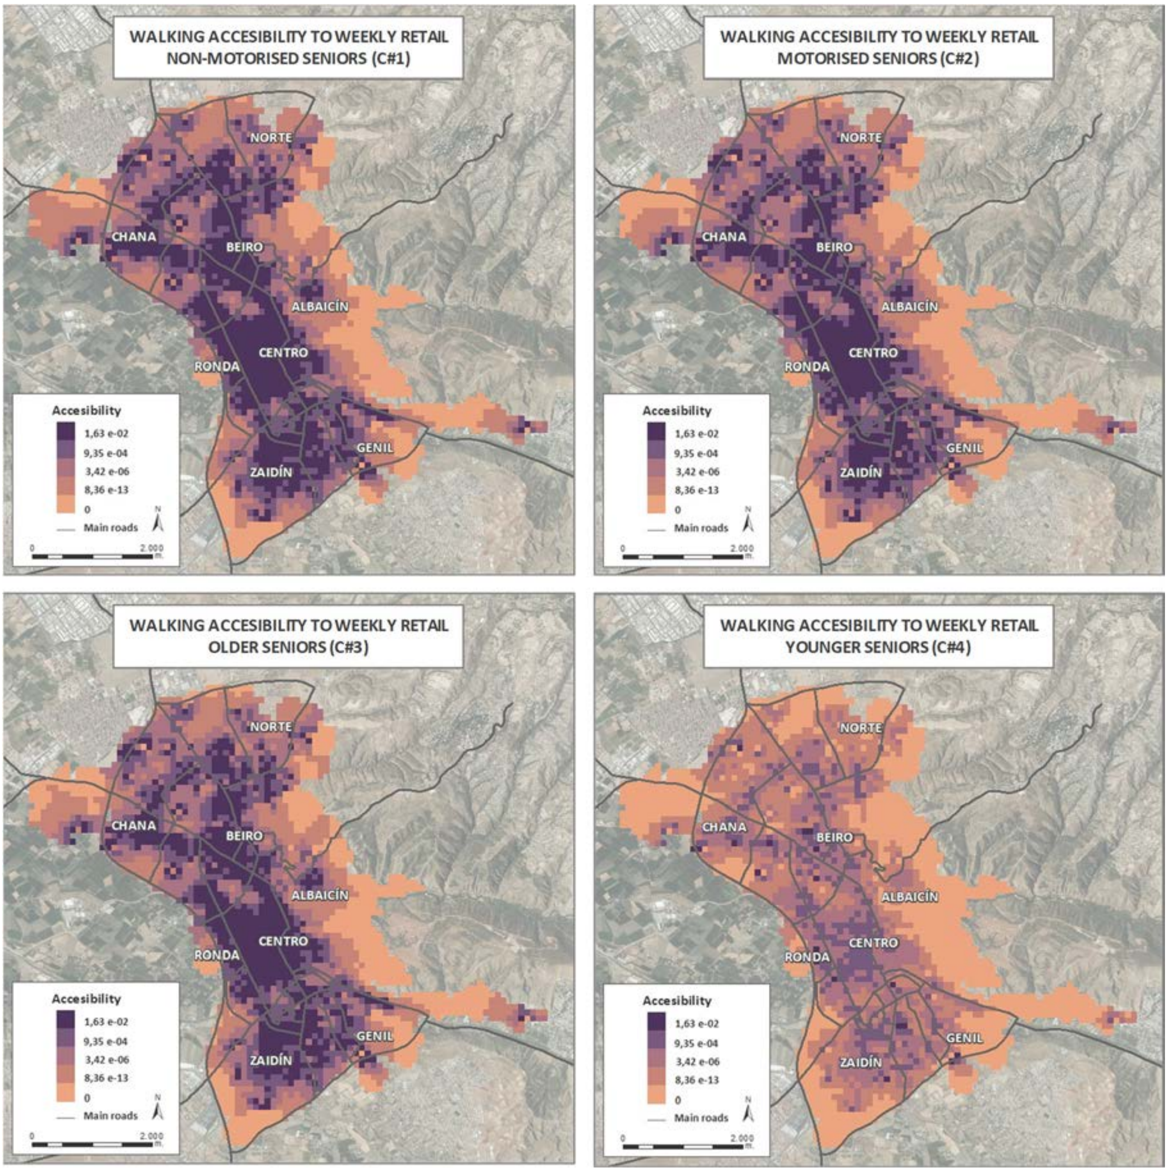

Figure 5: walking accessibility to weekly retail for the four clusters

Results show potential neighbourhoods with risk of presenting higher motorised rates to reach weekly retail, being geographical areas needed for the implementation of policies that foster a transition towards increasing walking accessibility levels to weekly retail. It was noticed that the less willingness to walk to the weekly retail of “younger-seniors” resulted in a loss of accessibility to weekly retail throughout the city. That is particularly relevant in the city centre, where “younger seniors” are less concentrated that the rest of ageing groups. However, weekly retail is highly present in that city centre, resulting in a strong increase of motorised trips from the “younger-seniors” to reach weekly retail.

Spatial analysis also identified places with low levels of walking accessibility to weekly retail for the four socio-economic clusters simultaneously. That is the case of the central-eastern zone. Those neighbourhoods have an important touristic activity and weekly retail does not predominate. However, such accessibility levels to weekly retail are also low in other residential neighbourhoods such as Genil, Chana, and Realejo. In those cases, the situation supposes a challenge for policy makers because of the ratio of senior population is high, leading a higher likelihood of weekly retail trips to the city centre. Policies that enhance the location of weekly retail in the mentioned neighbourhoods, as well as the promotion of pedestrian itineraries to the city centre would facilitate a reduction of traffic congestion in the city centre.

6. CONCLUSIONS AND DISCUSSION

The present research explored the following research questions: *to what extent is walking accessibility to retail activities similar for different socio-economic groups among the senior population?* Obtained results conclude that walking accessibility is significantly different for the case of weekly retail between the four studied clusters of seniors, while it is quite similar for both daily and incidental retail. In particular, it has been evidenced the existence of time-willingness thresholds in the slot between 20-30 minutes to access to weekly retail for the “younger seniors” in comparison with the rest of seniors, who have a significantly less willingness to go to this type of retail on foot for that time slot.

This research has revealed a strong preference between seniors for reaching different types of retail on foot in Granada, especially for “the motorized seniors”, “the non-motorized seniors”, and “the older seniors”. A total of 88% of participants declared to walk to daily retail, 66% to weekly retail, and 44% to incidental retail. Those results diverge from other studies that highlight the high dependence of motorized accessibility to major locations among seniors (Ricciardi et al., 2015). On the contrary, it represents a strong basis for obtaining sustainable planning outcomes in the mid-term in the case study, assuming that around 30% of population in the south of Spain will be over 65 years old (Soria-Lara and Banister, 2017). For that reason, future urban designs should facilitate walking itineraries for seniors (fundamentally for people over 65 years old), avoiding obstacles, stairs, and any other physical barrier that can impede the walking transit. Mapping those physical barriers and designing policies to overcome them are key issues to foster an effective transition towards lower carbon mobility in the city of Granada.

As seen in previous studies, seniors located in peripheries of cities are under situations of disadvantage accessibility in comparison with seniors living in the city centre (Páez et al., 2010). That also happen for walking accessibility to retail in the case study analyzed. On the one hand, the group of “younger seniors” predominate in those locations and they are group with the lowest willingness to reach retail on foot. On the other hand, peripheries use to have a poor dotation of retail (especially weekly retail), which foster motorized trips between the external neighbourhoods of the city and its centre. Representative examples of that situation in Granada are the neighbourhood of Chana and Zaidin. The implementation of policies that encourage the location of new retail in peripheries could help to solve this situation (e.g., reduced taxes), as well as carrying out policies that restrict the access of motorized vehicles to the city centre triggering a higher number of local and short-distance trips.

It was seen how preferences to reach retail on foot was highly related to the presence of small and traditional stores across the city. All socio-economic clusters with the exception of the "younger seniors" declared its preferences for buying in traditional stores, while "younger seniors" preferred using private vehicles to travel to mall shopping centre for weekly retail in the peripheries of the city.

In this respect, legal regulations that protect the small and traditional stores should prevail because of they are one of the most important source of non-motorized trips in Granada. In this respect, e-commerce is also an on-going threat, but it is still unexplored its impact on the time-willingness of seniors to reach retail on foot.

The obtained findings also open new research horizons. For example, by comparing how relevant is the size of the city in the time-willingness of seniors to reach retail on foot, and by analysing how e-commerce can affect to the walking accessibility. Furthermore, the use of living labs by implementing track systems can be another important source of knowledge to understand more in-depth how the walking accessibility of seniors is different for other groups and what to do to foster it.

ACKNOWLEDGEMENTS

This research has been developed in the context of the research project "TRANS-URBAN: Simulación de escenarios colaborativos para integrar políticas de transporte urbano sostenible y usos del suelo". The project was funded by the Spanish Government under National R+D Plan (2018–2020) JCR. Grant Agreement no. CSO2017-86914-C2-2-P.

ABSTRACT

Santiago, the capital city of Chile, has seven million inhabitants in an area of 850 km2. This city has a metro network with seven lines extending 140 kilometers and transports approximately 2.6 million people daily. The bus system has undergone significant transformations over the last three decades. The most relevant change having been Transantiago, the public transportation system implemented in 2007 for Santiago, Child, which combines the use of Metro and buses (BRT). Metropolitan Mobility Network (called Red) is the latest version of the public transportation plan.

This paper aims to analyze the current subway infrastructure using the continuous approximation method for Santiago, Chile. We previously proposed a macroscopic methodology to identify the needs for an adequate level of service in urban mobility and transportation, and we applied it to Santiago's Metro network. Our work focuses on functionality and demand distribution. Santiago's demand varies spatially in volume and extension throughout the city. Using the latest origin-destination survey from 2012, we deduct the critical components in this current network structure. It is worth mentioning that the metro design bases its network on a ring-radial structure.

With our macroscopic model applied to Santiago, Chile, we have detected infrastructure needs in the current transit network. The supply of infrastructure should increase for two reasons: first, to achieve balanced cost levels between users and the agency and second, to reduce subway occupations. The optimal model outcomes for Santiago define the optimal network in which the system requires five rings and ten end-to-end longitudinal lines (20 radial routes), including lower levels of occupation. The obtained results are a good preliminary solution, considering the subway infrastructure supply could be sub-estimated in the public transportation plan.

1. INTRODUCTION

Santiago de Chile is an extensive city of 850 km^2, with a population of 7 million inhabitants. The city's road network tends to have a concentric structure with the city's original principal roads crossing the city from East to West. However, only one of the rings proposed with the urban planning tools is in operation. Regarding public transportation, Transantiago is the urban public transportation system that operates in Santiago's metropolitan area, the Chilean capital city.

Transantiago is the result of a sequence of efforts by several governments to improve the public transport system since the early 1990s. Precisely, in 2007, the government launched the system that includes a network of trunk and feeder services whose structural mode is Santiago's subway called Metro, with an integrated and electronic payment system using the Bip card. Unfortunately, the operation exposed errors in design and implementation, which have attracted criticism so far. In 2019, Transantiago changed its name to Metropolitan Mobility Network (Red in Spanish) to improve the existing service.

Santiago's Metro is the articulated mode of transportation for Transantiago. The Metro transports more than 2.6 million people daily on its seven lines extending 138 kilometers and 136 stations. The Metro will continue to expand in the next decade, and is expected to reach 220 kilometers of extension with three new projected lines, lines 7, 8, and 9, in addition to the extension of existing lines 2, 3, and 4.

Several scientific works analytically study the operation of a transit system, e.g., classic articles such as Vuchic and Newell (1968), Wirasinghe and Ghoneim (1981), Chua (1984), and others. Some of these works analyze concentric cities using a structure of polar coordinates for radial networks, such as Haight (1964) and Smeed (1965, 1968).

In this paper, we analyze the current transit infrastructure in Santiago, Chile. The objective is to analyze the Metro network using a proposed macroscopic methodology to identify infrastructure needs to reach an adequate service level in urban mobility and transportation. The continuous approximation method uses analytical formulations and transit information from the latest origin-destination survey in 2012 to deduct the critical components in this current network structure. Our work focuses on functionality and demand. We assume that demand varies spatially in volume and extension over the city. A balance between user and agency costs provides the most efficient network configurations. The city of Santiago has a heterogeneous distribution considering its demand and network distribution.

The next section presents the city of Santiago and its structure, delving into the public transportation network. After that, we explain the methodology, which we apply to the Santiago case. Finally, we present the outcomes and conclusions.

2. GENERAL FEATURES OF SANTIAGO, CHILE

2.1 Santiago's Metropolitan Region and its urban structure

Santiago, founded in the 16th century around the Mapocho River. Currently, Santiago also known as *Gran Santiago* is the capital of Chile. The city belongs to the Metropolitan Region of Santiago, which has six provinces. The province of Santiago is the central province, which has 32 city councils called *Communes*. Fig shows *Gran Santiago* includes these 32 zones plus two more zones: San Bernardo and Puente Alto. The last two zones belong to other provinces; however, these zones are considered as part of the city.

Regarding private transportation, Santiago concentrates 37% of the Chilean automobile market. The city has over eight hundred cars in which the car rate is one car per 7 inhabitants. The primary road is Bernardo O'Higgins Avenue, well-known as Alameda. This road lies from the southwest to the northeast direction of the city, connecting Los Pajaritos Avenue to the west and avenues Providencia and Apoquindo to the east (Fig).

Several longitudinal roads cross the main avenue from the north to the south of the city, e.g., General Velásquez, Panamericana, Independencia, Gran Avenida, Recoleta, Santa Rosa, Vicuña Mackenna, Macul, and Tobalaba. Finally, the ring road called Américo Vespucio surrounds the intermediate zone of the city (Fig).

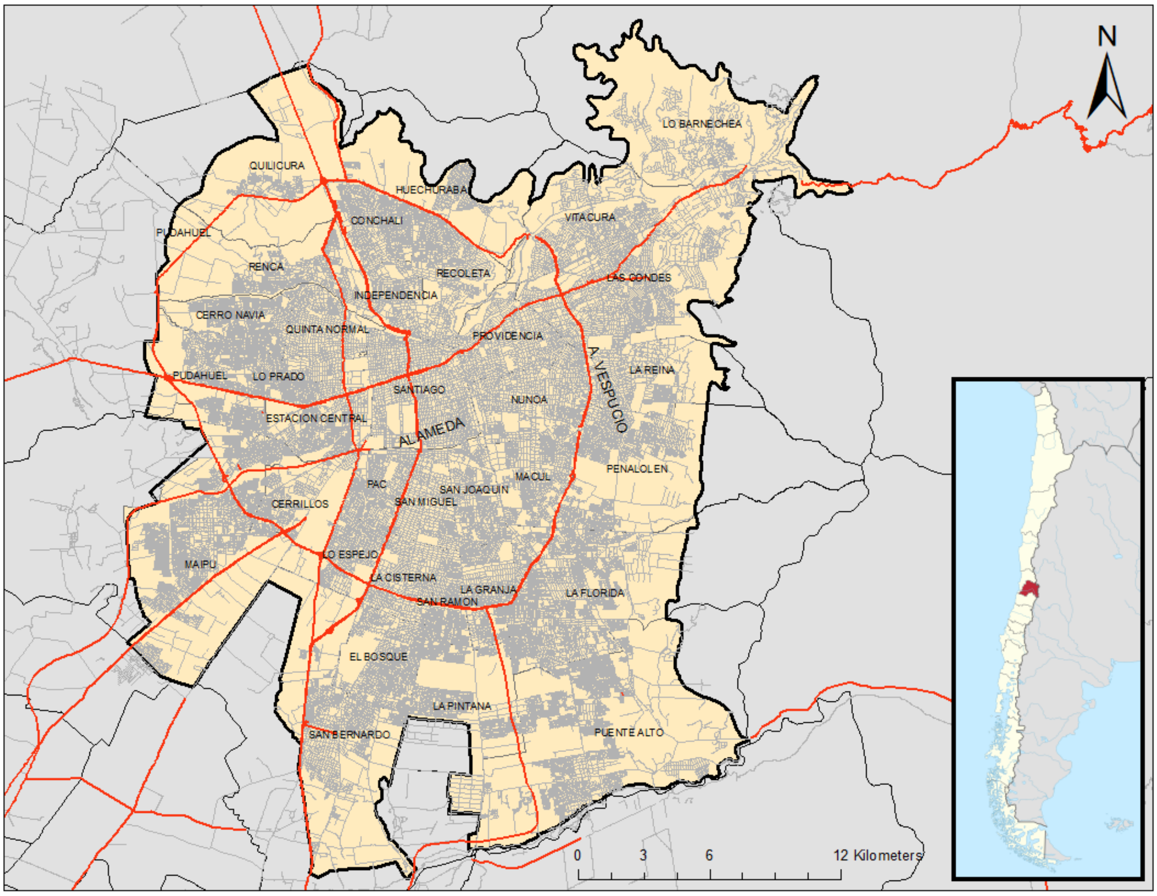

Figure 1: Map of Santiago's urban structure and primary road network.

Most of these roads are very old, even some of them are pre-Hispanic. The roadway had an intercity role from the founding city to other towns. In recent decades, the horizontal growth caused a conurbation of Santiago and the surrounding towns. The foundational Santiago is currently the central commune, a small area representing around 3% of Santiago's total area. Intercity roads become the primary urban roads of the city. Thus, Santiago's town tends to have a radial road structure, although urban planning in Santiago also has mixed development. The planning instruments in Santiago have defined several rings, but only one currently exists.

In 2000, Santiago began the construction of tendered urban freeways. First, Central Freeway runs inside the city from north to south using the old Panamericana road, incorporating General Velásquez Avenue. Second, Américo Vespucio Avenue changed into a freeway, and this road will soon be the first ring freeway in Chile. Third, the Norte Costanera freeway runs parallel to Mapocho River's riverbed and even runs under the river on a road segment. Subsequently, Santiago incorporates the San Cristóbal tunnel and the Access Northorient Highway. All freeways have a free flow toll system in an extension that exceeds 200 kilometers.

Furthermore, Santiago has a fleet of 25 thousand taxis and 11 thousand collective taxis. The latter refers to shared cars with a defined route. In recent years, Santiago promotes bicycles through an incipient network of bike-sharing and the investment of cycleways.

Regarding public transportation, Santiago has a transportation system with extensive subway coverage and buses. Moreover, it has a commuter train. The next sub-section presents information about those in detail.

2.2 History of Public Transportation in Santiago, Chile

Until the early 1970s, Chilean State maintained total control in the passenger transportation industry. The privatization of the urban transportation system began in 1975, increasing the bus fleet and, in the same way, the atomization of the system. In the same year, the first subway car operates a short stretch of the first line of the Chilean subway called *Metro*. Three years later (1978), the agency inaugurated a second metro line. By the early 1980s, the Metro was already an extension of 25 kilometers. On the other hand, surface transportation grouped small companies into Gremial Associations allowing a better operation to set fares and service routes (DTPM, 2019).

In 1989, Santiago's Metro became an independent company of the state apparatus. Metro continues to grow in the following years, incorporating a tunneling construction method without opening the surface and altering urban dynamics. The technique allowed the construction of Line 5 in 1997, starting the construction of Line 4 in 2002 and extending other lines.

On the other hand, the bus system has a new regulation process in 1990, unifying the atomized system through the *Yellow Buses* system. The new framework allows the fare integration between Metro and buses through a new service called Metrobus. The latter opened the system incorporating foreign companies in 2003, consolidating integration creating intermodal stations (subway & bus) in 2004.

The year 2003 began the urban transportation project called Transantiago, implemented in two primary stages. In the first phase, in 2005, the system incorporated the first articulated buses transforming transportation labor unions into traditional companies to operate the system. Also, the system created the financial manager (AFT). In a second phase, in 2007, Transantiago launched changes in all buses' network structure and fare integration. Moreover, it incorporates a single means of access and electronic payment called the *Bip* card. Finally, the system created a specialized unit dedicated to plan and coordinate the operation.

Transantiago covers an area of 2,353 km^2 called *Gran Santiago*. Initially, two sub-systems comprise Transantiago. The former is the trunk line network, whose basis is the Metro's network and bus services operating on the city's main roads, including BRT systems. The latter is the bus feeder network, consisting of local bus services operating on local streets of restricted geographical areas.

From 2010, the Chilean government adjusted the Transantiago system negotiating deals of transportation providers and complimentary services. The new deals came into force in 2012, eliminating the structure of trunk-feeder services and route exclusives for a company. Each company forms a business unit of transportation, which has a defined color. Moreover, 1,120 new high-tech buses entered with high levels of safety and comfort for users. In 2017, the suburban train service called Metrotren incorporated a train to Nos, which links Central Train Station with the southern part of the city.

In the following years, the system added new electric buses. Since March 2019, the transit aims to grow in quality by renaming the Metropolitan Mobility Network, known as the "*Red*" system.

3. PUBLIC TRANSPORTATION NETWORK STRUCTURE

Santiago has three modes of public transportation: subway (Metro), buses (BRTs and traditional buses), and a commuter train (*MetroTren*).

3.1 Metro network

Metro's current system has six lines. The opening of the last one (line 3) was in 2017. The future network plan incorporates three new lines and three extensions for old routes. Figure 2 presents the current subway network and the projected lines, including line extensions.

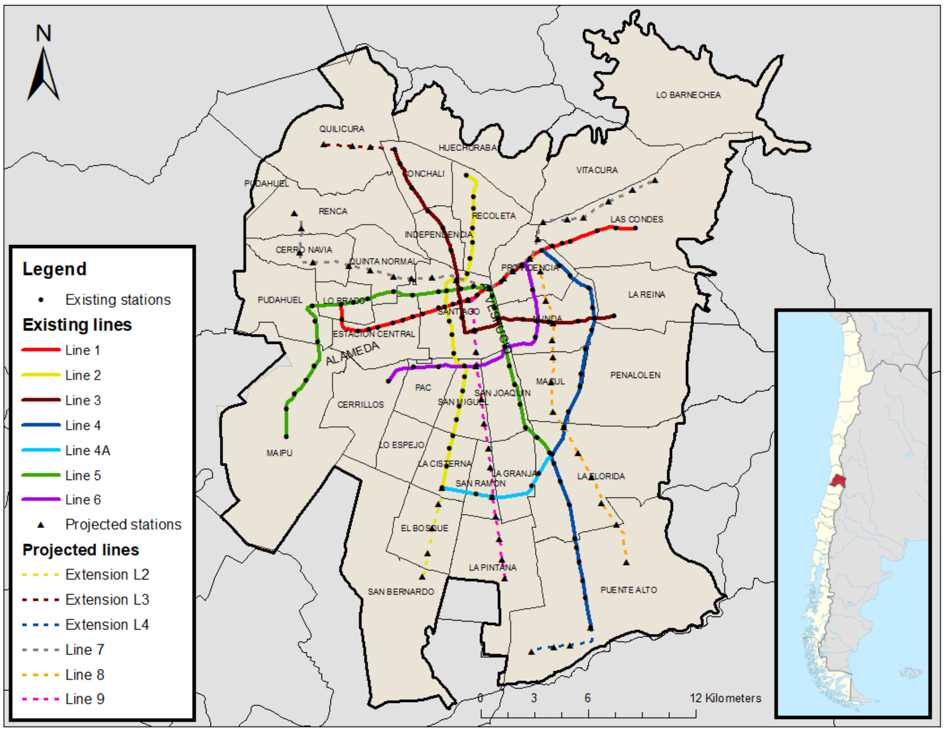

Figure 2: Metro network map: existing lines and future projects.

3.2 Buses network

Transit operators are transportation companies regulated by the National Ministry of Transportation and Telecommunications through the Executive Office called DTPM. Currently, the Red system has six business units, in which a company manages a set of bus services. The service identification is through numbers, letters, and colors. The buses meet the Euro VI emission standard or are electric. The most modern buses are red and white and have WIFI, USB ports and, air conditioning (DTPM, 2019).

The Santiago system has an infrastructure dedicated to bus services. The system has three infrastructure types: corridors, exclusive roads, and bus lanes (FiscalizacionMTT, 2019).

- Bus corridors: Roads include exclusive lanes for buses. These lanes are usually on the central zone of a road, separated from the other lanes. The objective is to increase the commercial speed of buses.
- Exclusive roads: Roads that transit services use exclusively at a schedule.
- Bus lanes: Lanes destined for buses located on the right side of a road, according to the direction of traffic operating at all times and days of the week.

Figure 3 shows the infrastructure dedicated to transit services. Santiago has 19 corridors (red lines), 11 exclusive roads (blue lines), and 53 bus lanes (purple lines). The figure shows that the infrastructure dedicated exclusively to buses has a radial structure from the city center without ring corridors. Moreover, the transit infrastructure reaches neither continuity nor high coverage in the city.

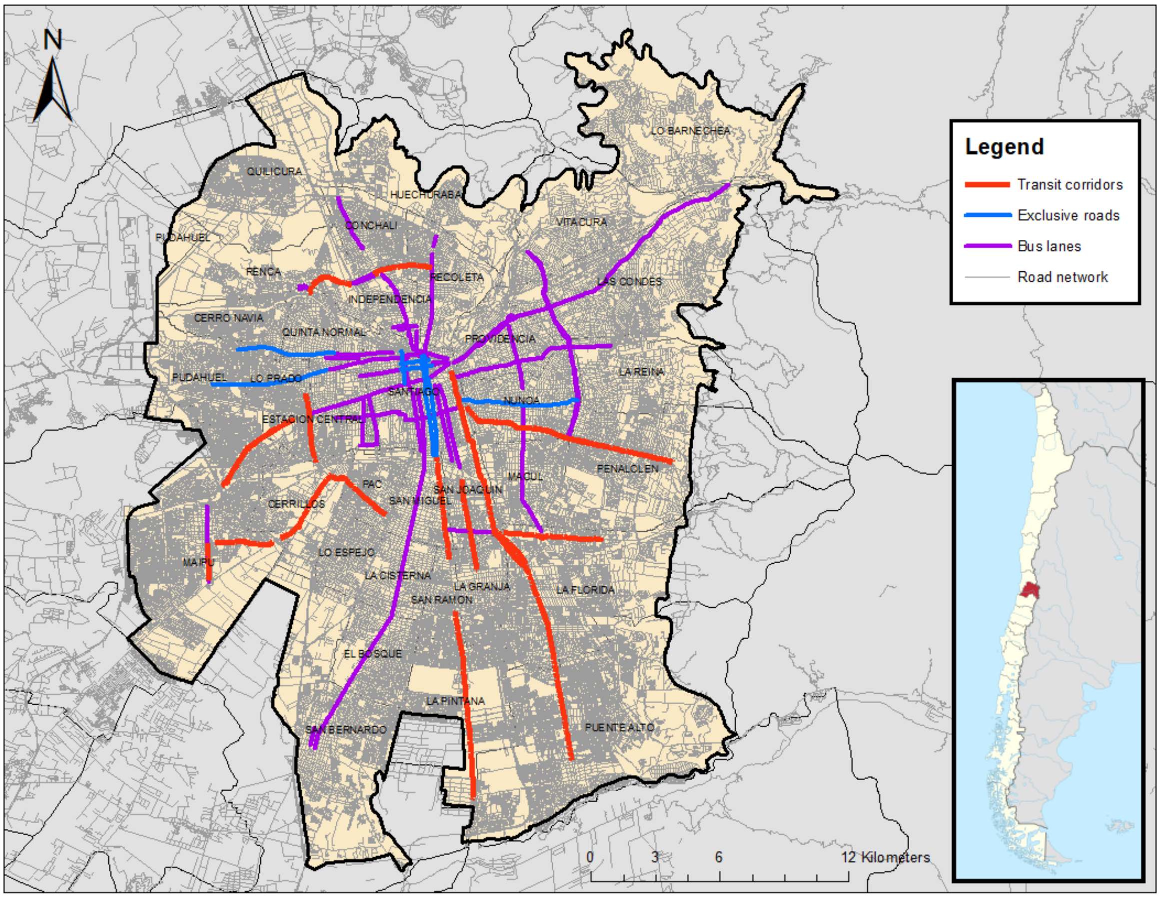

Figure 3: Buses networks: corridors, exclusive streets, and bus lanes.

4. METHODOLOGY

The mathematical model considers the continuous approximation (CA) method proposed by G.F. Newell. The method has applications for transit problems (e.g., Medina-Tapia, Giesen, & Muñoz, 2013; Medina-Tapia, Robusté, & Estrada, 2020, 2021), private transportation issues as well (e.g., Estrada, Salanova, Medina-Tapia, & Robusté, 2021; Medina-Tapia & Robusté, 2018, 2019), and logistics problems (e.g., Pulido, Muñoz, & Gazmuri, 2015).

The region of the modeling is a concentric city of radius R [km]. Santiago is not a perfectly circular city; thus, we adapted the urban area to the modeling but using the real parameters from surveys. The concentric city has ring and radial routes considering the rush hour of the city (P_m) as the period of analysis. We assume non-homogeneous continuous distribution over the city in which each point (r, θ) in polar coordinates has a different density value $D(r_f, \theta_f, r_t, \theta_t)$ in [user/km^4·h] represents the trip density distribution from a point (r_f, θ_f) to (r_t, θ_t).

4.1 Variables

The transit system's network design has four variables: two spatial variables and two temporary variables (Table 4).

Type	Route	Variable	Explanation
Spatial variables	Circular routes	$d^c(r)$	Distance between ring routes with a radius r [km/route]
	Radial routes	$\Phi^r(\theta)$	Distance as an angle between radial routes with an angle θ [radian/route]
Temporary variables	Circular routes	$h^c(r)$	Headway between vehicles at a ring route on r [h/veh]
	Radial routes	$h^r(\theta)$	Headway between vehicles at a radial route on θ [h/veh]

Table 4: Descriptions of decision variables.

4.2 Cost functions

The model formulation contains two components: user (T_T^u in [user·h/P_m]) and agency (C_T^a in [\$/P_m]) costs as show in Equation 1, where can also see that the travel time value (μ in [\$/user·h]) multiplies the user cost function.

$$TC_T = \mu \cdot T_T^u + C_T^a \quad (1)$$

4.2.1 User costs

The total time of users ($T_T^u = T_A + T_W + T_V + T_T$ in [user·h/P_m]) contains four functions (Equation 2): access (T_A), waiting (T_W), trip (T_V), and transfer time (T_T). These equations comes from Medina-Tapia et al. (2021). The time functions in Equation 2 represent the total time for each trip stage of a transit system. The calculation of these functions comes from the integration of the local time function over a circular region:

- Access time: Passengers lose time to get to the closest station or the destination from the origin. First, the demand in rush hour ($f^A(r,\theta) \cdot T$ in [user/km2·P_m]) is the density of users that board and alight at a station/stop during the rush hour. Second, the average accessibility time per user, $t^A(r,\theta)$ in [h], depends on the time perception and the average access time.
- Waiting time: The passenger density that boards a vehicle is $f_l^W(r,\theta) \cdot T$ in direction $l \in L$ during rush hour ([user/km2·P_m]). The average waiting time per passenger at a station is $t_l^W(r,\theta)$ in [h], which depends on the time perception factor and time headway of a service (Medina-Tapia et al., 2013).
- In-vehicle travel time: The total travel time depends on two components: the user load density in rush hour ($f_l^V(r,\theta) \cdot T$ in direction $l \in L$ in [user/km·P_m]), and the travel time per kilometer ([h/km]).

- Transfer time: Two factors comprise this local time function. The user density that transfers at a point (r, θ) to direction $l \in L$ ($f_l^T(r, \theta) \cdot T$ in [user/km2]) and the average transfer time function.

4.2.2 Agency costs

The agency cost has three components (C_T^a in [$/$P_m$]): capital ($C_K$), operational ($C_O$), and infrastructure cost (C_I). The last two costs have sub-components. The operational cost ($C_O = C_G + C_V$) includes the on-vehicle crew cost (C_G), and in-operation vehicle cost (C_V). The infrastructure cost ($C_I = C_P + C_S$) includes the linear (C_P) and nodal infrastructure (C_S). The explanations of Equations 2 are at Medina-Tapia et al. (2021).

- Capital cost: The cost value ($C_K = \sum_{l \in L} F_l \cdot \varphi^k$ in [$/$P_m$]) depends on the fleet in direction $l \in L$ (F_l in [veh]) and the cost per vehicle (φ^k in [$/veh·$P_m$]).
- Operational cost: First, the total salary ($C_G = F \cdot \eta^d \cdot T \cdot \varphi^g$ in [$]) is in proportion to three components: the fleet ($F_l, l \in L$), the number of work shifts on a vehicle (η^d), and the salary in rush hour ($T \cdot \varphi^g$). Second, the total operating cost (C_V in [$]) comprises two components: the number of vehicles that run on a corridor ($2T/h^c(r)$ or $2T/h^r(\theta)$ respectively), the operation cost per unit of distance traveled on a cruising speed (φ^o) considering the width of a transit corridor $d^c(r)$ or $\Phi^r(\theta)$.
- Infrastructure cost: The linear infrastructure cost (C_P) depends on the number of routes and its length of rings and radial routes ($\frac{1}{d^c(r)}$ or $\frac{1}{\Phi^r(\theta) \cdot r}$ in [km·route] in direction $l \in L$), and the unitary cost (φ^p in [$/km·route·$P_m$]). The unitary cost per km in the rush hour has a fixed component and another variable part ($\varphi^p = \varphi^{p(f)} + \varphi^{p(v)} \cdot T$ in [$/km·route·$P_m$]. The nodal infrastructure (C_S) depends on the number of intersections $\frac{1}{\Phi^r(\theta)} \cdot \frac{1}{d^c(r)}$ and the unitary cost φ^s in [$/station·route·$P_m$], considering each intersection has four stations or stops.

4.3 Problem formulation and optimization

The TNDFSP (transit network design and frequency setting problem) minimizes the system's total cost, taking a heterogeneous demand distribution into account. The formulation of the total cost of a transit system (Equation 1) in monetary units ([$/$P_m$] contains two components (Estrada, Roca-Riu, Badia, Robusté, & Daganzo, 2011): the user cost component (T_T^u in [user·h/P_m]), which is multiplied by the travel time value (μ in [$/user·h]), and the second component of agency costs (C_T^a in [$/$P_m$]).

$$Min\, TC_T = \mu \cdot (T_A + T_W + T_V + T_T) + (C_K + C_V + C_I) \quad (2a)$$

$$\max_{\theta, l \in \{c_c, c_a\}} \left(f_l^V(r, \theta) \cdot d^c(r) \cdot h^c(r) \right) \leq K^v \quad \forall\, r \quad (2b)$$

$$\max_{r,l\in\{r_i,r_o\}} \left(f_l^V(r,\theta)\cdot\Phi^r(\theta)\cdot(R+r)/2\cdot h^r(\theta)\right)\leq K^v \quad \forall\,\theta \tag{2c}$$

$$d^c(r)\geq K^{d(c)} \quad \forall\, r \tag{2d}$$

$$\Phi^r(\theta)\geq K^{d(r)} \quad \forall\,\theta \tag{2e}$$

$$h^c(r)\geq K^h \quad \forall\, r \quad (2af$$

$$h^r(\theta)\geq K^h \quad \forall\,\theta \tag{2g}$$

The problem framework is a fixed spatial transit system whose mathematical problem is a nonlinear system that includes inequality constraints.

First, the problem has four decision variables ($d^c(r), \Phi^r(\theta), h^c(r), h^r(\theta)$) according to the spatial and temporal deployment of resources. In this problem, the fixed variables do not change along a corridor. Second, the problem has three sets of constraints. The first of these (Equations 2b and 2c) ensures that occupancy does not exceed the capacity of each vehicle (K^v in [user/veh]). Second, the minimum distance between stations ensures that transit vehicles reach the cruising speed before arriving at the next station and can correctly brake (Equations 2d and 2e).

In the case of radial routes (Equation 2e)), $K^{d(r)} = K^{d(c)}/r_{min}$, where r_{min} is a minimum radius in which this constraint applies in [km/route] or [rad/route], respectively. Finally, the operator requires a minimum separation (time) between consecutive vehicles (TRB, 2013). Equations 2f and 2g ensure that the optimum frequency is feasible (K^h in [h/veh]).

5. RESULTS

The section has three parts. First, the section presents the parameters used in the modeling, including continuous demand density functions. Second, the section also presents the optimal solutions obtained from the model. Third, the section analyzes a comparison between the obtained optimal solutions and the metro network for Santiago, Chile.

5.1 Modeling inputs

5.1.1 Parameters

The modeling considers Santiago's urban shape approaching a concentric city, explained by Medina-Tapia et al. (2021). The modeled city has a radius of 15 km (R), and the rush hour lasts 1.5 hours (T). Table 5 shows the parameters in each stage of a trip, using the time perception from TRB (2013).

Demand parameters							
T [h]	α [dimensionless]	β [dimensionless]	γ [dimensionless]	δ [dimensionless]	v^w [km/h]	χ^T [m]	$v^a(r)$ [km/h]
1.5	2.2	2.1	1.0	2.5	3.0	40	$v^a(r) = 3.0 + 1.4\bar{6} \cdot r$

Operational parameters												
v^t	a^a	a^d	τ	τ'	τ''	τ'''	τ^s	t^f	η^d	K^v	K^d	K^h
[km/h]	[m/s²]		[s/station]					[min]	[shift/veh]	[user/veh]	[km/route]	[s/veh]
80	1.3	1.3	19.2	5	35	0	42.1	6	1	1,494	0.481	123

Economic parameters							
μ	φ^k	φ^g	φ^o	$\varphi^{p(f)}$	φ^p	$\varphi^{s(f)}$	φ^s
[$/user·h]	[$/veh]	[$/shift·h]	[$/km·veh]	[$/km·route·$P_m$]		[$/station·route·$P_m$]	
1.48	135.6	27	3.7	245.1	248.8	169.9	172.4

Table 5: Parameters used for user and agency cost functions.

5.1.2 Trip generation and attraction functions

The proposed model considers a concentric city, which has a public transportation system with two types of transit services: ring and radial routes. Santiago is a concentric city but does not have a perfect circular form; however, the modeling assimilates that the city has this urban form. The last Origin-Destination survey (MTT, 2012) sets over 700 zones for *Gran Santiago* city; however, the modeling simplifies zoning by dividing the city into 9 OD macro-zones: a central zone, four inner zones, and four outer zones (Fig). Table shows the information of subway trips at rush hour comes from the Santiago OD survey (MTT, 2012) using the OD grouping of the nine macro zones.

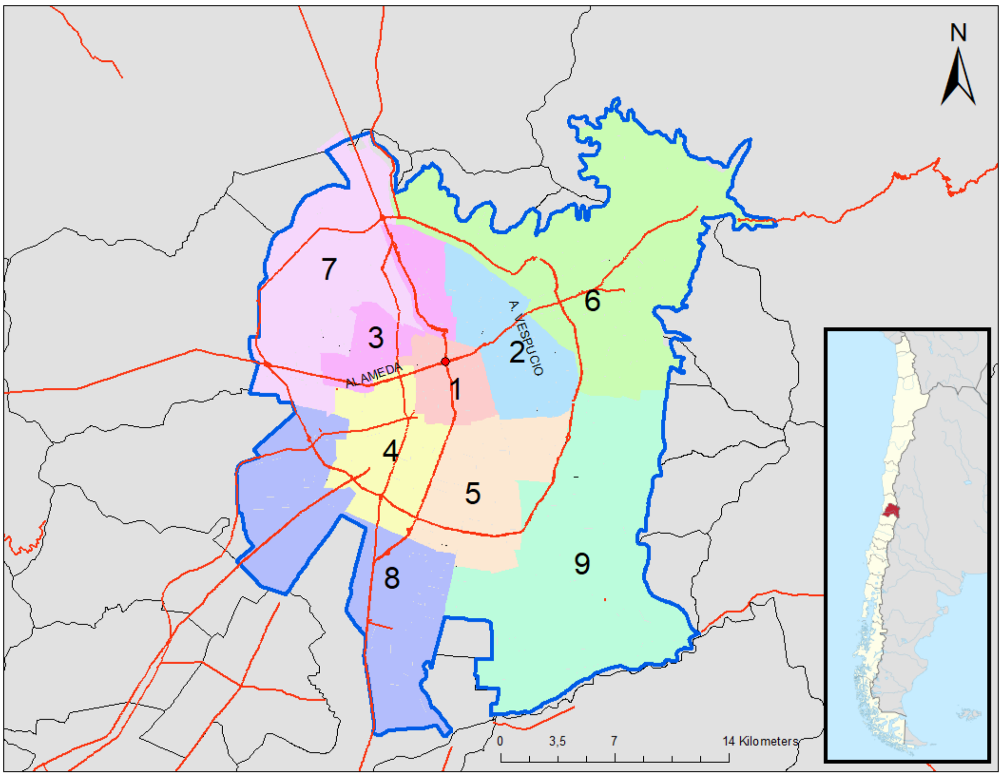

Figure 4: OD macro-zones used for the Santiago of Chile modeling.

Table 3: Santiago's OD macro-matrix in [trip/P_m] obtained from OD Survey (MTT, 2012).

The method calibrates a continuous function in which the total trips of each origin-destination (Table) is the value in the OD trip matrix (T_{ij} where i is the origin zone, and j is the destination zone), as shown in Equation 3. The coordinates $\theta^i_{f(2)}$-$\theta^i_{f(1)}$ and $r^i_{f(2)}$-$r^i_{f(1)}$ define the origin zone. Meanwhile, the coordinates $\theta^i_{t(2)}$-$\theta^i_{t(1)}$ and $r^i_{t(2)}$-$r^i_{t(1)}$ define the destination zone.

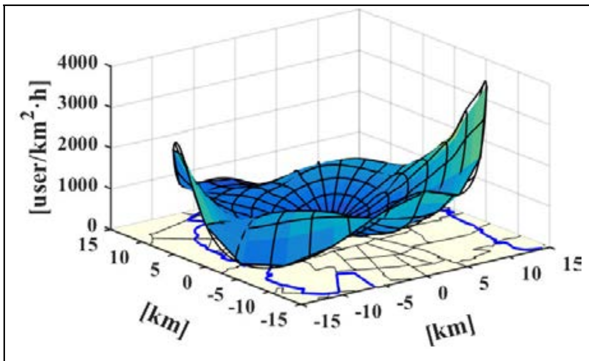
$$T_{ij} = \int_{\theta^i_{f(1)}}^{\theta^i_{f(2)}} \int_{r^i_{f(1)}}^{r^i_{f(2)}} \int_{\theta^i_{t(1)}}^{\theta^i_{t(2)}} \int_{r^i_{t(1)}}^{r^i_{t(2)}} D\left(r_f, \theta_f, r_t, \theta_t\right) r_t \, dr_t \, d\theta_t \; r_f \, dr_f \, d\theta_f \tag{3}$$

Using the function of Equation 3, we obtain the function of generated demand $\lambda(r,\theta)$ at a point (r,θ) in [user/km^2·h] (Equation 4, and attracted demand $\rho(r,\theta)$ at a point (r,θ) in [user/km^2·h] (Equation 5).

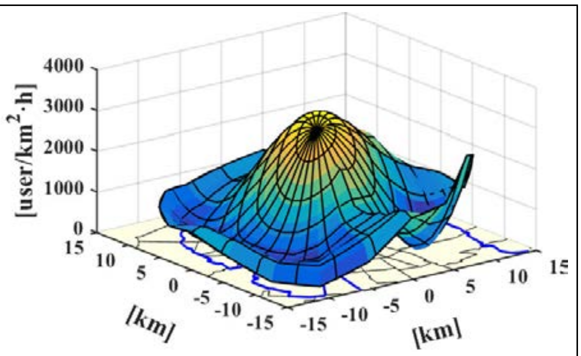
$$\lambda(r,\theta) = \int_0^{2\pi} \int_0^R D(r,\theta,r_t,\theta_t) \, r_t \, dr_t \, d\theta_t \tag{4}$$

$$\rho(r,\theta) = \int_0^{2\pi} \int_0^R D\left(r_f,\theta_f,r,\theta\right) r_f \, dr_f \, d\theta_f \tag{5}$$

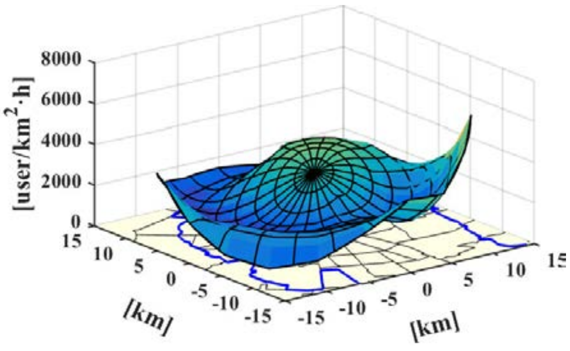
Fig 5 shows the functions of trip generation (Fig (5a)) and attraction (Fig (5b)) obtained from Equations 5. Fig (5c) represents the total trip density function, i.e., the sum of generated and attracted demand functions.



(a) Trip generation function



(b) Trip attraction function

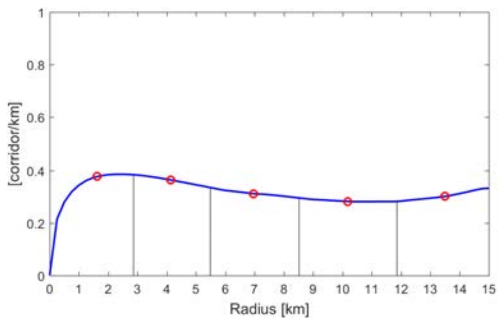


(c) Total trip function

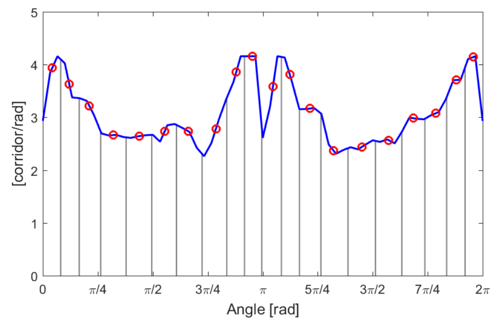
Figure 5: Functions of trip generation and attraction estimated from Santiago's OD matrix (MTT, 2012).

5.2 Optimal solutions obtained from the model

The problem formulation is optimized using KKT conditions. Each point has an optimal solution of density and headway for ring and radial routes. Fig 6 presents the optimal transit density profiles for Santiago, Chile, obtained from the model. The blue line in Fig (6a) represents the optimal ring route density, and Fig (6b) represents the optimal solution for radial routes. The red points represent the optimal location of a route obtained from the discretization process. From optimal transit densities, Fig (7a) shows the macroscopic scheme of transit corridors for Santiago, Chile. Fig (7b) contains the optimal network structure in which a label on each route shows the optimal headway in minutes and the fleet size in trains for rings and radial routes.

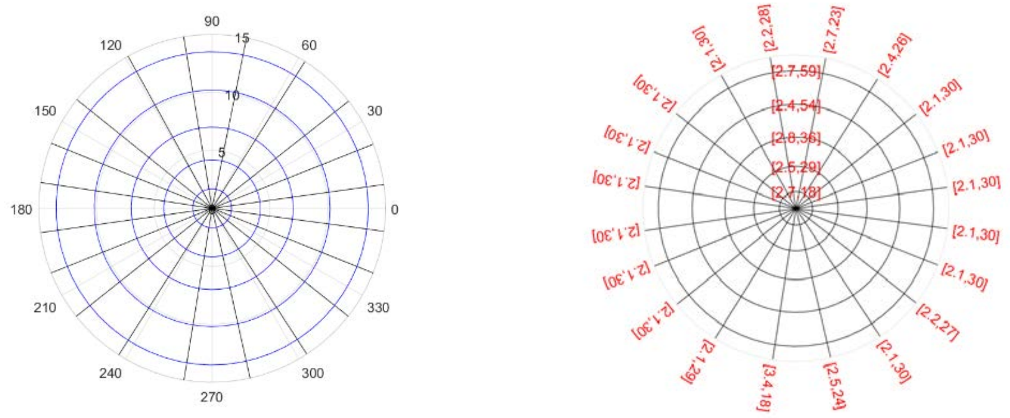


(a) Ring routes



(b) Radial routes

Figure 6: Optimal density profiles for Santiago, Chile.



(a) Optimal transit structure (b) Optimal headways

Figure 7: Optimal transit network scheme for Santiago, Chile.

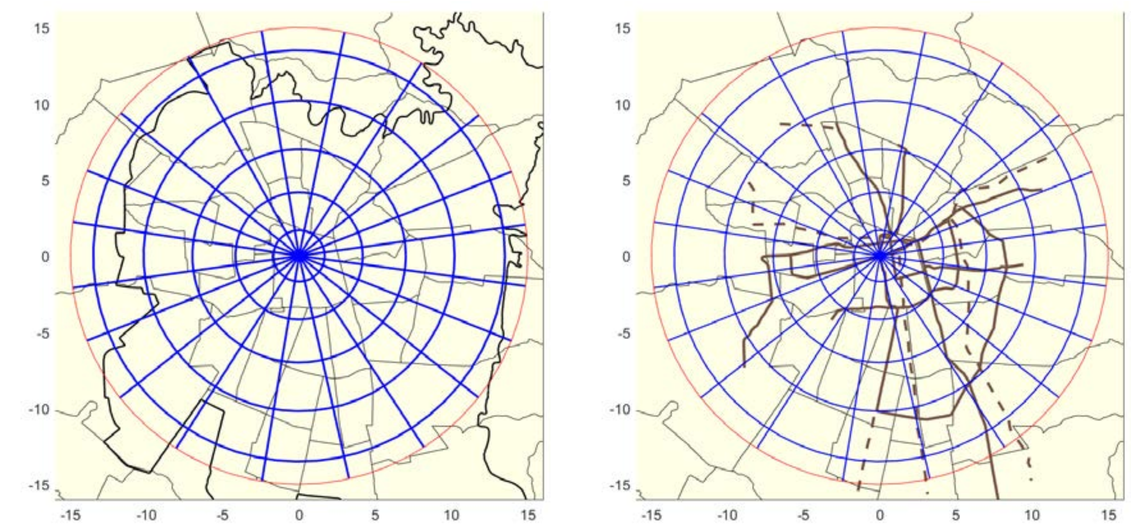
Note: In Fig(b), [X1, X2] in red represents the optimal operation attributes in which X1 is the time headway in minutes and X2 is the fleet size in trains for each route defined optimally.

Regarding ring routes in Fig (7a), the model proposes five transit corridors, whose distribution is slightly higher around the city center. Regarding radial routes in Fig (7a), the model proposes 20 corridors with non-homogeneous distribution with higher density in three zones: East zone (above 0 radians, including Providencia and Las Condes *communes*), West zone (above and below π radians, including Estación Central, Maipú, Pudahuel *communes*), and Southeast (below 0 radians, including La Florida and Puente Alto *communes*). It is worth noting that 20 radial lines could represent ten lines from one side of the city to the opposite.

Regarding ring routes in Fig (7b), headways take on similar values between 2.4 and 2.8 minutes. However, the cycle times on each route are different considering the vehicle-kilometers traveled increases as the route approached the city periphery. Thus, the fleet size that needs a route increases from 18 to 59 trains. Regarding radial routes in Fig (7b), all routes have the same length, but the fleet size depends on the headway and the optimal ring density giving fleet needs from 18 to 30 trains. In a city whose transit vehicles travel long distances, slight headways modify the fleet size significantly.

5.3 Comparison between the optimal solution and Santiago's metro network

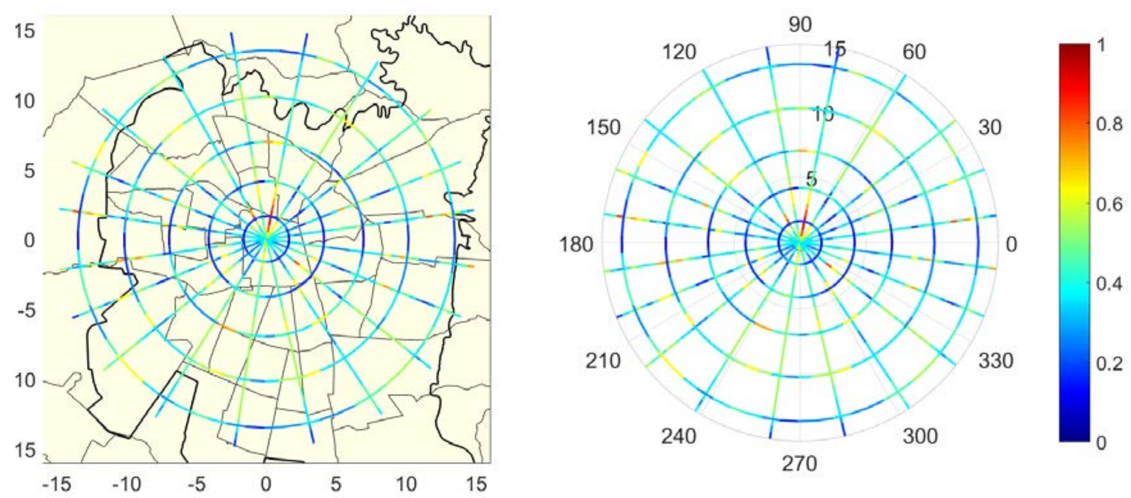
Fig presents a comparison between the subway infrastructure proposal obtained from modeling and future subway projects for Santiago, Chile.



(a) Optimal transit structure (b) Comparison of proposal and subway infrastructure

Figure 8: Comparison between subway infrastructure proposal and current and future projects for Santiago, Chile.

Fig (8a) shows blue lines representing the optimal transit structure, the red circle represents the analyzed area, and the map in the background shows the *communes* of Santiago city, Chile. Fig (8b) also includes the current infrastructure and the future subway projects as brown lines for Santiago, Chile, where continuous lines are existing infrastructure, and dashed lines are the future projects. Currently, Santiago's Metro has seven lines; however, it represents nine existing radial routes, including their extensions; meanwhile, the three new projected lines represent four more radial routes. Globally, the subway mobility plan proposes 13 radial routes, which should increase to 20 radial routes, according to the model. Regarding rings, the transit system only proposes two incomplete rings, which should increase to 5 ring routes.



(a) Santiago and occupation levels (b) Occupation levels

Figure 9: Map of occupation levels obtained from the optimal transit network.

From optimal transit densities, Fig (9a) and (9b) show occupation levels of transit routes for Santiago, Chile. The former overlays the optimal transit network with the map of *communes* of Santiago, Chile. Regarding occupation levels, rings have a maximum occupation of up 75%; however, the average occupation is around 25%. On the other hand, radial routes reach an occupation of up 92% with an average occupation around 37%. Therefore, the global transportation system is not stressed by high occupancy levels.

6. CONCLUSIONS

Santiago, Chile, has a consolidated subway network of more than 50 years with seven lines currently operating. The investment plan considers the extension of some of these lines and the construction of three future projects.

The modeling in the paper uses standard values of operating data. However, some parameters were adapted to the Chilean case, such as the value of time, the train capacity, and the transit demand. In this line, the continuous travel distribution function obtained from the travel matrix origin-destination between macro-zones allowed to represent the generation and attraction of trips. A territory does not have a staggered structure with breaks between two OD-zones boundaries. On the contrary, demand generally varies smoothly from one side of an OD zone boundary to the other side.

The model obtained a macroscopic proposal for subway infrastructure needs, i.e., the modeling applied a theoretical mathematical model previously presented, defining a relevant approach to determine the infrastructure needs for the city of Santiago. The proposed model for Santiago considers 5 rings and 20 radial routes. The comparison between this proposal and the current network plus the planned defines Santiago's infrastructure needs: 13 new radial routes (equivalent to 7 more lines) and four more rings.

Future studies could study complementing these central services with tram services, particularly in Santiago's central commune. It is worth noting that slight headway changes modify the fleet size significantly. The fleet size depends on the headway and the opposite optimal route density or transit stations for the modeling. The latter relates to the time spent due to users boarding, alighting, and others, increasing the cycle time.

The proposal network proposes lower occupation vehicle levels: the maximum occupation of rings is 75%, and radial lines have a maximum occupation of 92%. However, the average occupation of rings is around 25%, and the average radial occupation is 37%.

Therefore, Santiago, Chile, should increase infrastructure supply for the subway network in future strategic planning. The results are considered an interesting preliminary proposal; however, the research approach should be refined through complementary studies. These studies should consider information from all available origin-destination zones, periods, transport purposes, and others. Future studies should also analyze current services with complementary modes (e.g., tram services); and personal mobility modes within a sustainability framework.

ABSTRACT

Transport Scenario-Building is a well-established methodology to investigate strategic decisions for cities and its transport systems. It is often used to examine different futures where there is considerable uncertainty or where the business-as-usual is no longer appropriate. While the use of participatory approaches in Transport Scenario-Building has resulted in more democratic and implementable outcomes, the usefulness of those approaches is limited when the generation of disruptive transport futures and unusual policy solutions are considered.

This paper addresses the abovementioned issue by presenting a participatory approach aimed to obtain disruptive visions on land use and transport by 2050. The context of the Metropolitan Area of Madrid (Spain) is taken as case study. The novel approach incorporates disruptive factors about city futures - “wild cards”- during the participatory visioning process, triggering an unconventional thinking from participants. First, a total of 139 people were engaged by using semi-structured interviews on the future of land use and transport in the case study. Each semi-structured interview explored the desired future for each participant as well as disruptive futures according to “wild cards” previously established. Second, responses were transcribed, coded, and analysed resulting in seven different future narratives.

Third, a group of 20 experts in innovation and strategic thinking evaluated the disruptive level of each future narrative with respect to a business-as-usual scenario. The paper shows the methodological process, the future narratives obtained, and reflects on the capacity of this participatory approach to generate disruptive future visions for land use and transport.

1. INTRODUCTION

Cities and transport systems are changing faster than ever, which is a fertile ground for the emergence of sudden, unique, anomalous, and low predictable incidents (Barber et al., 2006; Dammers, 2010). In this apparently changing age, transport planning experiences challenging times, in which instrumental rationality has come under attack (Innes and Booher, 2018) and deep uncertainty must be treated when supporting decision-making (Lyons and Marsden, 2019; Marchau et al., 2019; Navarro-Ligero et al., 2019). The incorporation of low predictable incidents/processes into decision-making remains a challenge that strongly limits the options for non-linear policy pathways. Those low predictable incidents/processes are here called wild cards: sporadic events or long-lasting processes that are assumed to be improbable, but would have large consequences for cities, transport systems, and social trends if they finally take place (Mendoça et al., 2004; Smith and Dubois, 2010).

Transport scenario building is a well-established methodology that can effectively address the challenge of incorporating wild cards in decision-making (Hickman and Banister, 2014; Soria-Lara and Banister, 2017a; Van Drunen et al., 2011). Transport scenario building investigates strategic and long-term futures marked by considerable uncertainty (e.g., the role of street space in cities) and/or situations where business-as-usual is no longer appropriate (e.g., transport emissions). The visioning phase is a crucial methodological step in transport scenario building, where a series of explorative and/or normative visions are constructed about the city's future and its transport systems (Banister and Hickman, 2013). This methodological phase is seen as a democratic exercise where "all voices" should be heard (Wangel, 2011), engaging the widest variety of actors: members from the public, practitioners, policymakers, etc. (Soria-Lara and Banister, 2017b; Tuominen et al., 2014).

Although there has been a burgeoning application of participatory visioning approaches in the transport field (Zimerman et al., 2012; Wangel, 2011; Hickman et al., 2011; Schade and Schade, 2005; Olsson et al., 2015), limited attention has been paid to deal with non-linear thinking. The implementation of participatory visioning has usually followed consensus-based techniques (e.g., Delphi methods), which limits the capacity to add outlier views into future visions (Shiftan, 2003; Melander et al., 2019). Experts-guided processes have been predominant in participatory visioning exercises, and those experts are usually trained to visualise futures linearly (Hickman and Banister, 2014). Visionary participants are also heavily influenced by current social and technological trends, making outside-the-box thinking a challenge (Soria-Lara and Banister, 2018a). If those barriers persist, the social, democratic, and participatory value of visioning processes will be curtailed, and their strategic value for decision-making will be drastically reduced, due to the limited capacity to incorporate disruptive views. As a result, linear thinking will continue to dominate, reducing the usefulness of transport scenario building.

To address these challenges, this paper aims to explore the following research question: To what extent can the use of wild cards stimulate a more disruptive thinking in participatory visioning? To explore potential answers, a specific region in the Metropolitan Area of Madrid (the Henares Corridor) provides the empirical focus. In a first step, a total of 129 participants were engaged via semi-structured interviews to construct a desirable future vision on transport and land use by 2050. In a second step, the same participants were asked to distort their desired future vision according to six context-based wild cards, guiding participants to visualise additional endpoints outside of their comfort zone. The visioning exercise resulted in seven 2050 visions: one desired vision plus six wild card visions. Then, the level of disruptive thinking reached during the visioning process was evaluated by a group of 21 experts.

The remainder of the paper is organised as follows. Section 2 outlines the theoretical background and the working hypothesis. Section 3 provides details on the research design, including a description of the case study. Section 4 summarizes the main results. Finally, Section 5 closes with concluding remarks and reflections.

2. THEORETICAL BACKGROUND AND WORKING HYPOTHESIS

Current participatory approaches in transport scenario building usually do not generate radical, anomalous, and low predictable visions. A group of authors have used workshops and focus groups to stimulate open and deliberative visioning processes (Banister and Hickman, 2013; Hickman and Banister, 2007; Hickman et al., 2009), rather than implementing more-restricting methods (e.g., questionnaires). However, the obtained long-term visions are still very close to the business-as-usual (BAU) projection, being strongly focused on linear thinking. To overcome this limitation, Tuominen et al. (2014) involved young participants during the visioning stage, resulting in more “original” visions. Soria-Lara and Banister (2017b) also evidenced the higher capacity of younger and non-expert participants to visualize more disruptive visions compared to highly experienced professionals, adults, and seniors.

Traditionally, Delphi techniques, in-depth interviews, and workshops have been used for participatory visioning. The dominance of a consensus-based approach limits the chance to incorporate outliers and divergences. Delphi techniques usually build future visions by carrying out several rounds of questions, where experts are informed about the main agreements reached in past participatory rounds (Mason and Alamdari, 2007; Melander, 2018; Shiftan et al., 2003; Zimmerman et al., 2012). When other more open participatory methods are used (e.g., in-depth interviews and workshops), only highly frequent and common thoughts remain in the obtained visions, limiting the incorporation of “outside-the-box” thinking into the process (Soria-Lara and Banister, 2018b). Other aspects impeding disruptive thinking are the use of BAU projections to orient participants during visioning processes (Julsrud and Uteng, 2015; Piecyk and McKinnon, 2010; von der Gracht and Darkow, 2016), and the construction of a single long-term vision instead of a wide range of options (Mason and Alamdari, 2007; Schuckmann et al., 2012; Trolley et al., 2001).

It is believed that utilizing wild cards –low probability and high impact processes- in participatory visioning processes can break down the abovementioned barriers and stimulate inventive, non-traditional outcomes in participatory visioning exercises. Traditionally, wild cards have been used to analyse unexpected future trends (Barber et al., 2006) as well as to test the stability of future visions in light of external and internal interferences (Steinmuller, 2004). For example, four different wild cards are used to test the robustness of long-term visions in the framework of the European Spatial Planning Cohesion Policies (Dammers, 2010). In the particular context of transport scenario building, Hauphman et al. (2015) explore fourteen technological, geopolitical, and societal wild cards, analysing their likelihood of occurrence and potential effects. Walsh et al. (2015) also use wild cards as a destructive test to evaluate the behaviour of future transportation infrastructure systems. Finally, Von der Gracht and Darkow (2010) extract wild cards from a Delphi process and deploy them to visualise long-term transport logistics futures by using divergent views in combination with desk work. However, the mentioned authors do not test the level of disruptive thinking reached for each vision.

The basic hypothesis underlying this paper is that wild cards can be used to stimulate thinking outside of the BAU zone during participatory visioning processes. Specifically, wild cards could be useful for interrupting linearity in the participants’ visioning processes, resulting in more-disruptive outcomes (Figure 1). The confirmation of this hypothesis –even partially- can show useful and practical lessons for decision-making and planning processes.

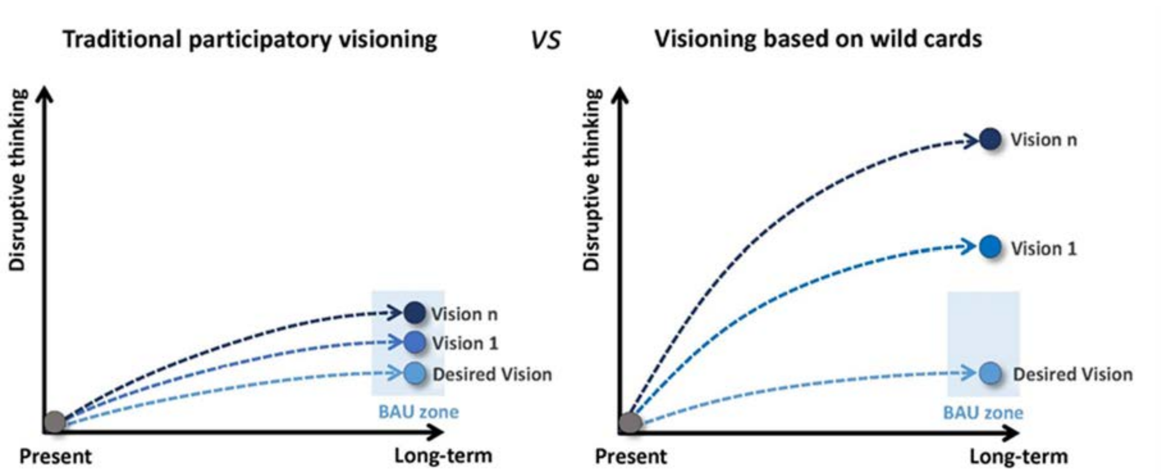

Figure 1: Working hypothesis

3. RESEARCH DESIGN

Our participatory visioning approach entailed three-stages:

- Case study and wild cards selection:
- Construction of 2050 visions and sample characteristics:
- Evaluation of disruption of 2050 visions.

3.1 Case study and wild card selection

The Henares Corridor (approx. 50 km) is located in the east part of the Metropolitan Area of Madrid (MAM) in Spain, connecting the cities of Madrid (3,223,334 inhabitants) and Guadalajara (255,336 inhabitants). More than a million people live in the 17 municipalities located in the Henares Corridor (INE, 2021). It is one of the most industrialised places in the MAM, originating a relevant number of commuters (Barreira-González et al., 2019; Cantergiani and Gómez-Delgado, 2018).

A set of context-based wild cards have been identified to confirm/deny our working hypothesis. Specifically, the research team identified six wild cards (table X) that would disrupt the BAU projections in official planning documents for the case study. The level of context-based surprise originated by those six wild cards was also discussed, identifying two different types:

- imaginable processes: possible surprises in the short and long term
- unimaginable processes: highly improbable surprises in both the short and long term.

Imaginable processes	Unimaginable processes
Zero-emission vehicles: Fossil fuel–powered vehicles will be fully prohibited in the case study, including individual and collective transport modes.	*Shared motorized mobility dominates:* Individual car ownership will be fully prohibited, and only shared motorized mobility can be used in the case study.
Non-motorized city centres: City centres along the corridor will be exclusively limited to active mobility (walking and cycling) and certain collective transport modes. Access to city centres by car will be fully prohibited.	*Overpopulation:* Natural disasters triggered by climate change will originate strong migratory movements from other geographical latitudes to European countries, resulting in a 200% population increase in the Henares Corridor.
E-working dominates: E-working will be implemented for all jobs where physical presence is not required.	*High levels of insecurity in urban areas:* The public space will become very insecure due to high social inequality rates. Walking, cycling, and motorbiking are not advisable actions.

Table 1: Wild cards selected.

3.2 Construction of 2050 visions

Semi-structured interviews were conducted to construct 2050 visions on transport and land use, totalling 129 valid interviews. Each semi-structured interview consisted of four-time blocks. In the first block participants provided socio-economic details (e.g., age, gender, frequent transport mode). In the second block participants shared their desired 2050 vision on transport and land use for the case study. They were asked to visualise an ideal workday in 2050. According to that imaginary day, they had to openly respond to the following questions:

- How do you see covering your daily travels to work, leisure, and shopping on this imaginary day?
- How does the neighbourhood you live in look like?

The third block of the interview focused on distorting the 2050 desired vision generated in the second block, by using the imaginable processes detailed in Section 3.1. First, participants had to select the most disruptive of the three imaginable processes (Table 1), according to their individual opinion. Second, participants had to respond to the same questions from the second block of the interview, conditioned by this imaginable process. Finally, the fourth block of the interview focused on distorting the 2050 desired vision generated in the second block of the survey, by using the unimaginable processes detailed in Section 3.1. First, participants had to select the most disruptive of the three unimaginable processes previously presented. Then, participants had to respond to the same questions from the second block, conditioned by this unimaginable process.

In summary, each semi-structured interview provided a total of three individual visions per participant: desired vision (block 2); vision based on one imaginable process previously selected by the interviewee (block 3); vision based on one unimaginable process previously selected by the interviewee (Block 4). Then, those individual visions were codified and added to other individual visions to obtain collective 2050 visions. Each collective vision was translated into a specific narrative, with seven narratives in total: the 2050 desired vision plus six 2050 wild card visions (three visions based on imaginable processes and three visions based on unimaginable processes). To provide legitimacy over the process, the sample target included members from both the public and professionals from a wide range of sectors. All selected participants were younger than 32 years old, i.e., those who would be at most 65 years old by 2050, the visioning horizon.

3.3 Evaluation of disruption of 2050 visions

To analyse to what extent this participatory approach can stimulate non-linear thinking, the seven 2050 visions were evaluated by a group of 21 experts in innovation, strategic decision-making, and creative thinking. The aim of the evaluation was to grade the seven 2050 visions according to their disruptive thinking level. The evaluation was completed via an on-line questionnaire, based on asking the expert to indicate whether the 2050 visions were:

- non-disruptive
- somewhat disruptive
- disruptive
- very disruptive
- highly disruptive.

Descriptive analysis based on the frequency of responses were used to evaluate the level of disruptive thinking reached by each 2050 vision.

4. RESULTS

4.1 The desired collective vision for 2050

Based on participant responses, the narrative for the desired vision could be formulated as follow:

> *This vision relies on decreasing the level of transport emissions; however, the daily modal split remains largely unaltered. Cleaner private vehicles dominate work commutes, while fossil fuel–powered vehicles are not fully replaced. E-working is seen as a marginal option and walking and cycling are the preferred modes for shopping and leisure activities. A relevant percentage of vehicles are autonomous. Cities have reduced the distances between residential, shopping, and leisure places – by high levels of mixed-use planning and by connecting amenities in a dense network of green corridors. However, workplaces are far away from residential areas and are still mainly located in the city's periphery. Both residential and work areas are connected by car infrastructures and efficient public transport services.*

4.2 Visions based on imaginable processes

Based on participant responses, the narrative for the "zero-emission vehicles" 2050 vision could be formulated as follows:

> *The vision relies on a fundamental technological change – the prohibition of motorized vehicles that are not zero-emission vehicles. However, it does not bring about a drastic change in the daily modal split. Zero-emission vehicles (collective and private) are the main mode for reaching daily work destinations. E-working is seen as a marginal option, while walking and cycling are the desired mode for reaching shopping and leisure activities. A relevant percentage of vehicles are autonomous. Also, car-sharing has a substantial share in personal mobility. Cities should provide for shorter distances between residential, shopping, and leisure places, requiring areas with a high mix of those activities and connected each other by a dense network of green corridors. Workplaces are mainly located in the city's periphery and far away from residential places. Both residential and working areas would be connected by car infrastructures and efficient collective transport services.*

According to participant responses, the following narrative was constructed for the imaginable process “non-motorized city centres”:

> *This 2050 future is fundamentally based on the full restriction of private vehicles access to city centres. All public space in city centres is recovered for active mobility – with the exception of public transport road space and platforms – and for the creation of socialization spaces (e.g., parks, leisure areas). That would increase walking and cycling levels to all daily destinations (work, shopping, and leisure activities). E-working is seen as a marginal option. The restriction of private vehicles access to city centres would severely limit both the rollout of autonomous vehicles and the promotion of car-sharing services. There would be a preference for cities that offer a high mix of residential, shopping, leisure, and working places, reduce the distances between those activities and foster active mobility patterns. Consequently, working places would be transformed into more mixed-use areas. A dense network of green corridors will connect different places of the case study.*

The following 2050 vision can be generated according to the wild card “e-working generalization”:

> *This 2050 future is distinguished by the e-working generalization, with all jobs not requiring physical presence. That would initiate a change in modal split patterns, increasing walking and cycling levels for daily destinations such as shopping and leisure activities. Car ownership rates would drastically decrease in favour of car-sharing solutions. Moreover, a percentage of vehicles would become autonomous. People would still prefer to live in the city’s periphery, but in mixed use neighbourhoods marked by shorter distances between residential, shopping, and leisure places, triggering an increase of active mobility. A dense network of green corridors will connect residential, shopping, and leisure activities. Current workplace destinations would be transformed into mixed use locations, as most of workplaces would be located at individual households or other community (co-working) locations.*

4.3 Visions based on unimaginable processes

Based on participant responses, the following narrative has been elaborated according to the wild card “Overpopulation”:

> *This 2050 vision would trigger changes in modal split patterns, with increased use of collective modes for work commuting and increased walking and cycling rates to shopping and leisure locations. Car ownerships rates would decrease in favour of a generalization of car-sharing habits. E-working would be seen as a marginal option. There would be a preference from high-income families to live in the city periphery and in low density places, but with a high land use mix. Current work areas – located in the city’s periphery – would be transformed into more multifunctional places. Low-income*

families would prefer to live in high-density areas in city centres. A dense green network of corridors would connect different places along the case study.

The 2050 vision based on the unimaginable process “shared motorized mobility dominates”, could be formulated as follows:

The future vision relies on a fundamental travel behaviour change, based on the prohibition of individual car ownership and the generalization of shared motorised mobility. Public modes would be the preferred option for reaching daily destinations – working, shopping, and leisure activities. Walking and cycling would be also a preferred mode, fundamentally for shopping and leisure trips. The use of car would be drastically limited to shared services. E-working would be seen as a marginal option. There would be a preference for living in city centres with shorter distances between residential, shopping, and leisure places. The built environment would provide these activities in mixed use location, connected by a dense network of green corridors. Workplaces – mainly located in the city’s periphery – would remain far away from residential areas. Both residential and work areas would be connected by efficient collective transport services.

Finally, the third unimaginable process, “high level of insecurity in urban areas”, led to the following vision:

The visualised transport future is strongly affected by a high level of insecurity in urban areas. Walking and cycling are not advisable. The modal split would be drastically altered, with the private car dominating all daily trips –work, shopping, and leisure. There would be also preferences for increasing the level of car sharing, as well as for the promotion of clean and autonomous vehicles with zero emissions. Public green areas would be removed and recovered for car infrastructures. There would be a preference by high-income families for living in the city periphery in private communities. Land uses would be highly segregated in homogenous areas connected by motorized infrastructure. City centres would be mainly transformed into work destinations, with most employees commuting from the city’s periphery. Low-income families would also tend to live in those insecure city centres.

4.4 Evaluation of disruptive thinking

The expert evaluation provides new insights into the basic hypothesis underlying this research, i.e., that different types of wild cards can be used to stimulate thinking outside of the BAU zone during participatory visioning processes. This working hypothesis was confirmed when unimaginable processes were used; however, some problems were noted in the 2050 visions based on imaginable processes.

The evaluation shows how the most disruptive 2050 visions – compared to the common 2050 desired vision – were those generated by using the following unimaginable processes "high level of insecurity in urban areas" and "shared motorised mobility dominates" (Figures 2 and 3). More than 90% of experts find that the 2050 vision "high level of insecurity in urban areas" is disruptive, very disruptive, and highly disruptive. Additionally, almost 70% of experts indicate that the 2050 vision "shared motorised mobility dominates" is disruptive and very disruptive. However, different results are found for the third vision generated through the other unimaginable process "overpopulation", where only 43% of experts signal this vision as disruptive and very disruptive.

Although multiple reasons can explain the previous results, one relevant aspect should be emphasized. The two most disruptive visions ("high level of insecurity in urban areas" and "shared motorised mobility dominates") were obtained from smaller portions of the sample of participants who selected those unimaginable processes during the interview process. Moreover, the socio-economic characteristics of these two sub-samples are highly homogenous unlike the population that selected "overpopulation". For example, employed people older than 25 years who travel daily along the corridor in public transport modes were the group that selected "shared motorised mobility dominates" during the interview. In the case of "high level of insecurity in urban areas", it was a majority of women younger than 25 years who travel daily along the corridor in public transport modes. In both cases, these sub-samples had divergent opinions regarding those participants selecting "overpopulation" during interviewed. In other words, smaller population sub-groups seem better equipped to generate divergences and disruptive thinking.

In the experts' opinion, the level of disruption reached by those visions generated on imaginable processes is more similar to the disruption level perceived for the 2050 desired vision (Figures 2 and 3). In all the three cases (non-motorized city centres; zero-emission vehicles; e-working dominates), only a percentage of experts lower than 52% signal these 2050 visions as disruptive, very disruptive, and highly disruptive. Even, the 2050 vision generated by the imaginable process "e-working dominates" is recognised as disruptive by a lower percentage of experts (33%) in comparison with the desired vision (43%). These assessments can indicate higher probability to generate disruptive thinking among participants when highly surprising factors (as unimaginable processes) are incorporated in the process, as participants are largely used to visualize short-term futures and are strongly affected by linear thinking. Nevertheless, it is worth mentioning that the most disruptive level of thinking has been found for the vision generated through the imaginable process "non-motorised city centres", which is selected by a minority of participants during the interview process (20% of participants). That reinforces the findings obtained for the visions generated through unimaginable processes, smaller sample sub-groups can have more divergent opinions on transport and land use futures.

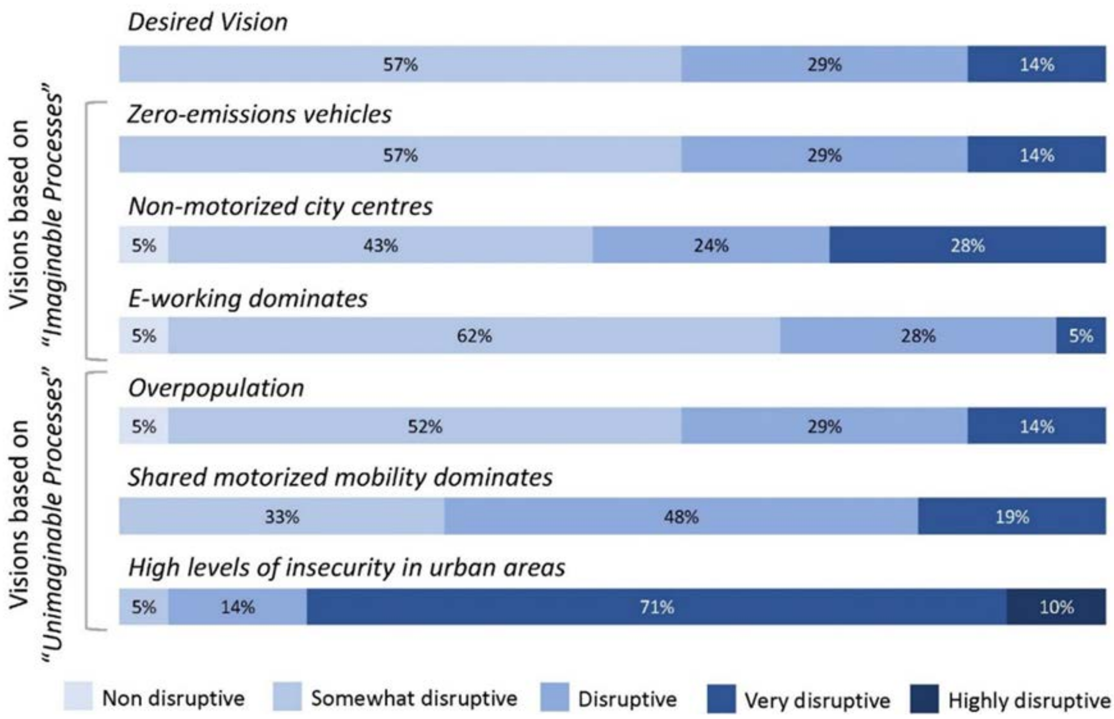

Figure 5: Percentage of experts identifying levels of disruptive thinking.

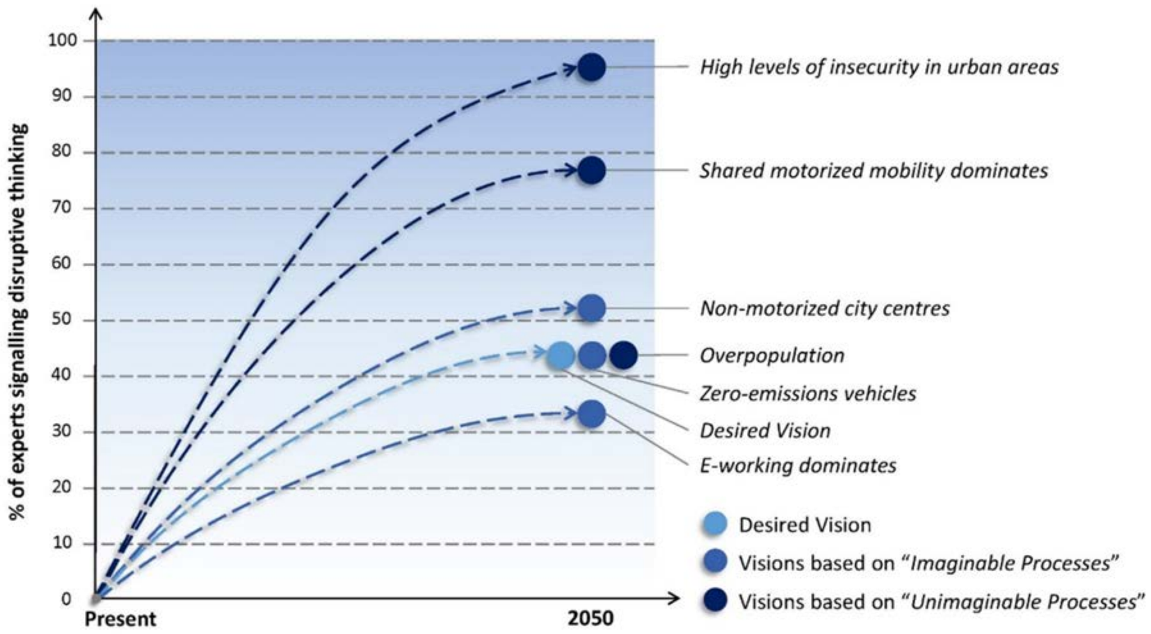

Figure 6 – Level of disruption identified by experts for each 2050 visions.

5. CONCLUSIONS AND DISCUSSION

In the reminder of this Section, a set of issues, limitations, and emerging questions are presented, discussing which elements of the visioning process have worked well (or not), and why. The purpose is to comment on what has been learned to distil some "prescriptions" for research and decision-making.

The visionary participants were local people between 18 and 32 years old. That is a convenience sample that allows the research team experimenting with a group of participants that can initially have more willingness to visualise futures under wild cards conditions. The limitation is that it would be impossible using the obtained 2050 visions in a real decision-making process, because it is unknown of what population this sample is representative. However, this convenience sample provides the research team with a more controlled environment to prove causality associated with the working hypothesis. Of course, further research steps are needed to distil usable "prescriptions" for thinking disruptively in decision-making, in which the control level of the research environment decreases, and the visionary participants are engaged according to the canons of probability sampling.

The research design opted for larger samples, engaging one of the highest number of participants in the field of transport scenario building. Larger samples would facilitate the emergence of smaller groups of participants with divergent views able to select the widest range of wild cards. For both imaginable and unimaginable processes, the most disruptive thinking (compared to the desired common vision) was obtained for those visions triggered by wild cards selected by a minority of participants. Moreover, those smaller sample sub-groups have tended in our context to be homogeneous regarding certain socio-economic characteristics. In this respect, most of participants selecting "shared motorised mobility generalization" were older than 25 years old, employed, and frequently used public transport modes to travel along the case study. The unimaginable process "high level of insecurity in urban areas" was mostly selected by women younger than 25 years old that frequently use public transport modes to travel along the case study.

The main limitation of semi-structured interviews is the null capacity of participants to interact with each other, missing the opportunity to activate learning processes. Both the structure and further analysis of semi-structured interviews in different blocks and phases, including multi-options to add several wild cards, facilitated the capture of minority views and their translation into narratives. It was seen how these minority views usually brought by homogenous group of populations resulted in higher level of disruptiveness. The comparison of a 2050 desired vision vs six wild cards visions has been conducted in this study. An alternative option is to run several visioning exercises separately, some of which had wild cards and some of which did not (control group). That would facilitate to gain additional and stronger insights into the capacity of wild cards to add non-linear thinking.

The use of wild cards proved useful for generating disruptive thinking between participants when unimaginable processes were used. However, imaginable processes provided 2050 visions with similar level of disruption as the common desired vision. This finding implies that highly surprising factors are needed to generate disruptions and break linear thinking. In this respect, using a wide range of wild cards can be crucial for two main reasons. First, the probability to generate disruption is higher as a larger number of highly surprising factors will be on the table. Second, larger numbers of wild cards can increase the chances to generate divergences between participants. In this respect, it is key that participants are forced to choose between wild cards rather than to visualize futures for all of them. Having to choose between wild cards triggers divergences, as proved during the participatory visioning presented in this research. Moreover, the choice of participants between different types of wild cards have served to incorporate outlier views from participants, represented by those wild cards selected by a minority of participants.

This participatory visioning provides decision-making with the option to incorporate unexpected incidents/processes but high impact in planning processes. It can contribute to define a more strategic vision of planning goals that include possible threats and/or accelerators originated by wild cards visions. For example, the COVID-19 crisis during 2020 underlines the importance of incorporating more diverse and non-linear visions into decision-making. Further steps are still needed to distil useful practice tools by using wild cards. This participatory approach that engages the widest range of participants provides legitimacy over planning processes. However, it must be said that each participatory process should be customized for each particular situation. Legal barriers and the low commitment of politicians to those participatory visioning exercises are also seen as obstacles to overcome in real practice.

Finally, this research presents a participatory visioning process aimed at evaluating the capacity of wild cards to stimulate disruptive thinking. The results are encouraging – especially when introducing wild cards. Further research could inform how to deploy wild cards more effectively used during transport visioning processes. In this respect, new challenges are related to the development of efficient methods to generate and identify wild cards as well as the design of effective mechanisms to assess the level of disruption generated through the visioning process.

ACKNOWLEDGEMENTS

This research has been developed in the context of the research project "TRANS-URBAN: Simulación de escenarios colaborativos para integrar políticas de transporte urbano sostenible y usos del suelo". The project was funded by the Spanish Government under National R+D Plan (2018–2020) JCR. Grant Agreement no. CSO2017-86914-C2-2-P.

QUANTIFICATION OF TRANSPORT OFFER LINKED TO A EUROPEAN HYPERLOOP NETWORK

José Ángel Fernández Gago
Technical Manager, Ineco, Spain
Federico Collado Pérez-Seoane
Senior Technical, Ineco, Spain

ABSTRACT

Hyperloop is the modern and environmentally friendly update of an idea that has been in people's head for more than 200 years, since Medhurst presented the first patents. When "Hyperloop Alpha" was published by Elon Musk in August 2013, the best trained labour force, the most capable financial capital and the bravest governments and institutions, moved forward to make it a reality.

Currently, there isn't any scientific publications that address with enough detail, and without self-bias, the transport offer linked to specific networks of this new mode. This paper presents an approach to an operational plan in the exploitation phase for a specific Hyperloop network in Europe.

About the proposed network, with an extension over 12,000 kilometres, the authors will analyse its social and economic benefits based on GDP and the directly connected population, describe its design parameters (radii of curvature, acceleration, deceleration and constant speed zones), outline the demand using simple gravity models, propose an annual service calendar with schedules and frequencies differentiated by country, and present the main magnitudes associated with its operation.

In addition, the presentation will show the results of the research carried out on the main obstacle that the Hyperloop implementation will pose in the future: the number of tubes needed per direction vs. the transport capacity of each capsule or pod.

1. INTRODUCTION

Hyperloop is the update of an idea that has been in men's head for more than 200 years, from Medhurst's first patents related to the atmospheric train (Medhurst, 1810).

Launching a pressurised capsule, loaded with goods or people, through a tube whose inner pressure has been considerably reduced, is nothing but the next evolutionary step of magnetic levitation trains.

Since its inception, railway speed has been related to different aerodynamic designs of trains and different traction typologies. Since the first horse-drawn and guided carriages, rail transport has known first the steam traction, then diesel traction and later electric traction. It was with high-speed railways (first with electric traction and then with magnetic levitation) that the aerodynamic design of trains began to gain importance, reaching top speeds of 600 km/h, as in the case of the Maglev.

The physical barrier that has so far prevented the achievement of better high-speed rail speeds has always been air friction. That is why the next step to achieve higher limit-speeds is to necessarily reduce the atmospheric pressure around the train, as proposed by Hyperloop concept. To help better understand the process being described, note anecdotally that a tube without pressure inside, and whose temperature is close to absolute zero, is conceptually very close to the representation of a particle accelerator, where the speed of particles is close to the speed of light.

Taking this idea as a backbone, in August 2013, Elon Musk and his support teams at SpaceX and Tesla published ‘Hyperloop Alpha’ (Musk, 2013). A document that, with a modern and ecological format, brought to the present the original ideas of Medhurst and many others who came after him, such as Lamson (1908), Goddard (1924), Salter (1972) or Olster (2010-2015).

The challenges posed by this new mode of transport are very diverse. There are obvious physical risks, but also economic, financial, legal, regulatory, budgetary, and even socio-political risks, taking into consideration that Hyperloop will be able to "deform" the territory, turning countries into neighbourhoods.

Regardless of this, in just 8 years, Musk's initiative has sparked the birth of a very dynamic new industry. Despite its notable shortcomings, ‘Hyperloop Alpha’ has become the dragging engine capable of bringing together the best trained human force, the most capable financial capital and the boldest governments and institutions.

The prospect of a new mode of land transport with the huge potential to bring closer together regions separated by long travel times, has attracted the interest of governments such as India or United Arab Emirates, which have shown their interest in hosting this type of infrastructure. At the level of countries and supra-national entities under the influence of the OECD, receptiveness to the Hyperloop project has also been high, although the approach is taking place in a more cautious manner.

In order to analyse the financial viability of such an investment project and, where appropriate, the sustainability of the public accounts of the region in which it is located, it is necessary to have certainly about the amounts of capex and opex linked to it. In this sense, this document provides information on a plausible Hyperloop network serving the European

Union, using different methodologies to capture its design characteristics and the amount of transport it would provide annually if all its lines were put into service in the same year.

2. BIAS PROBLEMS IN THE FACE OF THE NECESSARY SOCIETAL ENDORSEMENT OF A NEW TECHNOLOGY

In September 2020, Gkoumas and Christou published ‘A Triple-Helix Approach for the Assessment of Hyperloop Potential in Europe’ (Gkoumas and Christou, 2020), a paper which referred to the relative abundance of research devoted to capsules and operations, but the paucity of research on safety issues. This document refers to other research advocating that the commercial potential and financial viability of Hyperloop has yet to be demonstrated (Walker , 2018). Gkoumas and Christou also index an inconclusive study published in 2016 by the US Department of Transportation (Taylor et al., 2016) on the commercial viability of Hyperloop, and a more recent research that questions the financial viability of the system in a potential deployment in the Great Lakes environment (USA) (Transportation Economics & Management Systems, Inc, 2019).

The main problem with financial feasibility studies for disruptive technologies such as Hyperloop, which are not based on concrete applications, is always the lack of detail. This matter is even more striking when feasibility studies carried out on specific infrastructures and with well-proven technologies are observed, duties that usually have the support of the developer industry itself.

The risk of self-serving bias in innovations of this scale is something that infrastructure planners and policy makers need to be aware of from the earliest stages. Assuming this, it is worth remembering that Hansen (2020) has already warned of the risks of polarising the opinion of the different interest groups that could benefit from a transport solution such as Hyperloop.

This is something that has already happened in the past, and it was a step prior to the failure of a project of similar characteristics as was ‘ARAMIS’. Referring to this event, in 1993 the French philosopher Bruno Latour published a book (Latour and Poter, 1996) in which he described how technological passion for a concept can have a double detriment: on the one hand it can blind some of the promoters to the technical feasibility of the project, and on the other hand it can make others irrational denialists.

During the 1970s, in Paris, ARAMIS was the latest attempt to create a rapid passenger transport system whose concept had emerged in the United States a decade earlier. The goal was to develop an automatic-guided public transport system, in which the transport elements would resemble the private car in size and comfort. These elements would be hooked to each other forming trains of variable length, as the ‘carriages’ would be temporarily attached until the destination turnout of each other was reached. The project never materialised.

In 1994, Latour, in an article derived from his book and entitled ‘Ethnography of a case of ‘high technology’: on Aramis’ (Latour, 1993) put the spotlight on the different currents that in his opinion caused the project to fail: “Aramis is technically ready for homologation”, ... , “Aramis was technically ready, but would have been so costly that it would have been unsalable politically”, ... , “the Aramis cabin was not technically ready because the RATP (Regional Transport Authority of Paris requested that Matra respect specifications completely unsuited to such an innovative experimental prototype”, ... , “nothing can be gained from the Aramis, it produced no technical or cultural results, it was a false innovation from the outset, an impracticable idea”, ... , “the question of the technical feasibility of the Aramis should not be raised”.

In this context, two milestones can make the difference between Hyperloop and ARAMIS:

- February 2020: CEN-CENELEC announced the launch of a new joint technical committee, CEN/CLC/JTC20. Its purpose is the standardisation of Hyperloop systems. As several European and international industries are investing in Hyperloop systems supported by the interest of public and private actors, European standardisation is crucial to achieve a coherent deployment of this new mobility tool (CEN-CENELEC, 2020).
- October 2020: Shift2Rail, a body of the European Commission, promotes the financing of a new project called Hypernex. Led by the Polytechnic University of Madrid (UPM), it tries to identify the main challenges facing Europe in terms of research, innovation, and infrastructures. The objective is to lead the development of this new means of transport and seek the most appropriate solutions (Universidad Politécnica de Madrid, 2020).

But regardless of the above, and although there is a broad consensus on the viability of this subsystem-level technology, it is clear that it will be necessary to carry out prognosis exercises in which all of them operate in a joint and coordinated manner. These exercises should be extremely detailed and applied to concrete realities.

Today, the simulation possibilities in multiple fields allow, for example, to emulate the design characteristics of transport networks using artificial intelligence algorithms. Through specific commercial software, it is also possible to emulate the annual operation of the rolling stock linked to these networks. And through sophisticated spreadsheets it is possible to simulate the commercial life of a vehicle company project. The information derived from such tasks, properly processed and integrated, would be the first step to advance in a solid understanding of the financial viability and future budgetary sustainability of a concept like Hyperloop.

With the design of a transport network for Europe, connecting the main cultural and economic nodes, from which detailed physical information can be extracted, and on which a reasonable plan of operations can be projected, it will be possible to calculate the capex and opex that allows to advance in the knowledge of the economic viability of the system as a whole.

As a tangential result, this document provides the necessary inputs to calculate the volume of investment in infrastructure of a hypothetical network. As the main result, this paper provides the quantification of the transport supply linked to it. The measurement of the transport offer is the necessary input to calculate the volume of investment in rolling stock, as well as to calculate most of the operating costs.

3. A PROGNOSTIC EXERCISE THROUGH THE PROPOSAL FOR A EUROPEAN HYPERLOOP NETWORK

The land deformation effect that the speed of certain modes of transport generates is behind the positive socio-economic effects that occur when these modes come into operation.

The figure below shows what a European Hyperloop Transport Network would look like. In addition to others, the fundamental design premise has been to connect the capitals of the states over which it is deployed, as directly as possible.

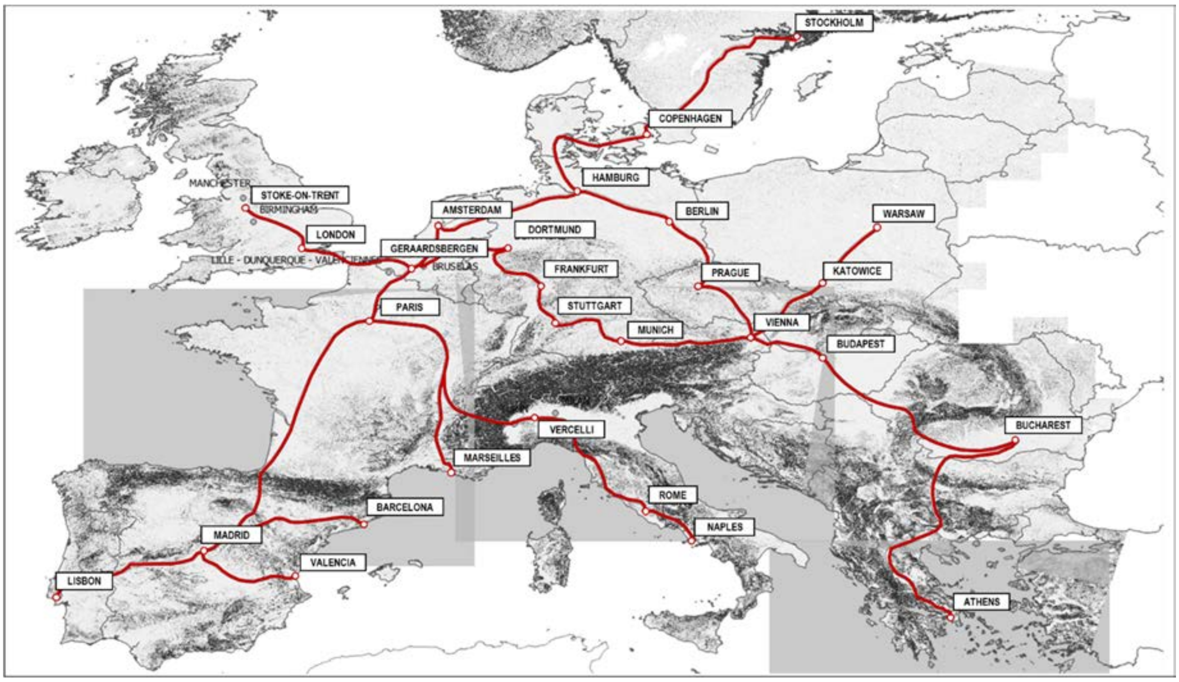

Figure 1: Lines of the proposed European Hyperloop Network

The name of the network lines and their length is shown in the table below.

Transport line name	Length [km]	Transport line name	Length [km]
01 LISBON - MADRID	537.66	15 MUNICH – STUTTGART	236.62
02 VALENCIA - MADRID	360.02	16 STUTTGART - FRANKFURT	169.32
03 MADRID - BARCELONA	544.65	17 FRANKFURT – DORTMUND	240.14
04 MADRID - PARIS	1,108.71	18 DORTMUND – GERAARDSBERGEN	274.62
05 MARSEILLE - PARIS	787.92	19 HAMBURG - COPENHAGEN	464.36
06 PARIS - GERAARDSBERGEN	247.53	20 COPENHAGEN – STOCKHOLM	595.13
07 GERAARDSBERGEN - LONDON	317.56	21 VIENNA – KATOWICE	304.38
08 LONDON - STOKE-ON-TRENT	238.33	22 KATOWICE - WARSAW	260.25
09 GERAADSBERGEN – AMSTERDAM	198.93	23 BUDAPEST – VIENNA	229.06
10 HAMBURG – AMSTERDAM	391.34	24 BUCHAREST – BUDAPEST	746.49
11 BERLIN – HAMBURG	262.40	25 ATHENS – BUCHAREST	1,079.47
12 PRAGUE – BERLIN	306.67	26 NAPLES – ROME	198.12
13 VIENNA – PRAGUE	280.89	27 ROME – VERCELLI	561.18
14 VIENNA – MUNICH	364.96	28 VERCELLI - PARIS	760.58

Table 1: Length between network nodes

The design of this network has been established within the framework of a research project linked to the University of the Basque Country.

3.1 Utility offered

In addition to the connection of state capitals, the European Hyperloop network includes the physical connection of European metropolitan regions with a census population of more than two million people.

The network thus consists of 28 lines with 28 nodes or stations (15 of which are located in state capitals). Three grouped nodes are suggested. The first of these would be in the Italian town of Vercelli, which would cover Milan and Turin. The second node would be located in Geraardsbergen, a Belgian town which would cover both Brussels and the Lille-Dunkerque-Valenciennes area. The third such node would be located in Stoke-on-Trent to cover both the Manchester and Birmingham agglomerations in the UK.

Starting from a Central European ring of 10 stations, the network extends to the rest of the continent via four branches. The northern branch would connect Hamburg with Stockholm. The southern branch would connect Geraardsbergen with the southern countries (Portugal, Spain, France and Italy). The eastern branch would connect Vienna with the peripheral countries of Poland, Romania and Greece. Finally, the north-west branch would also connect Geraardsbergen with the United Kingdom.

As an example, based on the latest available census data, the network would host seven super-nodes, defined as stations with the capacity to connect more than 15 million people (Geraardsbergen, Madrid, Paris, London, Stoke-on-Trent, Vienna and Marseille) through a single journey stage.

The proposed design would also allow direct access to the new high-speed mode of transport for 1/4 of the EU-28 population (120 million people), 1/3 of its GDP, 1/4 of its workforce, and 1/5 of all goods moved.

3.2 Methodology for the characterisation of the network layout.

Once the utility of the network has been described, the layout of the network should follow criteria that minimise the amount of investment required for its implementation. Following this premise, the layout process begins with the viewing of the slope map of Europe. Knowing the orography of a territory makes it possible to draw lines connecting cities through the flattest areas, and to use large radii of curvature.

After defining the layout of the network, the next step would be to determine its characteristics. In terms of capex, a linear infrastructure connecting two points through 15.45% of singular works (tunnels and viaducts) is not the same as another infrastructure with 18.76% of this type of works for the same connection.

3.3 Fundamentals of transport services operation

The stock of public capital allocated to transport services only achieves social utility when it is used to design a reasonable operational plan that makes it possible to present a specific transport offer to users. In order to determine the amount of transport that should be produced in a typical year in a network such as the one proposed, any planning office in the service of a public administration would have to go through a series of very well-defined phases.

3.3.1 About the radii of curvature

Firstly, the radii of curvature that apply on each section of each of the 28 lines must be known. This makes it possible to determine the maximum speed of the capsules on each of the aforementioned sections by means of equation (1), which is derived from ADIF's General Project Instruction IGP-3 (ADIF, 2011).

$$V = 6{,}4692 \times R^{0{,}4481} \qquad (1)$$

In this equation, R refers to the applicable radius of curvature expressed in metres and V to the speed of the capsule expressed in km/hour.

Figure 2: Curvature radii for a European Hyperloop Network

The radii of curvature recorded in the design of the proposed lines range from the 2.64 km in the vicinity of Athens (line 25 linking this city to Bucharest) to the 260.74 km in line 24 (Bucharest - Budapest). According to equation (1), when the proposed radius is 60,000 metres, the curve speed is 895.24 km/hour.

3.3.2 About acceleration, deceleration, and maximum speed

Although Hyperloop's maximum speed is theoretically 1,220 km/hour, the operational plan described here puts this figure at 850 km/hour. A sufficiently high speed, which does not rigidify the physical-technical boundary conditions of the system as much. In the same way, the acceleration and deceleration of the capsules is maintained at all times at values of 0.1G, coinciding, for example, with the hypotheses used by HTT in its own studies (Transportation Economics & Management Systems, Inc., 2018), but far from the value of 0.5G shown in the 'Hyperloop Alpha'. Under these conditions of movement, the time and space consumed by a capsule to reach a speed of 850 km/hour from 0 would be 240.766 seconds and 28,423.80 metres.

Adopting these assumptions, which could at some point be described as conservative, will allow the formulation of a reasonable financial viability analysis, which the industry could gradually beat with the introduction of more solid technical innovations.

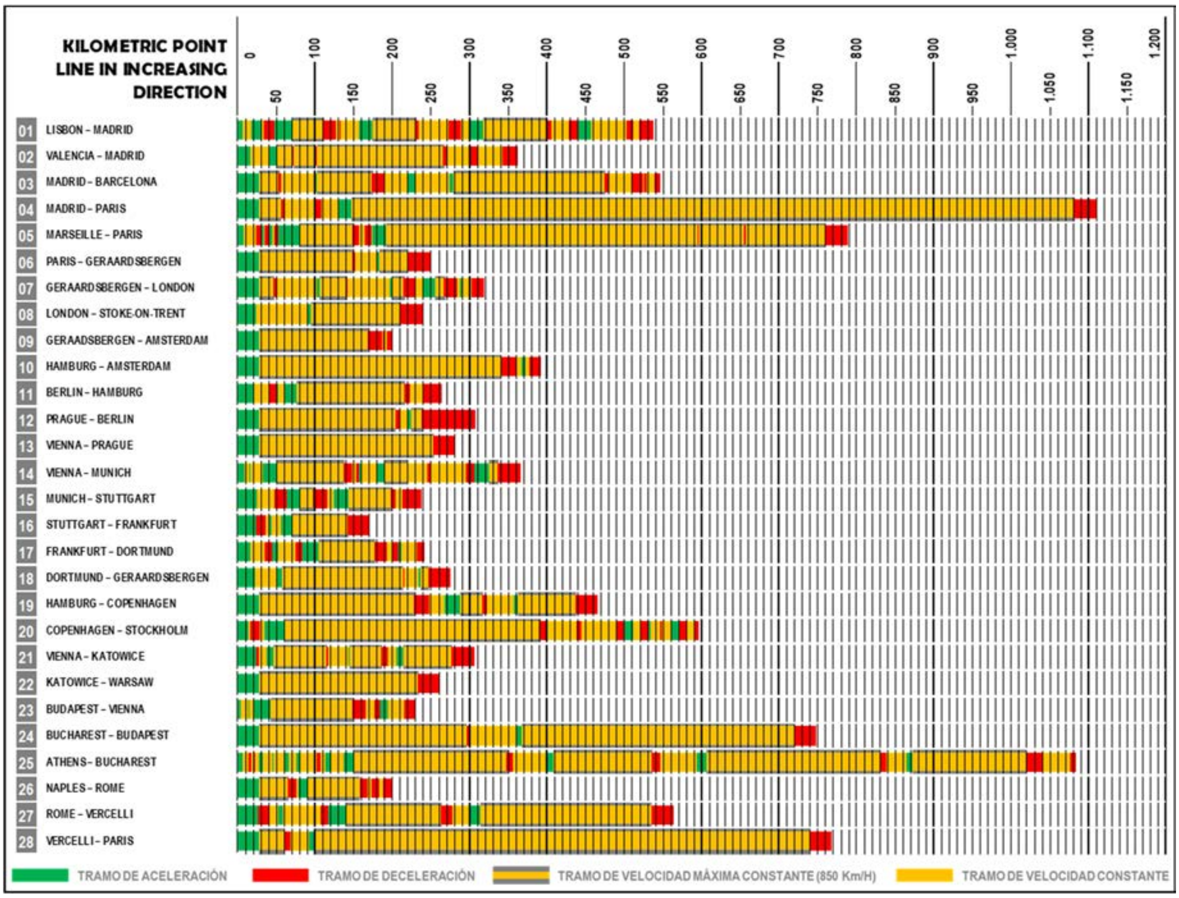

Figure 3: Overview of pod movement characteristics in the network

The figure above shows the acceleration, deceleration, constant speed and maximum constant speed zones, linked to each of the lines of the proposed European Hyperloop Network.

3.3.3 About time consumed in pre- and post-travel related tasks

A Hyperloop station or Hyperloop gateway will have many operational similarities to a high-speed rail station, but physically it will have two well distinct zones, as is the case in any airport. In this sense, while an airport differentiates between 'land side' and 'air side', a Hyperloop station will have to differentiate between an 'atmospheric pressure side' and a 'low pressure side'.

Under these conditions, the process of transporting a person or a load between the origin and destination of any line in the network would be affected by certain unalterable milestones and fix time consumptions. This is due to the need for persons or objects under atmospheric pressure to transit to a state where they maintain atmospheric pressure inside a capsule, but which, when it enters the tube through a lock, must be under low pressure.

The table below shows in a schematic way what should be the orderly process of access of users to the transport capsules. It also shows how the capsules access to the tubular infrastructure, the process of arrival of the capsules at the stations, and finally the disembarkation process.

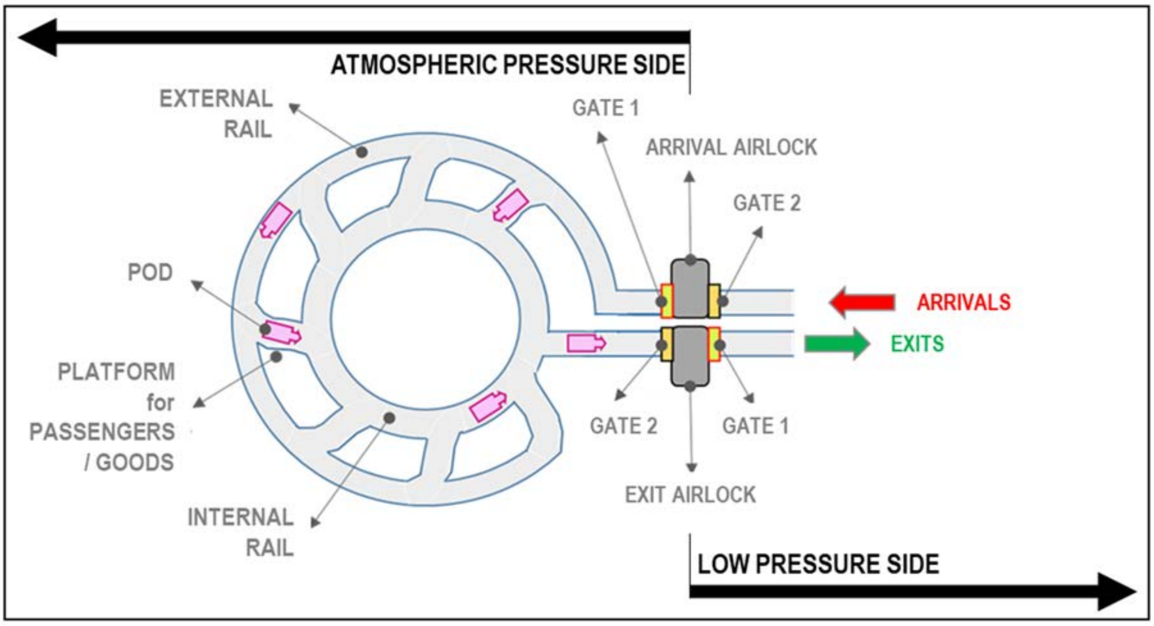

Figure 4: Approach to a Hyperloop station scheme

	Milestone	Duration [min]
1	Pod transition from platform to entrance to exit airlock (gate 1)	3.50
2	Pod entrance at departure airlock	0.75
3	Gate 1 closing in the exit airlock	0.58
4	Air extraction in the exit airlock	2.50
5	Gate 2 opening of the exit airlock	0.83
6	Pod movement towards the propulsion zone in the tube	0.42
7	Gate 2 closing in the exit airlock	0.83
8	Pod movement inside the tube to its destination	VARIABLE
9	Gate 1 opening at arrivals airlock	0.83
10	Pod entry at the arrival airlock	0.75
11	Gate 1 closing at the entrance to the arrival’s airlock	0.83
12	Pressurisation of the arrival’s airlock	0.67
13	Gate 2 opening at arrivals airlock	0.58
14	Pod movement from the arrival’s airlock to the platform by external rail	3.50
15	Pod reposed on platform	0.33
16	Uncoupling operation of passenger / cargo	1.50
17	Pod doors opening and orderly departure of passengers/cargo from the capsule interior	2.00
18	Equipment for sanitisation rapid intervention / pod condition checking	4.00
19	Battery replacement (or partial recharging if necessary)	5.00
20	Pod on standby until passenger/cargo occupancy starts	VARIABLE
21	Passenger/cargo occupancy	2.50
22	Anchoring of passengers/cargo and approval by a supervisor	2.00
23	Pod closure and automatic safety check	1.50
24	Transition of pod from platform to entrance to exit airlock (gate 1)	MILESTONE 1 AGAIN

Table 2: Description of milestones in pre and post trip operations and times allocation

The sum of the times of the above milestones amounts to 35.42 minutes (0.5903 hours). This amount could be equated to the boarding and alighting times for passengers boarding and alighting high-speed rail services.

The above table refers to both passengers and cargo. In the case of cargo, with the right logistics, these times could be even shorter.

3.3.4 About the commercial speed of the transport system

According to the Royal Academy of Engineering of Spain, commercial speed is defined as the "average travel speed used by public transport vehicles to complete a full circle of a route, including all delays and waiting time at terminals" (Real Academia de Ingeniería, 2012).

Transport line name	**(a)** Length [km]	**(b)** Variable time [hours]	**(c)** Fixed time [hours]	Commercial speed [km/hour] **(a) / (b)**	Commercial speed [km/hour] **(a) / (b+c)**
01 LISBON – MADRID	537.66	0.8069	0.5903	666.33	384.81
02 VALENCIA – MADRID	360.02	0.5129	0.5903	701.93	326.34
03 MADRID – BARCELONA	544.65	0.7628	0.5903	714.01	402.52
04 MADRID – PARIS	1,108.71	1.4006	0.5903	791.6	556.89
05 MARSEILLE – PARIS	787.92	1.0856	0.5903	725.79	470.15
06 PARIS – GERAARDSBERGEN	247.53	0.3614	0.5903	684.92	260.09
07 GERAARDSBERGEN – LONDON	317.56	0.4700	0.5903	675.66	299.5
08 LONDON – STOKE-ON-TRENT	238.33	0.3561	0.5903	669.28	251.83
09 GERAADSBERGEN – AMSTERDAM	198.93	0.3032	0.5903	656.1	222.64
10 HAMBURG – AMSTERDAM	391.34	0.5447	0.5903	718.45	344.79
11 BERLIN – HAMBURG	262.40	0.3951	0.5903	664.14	266.29
12 PRAGUE – BERLIN	306.67	0.4303	0.5903	712.69	300.48
13 VIENNA – PRAGUE	280.89	0.3979	0.5903	705.93	284.24
14 VIENNA – MUNICH	364.96	0.5449	0.5903	669.77	321.49
15 MUNICH – STUTTGART	236.62	0.3770	0.5903	627.64	244.62
16 STUTTGART – FRANKFURT	169.32	0.2844	0.5903	595.36	193.57
17 FRANKFURT – DORTMUND	240.14	0.4236	0.5903	566.9	236.85
18 DORTMUND – GERAARDSBERGEN	274.62	0.3974	0.5903	691.04	278.04
19 HAMBURG – COPENHAGEN	464.36	0.6526	0.5903	711.55	373.61
20 COPENHAGEN – STOCKHOLM	595.13	0.9241	0.5903	644.01	392.98
21 VIENNA – KATOWICE	304.38	0.4342	0.5903	701.01	297.1
22 KATOWICE – WARSAW	260.25	0.3744	0.5903	695.11	269.77
23 BUDAPEST – VIENNA	229.06	0.3984	0.5903	574.95	231.68
24 BUCHAREST – BUDAPEST	746.49	0.9563	0.5903	780.6	482.67
25 ATHENS – BUCHAREST	1,079.47	1.5699	0.5903	687.6	499.71
26 NAPLES – ROME	198.12	0.3141	0.5903	630.75	219.06
27 ROME – VERCELLI	561.18	0.7936	0.5903	707.13	405.51
28 VERCELLI – PARIS	760.58	0.9775	0.5903	778.09	485.13

Table 3: Detail of commercial speed on each line of the network

The table 3 shows the commercial speed that Hyperloop would offer on each of the lines of the proposed European network, taking into account both the time of the exclusive movement of the capsule on the so-called 'low pressure side' of the system (variable time), as the time resulting from the sum of the previous time and the fixed time defined in the previous section.

These data allow us to state that the commercial speed linked to the network would be 699.56 km/h when considering only the travel time of the capsules (variable time). If the predefined fixed time (0.5903 hours) is added to this time, the commercial speed would be 357.25 km/h.

3.3.5 About the monthly, weekly, and daily organisation of the transport services

The transport offer made available to users of the new European transport network should be designed according to values of frequency of departure of the capsules from the originating stations expressed in reasonable terms. The time that elapses at a station between the departure of one capsule and the next, may vary depending on the time of day, the day of the week, the season, and the country in which the station is located.

In view of this reality, it is proposed that there should be three annual seasons, quantifiable by months. During the so-called working season, the system's service offer will be mainly oriented to meet the demand generated from Monday to Friday. During the tourist season, the service offer will try to meet the demand generated on weekends. The so-called intermediate season is the period of time when the service supply transitions between the working and tourist season.

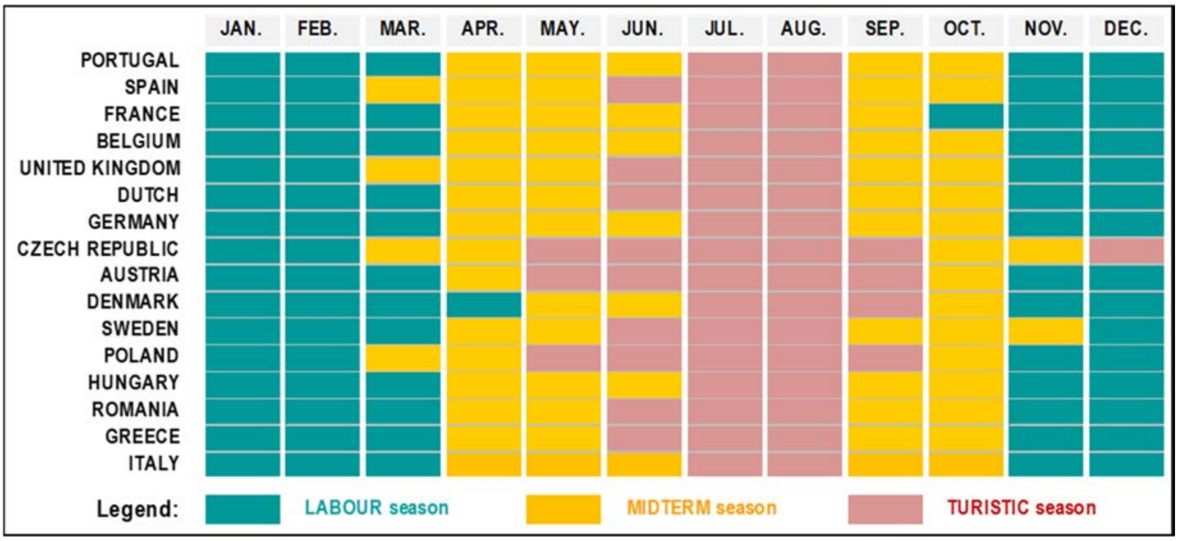

Figure 5: Variation of transport offer by season and country type

Within each season, the transport offer will vary according to the country and each of the four standard days to be considered. This research has considered the existence of 15 standard days.

	MON.	TUES.	WED.	THURS.	FRI.	SAT.	SUN. / HLDY.
WEEK of LABOUR SEASON	LS1				LS2	LS3	LS4
WEEK of MIDTERM SEASON	MS1				MS2	MS3	MS4
WEEK of TURISTIC SEASON	TS1				TS2	TS3	TS4

Figure 8: Pod frequency from stations (expressed in minutes between exits)

The idiosyncrasies of each country shape different patterns of how people spend their time. In the context of the working season, the number of people working and studying throughout the day in the different countries of the European Union tends to be distributed in a similar way, with two clearly differentiated peaks, especially on the days from Monday to Thursday. In terms of urban transport, the existence of these peaks leads to the existence of four peak periods of demand. One before and one after each peak.

There is a tendency to compare the utility of a Hyperloop network with the utility provided by any metro network in any urban agglomeration. Due to the very nature of the trips to be offered by this new transport system, this document will only consider the existence between Monday and Thursday of two peak periods when the frequency of the services offered should be higher.

The figure 7 shows, on the one hand, the time use curves of people on a working day in various European countries according to Eurostat (Madrid (Edizíones) - Europa Press, 2018), and on the other hand, the differentiated frequency periods that must be established within each day.

The figure 8 shows the time in minutes that should elapse in each period (of variable duration depending on the country) linked to each standard day between the departure, from the same station, of two consecutive capsules established in the operational plan. It is this information that defines the final transport offer made available to users of the network.

The amount of service offered for passenger transport ranges from a minimum of four capsule departures per hour and direction (15 minutes frequency) to a maximum of 20 capsule departures per hour and direction (3 minutes frequency).

It is proposed to provide a supplementary cargo service in addition to the passenger service, which will be provided on timetable sections of each standard day where the frequency is more than three minutes.

3.3.6 About inter-core travel, network usage demand and design demand for each line

Newton's gravity equation has served for many years as the basis for explaining the demand for travel between two distant points in the territory. This simple conceptual tool is based on the assumption that traffic between two population centres is proportional to the population of the two centres and inversely proportional to the square of the distance between them, i.e. a point is as attractive as its mass is important and vice versa.

Equation (2) allows the calculation of the displacements between two points i and j with population p_i and p_j and separated by a given physical distance.

$$\text{Total trips F}_{i,j} = K_F \times (p_{i \times} p_j)/(dF_{i,j}{}^2) \quad (2)$$

Equation (3) allows the calculation of the displacements between two points i and j with population p_i and p_j and separated by a given distance in time.

$$\text{Total trips T}_{i,j} = K_T \times p_{i \times} p_j)/(dT_{i,j}{}^2) \quad (3)$$

In both equations, K is a coefficient to be estimated that allows calibration. In this research, the calibration has been carried out considering the reality of population censuses, usage demands, and physical and temporal distances in the Iberian Peninsula, between the Madrid-Barcelona and Madrid-Valencia connections.

Proceeding in the manner described allows two types of displacements to be quantified. One comes from the consideration of an exclusively physical distance (kilometres) between two points, and the other comes from the consideration of an exclusively temporal distance (minutes).

The demand for use of the new system will come from the amount of journeys it is able to capture from other modes (air, rail, bus, car and motorbike), as well as the amount of journeys it is able to induce. Under these assumptions, it has been hypothesised here that 80% of any travel decision on the European Hyperloop network will be influenced by the time variable, while only 20% of that decision will be influenced by the physical distance variable.

Transport line name	Gravitational model total trips (TTGM) and demand for use of the European Hyperloop Network (DUEHN)					Demand for design in …

Table 4: Displacements according to different gravity model criteria. Demand for network use and design demand

Under the above assumptions, if the proposed network design had been fully implemented and operational in 2020, it would have registered an annual usage demand of 145.9 million passengers. Similarly, in the same year, the network would have served 530.6 thousand passengers on an average weekday, and 6,153.5 thousand passengers in a rush hour.

3.3.7 About the carrying capacity of each capsule

The proposed passenger transport demand should be satisfied by a transport supply that allows mobility without bottlenecks at the busiest time of the year (rush hour).

The existence of bottlenecks depends not only on the number of tubes in each direction on each line of the network, but also on the transport capacity of each capsule.

The first hypothesis on capsule capacity adopted by Musk's Alpha document was 28 people per transport unit. However, since 2013, the different studies that have been published have been raising this hypothetical capacity, and it is now beginning to be suggested in a very timid way that this figure, in the case of capsules intended for passenger transport, could even be as high as 200 passengers (European Hyperloop Week Mailbox, 2021). Notwithstanding the above, this document sets the limit for passenger capsules at 100 seats.

Under these conditions, as will be explained below, the new network will assign capsules with transport capacities of 40, 50, 60, 60, 80, 90 or 100 persons (in the case of passenger transport), and capsules with transport capacities of 5, 6.25, 7.5, 10, 11.25 or 12.5 tonnes (in the case of freight transport).

3.3.8 About the amount of tubular infrastructure per direction that will be necessary

The design demands on some of the lines in the proposed network can hardly be met with considerations of a maximum departure frequency of 3 minutes, a capsule capacity of 28 persons, and one tube per direction of travel.

This analysis was already carried out by Egea et al. (2016) when in a study entitled "Comparative analysis of the viability between Hyperloop and AVE means of transport in the Madrid-Barcelona corridor" (Egea et al., 2016), under the consideration of capsules with a capacity for 28 passengers, and operating conditions different from those proposed in this research, they already demonstrated the need for the existence of two Hyperloop tubes in each direction on a hypothetical Madrid - Barcelona route that would serve the current high-speed rail demand at rush hours in the corridor.

In this context, if the capsule capacity is brought to its maximum value of 100 seats, but the maximum frequency of passenger capsule departures from stations remains unchanged at 20, in the 2020 standard year, there will be two lines on the network that will need to have more than one tube per direction to meet the weekday design demand. Specifically, the

Geraardsbergen - London connection (line 7) will require three tubes in each direction, and the London - Stoke-on-Trent connection (line 8) will require two tubes in each direction.

Despite the above, the need for three tubes in each direction on line 7 results in unsatisfied demand at rush hour. This situation of unsatisfied demand at rush hour is repeated on three other lines in the network (line 3 Madrid - Barcelona, line 6 Paris - Geraardsbergen, and line 28 Vercelli - Paris), which quantify the number of tubes required in each direction at one. The existence of small bags of unsatisfied demand in some cases is justified by the rational need to ensure that there is no under-utilised stock of public capital at any point in the life cycle of any infrastructure.

3.3.9 About the relation between the transport capacity of each capsule and the amount of tubular infrastructure per way

The weekday and rush hour design demands provided for each line of the new network in section 3.3.6 are linked to the year 2020. There is a large body of research that attempts to link the annual growth in demand for any mode of transport to the evolution of the GDP of the countries in which it is generated. Thus, if no technical progress is made on the existence of capsules that overcome the self-imposed limitation of 100 seats, the need for more than one tube per direction will end up affecting more lines than initially enunciated.

The 2018 Ageing Report (European Commision, 2018), one of a series of reports regularly published by the European Commission, provides very long time series quantifying GDP growth by country. Similarly, through equation (4), which is the result of research led by Judith Fernández (2015) in the framework of the Optired project (Fernández Jáñez, J., 2012), it is possible to make prognoses on the growth of demand for a transport system according to the evolution of GDP linked to the territory that hosts them.

$$\%\triangle \text{ Demand} = 0{,}11698 \times (\%\triangle GDP - 0{,}8817)^2 + 1{,}906 \times (\%\triangle GDP - 0{,}8817) \quad (4)$$

Table 5: Evolution of the need for tubes by direction due to increases in demand in two pod capacity scenarios

Based on the approaches described above, table 5 is provided showing those lines which in the period 2020-2098 will gradually increase their need for tubes per direction by more than one. The table shows the values for the need for tubes both in the case where the capacity limit of the passenger capsules is 100 or 200 seats.

As an abacus, the figure below shows the results of a simulation relating the capacity of passenger capsules to the need for tubes per direction on five of the 28 lines in the network.

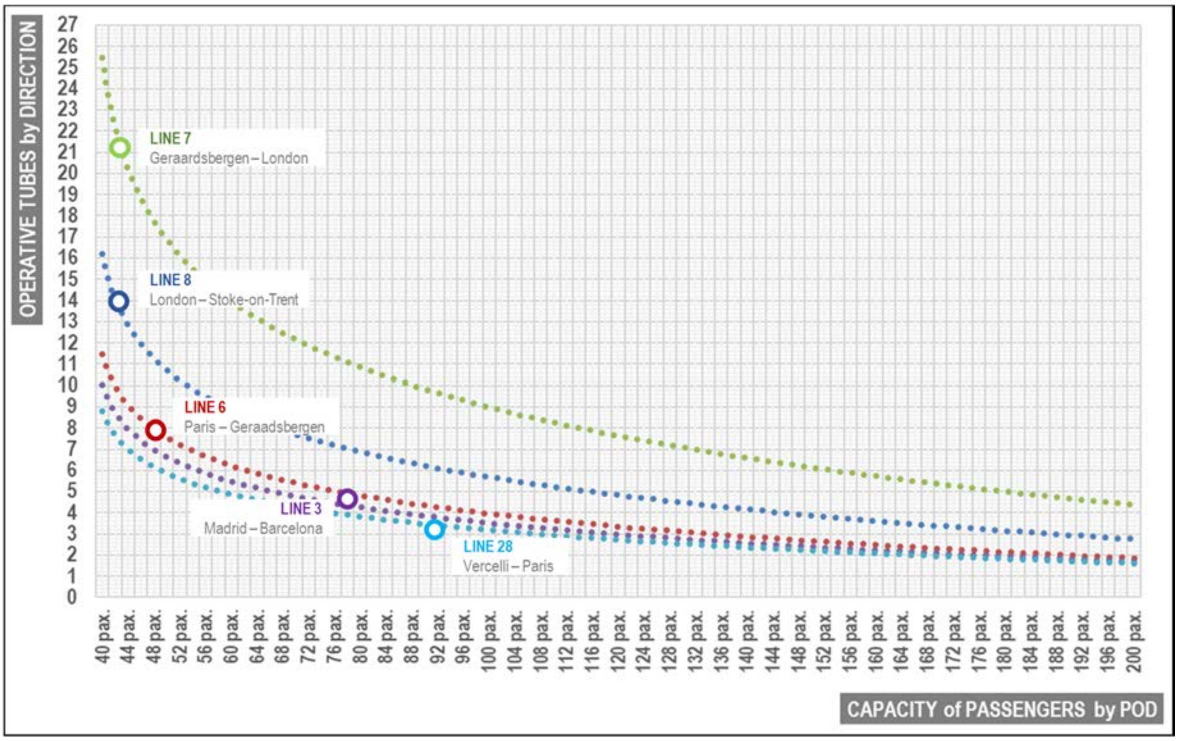

Figure 9: Relation between pod passenger capacity and the need to operate two tubes or more per direction

In any case, for reasons of space, the configuration of the line does not seem reasonable to exceed 3 operational tubes per direction and 1 additional tube as a backup. It is environmentally unacceptable to create tracks in the terrain that are more than 60 metres wide.

Table 7b: Quantification of the offer transport linked to a previously justified amount of infrastructure and pods.

5. CONCLUSIONS

The information set out in this document would already allow an approximation of the capex of network implementation and the opex linked to the operation of transport services. It will also make it possible to establish revenue scenarios based on assumptions of passenger and freight capsule occupancy for each of the proposed journeys.

Based on the above, it can be stated that the average length of a line in the network is 430.96 km, and the average journey time is 1.21 hours. 23% of the tubular infrastructure would correspond to backup tubes. This type of tube should have a pressure inside it such that, should it be necessary, due to an incident in the rest of the pipes, the service pressure would be reached in a short space of time.

The carrying capacity of the passenger capsules would range from 40 to 100 seats per trip. If each seat is assigned an equivalent payload of 125 kg, the carrying capacity of the cargo capsules would range from 5 to 12.5 tonnes. The cargo activity is envisaged as a complementary service to passenger transport and should be focused on high value-added and/or perishable cargo.

The need for passenger pods is quantified at 1,680 (73.5% of the total), and they would operate on a daily average of 8.70 journeys (4.35 journeys per direction). The average operating time of this type of capsule would be 4,111 hours per year (11.26 hours per day).

The average annual km travelled by each passenger capsule would be around 1.3 million (3,591 km per day).

The need for cargo capsules is quantified at 604, and they would operate on a daily average of 4.66 expeditions (2.33 expeditions per direction). The average operating time of this type of capsule would be 2,450 hours per year (6.71 hours per day). The average annual km travelled by each passenger pod would be around 0.70 million (1,921 km per day).

From the gravity demand models, a demand for the use of the network of 145.9 million passengers can be surmised for the year 2020. The calculation of this usage demand in a planning phase is particularly useful to obtain the design demands for an initial dimensioning of the number of tubes required in each direction.

The setting of operating timetables per line on each of the 14 predefined standard days, and of time slots within each day with differentiated service frequencies, would make it possible to offer a potential transport capacity of 355 million passengers per year and 8.7 million tonnes from 2020 onwards.

As a reference taken from Eurostat (2021), it is worth noting that in terms of air transport alone, the volume of passengers generated in 2019 by 47 European airports (providing a service equivalent to that provided by the 28 stations of the European Hyperloop Network) to any other airport in the European Union amounted to 256 million. These values show the possibility of growth in demand for use over a reasonable period of time during which it would not be necessary to undertake work to expand the capacity of the network.

6. NEXT STEPS

If the final decision on the part of governments is to provide this type of infrastructure through public-private partnership contracts, there must necessarily be Special Purpose Companies of a mercantile nature to make them a reality. In this sense, it is essential to determine the number of companies that will be necessary to carry out the investment projects, as well as to describe the corporate purpose of each.

In the process of technical, economic, financial, and legal structuring of this type of agreement between public and private agents, the amount of obligations to be met by the companies will emerge on the one hand, and the amount of rights on the other. The final balance resulting from the balancing of these rights and obligations will make it possible to quantify, where appropriate, the need for the contribution of public resources and their typology.

In this context, one of the most relevant obligations in the opex structure of the new operating companies will be electricity consumption.

As stated at the beginning of this paper, Hyperloop has been presented to the world as a new green mode of transport, and the existing proposals to date all advocate that the renewable energy source should be solar. Since 2009, the price of solar power generation has been gradually decreasing from USD 0.359 per kWh to USD 0.037 per kWh today. Similarly, in 2009 the cost of wind power generation was USD 0.135 per Kwh to USD 0.040 today (Schneider, 2021). Despite the relatively low prices on exhibit, and the technical availability of battery backup is becoming more and more feasible, there is still a problem of stable availability of this type of energy source.

It would therefore be worth exploring the possibility of linking Hyperloop with novel energy sources that are potentially more beneficial than solar and wind. In 2016, the European Patent Office approved the patent application for a Spanish invention called the Ionic Electric Power Station (Santana Ramirez, 2016), which, in addition to promising to generate electricity at a production cost of around USD 0.020 per kWh, has also been classified by the same body as a renewable energy source that mitigates climate change under the heading (Y02P20/133).

Keep going through further progress in the search for sustainable energy sources with more stable generation profiles will advance the financial viability of Hyperloop.

RESUMEN

En este trabajo abordamos un problema de localización que, a pesar de su gran interés y aplicabilidad en situaciones reales, ha sido poco estudiado en la literatura. No obstante, cada vez más empresas se enfrentan a él a la hora de determinar la localización óptima de sus instalaciones. Generalmente, cuando queremos localizar un conjunto de instalaciones, ya sean estaciones de bicicletas, centros comerciales u hospitales, entre muchas otras, se intenta que estén lo más cerca posible de sus puntos de demandas, esto es, usuarios de la bicicleta, clientes o pacientes. Pero, a su vez, se desea también que la carga de trabajo (la demanda) esté repartida de forma homogénea.

Así, los objetivos a optimizar serían: minimizar la mayor distancia entre las instalaciones y los puntos de demanda y balancear la carga de trabajo de las instalaciones que se localicen, entendiendo como carga de trabajo el número de puntos de demanda a los que una instalación presta servicio. Por tanto, se consideran dos objetivos que, habitualmente están en conflicto, esto es, si se trata de localizar instalaciones favoreciendo que los puntos de demanda estén lo más cerca posible de la instalación que le presta el servicio, podría conllevar que haya instalaciones que tengan una carga de trabajo más elevada que otras. Igualmente, si nos centramos en optimizar el balanceo de la carga de trabajo de las instalaciones, podría conllevar que los puntos de demanda estén más alejados. Debido a la complejidad del problema de optimización combinatoria bi-objetivo que sea plantea, los métodos exactos hacen que su resolución sea costosa o inviable. Esto nos lleva a proponer un algoritmo metaheurístico capaz de resolverlo rápidamente obteniéndose soluciones de gran calidad. Concretamente, se propone un algoritmo híbrido basado en Oscilación Estratégica combinado con Path Relinking capaz de ofrecer diferentes soluciones eficientes de gran calidad.

1. INTRODUCCIÓN

En general, los problemas de localización son problemas clásicos de optimización que consisten en encontrar la mejor localización para situar un conjunto de instalaciones, que deben servir a su vez a un conjunto de puntos de demandas. El término *mejor* dependerá de la función que se considere a la hora de resolver el problema de localización específico que tengamos entre manos. Normalmente, esta función suele definirse basándonos en la distancia o en el coste que hay entre los puntos de demandas y las instalaciones.

Además, en términos generales un problema de localización puede clasificarse como discreto o continuo, ponderado o sin ponderar, con capacidades o sin capacidades, determinístico o estocástico, y esto dependerá de las características que tengan asociados tanto los puntos de demanda a los que haya que dar servicio como las instalaciones a localizar. Por otro lado, cuando estamos resolviendo un problema real es común que se consideren más de un objetivo a la vez cuyos objetivos están en conflicto, es decir, es imposible mejorar uno de ellos sin empeorar otro, convirtiéndose el problema en un problema de optimización multi-objectivo ya que, en lugar de obtener una solución óptima, se debe obtener un conjunto de soluciones eficientes (también conocidas como soluciones no dominadas o soluciones Pareto). Diremos que una solución es eficiente cuando no exista ninguna otra solución posible que la mejore en, al menos, uno de los objetivos, igualando los niveles de los demás.

En este trabajo pretendemos resolver un problema de localización bi-objectivo, discreto, no ponderado, sin capacidades y determinístico conocido como el problema del k-centro balanceado, en adelante, k-BCL (por sus siglas en inglés, k-Balanced Center Location). Este problema fue estudiado por primera vez por Davoodi (2019) y su objetivo es localizar un k de instalaciones, seleccionadas de un conjunto m de posibles instalaciones candidatas, con $k<m$, para servir a un conjunto de n puntos de demanda de forma que se minimice la máxima distancia entre cada punto de demanda y su instalación más cercana, para que todos los puntos de demandas puedan tener las instalaciones que le prestarán el servicio lo más cerca posible, y al mismo tiempo minimizar el máximo número de puntos de demandas asignados a cada instalación para balancear la carga de trabajo de cada instalación.

Para abordar el problema del k-BCL se ha diseñado un algoritmo metaheurístico basado en la construcción soluciones usando un algoritmo GRASP (Festa y Resende, 2009). Estas soluciones se incluyen en un algoritmo de Oscilación Estratégica (Glover, 2000) combinado con Path Relinking (Ribeiro y Resende, 2012) capaz de ofrecer diferentes soluciones eficientes de gran calidad.

2. ALGORITMO

Como se introdujo anteriormente el problema del k-BCL pretende: minimizar la máxima distancia entre cada punto de demanda y su instalación más cercana, y al mismo tiempo, minimizar el máximo número de puntos de demandas asignados a cada instalación.

Teniendo estos dos objetivos en cuenta, a continuación, se detalla el algoritmo diseñado para obtener soluciones eficientes para este problema.

2.1 Construcción: GRASP

Para construir soluciones factibles usaremos una metodología GRASP (Festa y Resende, 2009) que es un algoritmo multi-arranque que se compone de dos fases: fase de construcción y fase de mejora. La fase de construcción es la encargada de construir soluciones factibles desde cero y la fase de mejora es la encargada de mejorar las soluciones aplicando una búsqueda local. Por tanto, para construir soluciones partimos de una solución vacía y se elige aleatoriamente la primera instalación que se va a localizar y a continuación se ordenan en una lista el resto de las instalaciones basándonos en una medida de contribución que dependerá de la función a optimizar. Este algoritmo en lugar de seleccionar siempre la mejor instalación elegirá aleatoriamente una instalación de las mejores hasta que se haya construido una solución completa, es decir, hasta que se hayan seleccionado (o abierto) *k* instalaciones. Esto se repite *N* veces para tener una población inicial de soluciones. Como estamos tratando con un problema con dos objetivos que están en conflicto, tendremos que quedarnos con todas aquellas soluciones que sean eficientes. Como es usual en un algoritmo GRASP, se intentarán mejorar las soluciones aplicándoles una búsqueda local. En este caso, hemos optado por una búsqueda local muy sencilla que consiste simplemente en intercambiar una instalación que haya sido incluida en la solución con otra que no lo haya sido y ver si somos capaces de mejorarlas haciendo este simple intercambio.

2.2 Oscilación Estratégica

Las soluciones eficientes obtenidas en la fase anterior serán incluidas en un procedimiento de oscilación estratégica (Glover, 2000) que consiste en explorar nuevas regiones del espacio de soluciones gracias a movernos entre la factibilidad y la infactibilidad de las soluciones.

En la Figura 1 puede observarse gráficamente como funciona la oscilación estratégica. Partimos de una solución factible obtenida en la Sección 2.1, S_i y añadiremos y eliminaremos instalaciones para obtener soluciones infactibles, S_i^a y S_i^r. En la mitad del camino obtendremos otra solución factible, S_i^c. Este procedimiento se repetirá un número de veces que denotaremos *Iter*.

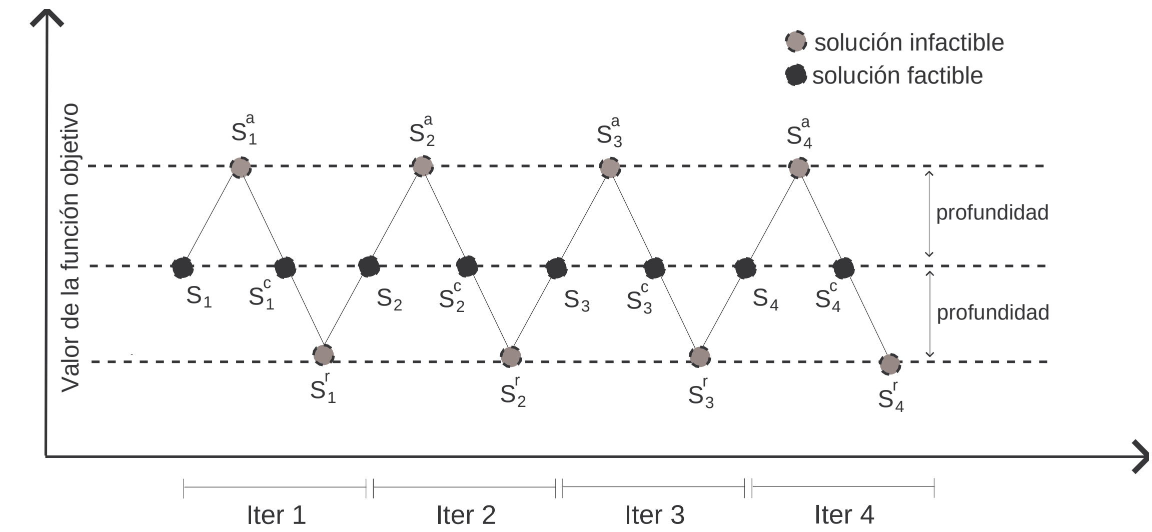

Figura 1: Oscilación estratégica

Recordemos que de nuevo, cada vez que obtengamos una solución factible, S_i y S_i^c, para *i=1,…,Iter,* debemos comprobar si es una solución eficiente, comparándolas con las previamente obtenidas.

2.3 Path Relinking

Para finalizar, exploraremos más soluciones uniendo trayectorias de soluciones que conecten dos soluciones infactibles cualesquiera obtenidas en la Sección 2.2 gracias a la oscilación estratégica, S_i^a y S_i^r.

En la Figura 2, se muestra un ejemplo en el que hay que localizar 6 instalaciones y partimos de dos soluciones infactibles con 2 instalaciones más (solución de partida) y 2 instalaciones menos (solución final). La metodología de Path Relingking va eliminando de la solución de partida las instalaciones que no estén en la solución final. A continuación, se eliminan instalaciones que estén en la solución de partida y se van sustituyendo por instalaciones que estén en la solución final. De esta forma se obtiene un camino para llegar de una solución a la otra que compartirán atributos de ambas soluciones y que además, convierte a estas soluciones en factibles.

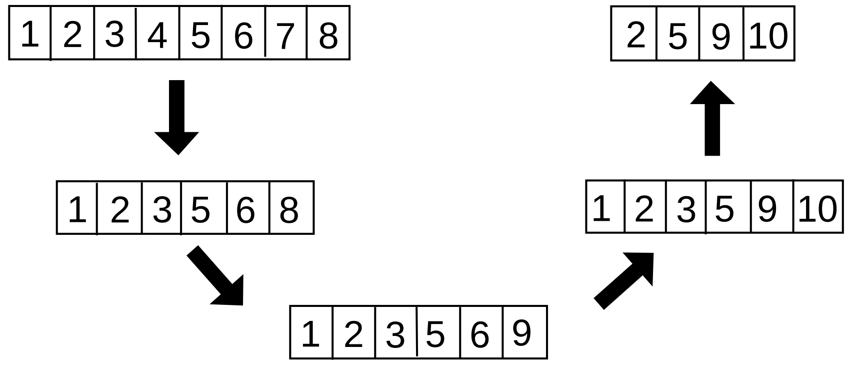

Figura 2: Ejemplo de Path Relinking entre dos soluciones infactibles

Una vez más, cada vez que obtengamos una solución factible debemos comprobar si es una solución eficiente, comparándolas las obtenidas con anterioridad.

3. RESULTADOS

En esta sección se muestran los resultados que se han obtenido al resolver 40 problemas del repositorio OR-lib (http://people.brunel.ac.uk/\textasciitilde mastjjb/jeb/info.html) con el algoritmo propuesto en este trabajo y con otros propuestos en la literatura: NSGA-II (Deb *et al.*, 2002), MOEA/D (Zhang y Li, 2007) y SPEA2 (Zitzler *et al.*, 2001).

Las soluciones eficientes obtenidas por los cuatro algoritmos han sido representadas para cada problema por separado pudiéndose observar que nuestro algoritmo denominado SO+PR es capaz de obtener en una mayoría de los problemas mejores soluciones eficientes.

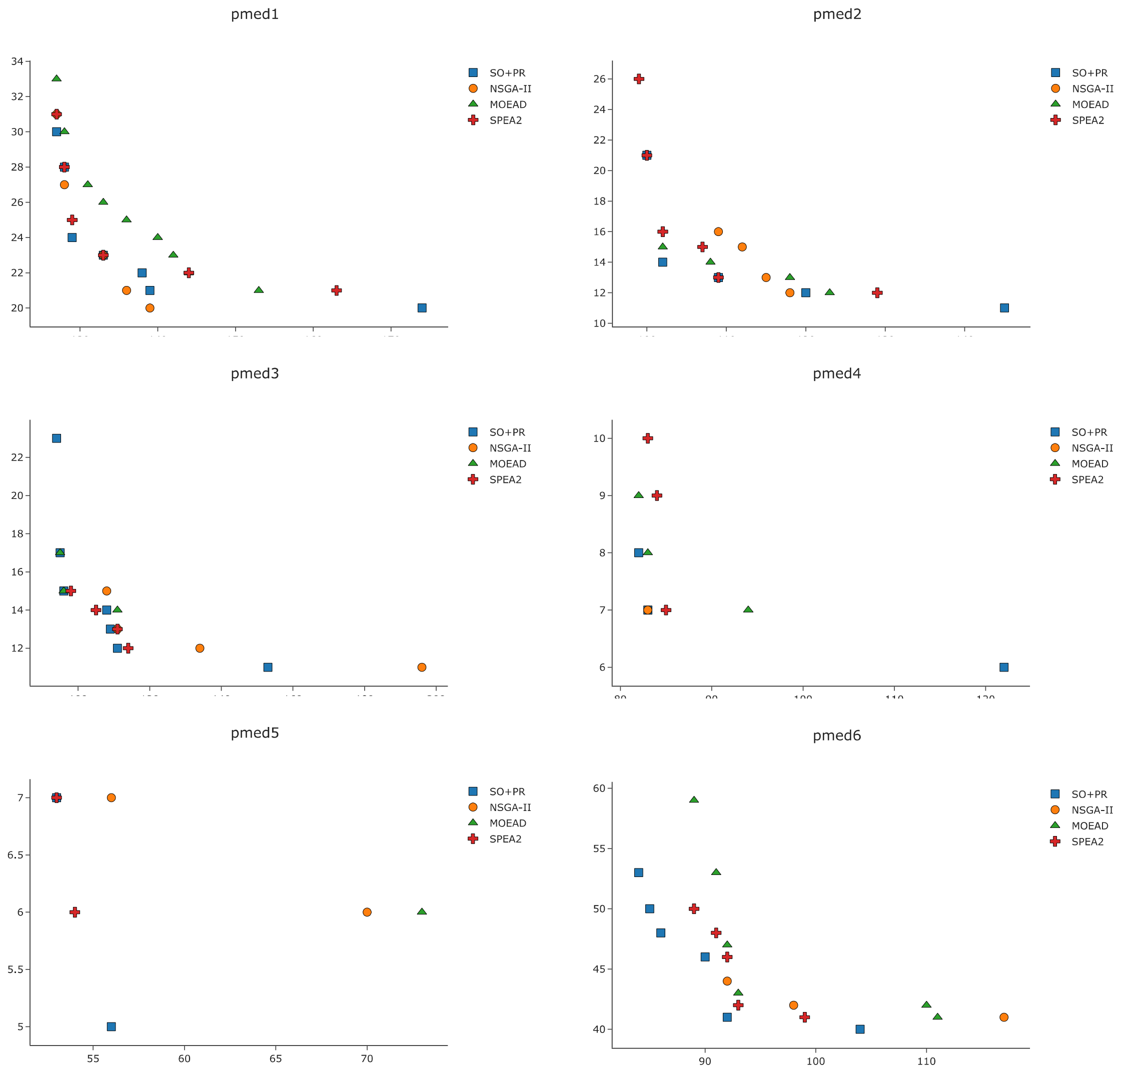

Figura 3: Soluciones eficientes 1-6.

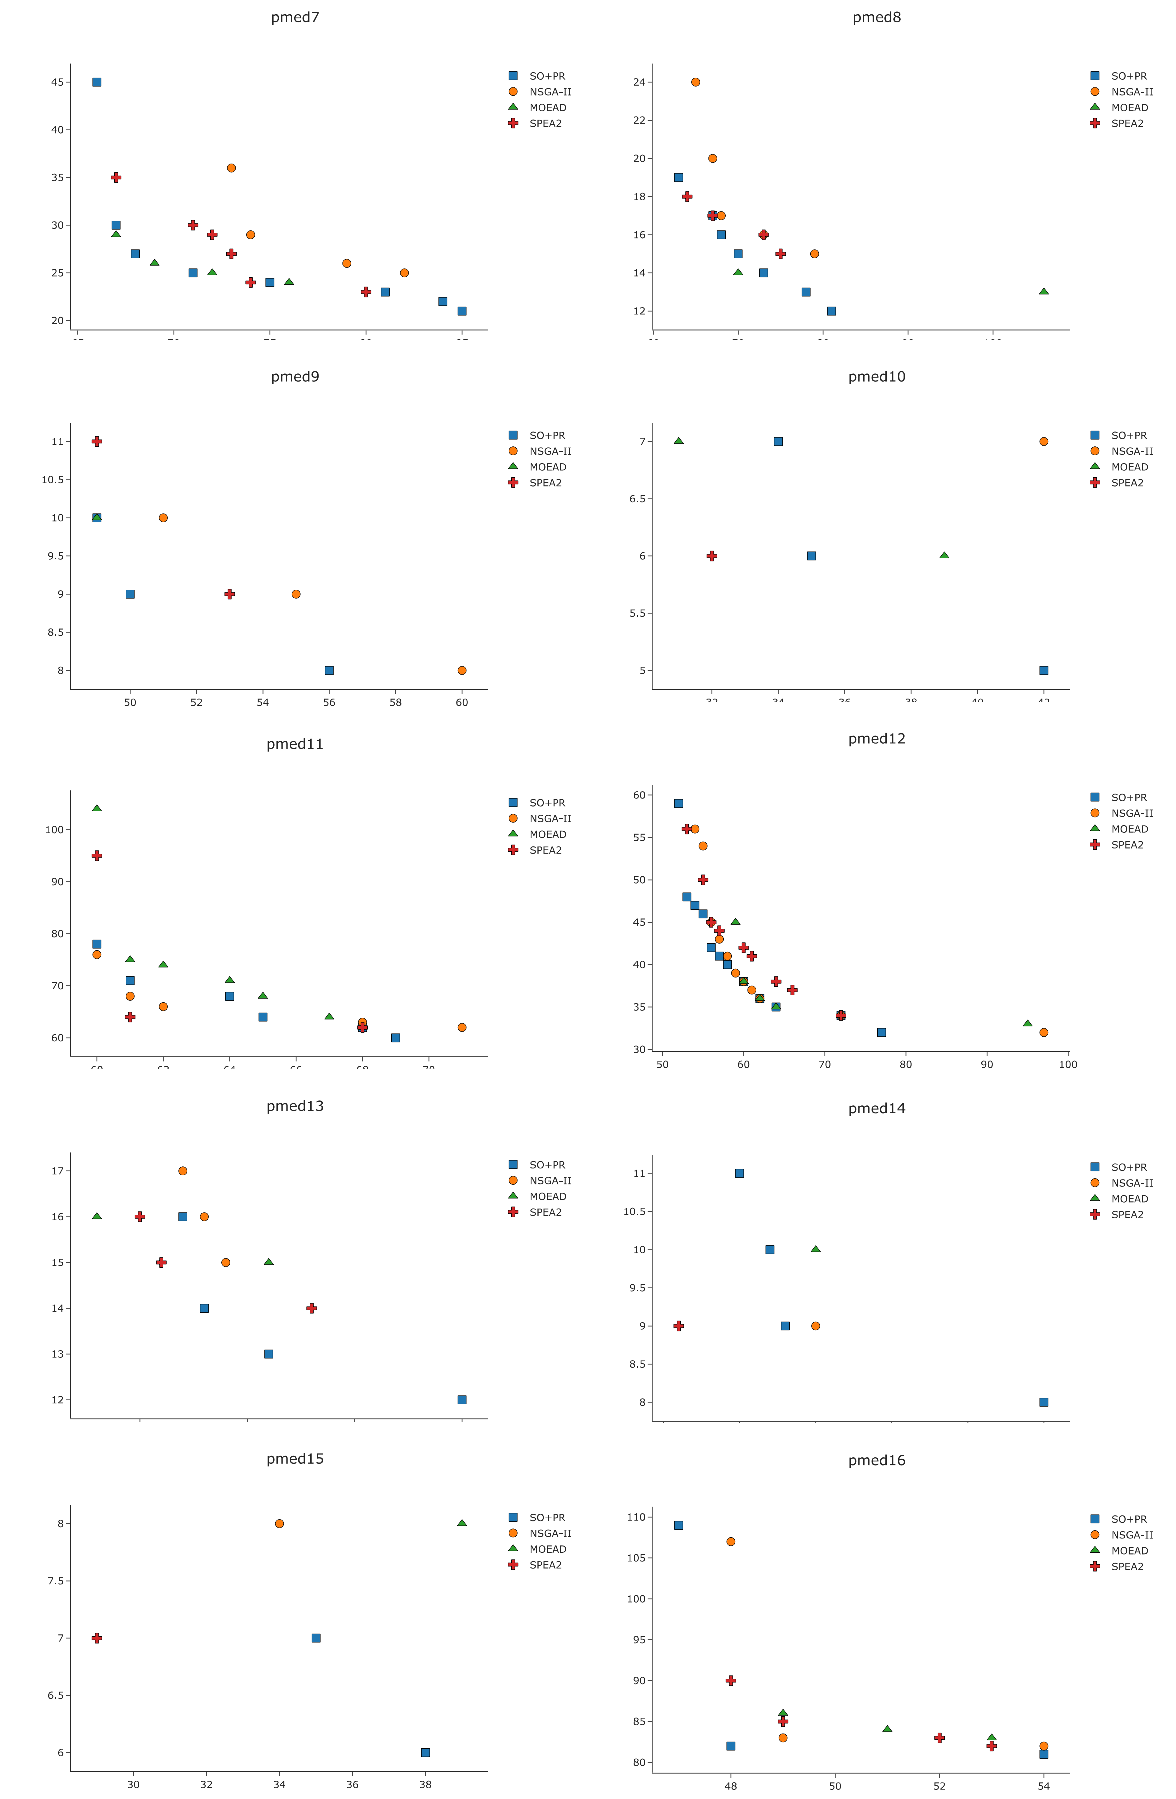

Figura 4: Soluciones eficientes 7-16.

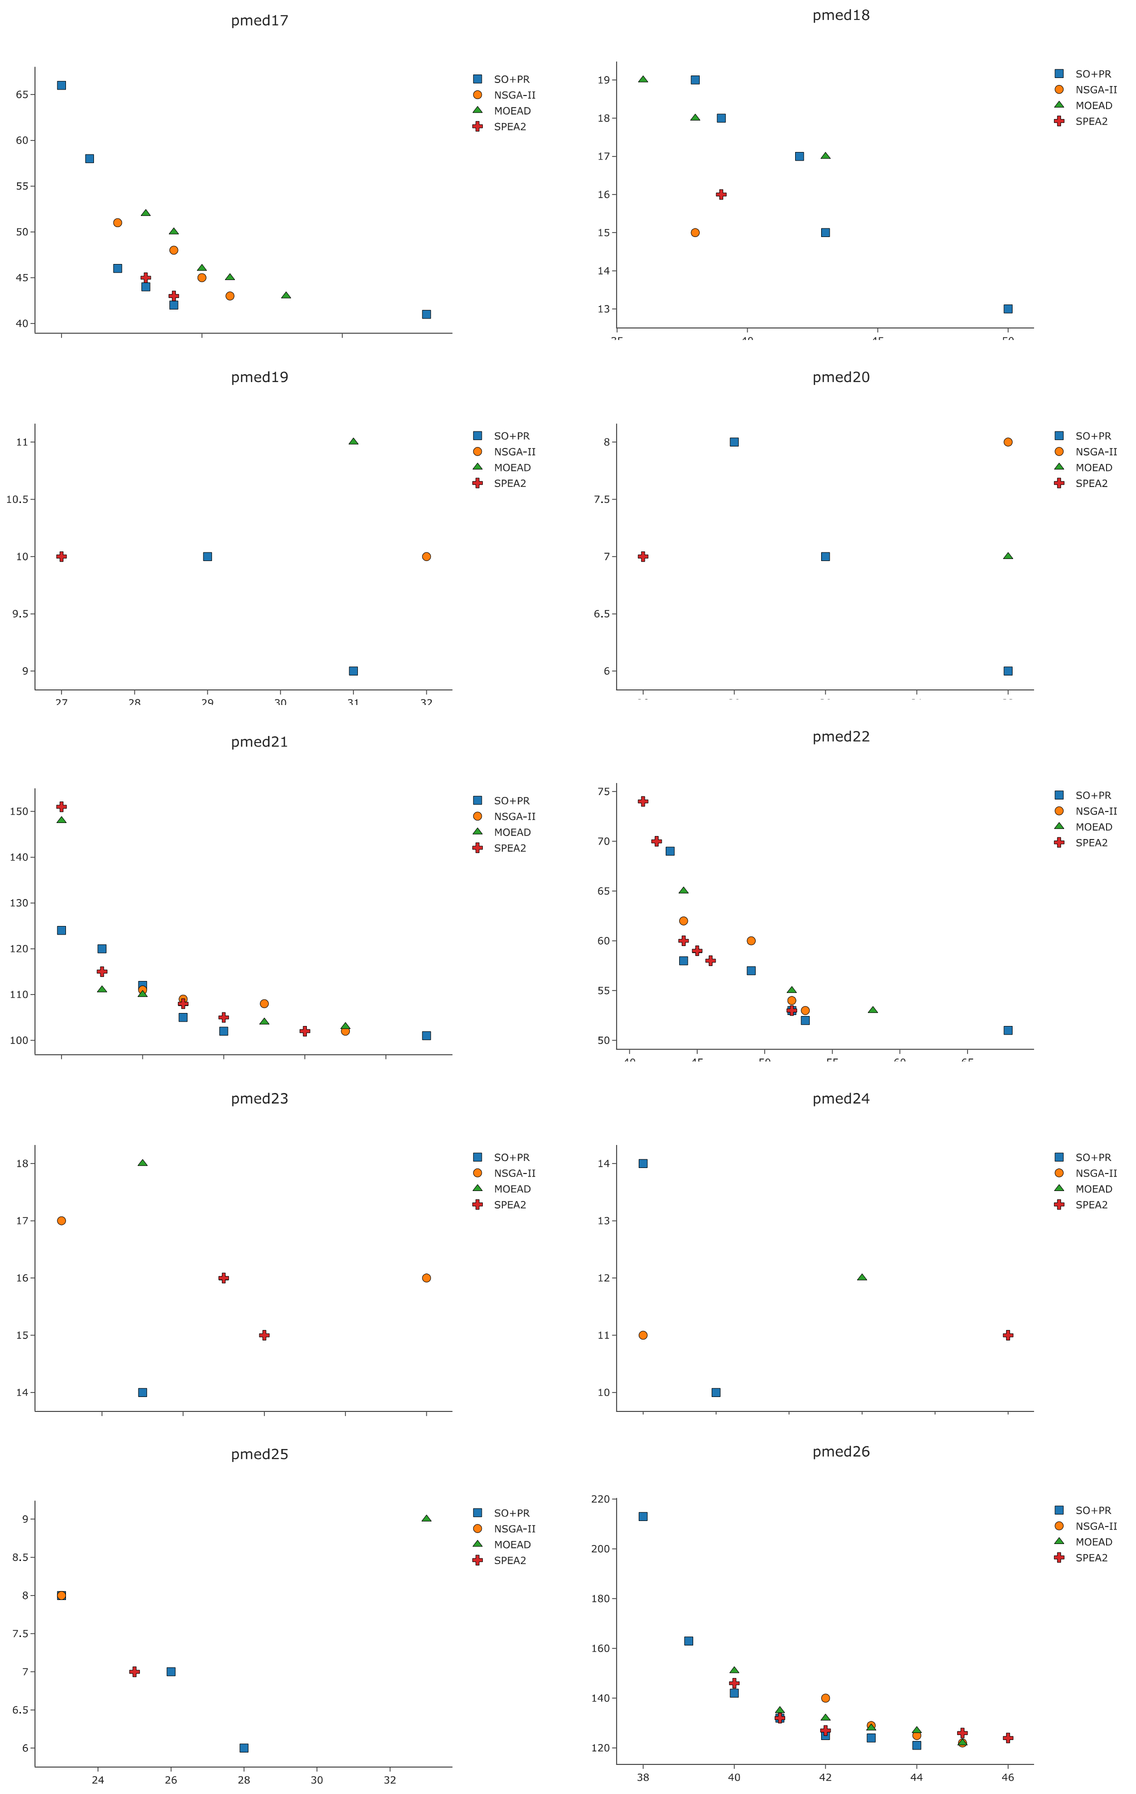

Figura 5: Soluciones eficientes 17-26.

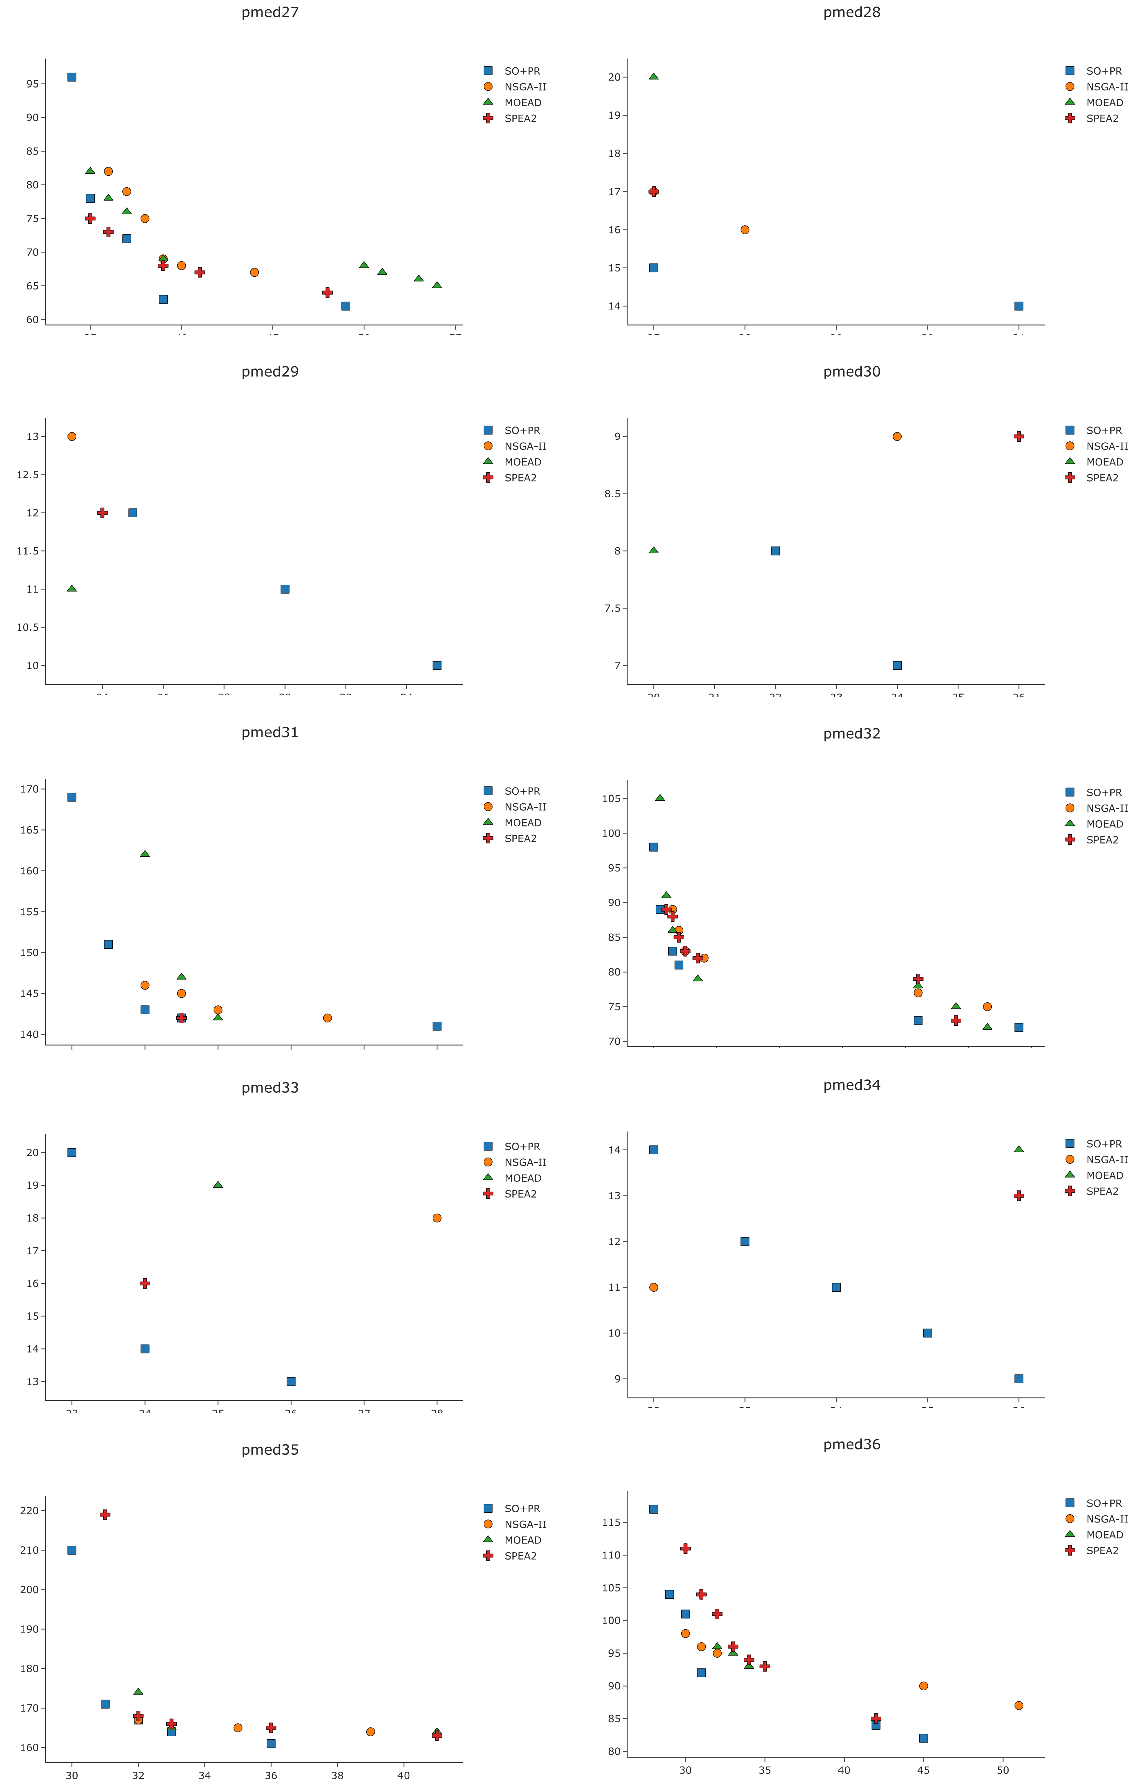

Figura 6: Soluciones eficientes 27-36.

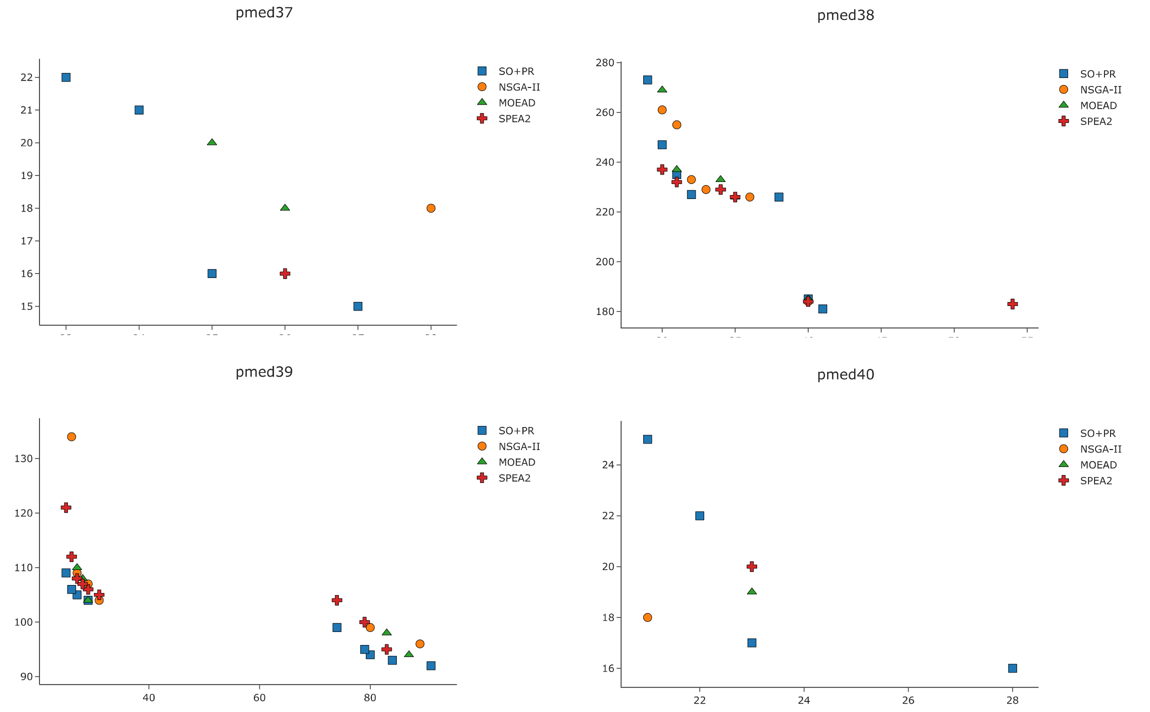

Figura 7: Soluciones eficientes 37-40.

4. CONCLUSIONES

En este trabajo se propone un algoritmo que es capaz de resolver de forma eficiente un problema de localización con dos objetivos que aparece en muchas situaciones reales, el problema que consiste en localizar cualquier tipo de instalaciones asegurando que todos los puntos de demandas puedan tener las instalaciones que le prestarán el servicio lo más cerca posible, y todas las instalaciones tenga una carga de trabajo similar para evitar desigualdades entre ellas.

RESUMEN

En este trabajo presentamos un problema de localización de instalaciones que aparece en múltiples situaciones reales y que, por tanto, es de gran interés para diversos sectores. Generalmente, cuando se desea localizar un conjunto de centros logísticos o de distribución que van a prestar un servicio tanto a empresas minoristas como mayoristas, se intenta que estén situados lo más cerca posible de estas empresas.

Además, se suele asumir que cada empresa recibirá el servicio del centro logístico más cercano. Esto se traduce en que el objetivo o criterio a optimizar sea situar los centros logísticos en aquellos lugares que minimicen la máxima distancia entre las empresas y su centro logístico, asegurando así que la empresa más alejada de su centro de distribución estará lo más cerca posible y, por tanto, todas las demás empresas recorrerán una distancia inferior.

Sin embargo, aparecen situaciones en las cuales algún o algunos centros logísticos podrían quedar inhabilitados debido, por ejemplo, a una catástrofe natural. En este caso, las empresas que son servidas por los centros logísticos afectados tendrán que recibir el servicio desde otro punto. Este otro centro podría ser el segundo más cercano o, si éste también estuviera no disponible, desde el tercero más cercano o, si éste tampoco pudiese dar servicio, desde el cuarto más cercano, y así sucesivamente. Este problema no ha sido muy estudiado en la literatura, pero cada vez se aplica más en situaciones reales propias, por ejemplo, de la Logística Humanitaria. Debido a su complejidad, los métodos exactos no permiten resolver este problema en tiempos razonables.

Por ello, proponemos un algoritmo metaheurístico capaz de resolverlo rápidamente obteniéndose soluciones de gran calidad. Concretamente, se propone un algoritmo GRASP combinado con una Búsqueda Tabú y una Oscilación Estratégica.

1. INTRODUCCIÓN

Existen muchas situaciones reales en las que hay que instalar un conjunto de instalaciones (hospitales, centros comerciales, estaciones de bicicleta, centros logísticos, etc.) para dar un servicio a un conjunto de puntos de demanda (pacientes, clientes, usuarios de bicicleta, empresas, etc.). Hay multitud de problemas de localización según la función que se desee optimizar, algunos de los más conocidos son el problema del p-centro, el problema del p-mediana o el problema de la máxima cobertura. Una característica común que la mayoría de los problemas de localización tienen es que cada punto de demanda será servido por su instalación más cercana ya que así se reduce el coste o el tiempo en el que se obtiene el servicio.

Sin embargo, podría ocurrir que algunas de las instalaciones se queden inhabilitadas debido a algún fallo y que haya que acudir a otra instalación para que preste el servicio requerido por los puntos de demanda. Podemos distinguir entre dos situaciones, que no se conozca de antemano qué instalaciones están inhabilitadas o que si se conozcan. En el primer caso, el cliente debe acudir a la instalación para poder comprobar que no puede obtener el servicio requerido, y una vez allí se dirigirá a la siguiente instalación más cercana a ésta. Este problema se conoce como el problema del próximo p-centro (Albareda-Sambola et al., 2015 o López-Sánchez et at., 2019) y el objetivo es minimizar la máxima distancia entre los puntos de demanda y las instalaciones más cercanas mas la distancia entre las instalaciones y las instalaciones más cercanas a éstas. En el segundo caso, el cliente sabe a priori qué instalaciones no están disponibles y en lugar de ir la instalación más cercana, si ésta no estuviese disponible, se dirigirá directamente a la segunda o si esta no estuviera disponible, se dirigirá a la tercera, y así sucesivamente. Este problema se conoce como el problema del $\propto$-ésimo p-centro (Chen y Chen, 2013) y el objetivo es minimizar la máxima distancia entre los puntos de demanda y la $\propto$-ésima instalación más cercana. En este trabajo se resolverá esta versión del problema, el $\propto$-ésimo p-centro que como se ha indicado su objetivo es localizar un conjunto p de instalaciones, seleccionadas de un conjunto m de posibles instalaciones candidatas, con $p<m$, para servir a un conjunto de n puntos de demanda de forma que se minimice la máxima distancia entre cada punto de demanda y su $\propto$-ésima instalación más cercana, para que todos los puntos de demandas puedan tener, no sólo una única instalación cercana sino $\propto$ instalaciones cercanas asegurando que en el caso de que alguna instalación quedase inhabilitada, poder dirigirnos a la siguiente y que ésta siga estando cerca.

Para abordar el problema se ha diseñado un algoritmo metaheurístico basado en un algoritmo GRASP (Festa y Resende, 2009) para construir soluciones y mejorarlas usando en lugar de una búsqueda local tradicional, una búsqueda Tabú (Glover y Laguna, 1998) Estas soluciones se incluyen en un algoritmo de Oscilación Estratégica (Glover, 2000).

2. ALGORITMO PROPUESTO

Como se introdujo anteriormente el problema del ∝-ésimo p-centro pretende: minimizar la máxima distancia entre cada punto de demanda y su ∝-ésima instalación más cercana. Teniendo este objetivo, a continuación, se detalla el algoritmo diseñado para obtener soluciones para este problema.

2.1 GRASP

Para construir soluciones factibles usaremos una metodología GRASP (Festa y Resende, 2009) que es un algoritmo multi-arranque con dos fases: fase de construcción, que es la encargada de obtener soluciones factibles desde cero y fase de mejora, que es la encargada de mejorar las soluciones obtenidas en la fase de construcción.

En la fase de construcción partimos de una solución vacía y se elige aleatoriamente la primera instalación que se va a localizar y a continuación se ordenan en una lista el resto de las instalaciones basándonos en una medida de contribución que dependerá de la función a optimizar. Este algoritmo en lugar de seleccionar siempre la mejor instalación elegirá aleatoriamente una instalación de las mejores instalaciones hasta que se haya construido una solución completa, es decir, hasta que se hayan seleccionado p instalaciones. Esto se repite N veces para tener una población inicial de soluciones.

Una vez construidas N soluciones factibles y como es usual en un algoritmo GRASP, se intentarán mejorar las soluciones aplicándoles una búsqueda local. Una búsqueda local sencilla consistiría simplemente en intercambiar una instalación que haya sido incluida en la solución con otra que no lo haya sido y ver si somos capaces de mejorarlas haciendo este simple intercambio. Sin embargo, en esta fase en lugar de optar por una búsqueda tradicional hemos implementado una búsqueda tabú (Glover y Laguna, 1998) puesto que uno de los inconvenientes de la búsqueda local tradicional es que la mejora de la solución depende fuertemente de la solución de partida, pudiendo quedar fácilmente en un óptimo local. La búsqueda tabú tiene dos características importantes, memoria adaptativa y aceptación o no de movimientos. En este caso, dispondremos de una memoria a corto plazo que almacenará los últimos movimientos que se hayan realizado, de esta forma no podrán repetirse movimientos mientras que estén almacenados en la memoria, con el fin de restringir los movimientos disponibles y se permitirá empeorar el valor de la función objetivo para evitar quedar atrapado en un óptimo local. La búsqueda tabú termina cuando no se encuentren mejoras después de un número determinado de iteraciones.

2.2 Oscilación estratégica

Las soluciones obtenidas en la fase anterior serán incluidas en un procedimiento de oscilación estratégica (Glover, 2000) que consiste en explorar nuevas regiones del espacio de soluciones gracias a movernos entre la factibilidad y la infactibilidad de las soluciones.

Partimos de una solución factible obtenida en la Sección 2.1, y añadiremos las δ instalaciones para obtener soluciones infactibles con $p + \delta$ instalaciones. A continuación, para recuperar la factibilidad se eliminan δ instalaciones. Se han seguido los siguientes criterios para incluir y eliminar instalaciones:

Insertar	**Eliminar**
Voraz	Voraz
Voraz	Aleatoriamente
Aleatoriamente	Voraz
Aleatoriamente	Aleatoriamente

Tabla 1: Estrategias para insertar y eliminar instalaciones en la oscilación estratégica.

3. RESULTADOS

En esta sección se muestran los resultados que se han obtenido al resolver 37 problemas del repositorio TSP-lib (http://elib.zib.de/pub/mp-testdata/tsp/tsplib/tsplib.html) con el algoritmo propuesto y hemos realizado una comparación con el estado del arte. Concretamente se ha resuelto el problema para $\alpha = 1,2,3$, siendo un total de 111 instancias. En las tablas 2, 3 y 4 se muestran los valores medios de la función objetivo (FO) y el tiempo de ejecución en segundos (CPU) para cada problema solucionado. Se muestra una comparativa de nuestro algoritmo propuesto denominado (SO) y el estado del arte (SOTA) y además se incluyen los límites inferiores (LB) para cada problema.

Como puede observarse en las tablas 2, 3 y 4, el algoritmo propuesto presenta un comportamiento robusto como mostraron las 30 ejecuciones independientes que se realizaron, independientemente del valor de $\propto$ seleccionado.

4. CONCLUSIONES

En este trabajo hemos abordado un problema de optimización conocido como el problema $\propto$-ésimo p-centro y que aparece cuando fallan las $\propto -1$-ésimas instalaciones más cercanas teniendo que ir a la $\propto$-ésima instalación más cercana. Aquí se han abordaddo situaciones con $\propto = 1,2,3$ puesto que en situaciones reales suele ser improbable que fallen más de 3 instalaciones. El algoritmo que se propone es capaz de obtener soluciones independientemente del valor de $\propto$ que se indique y esa flexibilidad es una de las fortalezas del algoritmo propuesto.

ANALYSIS OF PUBLIC-PRIVATE PARTNERSHIP MODELS IN HIGH-SPEED RAILWAY TRANSPORT IN PORTUGAL

Mario González-Medrano
PhD Student, University Camilo José Cela, Madrid, Spain
Tomás García Martín
Professor, University Camilo José Cela, Madrid, Spain

ABSTRACT

European railway transportation is not as efficient as it could be. Several factors contribute to this absence of efficiency, including a lack of private investment and exclusively public railway administrators and enterprises. Public-private partnerships can yield higher efficiency in railway transport. Within the high-speed railway sector there are a few implemented infrastructures through public-private partnerships and, in many of them, the result has not been the expected one. Hence, the purpose of this research is to develop a list of recommendations and good practices that allow governments, private investors, and railway stakeholders to take better and more efficient decisions on the implementation of new high-speed rail lines. Consequently, this research has analysed the Portuguese high-speed rail network called Rede Ferroviária de Alta Velocidade (RAVE) designed through public-private partnership. The research methodology is based on exploratory case study and on the identification of critical success factors. This article has made it possible to develop the following list of recommendations and good practices, cross-border cooperation for international sections, unique contracts for substructure and superstructure and an independent contract for signalling and communication systems.

1. INTRODUCTION

Exclusively public railway managers and operators, an absence of cost-reducing competition, and a lack of private investment can be classified as the historical factors that have not allowed railway transport to be as efficient as it might be (European Parliament, 2016). The European Union initiated railway transport liberalisation in 2006 with international freight transport, in 2007 with domestic freight transport, continued in 2010 with international passenger transport, and finished the 14th December 2020 with domestic passenger services (Diario Oficial de la Unión Europea, 2004b, 2007, 2016). These measures represent the initial actions taken toward an efficient railway system in Europe.

The most efficient railway transport management and development can be obtained through public–private partnership (PPP) contracts. PPP offers a reduction in public financing, mobilises private investment, and grants access to advantages connected with the private sector like skilled project management and innovation. Public services such as road transport have implemented this partnership successfully, but it is not a common model in high-speed railway transport. A limited number of high-speed railway lines have been constructed using PPP contracts. However, in many cases, the result has not been optimal. The following situations illustrate these facts (European PPP Expertise Centre 2020; World Bank, 2017, 2020).

Since 2007, a high-speed railway line has connected the Channel Tunnel with London. Formerly known as the Channel Tunnel Rail Link, this line is currently called High Speed 1. The PPP contract had to be restructured during the construction period due to two obstacles: difficulties in obtaining private financing and the British Government's opposition to augmenting the direct grants. High Speed 1's income came from the track access payments of Eurostar, the international railway enterprise that operates passenger rail services between France and the United Kingdom through the Channel Tunnel. The concession contract included the purchase of British public participation in Eurostar. Nevertheless, the Eurostar services were merely a third of what was forecasted, and the concessionaire had to sell its participation in Eurostar (Butcher, 2011; National Audit Office, 2001, 2005, 2012, 2015).
Since 2010, a cross-border high-speed line has connected the towns of Figueras (Spain) and Perpignan (France) through the Pyrenees. The PPP contract was awarded to the company TP Ferro. The Figueras-Perpignan line should receive traffic from the Spanish Barcelona-Figueras high-speed line. However, when the cross-border line was ready to begin operation, the Barcelona-Figueras line was under construction and the Figueras-Perpignan line had no rail traffic. The concession period was extended to solve this inconvenience, but ultimately, the PPP contract was terminated early. Currently, the Spanish and French national railway managers are operating this Spanish-French international section (Boletín Oficial del Estado, 2004, 2016; Eiffage 2013; Ministerio de Fomento, 2009, 2011; Sanz Gandásegui, 2005; Secretario de Estado de Relaciones con las Cortes, 2015).

These experiences reveal the need for a deep study of the reasons that high-speed railway PPP contracts fail, so that such failures can be avoided. In both cases, the failures proceeded from the decisions of public administrators and private investors. Hence, this article examines the RAVE Portuguese high-speed railway line which was designed through PPP contracts. Through this high-speed rail network, Portugal not only connected their capital with that of the neighboring country, but also connected with the European high-speed rail network. The RAVE Portuguese high-speed railway network was designed through six PPP contracts in 2004. However, it was only awarded the contract for the Poceirão and Caia section. Because of the 2008-2010 international financial crisis, which deeply affected Portugal, the PPP contract for the Poceirão-Caia section was rescinded during the design phase and the project for the whole network was discarded (Diário da República, 2011; Direcção-Geral do Tesouro e Finanças, 2010; Rede Ferroviária de Alta Velocidade, 2007; Tribunal de Contas, 2014).

In the general context of PPPs for high-speed railways, several economic aspects have already been studied. First, Bonnafous (1987) concluded that the first European high-speed railway line, which connected Paris and Lyon, generated direct economic benefits in the tourism and industry sectors. An extended article on railway PPPs was published by Dehornoy (2012), who deduced that the most successful concessions were those focussing on integrated traffic (for airport links) and availability traffic (for high-speed infrastructure). Moreover, Crozet (2016) concluded that PPPs permit the construction and opening of new high-speed lines in a timely fashion; however, public financial rescues are needed to solve financial problems. The relationship between investment and social benefits of high-speed rail transportation experiences in Europe (and worldwide) has been investigated by multiple researchers (De Rus, 2009; De Rus and Nash, 2009; Campos, de Rus and Barrón, 2009). They concluded that it was better than alternative modes of transport in terms of time savings, reliability, comfort, safety, and reduced pollution. Koppenjan and Leijten (2005, 2007) and Priemus (2011a, 2011b) analysed the Dutch sector in detail – the Hogesnelheidslijn Zuid (HSL-Zuid) high-speed line in particular – to assess the participation of private investors in railway infrastructure. They established that the Dutch government was not able to implement innovative contracts successfully due to its limited knowledge about PPP.

The RAVE Portuguese high-speed railway network has been developed in consideration of the interests of the Republic, politicians, private investors, and construction companies. De Azevedo Isidoro, Marat-Mendes, and Regina Tângari (2018) realised that the network’s layout has not suffered from large changes from 1845 to 2015 and that developments were successfully made during social and economics transformations. Despite its limited budget, Portugal has led the European Union in development new transport infrastructure through PPP. However, Macário, Ribeiro and Duarte Costa (2015) found several pitfalls related to PPP regulation. Through a huge study on Portuguese road and railway PPPs, Pereira (2016) explains that most of the projects overestimated the demand forecast. On the contrary, while exploring the advantages of PPP, Rolland Sobral and Neves Cruz (2011) noted the success of private financing, adherence to a budget and deadlines, and the know-how of private investors in Portugal.

The Portuguese public-private high-speed rail model has been analysed by many authors. Besanko and Tenreiro Gonçalves (2013) concluded that the state-owned company RAVE should have described how the social and economic benefits were higher than the infrastructures costs. Pedro, De Abreu e Silva and Brookes (2015) described the influence of the external stakeholders. Oliveira Cruz, Kokkaew, and Cunha Marques (2017) issued recommendations to reduce risks (e.g., construct initially only one line to test the PPP model, split the infrastructure and operation management, or re-bid the operation contract within 5 to 10 years). Regarding the financial implementation and management of the Portuguese high-speed railway network, De Abreu e Silva, Silva and Sussman (2011) also determined that PPPs must be adapted to each project and it is necessary to pay attention to the interface generated from the split between substructure and superstructure works.

The failures that appeared during implementation (as previously described) could be repeated, even if the conclusions of the studies reviewed were applied to new high-speed rail lines contracted by PPPs. Therefore, the present research aims to develop a list of recommendations and good practices that can serve as a tool for governments, private investors, and railway stakeholders to make the best decisions before the construction of a new line. For that reason, this study analyses the RAVE Portuguese high-speed railway network.

2. RESEARCH METHODOLOGY

Case study theory was applied to this research in accordance with Stake (1995) and Yin (2009), the most relevant authors in this area. A case study was defined by Stake (1995) as a “study of the particularity and complexity of a single case, coming to understand its activity within important circumstances” (p. 7) and by Yin (2009) as “an empirical inquiry that investigates a contemporary phenomenon in depth and within its real-life context, especially when the boundaries between phenomenon and context are not clearly evidence” (p. 9). These authors identified two groups of three case study types. According to the reason for selecting a case study, Stake (2003) identified intrinsic, instrumental and collective case studies, and according to the purpose of the research, Yin (2009) identified explanatory, descriptive and exploratory case studies. This research is classified as exploratory case study due to the novelty of the RAVE Portuguese high-speed network examination. This case study is analysed to identify the critical success factors (CSFs) in high-speed railway infrastructure contracted by PPPs. Rockart (1982) defined CSFs as “the few key areas of activity in which favourable results are necessary for a particular manager to reach his or her goals” (p. 4).

This methodology was proven in research related with PPP transport infrastructures (Koppenjan, 2005; Liyanage and Roumboutsos, 2016; Liyanage and Villalba-Romero, 2015; Liyanage, Njuangang and Villalba-Romero, 2016; Ribeiro, Couchinho, Macário and Liyanange, 2016; Voordijk, Liyanage and Temeljotov Salaj, 2016; Macário et al., 2015).
The research methodology steps applied to this article consisted of five sequential actions: (a) collection of a wide range of data for the RAVE Portuguese high-speed railway network from the railway infrastructure concessionaire, railway infrastructure manager, railway undertaking, public administrations and railway-specific publications; (b) classification of the data into six areas: project, infrastructure, transport service, contract, corporate structure and investment; (c) identification and analysis of the CSFs; (d); discussion of the CSFs and (e) development of a list of recommendations and good practices for governments, private investors, and railway stakeholders.

3. DESCRIPTION OF THE CASE STUDY

In 1988, Portugal launched the construction of a high-speed rail network in coordination with Spain; they agreed to design the lines with Union Internationale de Chemins de Fer (UIC)-gauge (1,435 mm) (Diário da República, 1988). RAVE was established as a company in 2000. This company was comprised of the Portuguese State (60%) and Rede Ferroviária Nacional (REFER) (40%), the Portuguese national railway infrastructure manager, whose aim was to analyse and prepare for implementation of the RAVE Portuguese high-speed railway network. In 2001, Portugal and Spain created a European economic interest group called Spain-Portugal high-speed—or, in Portuguese and Spanish, Alta Velocidade Espanha-Portugal and Alta Velocidad España-Portugal. Both nations were responsible for the cross-border sections. This group was made up of RAVE and Administrador de Infraestructuras Ferroviarias (ADIF), the Spanish national railway infrastructure management organization (Rede Ferroviária de Alta Velocidade, 2004; Tribunal de Contas, 2014).

In a binational summit between Portugal and Spain in 2003, the following cross-border sections were defined: Porto-Vigo, Lisbon-Madrid, Aveiro-Salamanca, and Faro-Huelva. In 2004, Portugal unveiled its high-speed railway network, which comprised the agreed-upon sections with Spain and a domestic section between Lisbon and Porto. The European Union included the Lisbon-Porto, Lisbon-Madrid, and Aveiro-Salamanca sections in the high-speed railway axis of its southwestern Europe priority project; and the Porto-Vigo section in the Iberian Peninsula priority project. The Lisbon-Madrid section was classified as one of the five highest-priority axes for the European Union (Diário da República, 2004; Diario Oficial de la Unión Europea, 2004a; Rede Ferroviária de Alta Velocidade, 2004; Tribunal de Contas, 2014).
Following various Portuguese-Spanish summits up to 2009, the Portuguese high-speed rail network was designed with the features described in Table 1:

Axis	Journey time	Traffic	Length	Maximum speed	Stations
Lisbon-Madrid	2 hours and 45 minutes	Passengers and freight	206 km	350 km/h	Lisbon, Évora and Elvas/Badajoz
Lisbon-Porto	1 hour and 15 minutes	Passengers	314 km	300 km/h	Lisbon, Ota, Leiria, Coímbra, Aveiro and Porto
Porto-Vigo	60 minutes	Passengers and freight	100 km	250 km/h	Porto, Sá Carnerio Airport, Braga and Valença/Tuy
Aveiro-Salamanca	2 hours and 45 minutes	Passengers and freight	70 km	250 km/h	Aveiro, Viseu and Guarda
Évora-Faro-Huelva	Lisboa-Faro 1 hour and 30 minutes Faro-Huelva 30 minutes	Passengers	200 km	300 km/h	Évora and Faro

Note: Data from Rede Ferroviária de Alta Velocidade (2006, 2008, 2009).

Table 1 – Portuguese high-speed rail network.

There is a high cross-border mobility between Portugal and Spain due to cultural, linguistic, economic and cultural relations. However, it exists an important deficit in public transport. The new high-speed railway axis benefits to Portugal and Spain, and specially to the Spanish regions of Galicia, Castilla y León, Extremadura and Andalucía, due to its geographical location (Gutiérrez Gallego, Naranjo Gómez, Jaraíz-Cabanillas, Ruiz Labrador, and Su Jeong, 2015; Chen, Correia and de Abreu e Silva, 2015; Carvalho, Partidario and Sheate, 2017; Varela Cornado, 2018).

The Portuguese government decided to start contracting only for the axes considered to be a priority for Portugal. Theses axes were Lisbon-Madrid, Lisbon-Porto, and Porto-Vigo's 1st Phase, which was designed with polyvalent sleepers in 1,668 mm Iberian gauge. These sections are summarised in Table 2.

Axis	Journey time	Traffic	Length	Maximum speed	Stations
Lisbon-Madrid	2 hours and 45 minutes	Passengers and freight	206 km	350 km/h	Lisboa, Évora and Elvas/Badajoz
Lisbon-Porto	1 hour and 15 minutes	Passengers	314 km	300 km/h	Lisboa, Ota, Leiria, Coímbra, Aveiro and Oporto
Porto-Vigo 1st Phase Braga-Valença	60 minutes	Passengers and freight	55 km	250 km/h	Braga and Valença/Tuy

Note: Data from RAVE (2006, 2007, 2008, 2009).

Table 2 – Portuguese high-speed rail network priority axes

The Portuguese government justified the construction of these three Portuguese high-speed rail priority axes mainly through the socioeconomic benefits introduced by the connection with the Spanish and European passenger and freight railway networks (Diário da República, 2010).

In 2010, due to the international financial crisis that affected Portugal in 2008 and especially in 2009, an economic program dedicated to stability and growth was established. This program included a delay on the contracting for the Lisbon-Porto and Porto-Vigo axes (Ministério das Finanças e da Administração Pública, 2010). In 2011, the Portuguese government published a strategic transport plan for the 2011-2015 period in which the Lisbon-Madrid high-speed railway line project was abandoned (Diário da República, 2011). That year, the RAVE society was extinguished and integrated into REFER, which assumed the role of RAVE in the Spain-Portugal high-speed European economic interest group (Tribunal de Contas, 2014).

4. ANALYSIS AND DISCUSSION OF THE CSFs

This research examines the PPP model developed for the RAVE Portuguese high-speed network. In this section are analysed and discussed the CSFs.

4.1. Cross-border cooperation for international sections

For the RAVE Portuguese high-speed network cooperation between Portugal and Spain is ongoing through the various binational summit meetings and involved the creation of a European economic interest group, in which both countries were responsible for the cross-border connection of the Lisbon-Madrid axis (Diário da República, 1988; Tribunal de Contas, 2014). Spain has experience in this type of cross-border cooperation, since the international high-speed rail section between Figueras and Perpignan that links the high-speed rail networks of Spain and France was built through a public-private collaboration model involving a joint agreement between the two countries. As with the connection between Portugal and Spain, these two countries principally made their decisions in bilateral summits to define the characteristics of the international section between Figueras and Perpignan. On October 10th, 1995, as a result of the Spanish-French summit meeting held in Madrid, Spain and France signed the so-called Madrid Agreement, the purpose of which was to establish the grounds for the construction and operation of a high-speed connection between Spain and France through Figueras and Perpignan. Subsequently, in the same way as Portugal and Spain, a European economic interest group was also set up between Spain and France to control and enable the development of the project (Boletín Oficial del Estado, 1998; López Pita, s.f.; Ministère de l'écologie, du développement durable, des transports et du logement, 2011). Another infrastructure that should be highlighted in terms of cross-border railway cooperation is the Channel Tunnel between France and the United Kingdom. This infrastructure was also developed through public-private collaboration, in a joint project between France and the United Kingdom enacted by the Treaty of Canterbury on February

12th, 1986 (Secretary of State for Foreign and Commonwealth, 1986). All these cross-border agreements and cooperation accords between different countries contrast with the case of the HSL-Zuid line where the Netherlands had to pay compensation to Belgium to agree and finalise the route for the cross-border connection (Omega Centre, 2011).

Currently in Europe, cross-border cooperation is an undeniable reality since it contributes to cohesion, sustainable social development, and facilitates increased economic activity in cross-border territories. Transport infrastructures play a fundamental role in cross-border cooperation and common planning policies are increasing in Europe. To provide cross-border projects with continuity and durability, it is necessary to create an alliance between cross-border territories, which must be institutionalised through an agreement. For this alliance to be robust, it is necessary to ensure the participation of interest groups, guarantee a coherent objective for all participants, and ensure that the results of the cooperation involve similar benefits on both sides of the border (Galko and Volodin, 2016; Castanho, Vulevic, Fernández, Fernández-Pozo, Gómez and Loures, 2017; Kurowska-Pysz, Castanho and Loures, 2018).

4.2. Unique contracts for substructure and superstructure

The infrastructure works were divided into the six PPP contracts displayed in Table 3:

Axis	Section	PPP Contract	Scope
Lisbon-Madrid	Poceirão-Caia	PPP1	Substructure and superstructure. Évora station. Conventional freight railway line between Évora and Caia.
	Lisbon-Poceirão	PPP2	Substructure and superstructure. Tejo new bridge, Terceira Travessia do Tejo (TTT).
Lisbon-Porto	Lisbon-Pombal	PPP3	Substructure and superstructure. Leiria station.
	Pombal-Porto	PPP4	Substructure and superstructure. Aveiro station.
Porto-Vigo	Braga-Valença	PPP5	Substructure and superstructure.
All axes	All sections	PPP6	Signalling and communications systems.

Note: Data from Rede Ferroviária de Alta Velocidade (2007) and Tribunal de Contas (2014).

Table 3 – PPP contract scope for the Portuguese high-speed rail network

Substructure and superstructure works were included in the same PPP contracts. The PPP1, PPP2, PPP3, PPP4, and PPP5 contracts had the following scope: design, construction, finance and maintenance for 40 years; during operation, the payments were based on availability, traffic, and maintenance. The PPP6 contract was for the signalling and

communications systems on the whole high-speed railway network. For the Lisbon-Madrid axis, Portugal was responsible for the connection between Lisbon, Poceirão and Caia, which was divided into 2 contracts. The first (contract PPP1) included the high-speed section between Poceirão and Caia. Contract PPP1 also included the construction and operation of Évora station and a conventional freight railway line between Évora and Caia. Contract PPP2 included the high-speed section between Lisbon and Poceirão and a new bridge in Lisbon called Terceira Travessia do Tejo. Contract PPP1 was signed in 2010 with ELOS–Ligações de Alta Velocidade. Contract PPP2, which connected Lisboa and Poceirão in the second Portuguese section of the Lisbon-Madrid axis, was launched in 2009. The consortiums called ELOS–Ligações de Alta Velocidade, ALTAVIA ALENTEJO–Infraestruturas de Alta Velocidade, and TAVE TEJO presented bids. In 2010, due to the financial crisis, the Portuguese government discarded this construction (Direcção-Geral do Tesouro e Finanças, 2008, 2009, 2010; Rede Ferroviária de Alta Velocidade, 2007; Tribunal de Contas, 2014).
For the RAVE Portuguese high-speed network, both the substructure and superstructure were included within the same contract (Rede Ferroviária de Alta Velocidade, 2007; Tribunal de Contas, 2014). This is also the case of the other high-speed lines contracted through public-private partnerships in Europe, namely, the High Speed 1 line, connecting the Channel Tunnel with London, in the United Kingdom, the French Bretagne-Pays de la Loire line, which links the towns of Le Mans and Rennes, the Sud-Europe Atlantique line, which links the towns of Tours and Bordeaux, the Contournement Nîmes-Montpellier bypass, and the international Figueras-Perpignan section between Spain and France (Boletín Oficial del Estado, 2016; ERE Eiffage Rail Express and Réseau Ferré de France, 2013; LISEA and SNCF Réseau, 2017; National Audit Office, 2001; OC'VIA and Réseau Ferré de France, 2012).

It is not a coincidence that all these lines, except for the Dutch HSL-Zuid line, combined the substructure and superstructure activities into a single contract. This need is justified by the following technical reasons. Firstly, it is necessary to indicate that the substructure supports the superstructure and transmits the loads to the foundation. Secondly, the superstructure is the area above ground level that receives the loads from the trains which are then transferred to the substructure. It is clear, therefore, that there is an interaction between the substructure and superstructure; for this reason, it is necessary for the design to take into account the factors that influence the dimensioning, such as stresses and deformations, in order to obtain a better performance from both the substructure and superstructure as well as vehicle dynamics (Alamaa, 2016; Byun, Hong and Lee, 2015; Giannakos, 2010; Li, Hyslip, Sussmann and Chrismer, 2015; Ministry of Housing and Urban Affairs, 2018; Selig and Waters, 1994).

4.3. An independent contract for signalling and communications systems

Portugal decided to equip its infrastructure with the following signalling and communication systems European Rail Traffic Management System (ERTMS) Level 2 and Global System for Mobile Communications-Railway (GSM-R). The implementation of these systems transpired through an independent PPP contract called PPP6. The scope of this contract was for the whole high-speed railway network. The contractor awarded was responsible for design, supply, installation, finance, and maintenance for 20 years, with a public payment based on availability (Rede Ferroviária de Alta Velocidade, 2004, 2007; Tribunal de Contas, 2014).

An independent contract for signalling and communications systems has the following advantages. Due to the reduced number of ERTMS suppliers, if they were integrated into consortiums with the rest of the infrastructure system companies, the number of bidders would decrease, the high technological risk during operation would be minimized, and a unique contract would increase the competitivity in the sector.

Analysing all the European high-speed railway lines constructed through public-private collaboration, Portugal was the only example involving this type of separate agreement for signalling and communication systems (Rede Ferroviária de Alta Velocidade, 2007; Boletín Oficial del Estado, 2016; ERE Eiffage Rail Express and Réseau Ferré de France, 2013; Geluk, 2007; LISEA and SNCF Réseau, 2017; National Audit Office, 2001; OC'VIA and Réseau Ferré de France , 2012; Tribunal de Contas, 2014; Tweede Kamer, 2008) .

Almost every country in the European Union had its own Automatic Train Protection (ATP) system, which were not compatible with one another in most cases. With the increase in international services, it was therefore necessary for the vehicles to possess all the ATP systems of the countries though which they were going to pass. Because of this, in 1989, the European Union launched the development of a single signalling system for the entire network that would facilitate transit between countries. This system was referred to as ERTMS and, in 2000, the first technical specification was published (European Union, 2021). In parallel to the development of the ERTMS system, it was necessary to implement a communication system between the railways and the trains. Thus, it was decided to adapt the existing communication system to the Global System for Mobile Communications (GSM) for railways, which led to the creation of the GSM-R communication system (UIC, 2021b).

Since the first technical specification of the ERTMS system in 2000, 12 new versions of this document have been published (European Union, 2021). The GSM-R communication system will now be replaced by a new development, known as the Future Railway Mobile Communication System (FRMCS) (UIC, 2021a). It is clear that this technology is constantly evolving, representing a significant investment for technologists, infrastructure managers, and railway companies. For this reason, the European Union, aware of the large outlay involved in implementing a single railway signalling system, supported the roll-out of this technology with a subsidy of 3.9 billion euros between 2007 and 2019. (European Commission, 2020). A peculiar fact about this continuous technological evolution is that in Spain, through a public-private collaboration contract, awarded to the technologist Alstom, the ERTMS signalling and GSM-R communication systems have been implemented in the Albacete-Alicante high-speed section, whereas the substructure and superstructure were implemented through a traditional contract (European Commission, 2014).

5. CONCLUSION

This research analysed RAVE high-speed rail network project. This project enabled Portugal to link to the European high-speed network.

This research has required the application of an exploratory approach and the identification of critical success factors (CSFs). The purpose of this research was to develop a list of recommendations and good practices that can serve as a tool for governments, private investors, and railway stakeholders to help them make the best and most efficient decisions in terms of new high-speed rail line construction.

To that end, we present the following recommendations and good practices. Cross-border cooperation for international sections must be established through an agreement between the countries involved, including stakeholders, to guarantee a common objective and the development of similar benefits for all countries. Single contracts should be awarded for a combination of substructure and superstructure, as the design must be implemented jointly by one group of engineers, since any modifications of the substructure affect the superstructure and vice versa, due to the load transmission relationship between these two elements. An independent contract for signalling and communication systems should also be awarded due to the enormous technological risk involved in implementing the ERTMS signalling and GSM-R communications systems, which are constantly evolving in terms of technical specifications. In addition, greater competitiveness must be allowed in this area due to the reduced number of existing technologists. With this list of recommendations and good practices, it is expected that the implementation efficiency of new high-speed rail infrastructures will improve. In addition, this project could be applied not only to the field of public-private collaborations but also to the railway environment as a whole.

LIST OF ABBREVIATIONS

ADIF: Administrador de Infraestructuras Ferroviarias
ATP: Automatic Train Protection
CSF : Critical Success Factor
ERTMS: European Rail Traffic Management System
FRMCS: Future Railway Mobile Communication System

FROM INNOVATION TO THE LAW: A COMPARATIVE ANALYSIS OF NEW TECHNOLOGIES IN AUTONOMOUS MOBILITY LEGISLATION

Héctor García Crespo
Researcher. University of Burgos

ABSTRACT

Spanish Autonomous Communities have been approving Transport Laws for regional and urban services for more than thirty years. An analysis comparing these rules allows us to see how they have evolved towards greater involvement in sustainable mobility. From simple texts, which are limited to delimiting competences and ordering coordination between Administrations, to rules that assume the drawbacks of the current mobility model. The most recent Laws introduce in its principles and objectives the promotion of sustainable public transport from the socioeconomic and environmental aspects. This means offeríng conditions of universal accessibility and universal design and encourages the introduction of information and communications technology and quality at service. This paper is a review of this evolution, highlighting those Laws that have been milestones and culminating with the last two: that of the Principality of Asturias and that of Castile and León. Even with some shortcomings, this introduction represents a commitment by the legislator to sustainable mobility and quality public transport.

1. INTRODUCTION

Technological innovation is a fundamental aspect of public passenger transport. Autonomous Laws have been introducing the promotion of quality and technology in public service beyond specific rules on vehicle approval, active and passive safety, and universal accessibility. All this has the aim of promoting an alternative for sustainable mobility. But we can ask ourselves: from what point has the law of transport been concerned with incorporating quality? How is innovation introduced into the legal regime of the public transport service?

2. EVOLUTION OF QUALITY AND NEW TECHNOLOGIES IN AUTONOMOUS LAWS

Public transport is regulated in Spain with two legislative levels, apart from European legislation. On the one hand, transport that takes place within an Autonomous Community is considered autonomous competence. On the other hand, transport transiting the territory of two or more Autonomous Communities is the responsibility of the State. These powers affect regulation (primary and secondary) and its management.

The first autonomous legislative rule is the Catalan *Ley 12/1987, de 28 de mayo, sobre regulación del transporte de viajeros por carretera mediante vehículos de motor* (Law 12/1987, of 28 May, on the regulation of the transport of passengers by road by motor vehicles). This rule is contemporaneous with State *Ley 16/1987, de 30 de julio, de ordenación de los transportes terrestres* (Law 16/1987, of July 30, on land transport ordinance).

The Catalan Law lacks any reference in the main text to quality or sustainability. For its part, Law 16/1987 has as general principles the establishment and maintenance of a common system throughout the country, the satisfaction of the needs of society with the maximum degree of efficiency and minimum social cost and the maintenance of the market unit.

The appeal of the Generalitat de Catalunya (Catalan Government) before the Constitutional Court of certain provisions of Law 16/1987 was decided by Judgment 118/1996 of 27 June. That judgment annulled the provisions which supplementally regulated urban transport. The annulment led to a regulatory gap that had to be covered by regional legislation, so in the following years the Autonomous Communities passed laws to regulate urban transport and coordinate it with the regional intercity service.

The first autonomous laws after the Judgment were passed in Galicia and the Foral Community of Navarra. Specifically, they were *Ley 6/1996, de 9 de julio, de coordinación de los transportes urbanos e interurbanos por carretera de Galicia* (Law 6/1996, of July 9, coordination of urban and intercity transport by road of Galicia) and *Ley Foral 7/1998, de 1 de junio, reguladora del transporte público urbano por carretera* (Law 7/1998, of June 1, regulating public urban transport by road), respectively. None of them have references in their articles to sustainability or quality of service.

A first precept is found in *Ley 20/1998, de 27 de noviembre de ordenación y coordinación de los transportes urbanos de la Comunidad de Madrid* (Law 20/1998, of 27 November on the ordinance and coordination of urban transport in the Community of Madrid). This Law contains a brief chapter about environmental conditions. It consists of a single article, the 15th. This article indicates that sustainability will be promoted in the processes of renewal and expansion of fleets and in the setting of the technical conditions of taxis. This would be achieved through technologies that pursue maximum energy efficiency, the use of renewable fuels, the reduction of air and noise pollution and the recycling of materials. This inclusion of environmental or quality issues can be described as exceptional.

Both the *14/1998, de 30 de diciembre, de los Transportes Urbanos de la Comunidad Autónoma de Aragón* (Law, 14/1998, of December 30, of the Urban Transports of the Autonomous Community of Aragon) and the *15/2002, de 28 de noviembre, de transporte urbano y metropolitano de Castilla y León* (15/2002, of November 28, of urban and metropolitan transport of Castile and León), antecedenty the current Law of this Community lack objectives, principles or precepts linked to the quality and innovation in transport.

Ley 2/2003, de 12 de mayo, de Ordenación de los Transportes Urbanos y Metropolitanos de Viajeros de Andalucía (Law 2/2003, of 12 May, on Ordinance of Urban and Metropolitan Transports of Travellers of Andalusia) was a milestone. Its Preamble introduced the recognition of mobility problems in urban areas.

Its article 3, dedicated to the purpose and principles of public action, incorporates objectives linked to mobility. In particular, the Administrations will promote the adequate satisfaction of the transport needs of citizens, under conditions of social equity, territorial solidarity, security and accessibility for persons with reduced mobility.

The same article 3, in its second section, adds that the purpose Law is to promote and improve the quality and safety of the public passenger transport service. This is the first time that the improvement in the quality of transport is reflected in an autonomous law and, of course, it does so with prominence.

Article 4, concerning definitions, defines mobility as a set of displacements that persons and goods must make on the basis of work, training, health, social, culture or leisure, or by any other. Regarding sustainable mobility, the Law defines it as mobility that satisfies at a reasonable time and cost and minimizes the negative effects on the environment and the quality of life of people. It is the first definition of the concept of sustainable mobility in a Spanish law.

According to Moreu (2014), the legal concept of sustainable mobility is profiled by the following elements: holistic and integrated view of public policies: it is cross-cutting in including not only traffic and transport, but urban planning, education, health or the environment; pursues social and territorial cohesion; environmental objective, to reduce negative effects such as polluting emissions; economic outlook through low consumption and lower energy dependence; accessibility, especially for persons with reduced mobility; citizen participation.

This Law 2/2003 represents a qualitative leap. It is not limited to being a rule that seeks to order and coordinate, but takes mobility as a necessity of citizenship, which must be addressed through services. In addition, it is the first Law that introduces the concept of mobility linked to universal accessibility and sustainable development, as well as quality improvement.

A new step forward is found in *Ley 9/2003, de 13 de junio, de la movilidad* (Law 9/2003, of 13 June, on mobility). This Catalan rule is the first to introduce the concept of mobility into its title. Its first principle is based on the characteristics of what it is known as sustainable mobility, with its three facets: social, economic and environmental. It includes the promotion, not only of public transport, but of zero impact modes, such as on foot and bicycle. This Law also introduces sustainable urban development.

The objectives of the mobility policy are a catalogue of measures. Actions linked to public transport include studying fare integration formulas, improving commercial speed and promoting demand-responsive transport. It should be noted that this Law does not regulate public transport, but mobility, in particular, instruments for planning, programming, evaluation and monitoring. Participation and management bodies are also regulated.

Law 4/2004, on the Transport of Road Travellers, of the Basque Country, recognizes in its Preamble the strategic nature of public transport for social, economic and territorial development and cohesion, aimed at meeting the population needs of society, within sustainable development. The safety and quality of this service are described as priority elements.

The article on the principles of the Law reproduces the above paragraph and has the basis of transport policy. In addition, this policy will also comply with other principles: meeting mobility needs effectively and lower social cost and promoting intermodality. Quality and environmental sustainability are each reflected in two principles. The quality of serviceis explained through the rights and obligations of users and through the development of quality transports. With regard to environmental criteria, the promotion of technology is established for this purpose, and more generically, the promotion of sustainable transport.

We move forward in this temporary review with *Ley 8/2005, de 30 de junio, reguladora del Transporte Urbano por Carretera de La Rioja* (Law 8/2005, of June 30, regulator of Urban Transport by Road of La Rioja). In this Community we find the peculiarity of being the only one where one Law regulates urban transport and another, which we will talk about later, establishes the legal regime for intercity transport. Both its Preamble and articles lack references to quality or sustainability.

The next rule is *Ley 14/2005, de 29 de diciembre, de Ordenación del Transporte de Personas por Carretera por Castilla-La Mancha* (Law 14/2005, of December 29, on the Ordinance of the Transport of People by Road in Castilla-La Mancha). This Law acknowledges in its Preamble that is based on the need for a transport system that responds the demand of the inhabitants, taking into account the geographical, demographic and economic peculiarities of the Community. It is based on the right to mobility, giving the importance it deserves to public transport.

The article on principles recognizes public transport as an essential public service to respond the mobility needs of the population. Among other objectives, transport policy will be aimed at meeting the demand for the mobility of the population, in conditions of safety and comfort.

This objective focuses on people with fewer resources, with reduced mobility or special transport needs, as well as in areas with low population density or remoteness.

Another objective is the achievement of optimal quality and safety objectives, through efficient use of resources, to reduce environmental costs. It is also mentioned the promotion of public transport spreading its knowledge and boosting its use.

We return again to La Rioja, because, as stated above, Law 8/2005 regulates only urban transport. Intercity service has its regulation in Law 8/2006 of 18 October. In its Preamble there is not relevant reference to quality or sustainability.

Within the purpose of the Law, in addition to the usual ones, it is intended to promote public transport through measures aimed at modernizing vehicles, a homogeneous corporate image of public services, improving access to persons with reduced mobility and incorporating technological innovations that improve the service.

The next law in this chronological review is the *Ley 13/2007, de 17 de mayo, de ordenación del Transporte por Carretera de Canarias* (Law 13/2007, of May 17, of planning of Transport by Road of the Canary Islands). The summary of the content made in the Preamble highlights the objective of promoting public passenger transport that responds the demand for population mobility by guaranteeing the right to quality and sustainable transport, with particular attention to people under-favoured and disabled. This is, undoubtedly, an object that is repeated in the different laws.

We also find other objectives in this Law: the promotion of public transport versus the private; the rational use of public resources, the achievement of the highest quality and safety in the provision of the service and the reduction of environmental impacts and costs.

Finally, within the Second Chapter, named mobility planning, sector promotion and financing of regular public transport, in title III, road transport services, there is a small section called promotion actions. The corresponding Regional Department may, in collaboration with the Island Councils, carry out development programmes.

Those promotion programmes will seek the modernization of company facilities and systems; the dissemination of the transport sector and any measures to facilitate the competitiveness and efficiency of the sector.

The next Law of this analysis is of the Community of Madrid, *Ley 5/2009, de 20 de octubre, de Ordenación del Transporte y la Movilidad por Carretera* (Law 5/2009, of October 20, on Transport and Road Mobility Ordinance). The brief Preamble to this rule indicates that its enactment responds to the relevance of road transport to the socio-economic development of the Community and at the will to ensure sustainable mobility. In general, it is a law simpler than its contemporaries. The purpose of this Madrid Law is to achieve an efficient and coordinated transport system that meets the mobility needs of citizens.

As regards principles and objectives, the Law aims to facilitate mobility and contribute to territorial articulation, economic development, social cohesion and improve, in short, the quality of life of citizens. The provision of the service, as well as the construction and maintenance of the facilities should minimize the environmental impact, as well as seek the optimal consumption of resources. Finally, operators should ensure accessibility to persons with reduced mobility.

More advanced is *Ley 6/2011, de 6 de abril, de la Generalitat, de Movilidad de la Comunidad Valenciana* (Law 6/2011, of April 6, on Mobility of the Valencian Community). Its Preamble is noteworthy, recognizing the role of mobility in the progress of advanced society. Even more remarkable is the recognition of the limitations and conditions of mobility and development. The text refers to Buchanan's *Traffic in Towns*. The goal is to maintain the level of mobility by making it compatible with an urban space suitable for people and without falling into unacceptable energy dependencies.

The Preamble refers to European legislation for the legal framework for transport and mobility. The aim is to promote non-motorized modes and public transport. It recognizes the advantages of the Mediterranean urban model, which facilitates sustainable mobility by relying on integration of uses, intermediate densities and occupation of adjoining spaces. According to the Preamble, this model must be protected by the regulation. Therefore, it seeks to integrate mobility plans into urban development.

In the light of the main text, it is established that the purpose of the Law is the regulation of the powers of the *Generalitat* (Regional Government) in the field of mobility, i.e. to regulate planning instruments, the land transport of passengers and infrastructure.

The first principle of the Law is that administrations will facilitate the mobility of people, understanding that it is a backbone of their quality of life, by allowing them access to work, training, services and leisure.

The second principle is that administrations will promote the growth of mobility in a way that a number of objectives related to safety, accessibility, reduction of air and noise pollution, efficiency in energy consumption, participation of society in decision-making and the promotion of public transport and intermodality are met simultaneously.

Boix (2014) considers that this rule does not, despite what is stated in the Preamble and the principles, bring anything new in terms of transport to the problem of mobility. Thus, he tells us:

> "All Title II of the Law, referring to the regulation of passenger transport, seems transplanted from a legal rule that had been prepared regardless of what the Law says in its preamble or the regulation and principles of Title I. The idea of sustainability disappears from the purposes and objectives to guide public authorities in setting routes, programmes or contracts, award procedures, exclusivity or subsidy mechanisms (...) but in no case links to mobility considerations these elements, as it was able to, for example, by identifying certain preferences for a certain type of vehicle or performance that guarantee less polluting emissions in the general rules that should be awards which, however, choose to give not a few technical and legal indications as to how these are to be carried out, but say nothing about the issue at hand."

Through various planning instruments, dedicated to territorial areas, but also to mobility-generating locations, the aim is to achieve the objectives of the Law. In particular, planning instruments should seek a modal distribution where the use of non-motorized modes and public transport expands. Also, the public transport must be accessible. These plans affect both the organization of transportation and the configuration of urban space.

The next rule of this study is *Ley 4/2014, de 20 de junio, de transportes terrestres y movilidad sostenible de las Illes Balears* (Law 4/2014, of June 20, on land transport and sustainable mobility of the Balearic Islands). This Law, the first to incorporate the qualifier of *sustainable* in its title, is very broad and regulates road and rail services in detail.

According to its Preamble, public administrations will promote the satisfaction of transport needs and favour the mobility of citizens. All this actions must be in accordance with a series of general principles, such as free access to goods and services, through adequate, accessible and safe mobility, with minimal social and environmental impact. Efficiency and rationalization in the use of media, resources and spaces are part of mobility policy.

One concept that is introduced in this catalogue of principles is that of social profitability. It is qualified as the assumption, according to the means available, of the needs of public service in terms of spatial or temporal availability, of attention to specific groups or the achievement of average levels of quality. Other principles included in this Law are the proper distribution of costs of implementation and management of transport, and the involvement of citizens through social participation.

We have left for the end another interesting principle, that of subsidiarity of the establishment of new transport services. It implies that such establishment will be subject to the existence of a demand commensurate with investment and environmental costs, and will take into account alternative modes of transport according to their price, safety, quality and environmental assessment results. If this principle had been applied in a widespread and rigorous manner, disproportionate investments would have been avoided, not only in public transport, but also in road infrastructure.

As regards the purposes of the Law, it retains a similar structure to the Law of the Valencian Community. Thus, this rule regulates public transport of travellers, urban and intercity; rail service, and mobility management through planning tools. Another purpose is to set the objectives and contents of the Sectoral Mobility Master Plan, island plans for regular road transport and mobility plans.

In addition to the principles and purposes of the Law, the objectives of the public transport service itself are also listed. These must constitute an integrated offer, organized as a network or multimodal infrastructure, to offer citizens the possibility of covering their travels.

A quality, safe, accessible and appropriately priced public transport is the first right of users listed in the Balearic Law. Others include the provision of services adapted for people with disabilities or transporting bicycles in public transport vehicles.

We move forward to reach the *Ley de Cantabria 1/2014, de 17 de noviembre, de Transporte de Viajeros por Carretera* (Law of Cantabria 1/2014, of November 17, on Road Passenger Transport). Its Preamble introduces equality and equity between men and women as a fundamental principle. This principle responds to the role of transport as an element of social and territorial cohesion, as well as the promotion of work-life balance. Also, sustainable mobility is pursued through intermodality and the transfer of travellers to greener ways.

The Preamble highlights several objectives of the Law, such as sustainability, transport modernization, attention to less-favoured sectors, persons with reduced mobility and areas with low population density. It should be noted that this section highlights the importance of public transport in a region with important demographic and orographic conditions. This point coincides with what is analyzed in the Law of Castilla- La Mancha.

The transport policy will also respond to these principles: achieving the optimum degrees of quality and safety in the provision of the service, through the appropriate use of available resources and the reduction of environmental cost; the rational use of resources for promotion and investment in transport, by prioritising projects with greater viability, social and environmental profitability and respect for the environment; combating climate change by promoting collective or non-motorized modes, encouraging the implementation and use of non-polluting technologies.

This last point is noteworthy, since, after the early inclusion in Law 20/1998 of the Community of Madrid, no autonomous law had met the factor of less polluting propulsion technologies.

Similar to the Balearic Islands Law, the Cantabrian one recognizes the right to use vehicles in conditions of comfort, hygiene and safety, with accessibility conditions, a timely and regular service.

Turning to planning regulation, sustainable mobility plans should accommodate novel solutions to reduce environmental impact, at the lowest possible cost and contribute to road safety.

We reached the last rule before entering the Laws of the Principality of Asturias and Castile and León, *Ley 10/2015, de 24 de marzo, por la que se establece el sistema competencial en el transporte urbano e interurbano de la Región de Murcia* (Law 10/2015, of March 24, which establishes the competency system in urban and intercity transport of the Region of Murcia).

The Preamble is more typical of the oldest laws. It should be noted, however, that this introductory statement expressly points out that the regulation of the mobility of persons is not an object of the Law. On the contrary, it merely regulates the competency frameworks for urban and intercity transport within the Community. Some aspects are outside, such as mobility planning and management, the operation of services, and the inspector and sanctioning regime. It should therefore come as no surprise that the objectives of the Act are limited to issues of service coordination and cooperation between operators. All other elements will be regulated by another rule, which has not been approved so far.

3. INNOVATION AND QUALITY IN THE MOBILITY AND TRANSPORT LAWS OF THE PRINCIPALITY OF ASTURIAS AND CASTILE AND LEÓN

The Autonomous Communities of the Principality of Asturias and Castile and León have common factors, such as a low density and areas with scattered, aged population and with complicated orography. This is a real challenge for an adequate sustainable mobility policy, and in particular for the provision of the public transport service. It should be noted that while the Asturian Law is broader, it includes more elements of mobility, as well as rail transport, its Castilian and Lioness counterpart focuses on the transport of passengers by road.

Ley del Principado de Asturias 12/2018, de 23 de noviembre, de Transportes y Movilidad Sostenible (Law of the Principality of Asturias 12/2018, of November 23, on Transport and Sustainable Mobility) seeks, according to its Preamble, a legislative body (since they already have a prior Law regulating their Transport Consortium) that takes into account territorial, population and orographic singularities. Public transport should be part of a mobility model aimed at improving the quality of life of citizens, which is more economically sustainable, ensuring greater territorial and social accessibility, affordable and with care for persons with reduced mobility or disabilities.

The new model should offer alternatives to private transport, such as non-motorized modes, on foot and by bicycle, and public transport. The latter is intended to be empowered by its ability to reduce the environmental and social impact for mobility.

The Asturian Law clearly distinguishes between principles and objectives. The first are enumerated in a list of words or short concepts, without expound on them: safety, minimization of environmental impact, minimization of social costs, intermodality, sustainability and rational use of the territory, cost assessment and management, priority of universal accessibility in the allocation of public resources, coordination between public administrations, citizen participation, and incorporation of the gender perspective into transport planning and management.

The index of objectives stands out for its extension, thirty-three headings. A first transport policy block, with objectives aimed at improving transport accessibility by reducing its negative impacts. At this point, two objectives relating to the drive towards the knowledge economy can be highlighted through the development and application of technological advances to public transport; another is to introduce technological means linked to management and information.

The second goal block concerns urban planning and territorial and environmental impact of transport. More interesting for our study is the third block, related to innovation, security and education.

In that third block of objectives we find the introduction of new technologies in transport and mobility management, especially in user information and payment methods; encourage proposals that reduce accidents; incorporate safety measures into vehicles, and training programmes to promote sustainable ways.

Another section where we find references to innovation and quality in transport is in the planning instruments, something that we have already seen also happens in other studied laws. In this regard, we can underline that the Sustainable Mobility Strategy will have sectoral strategies as development instruments.

Several areas to be developed in Sectoral Strategies: the implementation of the electric vehicle and its infrastructures for public and private transport, with the objective of zero emissions; intermodality for the implementation of new technologies, fare unification, user rights status and physical adaptation of facilities and vehicles, and finally, the development of the bicycle and other active means without emissions. The content of some of these Strategies is developed, as detailed by Blasco (2019 a), in the Additional Provisions of the Law.

Finally we move on to *Ley 9/2018, de 20 de diciembre, de Transporte Público de Viajeros por Carretera de Castilla y León* (Law 9/2018, of December 20, Public Transport of Travelers by Road of Castile and León). Perhaps the most noteworthy facet about its Preamble is that it attaches great importance to the rural area of the Autonomous Community, where it is considered that ensuring mobility is fundamental.

The summary of the objectives highlights the adaptation of management contracts to mobility in a sustainable way, with the highest quality, safety and incorporating new technologies, elements that interest us in this study. The aim is also to improve environmental and economic efficiency. It is clearly stated that the Law is committed to sustainable mobility as a basic principle through a series of measures and instruments.

The Castilian and Lioness Law has only a catalogue of principles, not objectives, making it more succinct at this point than its Asturian counterpart. As we will see below, the accessibility of the rural environment will have great prominence in these principles.

The first principle is the satisfaction of the mobility needs of citizens, with special attention to persons with reduced mobility or disabilities, with guarantee of equal access to transport throughout the territory. Another principle is the development of a coordinated autonomous transport system, which promotes intermodality and promotes socio-economic cohesion and territorial structuring, especially in rural areas. The third principle is the promotion of sustainable mobility as an instrument towards less pollution and more efficient use of energy.

Two particularly relevant principles are the fourth and fifth. The fourth is the guarantee of the highest level of safety, quality and comfort in service, with the use of technological development in intelligent transport systems. The fifth is the promotion of the use of information and communications technology in the management of public transport.

The other principles concern issues of great importance such as universal accessibility and universal design, flexibility of modes of exploitation for better adaptation to social and territorial changes, an adequate fare regime, the promotion and prioritisation of public versus private transport, the integration of the autonomous transport network into the national single market, the guarantee and defence of user rights and the rational and efficient use of public resources in projects with greater social profitability.

The quality in public transport is reflected in a specific Chapter, dedicated to quality, sustainability, intelligent transport systems and automated driving. In his brief analysis of this Law, Blasco (2019) stops in this section, delving into its novel aspects.

As regards the quality of service, on the one hand the Administration will promote the obtaining of quality certifications. On the other hand, the Autonomous Government will establish the certifications required in this matter.

This quality shall be measured by controls by the Administration. The operators shall provide the required information. Several systems are indicated: user surveys, level of complaint response and contingency protocols. Vehicle technical requirements and employee working conditions will also be monitored.

Information and communication technologies also have a presence in the new Law of Castile and León. The transport network must have intelligent transport systems according to the characteristics of the service. This channel will serve citizens and operators. The Administration will promote the use of social networking services.

The Transport Department also assumes the role of collecting, systematizing and disseminating essential information on public transport. The Law establishes minimum data: critical qualitative and quantitative objectives of the service, impact on ecological footprint, supply and demand, costs, and, finally, occupational safety and health issues.

Another function of the Administration will be the impulse of marketing elements. The objective is the dissemination and promotion of public transport. In particular, a homogeneous corporate identity is mentioned.

An information tool would be a web portal, which would be launched within a year. This website would include data from all public transport services in the Community. The minimum information would be itineraries, schedules, universal accessibility, the possibility of traveling with bicycles and links to the purchase of tickets.

The Law includes the implementation of automated mobility systems. The goal is to improve efficiency, safety and environmental impact. The role of the Administration will be to facilitate testing for these systems.

In summary, the precepts collected focus on quality certifications, promotion of alternative propulsions, intermodality with the bicycle, quality control, information and promotion and automated systems. In the case of this Law, we see a remarkable emphasis on innovation and transport quality, something novel in regional transport legislation.

4. INNOVATION AND QUALITY IN LAWS

The presence of innovation refers to two main aspects. The first, in information and communication technologies, oriented both to the management of the service itself, mainly through navigation and geolocation systems, and to the user, through websites that, among other things, collect the information of others Systems. As for vehicles, the most noteworthy is the technology oriented to the reduction of pollution through more efficient propulsions or with reduced emissions. At this point, the most notable is the electric vehicle, both for private and public use.

Rojo (2011) developed an analysis method on the quality of the urban transport service. Its peculiarity was the introduction of variables in addition to those of frequency and fares, such as newer vehicles, large-class vehicles, fast-track traffic, fewer intermediate stops or the use of air conditioning, variables that affected demand and satisfaction. It is true that more advanced elements such as Wi-Fi connection, USB connectors and, on long journeys, individual screens are currently valued.

Therefore, we have two models to regulate quality and innovation in the two most recent laws. On the one hand, a Law contains a specific chapter, albeit with somewhat open promotion measures. On the other hand, mobility and transport planning instruments includes determinations about innovation and quality.

5. IN CONCLUSION. FROM LAWS TO THE ROAD

Sectoral legislation on passenger transport has been leading an evolutionary trajectory towards greater involvement in sustainable mobility. It has moved from rules aimed at regulating the delimitation of competences and coordination between administrative bodies to others that seek to increase quality and innovation in public service.

The inclusion of quality and innovation in the Laws are a sign of the involvement of autonomous legislatures in the improvement of public transport. It is recognition of the need to provide accessibility to citizens and to have alternatives for sustainable mobility.

The incorporation of these elements into the Laws, which have a vocation of permanence, has the risk of being too advanced or, on the contrary, being outdated by technological evolution. That is why, while positively reflected in the Laws, this carries certain risks.

On the other hand, these legislative developments generally lack of putting in place, as they refer to planning instruments or are not reflected in the conditions of management contracts. This limits the possibility of all these improvements reaching the road.

Moreover, there is no doubt that developments in the rules would become just theory if the Administrations do not support through appropriate compensation for the transport deficit to facilitate the incorporation of innovations.

Therefore, and with the limitations indicated, the incorporation of quality, safety and environmental sustainability implies the clear will of the regional legislator to enhance public transport as a quality tool for sustainable mobility.

RESUMEN

Determinar las tasas de accidentalidad y mortalidad de diferentes colectivos de conductores es un objetivo importante de la investigación científica de accidentes de tráfico. Para ello, es necesario contar con información acerca de los niveles de exposición de los conductores de manera desagregada.

Sin embargo, el nivel de exposición de diferentes colectivos de conductores no es conocido al nivel requerido y, esta carencia, puede salvarse mediante el método de exposición cuasi-inducida, que permite determinarlo de forma relativa a partir de los datos contenidos en las bases de accidentes de tráfico. La hipótesis principal es que entre los conductores implicados en un accidente entre dos vehículos, se puede distinguir al responsable y no responsable de su ocurrencia y que, éstos últimos, constituyen una muestra aleatoria de la población de conductores. Por lo tanto, determinar correctamente la responsabilidad del conductor, es un objetivo secundario, pero de gran importancia en la investigación.

Hasta el momento, la asignación de responsabilidad se hace, fundamentalmente, en base a dos tipos de infracciones: del conductor y de velocidad, dejando de lado otros registros que sí que podrían incrementar la probabilidad de que un conductor sea responsable.

En este trabajo se presenta la exploración del conjunto de registros de infracciones y condiciones desfavorables de los conductores, que pueden influir en la responsabilidad de los conductores con la metodología Self-Organizing Maps (SOM).

Los resultados obtenidos indican que la clasificación de conductores mejora en comparación con la clasificación tradicional: más conductores clasificados, mayor número de variables consideradas y mayor calidad esperada en el proceso de asignación de responsabilidad.

1. INTRODUCCIÓN

Determinar las tasas de accidentalidad o el riesgo de colisión de diferentes colectivos de conductores es muy importante en seguridad vial con el objetivo de establecer medidas preventivas que traten de evitar el accidente o minimicen sus impactos, tal y como han señalado investigadores como Stamatiadis y Deacon (1997); Redondo et al. (2000); Hing et al. (2003); Jiang y Lyles (2007, 2010); Lenguerrand et al. (2008); Chandraratna y Stamatiadis (2009); Lardelli et al. (2011); Jiang et al. (2012, 2014); Haque et al. (2013); Huggins (2013); Martínez et al. (2013); Pulido et al. (2016).

Las tasas de accidentalidad de un colectivo de conductores se definen como el cociente entre el número de accidentes de este colectivo y la exposición del mismo (Chandraratna y Stamatiadis, 2009; Gómez y Aparicio, 2010; Huggins, 2013). Por lo tanto, para determinarlas es necesario contar con alguna medida de los niveles de exposición del colectivo en cuestión, lo que supone un importante desafío entre los investigadores de seguridad vial (Redondo, 2000; Chandraratna y Stamatiadis, 2009; Gómez y Aparicio, 2010; Lardelli et al., 2011; Haque et al., 2013; Pulido et al., 2016).

Por ello, se recurre al método de exposición cuasi-inducida, que es una modificación del trabajo de Thorpe (1967), realizada por Carr (1969), Hall (1970), Carlson (1970) y Haight (1970) y que permite la estimación relativa de la exposición de un grupo de conductores a partir de la información contenida en la base de datos de accidentes (Stamatiadis y Deacon, 1997; Lardelli et al., 2005; Redondo et al., 2000; Lenguerrand et al., 2008; Chandraratna y Stamatiadis, 2009; Cooper et al., 2010; Lardelli et al., 2011; Huggins, 2013; Jiang et al., 2012, 2014; Pulido et al., 2016).

La hipótesis principal de este método es que los conductores no responsables en accidentes entre dos turismos constituyen una muestra aleatoria de la población general de conductores (Stamatiadis y Deacon, 1997; Hing et al., 2003; Lardelli et al., 2005, 2011; Yan et al., 2005; Yan y Radwan, 2006; Jiang y Lyles, 2007, 2010, 2011; Lenguerrand et al., 2008; Chandraratna y Stamatiadis, 2009; Gómez y Aparicio, 2010; Cooper et al., 2010; Mohaymany et al., 2010; Jiang et al., 2012, 2014; Haque et al., 2013; Martínez Ruíz et al., 2013). Por tanto, la correcta asignación de responsabilidad a partir de la información de la base de datos de accidentes constituye una importante tarea para la estimación posterior de la exposición relativa.

El registro de accidentes de tráfico con víctimas de España no contiene información específica sobre la responsabilidad de cada conductor implicado en un accidente, aunque sí registra las infracciones cometidas por los mismos, así como el estado de dichos conductores (Martínez et al., 2013; Pulido et al., 2016). Sin embargo, no existe un consenso claro acerca de cuáles son las variables que se deberían utilizar para realizar tal asignación de responsabilidad, dado que algunos autores como DeYoung et al. (1997), Jiang y Lyles (2007, 2010), Jiang et al. (2012, 2014) pusieron de manifiesto que asignar la responsabilidad en base a comportamientos no relacionados con la conducción podrían sesgar los resultados. Por ello, fundamentalmente en los últimos años, los investigadores se han inclinado más a asignar la responsabilidad del conductor en base a acciones de conducción peligrosas (Jiang y Lyles, 2010, 2011; Jiang et al., 2012, 2014), principalmente englobadas en las variables infracción del conductor e infracción de velocidad.

En esta investigación se lleva a cabo el análisis de un conjunto más amplio de variables que podrían influir sobre la responsabilidad de los conductores, pero no suelen ser tenidas en cuenta. Para ello, se propone el uso de la metodología de clúster Self-Organizang Maps (SOM) al conjunto de datos de los conductores con dos objetivos fundamentales: (a) Establecer cuáles podrían ser las variables más relevantes en la asignación de responsabilidad y (b) Realizar una propuesta de asignación de responsabilidad que será comparada con la asignación tradicionalmente realizada.

2. MATERIAL Y MÉTODOS

La base de datos utilizada para llevar a cabo esta investigación fue proporcionada por la Dirección General de Tráfico (DGT) y contiene información de los conductores implicados en accidentes de tráfico ocurridos en España entre 2004 y 2013.

Inicialmente la base de datos fue sometida a un proceso de filtrado para únicamente mantener los accidentes en vía interurbana de tipo frontal, frontolateral, lateral y de alcance, entre dos turismos. Además, se realizó un importante trabajo de depuración de la base de datos filtrada, dado que se detectaron errores que podrían sesgar los resultados de la posterior investigación. Por tanto, la base de datos de partida contaba con un total de 836.598 conductores y tras el filtrado y la depuración de la misma esta quedó finalmente reducida a 145.904 conductores.

La base de datos cuenta con la información relacionada con el conductor (edad, género, infracciones, etc.), con el accidente (día, lugar, etc.) y con el vehículo (tipo, defectos, etc.). Por tanto, a partir de estas variables se seleccionaron todas aquellas que se consideraron que podrían afectar, en mayor o menor medida, a la asignación de responsabilidad del conductor. Por este motivo, las variables seleccionadas para la construcción posterior de los mapas Self-Organizing Maps (SOM) son: infracción del conductor, infracción de velocidad, infracción administrativa, consumo de alcohol y/o drogas, enfermedad súbita, sueño, cansancio y/o preocupación (englobada bajo la variable sueño), defecto físico previo del conductor y estado del vehículo.

Por otro lado, para poder trabajar con estas variables aplicando la metodología SOM, ha sido necesario llevar a cabo un proceso de transformación de los valores de las mismas de forma que estas pasasen de ser categóricas a numéricas. Por convenio, se adoptó el valor de 0 para indicar que dicha infracción o condición no estaba presente, mientras que el valor 2 indicaba justo lo contrario. Además, se ha utilizado el valor intermedio de 0,25 para indicar que se ignora si está presente o no dicha infracción. Para tomar este valor, se ha partido de dos hipótesis: (a) el mismo tendría que estar comprendido entre 0 ó 2, dado que su categoría es intermedia a las otras dos y (b) si este valor está indicado como “Se ignora” es más probable que sea porque no estuviese presente, por lo que debe asignarse un valor más cercano al 0. Para validar esta cuestión se realizó un análisis de sensibilidad de los mapas SOM para distintos valores (comprendidos entre 0,25 y 1) para los casos en los que el valor de una o más variables era desconocido. Los resultados obtenidos, que no son mostrados aquí por no ser objeto de esta publicación, demostraron que no era significativa la elección de este valor de entre todos los valores probados. Por tanto, basándonos en las hipótesis planteadas, se escogió el valor de 0,25 para los casos en los que se desconocía el valor de la variable. Más información puede encontrarse en Sanjurjo-de-No et al. (2021).

La metodología empleada para llevar a cabo esta investigación es el método clúster conocido como Self-Organizing Maps (SOM).

Self-Organizing map es una técnica de aprendizaje no supervisado que fue desarrollado por Kohonen (1990) y forma parte de las técnicas de Machine Learning. El propósito de SOM es representar datos que, originalmente están en un espacio multidimensional, en un espacio de dimensión más reducida, pero manteniendo la topología original de los datos. Así, conductores que por sus características estuviesen cercanos en el espacio original, deberían seguir estando cercanos en el espacio proyectado. Como señalan algunos autores como Liu, P. (2009), Kohonen, T. (2013), Kohonen, T. (1998) o Lagus, K. (2002), esto supone una importante ventaja del SOM con respecto otros métodos de clúster, dado que permite la visualización de las nubes de puntos generadas por la proyección de los datos, ya que estas suele realizarse en 2 ó 3 dimensiones.

En la presente investigación, la metodología SOM permite realizar un análisis conjunto de las 8 variables anteriormente seleccionadas. De esta forma, se realiza un análisis conjunto de los conductores en el espacio original de 8 dimensiones el cual es proyectado sobre el espacio de 2 dimensiones, pero manteniendo la topología original de los datos de los conductores. Esto tiene por objetivo ayudar a identificar patrones de comportamiento entre los conductores en función de las infracciones que estos pueden o no haber cometido, lo que permitirá arrojar mayor nitidez sobre la responsabilidad de los mismos. Además, al apoyar la asignación de responsabilidad con esta metodología se está proporcionando más información acerca de cómo son los datos de manera multivariante, dado que se tiene en cuenta la distancia conjunta de todas las variables. Esto hace que el proceso de asignación de responsabilidad sea menos radical, esperando con esto que la asignación sea más precisa.

3. RESULTADOS

El mapa SOM de infracciones sobre el que se reparten los 145.904 conductores de la base de datos es el que se muestra en la Figura 1. Este mapa está dividido en 25 clústers o nodos y cada uno de los cuales alberga el número de conductores que se indica en negro en la parte superior de cada clúster. En rojo, se indica el número del clúster en cuestión. Así, por ejemplo, el clúster 15 contiene un total de 30.729 conductores, mientras que en el clúster 23 no hay ningún conductor. Un análisis más detallado puede encontrarse en Sanjurjo-de-No et al. (2021).

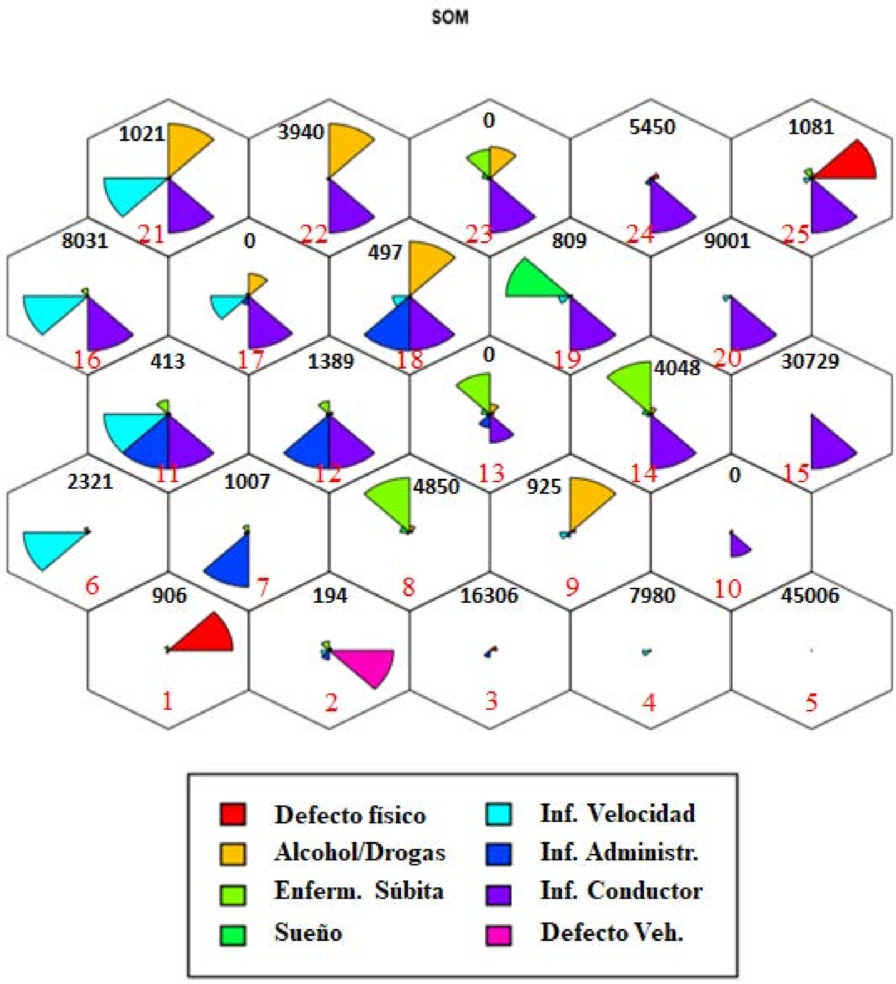

Fig. 1 – Mapa SOM de infracciones

En cada clúster es posible visualizar las características de los conductores en el espacio proyectado de 2 dimensiones, cuando originalmente estaban en el espacio de 8 dimensiones (una dimensión por cada variable contemplada en el SOM). Cada uno de los vectores de colores que se muestran en cada clúster indica el valor promedio de la variable que representan para todos los datos (conductores) que han sido asignados a ese clúster. En la Tabla 1 se indica numéricamente dicho valor promedio para cada una de las variables en cada uno de los clústers en los que hay algún conductor asignado.

	Defecto físico	Alcohol/Drogas	Enfermedad súbita	Sueño/Cansancio	Inf. Velocidad	Infr. Administrativa	Inf. Conductor	Defecto del vehículo
Cluster 1	2	0.02	0.02	0.02	0	0.09	0	0
Cluster 2	0.10	0.10	0.05	0.06	0.25	0.33	0	2
Cluster 3	0.22	0	0	0	0	0.25	0	0
Cluster 4	0	0	0	0	0.25	0.03	0	0
Cluster 5	0	0	0	0	0	0	0	0
Cluster 6	0.09	0.02	0.02	0.02	2	0.07	0	0
Cluster 7	0.02	0.03	0.03	0.07	0	2	0	0
Cluster 8	0.10	0.24	0.27	0.29	0	0.03	0	0
Cluster 9	0.17	2	0	0	0.32	0.18	0	0
Cluster 11	0.07	0.07	0.07	0.08	2	2	2	0.07
Cluster 12	0.13	0.05	0.06	0.08	0	2	2	0.05
Cluster 14	0.09	0.25	0.26	0.25	0	0.04	2	0
Cluster 15	0	0	0	0	0	0	2	0
Cluster 16	0.02	0.04	0.04	0.04	2	0.03	2	0.03
Cluster 18	0.05	2	0	0	0.52	2	2	0.04
Cluster 19	0.07	0	0	2	0.36	0.02	2	0.02
Cluster 20	0	0	0	0	0.25	0.02	2	0
Cluster 21	0.09	2	0	0	2	0.03	2	0.02
Cluster 22	0.03	2	0	0	0	0.04	2	0.03
Cluster 24	0.25	0	0	0	0	0.24	2	0.12
Cluster 25	2	0.17	0.04	0.02	0.25	0.02	2	0

Tabla 1 – Valor promedio de cada variable en cada clúster

3.1 Variables importantes en la asignación de responsabilidad

En este apartado se realiza un análisis de las variables introducidas en el SOM con el objetivo de determinar cuáles son aquellas que mejor identifican a los grupos o clústers de conductores del SOM. Se debe llegar a una solución de compromiso entre usar un número excesivo de variables para realizar la asignación de responsabilidad y tener en cuenta el suficiente número de variables para la identificación de los grupos de conductores responsables y no responsables de forma que se pierda la menor cantidad posible de información.

En la Tabla 1 y Figura 1 puede observarse que la variable que mejor divide a los conductores en dos grupos es la infracción del conductor, dado que, entre todos los clústers con conductores asignados, esta variable siempre adopta valor 0 ó 2 y no un valor intermedio entre estos. Por lo que se trata de la variable que mejor define la responsabilidad de los conductores. Por otro lado, se observa que la infracción de velocidad es una variable también relevante en la agrupación de los conductores en diferentes clústers y mide comportamientos de conducción peligrosos. Por tanto, esta variable también debería ser considerada en el proceso de asignación de responsabilidad.

La variable defecto físico previo aparece sólo en los clústers 1 y 25 del mapa, lo que hace pensar que no es significativa en la responsabilidad de los conductores. Los defectos físicos de los conductores son principalmente defectos de visión y audición y estos defectos están relacionados con la edad de los conductores (Sanjurjo-de-No et al., 2020) y hay investigaciones, como la realizada por Sagar et al. (2020), que indican que los conductores más mayores tienen más probabilidad de ser responsables en un accidente que los conductores pertenecientes a otras franjas de edad. Esta variable debería, por tanto, ser sometida a análisis futuros que evalúen más profundamente su grado de influencia sobre la responsabilidad del conductor.

Por otro lado, se observa que las variables denominadas “Estado del vehículo” y “Sueño” aparecen de manera aislada en muy pocos casos o aparecen combinadas con otras variables, como la infracción del conductor, que ya por sí sola permitía clasificar a los conductores. Por lo que, se considera que estas variables podrían no ser tenidas en cuenta en el proceso de asignación de responsabilidad.

En relación con las infracciones administrativas, se considera que la única infracción de este tipo que podría ser relevante sobre la responsabilidad es no haber efectuado la Inspección Técnica Reglamentaria del Vehículo (ITV) cuando esta va unida a un mal estado de dicho vehículo. Sin embargo, no se ha identificado ningún clúster en los que ambas variables de infracción aparezcan en un estado desfavorable de manera conjunta. Por lo tanto, se considera poco relevante el uso de esta variable a la hora de realizar la asignación de responsabilidad.

Finalmente, en relación a la variable “Enfermedad súbita”, es importante señalar que en la base de datos de accidentes no se especifica el tipo de enfermedad súbita sufrida por el conductor que la padece. Realmente esta variable no aparece por sí sola en muchos de los clústers, por lo que podríamos no considerarla en el modelo. Sin embargo, teniendo en cuenta la definición de enfermedad súbita como aquellas que aparecen sin ser esperadas y normalmente hacen perder las facultades normales que presenta la persona que las padece (desmayo, ataque de ansiedad, infarto, etc), podríamos considerar que puede afectar a la probabilidad de que un conductor que la padezca pueda ser responsable de un accidente de tráfico. Por esta razón, análisis adicionales también deberían llevarse a cabo en relación a esta variable para determinar el grado de influencia de la misma sobre la responsabilidad de los conductores.

En la Tabla 2 se muestran finalmente las variables consideradas más importantes para realizar la asignación de responsabilidad.

Variables más influyentes en la asignación de responsabilidad	Variables menos influyentes en la asignación de responsabilidad	Relevancia desconocida en el proceso de asignación de responsabilidad
Infracción del conductor	Infracción administrativa	Defecto físico previo
Infracción de velocidad	Sueño	Enfermedad súbita
Consumo de alcohol/drogas	Estado del vehículo	

Tabla 2 – Variables más relevantes para la asignación de responsabilidad con mapas SOM

3.2 Propuesta de asignación de responsabilidad en base al SOM

En este apartado se realiza el análisis del mapa SOM anteriormente creado desde el punto de vista de la responsabilidad de los conductores. Para ello, se tratará de identificar el perfil de cada uno de los conductores en función del clúster al que estos pertenezcan.

Como puede observarse en la Figura 2, es posible establecer una frontera en el mapa, por criterio experto, en función de la combinación de variables que aparece en cada uno de los clústers.

Así, a través de la agrupación de los conductores en diferentes clústers gracias a la proyección de los mismos en el espacio de 2 dimensiones, es posible distinguir dos regiones: potencialmente responsables y potencialmente no responsables.

En la región superior (Potencialmente responsables) se localizan todos aquellos conductores que han cometido una o múltiples infracciones o presentan condiciones desfavorables para la conducción. Se considera que estos conductores son responsables, dado que el perfil de infracciones presentes en esta zona del mapa.

Por otro lado, en la región inferior del mapa (Potencialmente no responsables) se encuentran los conductores que con seguridad no han sido responsables (en el clúster 5) y aquellos conductores que habría que analizar en profundidad junto con el otro conductor del accidente, con el objetivo de determinar si es posible la clasificación de los mismos.

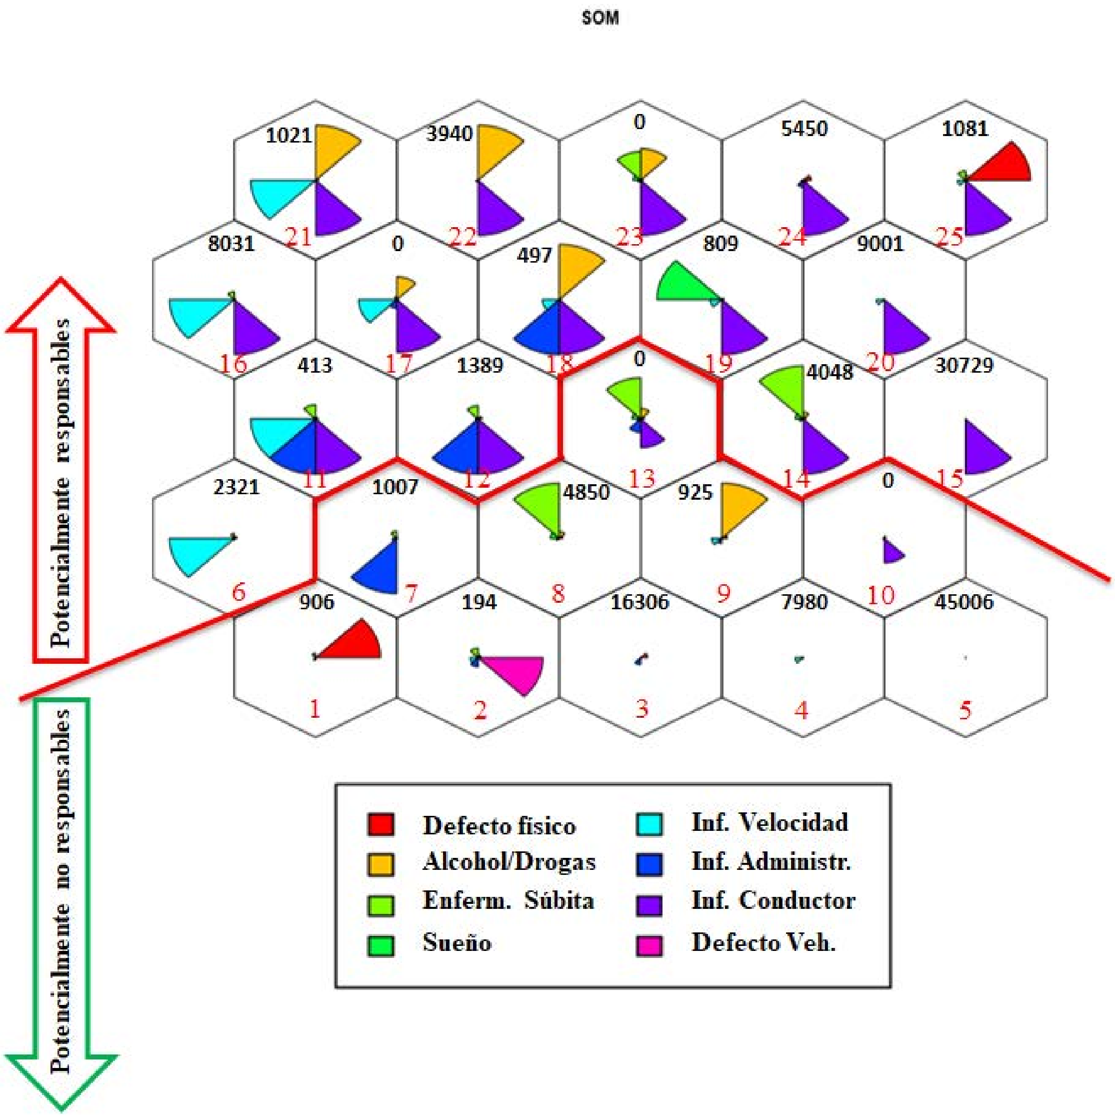

Fig. 2 – Mapa SOM de infracciones con la frontera de separación de regiones

El análisis conjunto de las parejas de conductores implicados en un mismo accidente dio lugar a la identificación de varias casuísticas posibles: (I) Responsable / No Responsable: Si un conductor está situado en la parte superior del mapa y el otro conductor con el que tuvo el accidente está situado en la parte inferior del mapa (establecido por la frontera), entonces el primer conductor podría considerarse responsable del accidente, mientras que el segundo sería considerado como no responsable; (II) Responsable / Responsable: Si ambos conductores están situados en la parte superior del mapa de acuerdo con la frontera establecida, entonces ambos podrían considerarse responsables y, por lo tanto, no se tendrían en cuenta en el análisis; (III) No responsable / No responsable: Si ambos conductores implicados en un mismo accidente están en el clúster 5, entonces los dos podrían ser considerados no responsables y, por lo tanto, podrían no ser tenidos en cuenta en el posterior análisis; Y (IV) Casos de Análisis: Si ambos conductores están en la parte inferior del mapa de acuerdo con la frontera establecida y, al menos uno de ellos en un clúster diferente al 5, entonces habría que realizar análisis adicionales para determinar si es posible saber cuál de ellos podría haber sido el responsable del accidente.

En la Tabla 3, se muestra el reparto de conductores en cada una de estas categorías y, puede observarse como, a partir de la interpretación del mapa SOM, podrían llegarse a clasificar un total de 83,76% de los conductores en Responsable / No responsable.

	Número de conductores	%
Responsable / No responsable	122.208	83,76%
Responsable / Responsable	7.626	5,23%
No responsable / No responsable	2.014	1,38%
Casos de Análisis	14.056	9,63%
TOTAL	145.904	100%

Tabla 3 – Clasificación de los conductores con mapas SOM

Los resultados obtenidos usando los mapas SOM para realizar la asignación de responsabilidad fueron comparados con los resultados obtenidos cuando dicha asignación se hace teniendo en cuenta únicamente la infracción del conductor y la de velocidad, que son las variables más comúnmente utilizadas para realizar esta asignación. En este caso, se considera que un conductor es responsable si ha cometido infracción del conductor y/o de velocidad y no será responsable en caso contrario.

Los resultados son los que se muestran en la Tabla 4, donde se observa que se logra clasificar al 72,47% de los conductores.

Por tanto, realizando la asignación de responsabilidad utilizando la metodología SOM logramos rescatar a un mayor número de conductores para el análisis posterior. Además, tiene en cuenta una mayor cantidad de variables a la hora de realizar dicha asignación. Por lo que se espera que la calidad de la misma sea mayor.

	Número de conductores	%
Responsable / No responsable	105.736	72,47%
Responsable / Responsable	7.706	5,28%
No responsable / No responsable	13.098	8,98%
Casos de Análisis	19.364	13,27%
TOTAL	145.904	100%

Tabla 4 – Clasificación de los conductores en función sólo de las infracciones del conductor y de velocidad (método tradicional)

4. CONCLUSIONES

En esta investigación se propone el uso de la metodología Self-Organizing Maps (SOM) de cluster como herramienta alternativa de ayuda para la asignación de responsabilidad. Con el SOM es posible identificar diferentes patrones en los conductores en relación a las infracciones que estos han cometido. Esto permite, en primer lugar, identificar las variables más y menos relevantes para llevar a cabo la asignación de responsabilidad y, en segundo lugar, estos patrones nos servirán como herramienta de ayuda para llevar a cabo el proceso de asignación de responsabilidad.

Así, se ha observado que las variables más relevantes a la hora de asignar la responsabilidad son: infracción del conductor, infracción de velocidad y consumo de alcohol y/o drogas.

Finalmente, la distribución de los conductores en el mapa SOM permite ayudar en la identificación de la responsabilidad de los conductores, clasificando un total del 83,76% de los conductores frente a los 72,47% de los conductores clasificados mediante la asignación tradicional que, fundamentalmente, tiene en cuenta sólo las infracciones del conductor y las de velocidad. Por tanto, además de conseguir una mayor clasificación de los conductores aplicando la metodología SOM, se tienen en cuenta de manera multivariante un mayor número de variables, por lo que se espera que la calidad de los conductores clasificados sea mayor.

AGRADECIMIENTOS

DOES SIZE REALLY MATTER? DUAL DISTRIBUTION CHANNEL WITH VANS AND AUTONOMOUS DELIVERY DEVICES

ABSTRACT

E-commerce sales worldwide are expected to skyrocket in future years, increasing freight traffic in cities. In this context, sidewalk autonomous delivery devices (ADDs) show great potentialities to decrease carriers' last-mile operation costs. Nevertheless, the implementation of these autonomous robots requires some adjustments in the supply chain because of their particular characteristics. To avoid severe accidents with pedestrians, their speed and size will be limited and, as a consequence, ADDs seem more adapted to the delivery of small items. The objective of this paper is to estimate the carrier's total operation costs in a dual delivery channel. If its size is lower than a given threshold, the parcel is delivered to the customer through a supply chain compound of a logistics micro-hub and ADDs. Otherwise, if the parcel is bigger than the given threshold, it is delivered through a business-as-usual supply chain with delivery vans. The carrier's total operation costs is the sum of the costs induced by the two distribution channels. Assuming that the parcel size follows a known probability distribution function, the carrier's total operation costs are estimated using the continuous approximation methodology. Different probability distribution functions modelling the size of the parcels are studied in the paper. Finally, the dual distribution channel is optimized considering the size threshold as a decision variable of the system.

1. INTRODUCTION

Freight vehicles represent around 20% of traffic in cities (Russo and Comi, 2012). Last-mile operations in dense urban environments is a major concern for carriers and logistics service providers. The rise of e-commerce is likely to worsen this situation if no measures are taken. To address these challenges and decrease last-mile operation costs, autonomous delivery devices (ADDs) could be used in future years (Figliozzi and Jennings, 2020). Nevertheless, because ADDs are medium-size vehicles that are only able to deliver small items, a dual supply chain (SC) that depends on the parcel size has to be implemented. The main objective of this paper is to quantify the carrier's total operation costs in this dual SC and compare them with the business-as-usual (BAU) deliveries.

2. OPERATION COSTS MODELLING

The continuous approximation methodology (Daganzo, 1984) will be used. The carrier's job is to deliver the parcels that are in its distribution center (DC) to final customers (see Fig. 1). The distance between the carrier's DC and the center of the service region is ρ_{DC} (see Fig. 1). In this process, the total operation costs have to be minimized. This is a particular instance of the vehicle routing problem.

2.1 Model description

A uniform demand density δ (expressed in receivers/km^2/day) is served in a service region of area A. The parcel volume stochastic variable y follows a probability distribution function (PDF) $f(y)$ (see Fig. 1). If its volume is superior to a given threshold y_{lim}, the parcel passes through a supply chain (SC) with conventional light commercial vehicles (LCVs). This is the first supply chain SC1 (see Fig. 1). On the contrary, if its volume is inferior to y_{lim}, the parcel is taken from the carrier's distribution center (DC) to a micro-hub located within the service region. Then, some ADDs perform the delivery to the final receiver. This is the second supply chain SC2 (see Fig. 1).

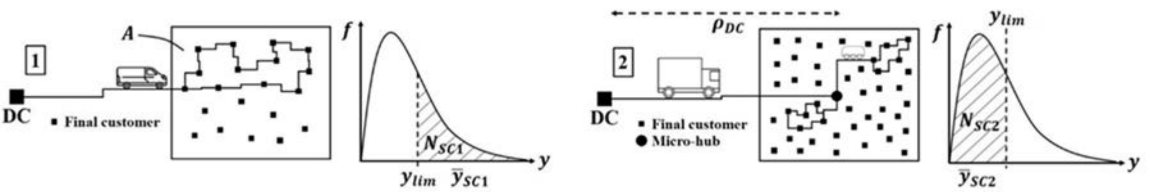

Fig. 1 – Dual SC with HDVs, LCVs and ADDs

We consider that N_{SC1} parcels with an expected volume $\bar{y}_{SC1}$ are delivered through SC1. Similar variables are denoted for the SC2 Scenario. In SC2, we assume that the parcels are carried from the carrier's DC to the micro-hub with heavy-duty vehicles (HDVs) to maximize the economies of scale. The expressions of N_{SC1}, N_{SC2}, $\bar{y}_{SC1}$ and $\bar{y}_{SC2}$ are given in Equations (1) and (2).

$$N_{SC1} = \left[\int_{y_{lim}}^{+\infty} f(y)dy\right]\delta A \; ; \; \bar{y}_{SC1} = \left(\int_{y_{lim}}^{+\infty} yf(y)dy\right) / \left(\int_{y_{lim}}^{+\infty} f(y)dy\right) \quad (1)$$

$$N_{SC2} = \left[\int_{0}^{y_{lim}} f(y)dy\right]\delta A \; ; \; \bar{y}_{SC2} = \left(\int_{0}^{y_{lim}} yf(y)dy\right)/\left(\int_{0}^{y_{lim}} f(y)dy\right) \quad (2)$$

2.2 SC1

The expected time spent per delivery in SC1 t_{SC1}^{d} is estimated by Equation (3) considering the work of Daganzo (1984).

$$t_{SC1}^{d} = \frac{1}{v_L^{LCV}} \frac{2}{\sqrt{3}} \sqrt{\frac{A}{N_{SC1}}} + \tau_s^{LCV} \tag{3}$$

Where v_L^{LCV} is the speed of LCVs in the local road grid and τ_s^{LCV} the LCV unit stop time, including parking and customer delivery process.
Then, the number of parcels delivered along one LCV route Ψ_{SC1}^{LCV} can be computed as

$$\Psi_{SC1}^{LCV} = min\left\{\frac{C^{LCV}}{\bar{y}_{SC1}}; \frac{H_{SC1} - \frac{2\rho_{DC}}{v_{LH}^{LCV}}}{t_{SC1}^{d}}\right\} \tag{4}$$

Where C^{LCV} is the LCV volume capacity, ρ_{DC} the distance between the carrier's DC and the center of the service region (see Fig. 1), H_{SC1} the operation time window of SC1, and v_{LH}^{LCV} the speed of LCVs on metropolitan highways.

To estimate Ψ_{SC1}^{LCV}, two restrictions are considered: the number of parcels loaded in a LCV is limited and the LCV route duration cannot be longer than H_{SC1}.

Then, the total distance travelled on metropolitan highways D_{SC1}^{LH} (respectively in the local road grid D_{SC1}^{L}) and the total time worked by the LCV fleet T_{SC1} are computed.

$$D_{SC1}^{LH} = 2\rho_{DC} \left[\frac{N_{SC1}}{\Psi_{SC1}^{LCV}}\right]^{+} ;\ D_{SC1}^{L} = \frac{2}{\sqrt{3}} \sqrt{AN_{SC1}} ;\ T_{SC1} = \frac{D_{SC1}^{LH}}{v_{LH}^{LCV}} + \frac{D_{SC1}^{L}}{v_L^{LCV}} + \tau_s^{LCV} N_{SC1} \tag{5}$$

Finally, the LCV operation costs in SC1 are estimated in Equation (6), where c_t^{LCV} and c_d^{LCV} are the LCV unit time and distance operation costs.

$$Z_{SC1} = c_t^{LCV} T_{SC1} + c_d^{LCV} (D_{SC1}^{LH} + D_{SC1}^{L}) \tag{6}$$

2.3 SC2

Once the operation costs of SC1 have been modelled, let us focus on SC2 (parcels whose volume is inferior to the threshold y_{lim}).

2.3.1 From the carrier's DC to the micro-hub

The parcels are first taken from the carrier's DC to the micro-hub with HDVs (see Fig. 1). As previously, the first step is to compute the HDV capacity Ψ_{SC2}^{HDV} in Equation (7), where C^{HDV} is the HDV volume capacity and $\bar{y}_{SC2}$ the expected parcel volume in this SC2.

$$\Psi_{SC2}^{HDV} = \frac{C^{HDV}}{\bar{y}_{SC2}} \quad (7)$$

The term Ψ_{SC2}^{HDV} corresponds to the maximum number of parcels that can be loaded in the HDV at the carrier's DC. Then, the total distance travelled D_{SC2}^{HDV} and total time worked T_{SC2}^{HDV} by the HDV fleet are determined in Equation (8), where v_{LH}^{HDV} is the speed of HDVs on metropolitan highways and τ_{LU}^{HDV} the expected time needed to load and unload one HDV at the carrier's DC and micro-hub.

$$D_{SC2}^{HDV} = 2\rho_{DC}\left[\frac{N_{SC2}}{\Psi_{SC2}^{HDV}}\right]^{+} \; ; \; T_{SC2}^{HDV} = \frac{D_{SC2}^{HDV}}{v_{LH}^{HDV}} + 2\tau_{LU}^{HDV}\left[\frac{N_{SC2}}{\Psi_{SC2}^{HDV}}\right]^{+} \quad (8)$$

Finally, the HDV total operation costs in SC2 Z_{SC2}^{HDV} are presented in Equation (9), as the sum of the time-based and distance-based operation costs. The parameters c_t^{HDV} and c_d^{HDV} are the HDV unit time and distance operation costs.

$$Z_{SC2}^{HDV} = c_t^{HDV} T_{SC2}^{HDV} + c_d^{HDV} D_{SC2}^{HDV} \quad (9)$$

2.3.2 From the micro-hub to the final receiver

This is the second stage of SC2. The parcels are taken from the micro-hub to the final receivers with ADDs. The methodology presented by Daganzo (1984) will be used.

The expected distance between the micro-hub and the locations of the visited points ρ_h is assumed to be $\rho_h = \frac{\sqrt{A}}{2}$, where A is the total area of the service region. We assume that the logistic micro-hub is located in the center of the service region, and we define an expected distance d_{SC2}^{d} and expected time t_{SC2}^{d} per parcel delivery (see Equation 10).

$$d_{SC2}^{d} = \frac{2}{\sqrt{3}}\sqrt{\frac{A}{N_{SC2}}} \; ; \; t_{SC2}^{d} = \frac{1}{v^{ADD}}\frac{2}{\sqrt{3}}\sqrt{\frac{A}{N_{SC2}}} + \tau_s^{ADD} \quad (10)$$

Where v^{ADD} is the ADD speed and τ_s^{ADD} the ADD expected unit stop time per parcel delivery to give the parcel to the final customer. We can now estimate the expected number of parcels delivered along one ADD route Ψ_{SC2}^{ADD} by Equation (11)

$$\Psi_{SC2}^{ADD} = min\left\{\frac{C^{ADD}}{\bar{y}_{SC2}}; \frac{H_{SC2} - \frac{2\rho_{DC}}{v_{LH}^{HDV}} - \tau_{LU}^{HDV} - \frac{2\rho_h}{v^{ADD}}}{t_{SC2}^{d}}; \frac{L_b^{ADD} - 2\rho_h}{d_{SC2}^{d}}\right\} \quad (11)$$

Where C^{ADD} is the ADD volume capacity, H_{SC2} the SC2 operation time window, v_{LH}^{HDV} the speed of HDVs on metropolitan highways, τ_{LU}^{HDV} the HDV loading/unloading time at the micro-hub and L_b^{ADD} the maximum distance that an ADD can travel considering its limited battery capacity restriction.

In addition to the volume and time horizon restrictions, we also need to consider the ADD limited range (because of the robot limited battery capacity) in this SC2. Thanks to the expression of Ψ_{SC2}^{ADD}, we are able to define the total distance D_{SC2}^{ADD} and total time worked T_{SC2}^{ADD} by the ADD fleet in Equation (12). This Equation is valid only if the following consition is met (Robusté et al., 1990): $7 < \Psi_{SC2}^{ADD} < 1.5\left(\frac{N_{SC2}}{\Psi_{SC2}^{ADD}}\right)$.

$$D_{SC2}^{ADD} = 2\rho_h \left[\frac{N_{SC2}}{\Psi_{SC2}^{ADD}}\right]^+ + \frac{2}{\sqrt{3}}\sqrt{AN_{SC2}}\ ;\ T_{SC2}^{ADD} = \frac{D_{SC2}^{ADD}}{v^{ADD}} + \tau_s^{ADD} N_{SC2} \tag{12}$$

We now compute the operation costs induced by the ADD fleet in SC2 Z_{SC2}^{ADD}, by Equaiton (13), where c_t^{ADD} and c_d^{ADD} are the ADD unit time and distance operation costs.

$$Z_{SC2}^{ADD} = c_t^{ADD} T_{SC2}^{ADD} + c_d^{ADD} D_{SC2}^{ADD} \tag{13}$$

2.3.3 SC2 total operation costs

We obtain the SC2 total operation costs Z_{SC2} aggregating the HDV, ADD and micro-hub operation costs, by Equation (14), where Ω_h is the micro-hub daily operation costs.

$$Z_{SC2} = Z_{SC2}^{HDV} + Z_{SC2}^{ADD} + \Omega_h \tag{14}$$

3. NUMERICAL USE CASE

3.1 Input parameters

Different parcel volume PDFs will be considered in this paper (see Fig. 2).

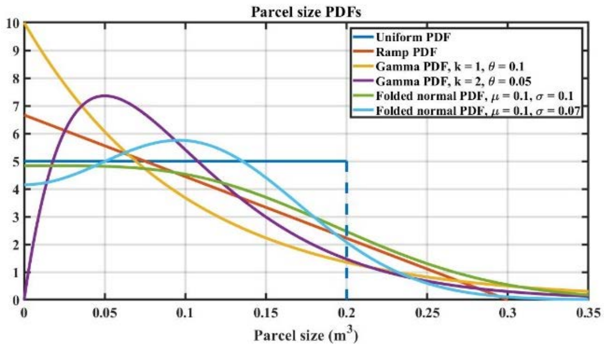

Fig. 2 – Parcel volume PDFs

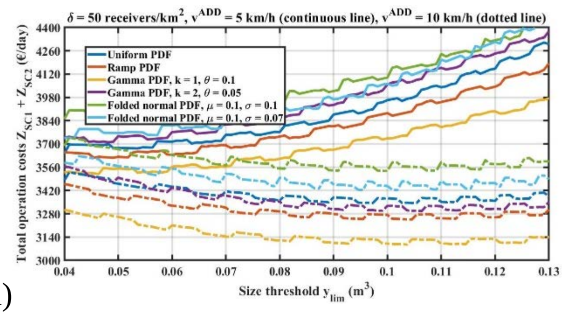
We built the PDFs presented in Fig. 2 considering the standard boxes available in-store at FedEx Office (FedEx, 2021) and assuming small parcels represent the biggest trade volume. For comparison purposes, the PDFs have the same expected parcel volume $\bar{y}$ = 0.1 m^3. The other input parameters are A = 50 km^2, ρ_{DC} = 20 km, $H_{SC1} = H_{SC2}$ = 8 h, Ω_h = 68 EUR/day, v_{LH}^{LCV} = 70 km/h, v_L^{LCV} = 20 km/h, τ_s^{LCV} = 2 min, C^{LCV} = 5 m^3, c_t^{LCV}= € 24/veh-h, c_d^{LCV}= € 0.2/veh-km, v_{LH}^{HDV} = 60 km/h, τ_{LU}^{HDV} = 30 min, C^{HDV} = 10 m^3, c_t^{HDV} = € 25/veh-h, c_d^{HDV}= €

0.3/veh-km, v^{ADD} = 5-10 km/h, τ_s^{ADD} = 1 min, C^{ADD} = 0.5 m^3, L_b^{ADD} = 50 km, c_t^{ADD} = € 5/veh-h and c_d^{ADD} = c€ 0.8/veh-km.

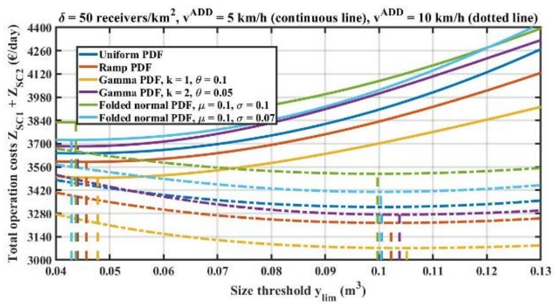
A service region of area A = 50 km^2 approximately corresponds to the city of Barcelona. We estimated the micro-hub daily operation costs Ω_h based on the work done by Estrada & Roca-Riu (2017). The ADD unit stop time τ_s^{ADD} is twice lower as τ_s^{LCV} because ADDs do not have to look for a parking spot and park. Then can access final customers more easily. We estimated the LCV (respectively HDV) unit time and distance operation costs c_t^{LCV} and c_d^{LCV} (respectively c_t^{HDV} and c_d^{HDV}) using data from the Observatory of Road Freight Transport in Catalonia (2019). To compute the ADD unit distance operation cost c_d^{ADD}, we estimate that the robot energy consumption is around 30 Wh/km (at 5 km/h) and that 1 kWh of electricity costs € 0.25 in Spain. As for the ADD unit time operation cost c_t^{ADD}, we assume that a robot costs around € 6,000 and is linearly depreciated over 4 years (2,500 working hours per year). We estimate the ADD maintenance costs to be around 20% of the capital costs on a yearly basis, i.e. 0.2 x € 6,000 = € 1,200/year-veh = € 0.5/veh-h (still with 2,500 working hours per year). One operator is in charge of 10 ADDs, i.e. € 20/10 = € 2/ADD-h. The ADD insurance costs are assumed to be around € 2,000/ADD-year as well as the carrier's structural costs.

3.2 Results

Fig. 3 presents the total operation costs Z_{SC1} + Z_{SC2} of the dual SC as a function of the volume threshold y_{lim}. We consider the different PDFs depicted in Fig. 2 and two ADD speed: 5 km/h (continuous lines in Fig. 3) and 10 km/h (dotted lines in Fig. 3). Fig. 3a shows the outputs of the equations presented in Section 3. Some discontinuities appear in the graphs because we considered the upper integer to compute the number of LCV, HDV and ADD routes. Fig. 3b depicts the same results considering that the number of vehicle route is directly N/C, where N refers to the total number of parcels that are to be delivered and C the capacity of the vehicle. In Fig. 3, a total demand density of 50 receivers/km^2 is considered.



a)

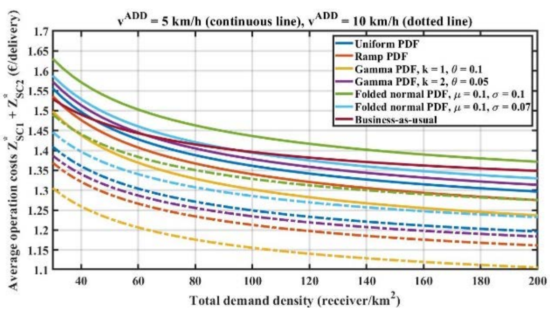


b)

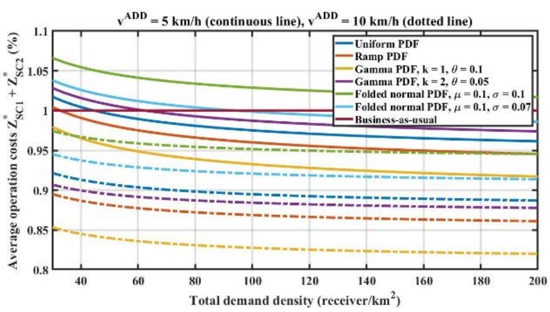
Fig. 3 – Total operation costs as a function of the volume threshold y_{lim}

Two main results can be drawn from Fig. 3. First, the parcel volume PDF has an impact on the carrier's total operation costs. The PDF that generates less operation costs is the gamma PDF with k = 1 and θ = 0.1. This result makes sense because this is the PDF for which the parcel volumes are the most "concentrated" around 0 m^3 (see Fig. 2). More parcels are delivered through SC2 and the economies of scale generated by the ADDs are increased. On the contrary, the carrier's total operation costs are the highest when a folded normal PDF is considered. In this case, less parcels are delivered through SC2 because their volume is more uniformly distributed. There are fewer small parcels and more big parcels than in the gamma PDF. For y_{lim} = 0.1 m^3 and v^{ADD} = 10 km/h, the difference between the gamma and folded normal PDFs is around 15% (€ 3,500/day approximately for the normal folded PDF and € 3,050/day approximately for the gamma PDF, see Fig. 3b).

The second main result is that the volume threshold y_{lim} is an important decision variable of the problem and that the carrier can optimize its total operation costs. This is especially the case when v^{ADD} = 5 km/h. For a gamma PDF (μ = 0.1, σ = 0.1) and v^{ADD} = 5 km/h, when y_{lim} passes from 0.04 m^3 to 0.13 m^3, the carrier's total operation costs are increased by 14% (from € 3,840/day to € 4,400/day). The optimal threshold y^*_{lim} for which the carrier's total operation costs are minimum depends on the ADD speed. For v^{ADD} = 5 km/h, y^*_{lim} is around 0.045 m^3 whereas it is around 0.1 m^3 for v^{ADD} = 10 km/h (see Fig. 3b). At a higher speed, ADDs are more competitive and the carrier should deliver more parcels through SC2 to minimize its costs. At a lower speed, ADDs are not so competitive when compared to the LCVs of SC1 and the robots are only dedicated to the smallest parcels. In the rest of the section, we consider that the number of vehicle routes is a continuous function (see Fig. 3b). Fig. 4 presents the carrier's optimized average operation costs $(z_{SC1} + z_{SC2})^*$ per parcel delivery as a function of the total demand density δ. The average operation costs correspond to the total operation costs (see Fig. 3) divided by the total number of parcels δA. Fig. 4a shows these optimized average operation costs in absolute value (as in Fig. 3). On the contrary, they are expressed as a percentage of the business-as-usual (BAU) average operation costs in Fig. 4b. The BAU scenario corresponds to the delivery of all the parcels through SC1, without using the micro-hub or the ADDs. The micro-hub daily operation costs are not considered in this BAU situation.



a)



b)

Fig. 4 – Optimized average operation costs as a function of the total demand density δ

The dual SC presents economies of scale because the average operation costs per parcel delivery decreases when the demand density increases. This is a common result is logistics operation analysis. As we observed previously, the parcel volume PDF and the ADD speed are important variables that condition the carrier's operation costs. At a demand density of 30 receivers per km^2, if the robot speed is 5 km/h, the operation costs induced by the dual SC are equal or higher (except in the case of the negative exponential PDF) than the BAU operation costs. On the contrary, if v^{ADD} = 10 km/h, the carrier's operation costs are reduced between 2% (with the worst PDF) and 15% (with the best PDF). At a higher density of 200 parcels/km^2, almost all configurations are more favorable to the dual SC. Only the combination of a normal folded PDF and a robot speed of 5 km/h generates more operation costs than the BAU delivery pattern. For v^{ADD} = 10 km/h, the cost reduction ranges from 5% to 17% depending on the considered PDF.

Finally, the optimal volume threshold y^*_{lim} as a function of the demand density δ is presented in Fig. 5.

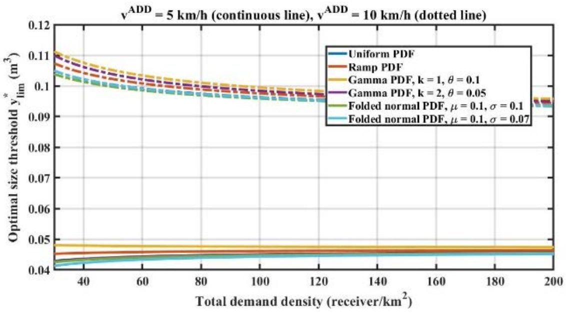


Fig. 5 – Optimized volume threshold y^*_{lim} as a function of the total demand density δ

When the robot speed is defined, y^*_{lim} is quite robust and does not depend on the demand density. For v^{ADD} = 5 km/h, the optimal threshold is around 0.045 m^3 whereas it is 0.1 m^3 when v^{ADD} = 10 km/h.

4. CONCLUSION AND FURTHER RESEARCH

In the numerical use case presented in this paper, the dual SC using ADDs could decrease the carrier's total last-mile operation costs up to 15% in the best configuration. Nevertheless, this cost reduction highly depends on the parcel volume PDF and the robot speed. If the parcel volumes are more uniformly distributed, the cost reduction is lower because less items are distributed by the ADDs. If we increase the speed of the robots, the operation cost reduction is higher because ADD operations take less time. It will be important to describe some realistic operative scenarios for ADDs in future years (circulation on secondary roads, bike lanes, sidewalks) to more precisely quantify the potential of these autonomous technologies. However, since the boom of e-commerce is expected to generate smaller parcels with higher delivery frequencies, the use of ADDs could be even more justified.

To conclude, some limitations to the developed model appear. First, the unit time and distance operation costs of ADDs are highly uncertain, which limits the representativeness of the results. Secondly, we considered that only one logistic micro-hub was implemented for a service region whose size is equivalent to the city of Barcelona. Creating a network of micro-hubs, adequately located, would certainly increase the efficiency of operations. This is left for further research.

CASE OF STUDY OF A MIXED CARSHARING SYSTEM DESIGN

Enrique Jiménez Meroño
PhD Candidate, BIT – Universitat Politècnica de Catalunya (UPC), Spain
Francesc Soriguera Martí
Associate Professor, BIT – Universitat Politècnica de Catalunya (UPC), Spain

ABSTRACT

One of the most significant issues when designing a carsharing system is the decision of implementing a free-floating or stations-based system. The advantages and drawbacks of each system are well known. Free-floating systems provide more accessibility to users. But they are more sensible to demand imbalance and can be limited if public space availability is restricted by municipalities. Station-based don't need public space occupation, but the station infrastructure requires more investment. The authors have developed a macroscopic design model that considers the case of a mixed carsharing system, which includes both free-floating and station-based options working together. This model not only allows to compare which option will perform better on any given scenario, but also to provide solutions that combine the accessibility and cheapness of free-floating with the lack of public space limitations of station-based systems. This document describes that model and shows its application to a case of study.

1. INTRODUCTION

Carsharing is the evolution of car rentals. The idea behind them is the same: to provide a flexible on-demand transportation alternative with less costs than acquiring a private car or vehicles for hire (e.g. taxis). And from this idea, the system has been improved using new technologies in order to increase its flexibility. Membership systems, geolocations, and mobile apps have eased a lot the process of search, reservation, and payment for the use. Allowing users, for example, to spend less time in the renting process, making only one-way trips, or paying per minutes instead of an hourly or daily basis.

These new features have produced a positive effect on the market size. As of October 2016, carsharing was operating in 2095 cities in 46 countries with approximately 15 million members sharing over 157.000 vehicles. The second carsharing market is Europe with 19% of worldwide members and 37% of the fleet. (Shaheen and Cohen, 2020)

However, those features have also added a completely new dimension on the complexity of the design and management of these systems. One of the most significant issues is the decision of implementing a free-floating or station-based carsharing configuration.

	2006	2008	2010	2012	2014	2016
Members	346,610	670,822	1,163,645	1,788,027	4,842,616	15,050,192
Compound Annual Member Growth Rate (2 yr)	0%	39%	32%	24%	65%	76%
Vehicles	11,501	19,403	31,967	43,554	104,125	157,416
Compound Annual Fleet Growth Rate (2 yr)	0%	30%	28%	17%	55%	23%
Member-Vehicle Ratio	30.1	34.6	36.4	41.1	46.5	95.6

Fig. 1 – Global carsharing market (Source: Shaheen and Cohen, 2020)

On free-floating carsharing (FF), the fleet of cars is placed on the city streets. Users can check the location of nearby available cars through a mobile app and reserve the desired vehicle to make their trips. Once the ride has been complete, users can return the car by parking it on any available place inside a designed service region (typically the whole municipality area).

On station-based carsharing (SB), the fleet is distributed through certain specific parking lots or stations. Users can also check the availability of cars via mobile app, and make a reservation. But, at the end, they must return the car on any of those designated parking locations. So, in practice, all trips are station-to-station.

Each carsharing type has some advantages and drawbacks, Soriguera and Jiménez (2017), Tournier (2017) and Ciari et al. (2014) mentioned a few of them:

- Firstly, from the operator point of view, FF requires less infrastructure costs since there is no need to pay any fee to the local parking provider in order to reserve parking spots. The cars can be parked at any free parking slot in the street, so there is no cost of renting the parking.
- Following this line, it is also important to emphasize in the fact that a FF service is easier to implement than a SB since it is not dependent of the construction times of parking slots.
- However, note that municipalities and local administrations could be reluctant to concede the free usage of public space, and therefore, they could limit the number of FF cars in service.
- From a customer perspective, accessibility is key. In the case of SB carsharing, there might not be stations near the trip origin or destination point. Hence, customers will lose

more time by accessing to the system, or even discard the trip if the access or egress distance is too big.

- However, on SB systems it is easier to ensure a good distribution and availability of cars, since the stations distribution and capacity limits demand imbalance. FF services are usually perceived as less reliable. Users don't take for granted to find a car. Either for that current trip, or on the way back home after the activity on destination is finished. So, service usage is discouraged when there's no a viable alternative.

Since both the SB and FF systems have different pros and cons, during the design phase it's crucial to compare the expected performance of both configurations in order to decide which one would be better in our case. Or, moreover, it could be interesting to design mixed configurations that combine the advantages of both. For example, SB systems with a limited number of stations can improve their coverage by including a number of FF cars. Or otherwise, if the public space occupation is very limited by the municipalities, FF systems could operate with a bigger fleet by including cars on stations.

With that purpose, the authors developed a macroscopic design model defined for a mixed carsharing system, which includes a FF and a SB part working simultaneously (Jiménez-Meroño and Soriguera, 2021). The model is based on the continuous approximations methodology. The main advantage of those models is their simplicity. They can be run with easily obtainable parameters. And its insights are depicted more clearly than more complex models without losing much accuracy or robustness in their results. Therefore, this methodology is adequate to evaluate the performance and take strategic decisions in the design phase.

In the following section of the document, an overview of the model is provided. Section 2 corresponds to the state of art and the review of academic literature. On Section 3, the main characteristics of the model are presented. That includes the tradeoff and decision variables characterization, the demand modelling, the cost equations, and the possible restrictions to apply. On Section 4, the model is applied to a case study based on the city of Barcelona, in order to provide an example of how it works and how it can be used in practice. Finally, the document ends with the conclusions section, acknowledgments and reference list.

2. CARSHARING STATE OF ART

2.1 Current picture of carsharing

Carsharing companies can be classified into two groups. The first one are agencies that were founded as rent-a-car companies, but they have been gradually introducing new features that change their business model. That's the case of Communauto, Enterprise, Flinkster, or Zipcar. Since those companies do not implement the same features on all cities or regions at once, many of them still rely on round-trip rentals.

The second group are companies that were founded with the carsharing business model in mind. Most of them, later than 2010. ShareNow, Enjoy, or Yandex.Drive belong to this group. They all operate offering one-way trips, either on SB or FF mode.

The authors consider that this trend shows that one-way services will be the prevailing option on future implementations. And, under a design point of view, it would be more useful to focus on that option. It could be argued that round-trip services are a remainder of the former rent-a-car structure due to the difficulty to adapt an existing business model. So, for the purpose of this work, only the one-way case is studied.

Name	Location	Service Type	Fleet size	Members	Vehicle Type	Fare
Cambio Carsharing	Belgium, Germany	Station-based round-trip	+1.700	63.500	Car/e-car	From 0.23 €/min
Communauto	France, Canada	Free-floating one-way Station-based round-trip	+2.000	+40.000	Car/e-car	From 0.28 €/h
Delimobil	Russia	Free-floating one-way	+12.000	+1.000.000	Car	
Enjoy	Italy	Free-floating one-way	2.670		Car	From 0.25 €/min
Enterprise Car Club	UK	Station-based round-trip	+500	20.000	Car/e-car	From 3.53 €/h
Flinkster	Austria, Germany, Netherlands	Free-floating one-way & round-trip	+6.500	+300.000	Car/e-car	From 1.50 €/h
ShareNow	Many European cities (see Table 4) and USA*	Free-floating one-way	+20.000		Car/e-car	From 0.19 €/min
Stadtmobil	Germany	Station-based round-trip	+2.600	+40.000	Car	From 0.26 €/km
Ubeeqo	Belgium, France, Germany, Italy, Spain, UK	Station-based one-way			Car/e-car	From 3.50 €/h
Yandex Drive	Russia	Free-floating one-way	+21.000		Car	
Zipcar	UK, USA, Canada, Costa Rica, Iceland, Turkey, Taiwan	Station-based round-trip and one-way trip	12.000	+1.000.000	Car/e-car	From 4.05 €/h

*On February, 29th 2020, ShareNow stopped its activity in North America, London, Brussels and Florence.

Table 1 – Main car-sharing operators in operation in Europe.

City	GDP [€/capita]	Fleet size [vehicles]	Service area [km^2]	Average price [€/min]	Average demand [trips/day]	Average trip
Berlin	41.967	2.975	165	0.25	-	
Madrid	35.041	2.400	80	0.27	-	31.9 min
Milan	49.500	3.021	120	0.26	3.500	
Moscow	19.696	30.000	850	0.079	150.000	13.34 km

Table 2 – Aggregated car-sharing services offered for different European cities.

2.2 Literature review

Many scientific papers have provided a good overview of the key factors for the success of carsharing programs. For instance, Alzahrani et al. (2019) and Münzel et al. (2018) analyze market studies and the factors that influence the selection of the best carsharing alternative of Portland and Germany, respectively. Schmöller et al. (2015), or Le Vine and Polak (2019) focused on different impacts that carsharing systems have had in different aspects of Munich and Berlin and London, respectively. From a more environmental point of view, Martin and Shaheen (2011) provide an overview on the green-house emission impacts of carsharing in North America. Another interesting work was carried out by Vosooghi et al. (2017) where different existing methods of demand estimation for one-way carsharing systems are analyzed. The main conclusion is that there are research gaps to be addressed regarding carsharing systems. For example, the integration of carsharing with the more traditional transportation modes or the general benefits of using autonomous vehicles in carsharing systems.

Regarding the carsharing system design, research can be classified into two different levels: strategical level, basically the planning of the system layout and the vehicle fleet; and operative level, mainly the optimization of the repositioning operations basically in one-way systems. Significant literature is reviewed next, following this classification.

Strategical planning addresses all the decisions that need to be taken when dealing with the implementation/expansion of a carsharing system. These decisions will be valid for the medium to long term. They include the study and optimization of the number and location of stations in the station-based system or the sub-zones in the free-floating system, the required number of parking spots, the dimensioning of the vehicle fleet and the definition of the repositioning period.

Kortum et al. (2016) provide an overall overview on free-floating carsharing. They evaluate empirical data on use of free-floating carsharing in different cities of Europe and North America. They make evident that carsharing is becoming a more integral part of the mobility of city, although different growth patterns can be observed for the different analysed cities. It is remarkable that the data included in this study is until 2015 and some cities appeared saturated at that time.

Recently, Ampudia-Renuncio et al. (2020) provide a spatial evaluation of the FFCS trip profile, obtaining the main flows throughout the whole service area. This spatial analysis is the first one carried out in Spain that uses real rental data collected from the different operators. Their results show that for short distance, users prefer carsharing system than the available public transport since carsharing is faster and public transport is highly correlated with parking availability at origin and destination.

The station-based one-way carsharing problem was assessed by Huang et al. (2018). They included to the problem relocations and non-linear demand. For relocations, they presented a Mixed-integer Non-linear Programming model to solve the carsharing station location and capacity problem. Then, for flexible demand, they construct a logit model to represent the non-linear demand rate by using the utility of carsharing and private cars. They draw the conclusion that pricing and parking space rental costs are key factors that influence the profitability of carsharing operators.

The operational level includes daily decisions. They mainly assess the rebalancing operations, which take place mainly in one-way carsharing systems. Different strategies are proposed to solve the system imbalance across the whole service area. Some of the most influential literature regarding this topic is herein presented.

An overall literature review of the vehicle relocation problem in one-way carsharing was carried out by Illgen and Höck (2019), who revised the relevant literature regarding one-way trips and relocations from 2012 to 2019 with several case studies in order to give a more thorough overview on different methodologies proposed by different authors.

Boyaci et al. (2017) carried out a simulation for a station-based carsharing system where, iteratively, optimize the decision variables related to vehicle and relocation personnel. In their work, the results show the importance of efficient algorithms when dealing with relocation operations. They proved the importance of forecasting the demand to optimize the initial locations of vehicles for an efficient use of the resources.

A relocation algorithm for free-floating carsharing with conventional and electric vehicles is proposed by Weikl and Bogenberger (2015). In their work, they carried out three real world field tests for different stages of development of the model. In the final result they achieve promising results in reducing the idle time of the vehicles and a high efficiency of relocations. It is interesting since the model was applied to the carsharing system in Munich (Germany). So, it provides a realistic scenario that can be easily applied to other free-floating carsharing systems.

3. MODEL DEFINITION

In this section, the main characteristics of the model are summarized. The complete formulation and details of the model are described in Jiménez-Meroño & Soriguera (2021).

3.1 Model overview and decision variables

Model is defined over a continuous service region, where the free-floating (FF) and station-based (SB) systems act simultaneously. Users will behave as it follows:

- The FF service is preferred on origin due to accessibility reasons. Users will check first for vehicles on street inside their virtual station. If there's any available vehicle, users will reserve and rent that vehicle.
- If the virtual station is empty, users will try to use the SB system. If users are inside the coverage of the SB system, they will opt for the SB system. Otherwise, the trip is lost.
- When opting for the SB system, users will check the nearest station. If there is any available vehicle, users will reserve and rent that vehicle. Otherwise, the trip is lost.

In order to control the tradeoff between demand losses and agency costs, operators have five options that correspond to the five degrees of freedom of the system. Each one is associated to a single decision variable:

- Change the on-street FF fleet size ($\boldsymbol{m_{FF}}$) or the SB fleet size ($\boldsymbol{m_{SB}}$).
- Change the number of employees carrying repositioning operations. The variable that characterizes repositioning operations is the repositioning period. It defines the average time until a station (or virtual station) is rebalanced. That variable can be different for FF and SB and their values are $\boldsymbol{h_{FF}}$, $\boldsymbol{h_{SB}}$.
- Change the number of stations in order to modify the coverage and accessibility of the SB system. This coverage is determined by the density of stations per km^2 is defined as $\boldsymbol{\Delta_{SB}}$. And, therefore, the total number of stations is $\Delta_{SB} \cdot R$.

Name	Description		Symbol	Units
Station density	Number of parking stations per area unit		$\boldsymbol{\Delta_{SB}}$	[stations/km2]
Available fleet size	Number of available vehicles in the system	Total	$\boldsymbol{m}$	[cars]
		Free-floating	$\boldsymbol{m_{FF}}$	
		Station-based	$\boldsymbol{m_{SB}}$	
Repositioning period	Avg. time between complete rebalancing	Free-floating	$\boldsymbol{h_{FF}}$	[hours]
		Station-based	$\boldsymbol{h_{SB}}$	

Table 3 – Decision variables summary.

There are two additional degrees of freedom not considered in this model: changing the available parking, and changing the battery recharging system.

The model considers that parking availability only affects demand on long term decisions. Not finding parking on the desired destination can discourage users from using the service more times in the future. But the current trip will be made eventually, either parking on street or on a station. For that reason, the number of parking places is considered an output here. And it is restricted to be at least as big as the fleet size.

Finally, battery recharging is a complex process by itself with several decision variables. The number of electric cars, the number and type of chargers, or battery autonomy can be changed and result in more or less demand losses. Including all of them would overcomplicate the model and shadow the main design insights. Therefore, battery recharging is considered here a constraint.

3.2 Demand modelling

The amount of served trips (λ_{FF} and λ_{SB} in trips/km^2·h) depends on two factors. First, if there is enough demand of trips in the system (i.e. potential demand density, input of the model). And second, if there is enough fleet capacity to serve those trips. Served trips will be the minimum of both.

However, note that potential demand and fleet are variable in time and space. This phenomenon is accounted by the definition of three correction factors defined stochastically:

- Temporal fluctuations. On off-peak hours, potential demand will be lower than the average. So, there’s a probability of having more available vehicles than potential demand. Therefore, demand served is reduced.
- Demand spatial imbalance. There are regions that are usually attraction poles. Cars tend to accumulate on those zones. If the accumulation of cars exceeds the potential demand, some of the cars will remain unused. Therefore, demand served is reduced.
- Demand spatial decentralization. This phenomenon is equivalent to the previous one but on a station level. In this case, one station can randomly exceed the potential demand at any moment, no matter if it’s located near of an attraction pole or not.

According to those criteria and stochastic phenomena, demand served is estimated.

3.3 System cost equations

Once demand is estimated, it is possible to calculate all costs of the system. Costs are depicted in monetary units per time unit (€/h in our case). So, consequently, all results will be also divided per time units (i.e. trips per hour, penalties per hour, or even hours of repositioning work per hour).

Both agency and user costs are considered in order to define two possible objective functions: the total generalized cost and the agency revenue.

- Infrastructure costs ($\boldsymbol{Z_I}$). It accounts for all the investments made to acquire and renew the vehicle fleet and parkings.
- Operative costs excluding repositioning ($\boldsymbol{Z_O}$). This term includes all charges that can be imputed to vehicle usage, such as maintenance, cleaning, and fuel consumption.
- Repositioning cost ($\boldsymbol{Z_R}$). It's the cost that summarizes all relocation operations. Those operations are meant to compensate system demand imbalance or move electric vehicles to recharging points.
- User access cost ($\boldsymbol{Z_{AC}}$). It accounts the walking time of users at origin or destination.
- User no service penalties ($\boldsymbol{Z_{NSP}}$). This cost applies to all lost demand in order to account the losses and annoyance perceived by the users after a failed trip attempt.

With those costs, two objective functions are defined. The first one is the total generalized cost per time unit. It includes all user and agency costs. The second one is the agency profit per time unit. It consists in the revenue generated by the served demand minus the agency costs.

$$Z_{GCF} = Z_I + Z_O + Z_R + Z_A + Z_{NSP} \tag{1}$$

$$Z_{PRF} = fare \cdot (\lambda_{FF} + \lambda_{SB}) \cdot R - (Z_I + Z_O + Z_R) \tag{2}$$

Note that, in case of agency revenue maximization, the fare must be an input of the model.

3.4 Battery consumption and charging restrictions

The design model could be applied for any type of fleet, including partially or totally electric vehicles. In that case, the model includes solutions to ensure that the average recharging ratio is enough to compensate the battery consumption ratio. To do so, two different charging systems are defined: distributed and centralized charging.

Distributed charging uses the SB parking facilities to install domestic recharging points. Recharging with these devices is slow, but installation is cheaper and easier than other faster alternatives. If this option is considered, the solution must ensure that vehicles on stations and relocating operations are enough to reach the minimum recharging rate.

Alternatively, centralized charging considers a central hub, inaccessible to users, where all recharging operations take place. This infrastructure is equipped with superchargers, which allow to recharge vehicles quicker. However, they require a more expensive installation and additional repositioning operations in order to move the cars to the hub and redistribute them again once the battery is charged.

4. CASE OF STUDY: BARCELONA

4.1 Description of the scenarios

The base for this case study will be a mixed carsharing system placed in a region of 39.19 km^2 in central Barcelona. Six different optimization scenarios are compared. In three of them the sum of users' and agency costs will be minimized. And in the other three, the agency profit will be maximized. For each objective function, three different vehicle and recharging configurations will be addressed: 100% of electric vehicles with decentralized recharge on stations, 100% of electric vehicles with hub recharging, and 0% of electric vehicles (all ICE vehicles).

Scenario	Objective function	% of electric vehicles	Battery charging configuration
#1	Max. profit	100 %	Distributed
#2	Max. profit	100 %	Centralized
#3	Max. profit	0 %	-
#4	Min. GCF	100 %	Distributed
#5	Min. GCF	100 %	Centralized
#6	Min. GCF	0 %	-

Table 4 – Optimization scenarios summary.

Since the number of parking places and recharging parameters are not decision variables, and therefore, are not subject to optimization, further considerations must be taken into account:

- By default, the number of parking places is set to the minimum feasible.
- In case of decentralized recharging, if the fleet constraint is not fulfilled, the number of SB vehicles will be increased until reaching the minimum. Note that reducing the FF fleet size is another possible solution. But it is considered that, in general, that case would result in less demand served and a worse performance.
- The number of charging devices on parkings is also set to the minimum feasible.

Tables 5 and 6 summarize the parameter estimation for the city of Barcelona.

	Parameter description	Units	Value	Source
Demand inputs	Area of the service region	[km²]	39.19	The area selected was a region of central Barcelona. Demand data was provided by Inlab UPC as a O/D matrix of 228 zones. Only trips longer than 1.5km were considered, and a carsharing market penetration of 0.5%. (InLab, 2019)
	Request subregion	[-]	0.53	
	Return subregion	[-]	0.47	
	Average potential demand density	[trips/h·km²]	9.77	
	Standard temporal deviation	[trips/h·km²]	0.977	
	Request imbalance	[-]	0.215	
	Return imbalance	[-]	0.241	
	Fraction of station returns	[-]	0.43	Estimation from EMEF 2019 (Autoritat del Transport Metropolità, 2020).
User behavior inputs	Maximum access distance	[km]	0.4	Transportation Research Board (2013)
	Average walking speed	[km/h]	3	Generalitat de Catalunya (2017)
	Users' average value of time	[€/h]	11.4	Official value used for transport investment appraisal in Barcelona (Autoritat del Transport Metropolità, personal communication, July 2017).
	Users' no service penalty (FF)	[€/trip]	7.93	Considered as the average taxi fare in central Barcelona (Autoritat Catalana de la Competencia, 2018; Institut Metropolità del Taxi, 2020)
	Users' no service penalty (SB)	[€/trip]	2.50	Estimation according to the works of Herrmann et al. (2014) and Ampudia-Renuncio et al. (2018). 80% avg. public transportation fare (Transport Metropolità de Barcelona, 2020) + 20% Avg. taxi fare in Barcelona (see above).

Table 5 – Input estimation (Part 1).

	Parameter description	Units	Value	Source
City inputs	Average circulating time	[min]	11.1	Result of dividing the average trip distance by the average car speed.
	Average parking time	[min]	6.6	Survey conducted in nineteen major European cities (Conduent, 2016)
	Average service time	[min]	27.7	Result of $\tau_c + \tau_p + \tau_r/2$.
	Average car speed in the city	[km/h]	15.3	This is 2/3 of the average measured speed in Barcelona. The 1/3 reduction considers delays at intersections. (Ajuntament de Barcelona, 2018)
	Average repositioning speed (in electric scooter)	[km/h]	8.8	Liu et al. (2019)
Agency costs and policies	Acquisition cost per vehicle	[€/car·h]	0.33 (electric car)	Seat Mii market cost (SEAT, 2020a), considering a useful life of 5 years, a residual value of 50%, an unavailability ratio of %5 due to maintenance and repairs (Bösch et al., 2018), and average insurance costs.
			0.23 (ICE car)	
	Average cost per parking (SB)	[€/parking·h]	0.25 (no charger)	Long-term renting cost of a parking slot in Barcelona (B:SM, 2020; SABA, 2020) plus the installation of charging infrastructure (Wallbox, 2020; Schroeder and Traber, 2012; Zhang et al., 2018).
			0.30 (Wallbox)	
			1.18 (fast charger)	
	Average cost per parking (FF)	[€/parking·h]	0	Subsidized on-street parking
	Average operative cost per trip	[€/trip]	1.37 (electric car)	Energy and fuel consumption is estimated according to trip distance, the SEAT Mii technical specifications (SEAT, 2020b), and the price index in Catalonia (IDESCAT, 2017). Cost of administrative control and manteinance are adapted from Bösch et al. (2018) to the currency and power purchase in Spain.
			1.45 (ICE car)	
	Average cost per repositioning worker	[€/worker·h]	21.54	Labor cost of 14.32 €/h according to IDESCAT (2017). 33% of the working time is considered lost or ineffective for repositioning. The prorated acquisition cost of scooters is included but it is residual (0.04 €/h).
	Average time spent on fixed repositioning operations	[min]	6	(SEAT, personal communication, March 2020)
	Average autonomy of electric vehicles	[h]	13.07	SEAT Mii technical specifications (SEAT 2020b).
	Average recharging time of electric vehicles	[h]	4	
			1	
	Hub location	[km]	0	The hub is considered near the city centre.
	Maximum reservation time	[min]	20	Similar to Car2Go policies in Madrid. (Car2Go, 2020).
	Average fare	[€/min]	0.27	

Table 6 – Input estimation (Part 2).

4.1.2 Limitation of the number of stations

Before examining other results, it should be noted that the optimum station density, Δ_{SB}, resulted in a huge value for all studied scenarios.

When the generalized cost is minimized, user access cost is much larger than all the other agency costs and user penalties. So, the model keeps adding stations in order to minimize access distance even after reaching the full SB coverage.

In case of maximizing profit, where user costs are not considered, the effect is attenuated, but still the optimal Δ_{SB} results unrealistically large. This is because sometimes the number of repositioning operations is determined by the battery recharging operations or the compensation between the FF and SB modes (i.e. returning cars to station). In those cases, the station density, Δ_{SB}, has no effect on increasing the number of operations. In fact, it decreases its cost because it reduces the average repositioning distance. That effect exceeds any other cost increase associated to the number of stations.

The conclusion is that in those cases, the number of parking stations to be used should be as large as possible, because this will reduce both, user and agency cost. This conclusion could change if the infrastructure cost includes some kind of penalty for being able to park on several different stations.

Taking the previous conclusion into account, for the purpose of this study, the number of parking stations has been set to a more realistic fixed number of 48 stations. This corresponds to $\Delta_{SB} = 1.22$ stations/km2 and represents a SB coverage of roughly 20% of the service region ($c \cdot \Delta_{SB} = 0.195$).

4.2 Optimization results

Tables 7, 8 and 9 summarize the main optimization results for all scenarios. In the following subchapters, the main findings and comparisons are explained with more detail.

Parameter		Units	Max. Agency Profit			Min. Generalized Cost		
			Scn. 1	Scn. 2	Scn. 3	Scn. 4	Scn. 5	Scn. 6
Density of stations		[stations/km^2]	1,22	1,22	1,22	1,22	1,22	1,22
Fleet size	FF	[cars]	314	166	370	91	99	121
	SB	[cars]	31	27	26	47	8	9

Table 9 – Optimization results. Costs.

4.2.1 Optimum demand served

In all scenarios, SB served demand is a small fraction of total served demand. This is due to three reasons. The FF preference and lesser coverage makes that only a fraction of users is a potential candidate to access the SB system. SB cars are more expensive than the FF cars because of the associated cost of renting the parking place on a station. And, since only a fraction of users returns the car to stations, serving more SB demand means additional repositioning costs to compensate that imbalance. For those reasons, the optimal system for all scenarios in this case is almost a pure FF system.

Also, in all scenarios only a fraction of the demand is served. This allows increasing the vehicle utilization rates and reducing artificial rebalancing needs, which is translated into reduced agency costs and higher profit.

Difference between both objective functions lays in which is that percentage of served demand (70-75% in case of agency profit maximization and 53-60% in case of minimizing users and agency costs). The reason for that is that no-service penalties are less expensive than the revenue lost when maximizing profit. Therefore, when profit is maximized, more vehicles are necessary. Because of this higher vehicle availability in the max. profit scenario, the average usage of each vehicle (trips/day) decays. This yields a lower profit per trip, but is compensated by the larger demand served.

4.2.2 Electric vehicles and recharging

With respect to the difference between the electric vehicles or ICE, in general, the system seems to perform a bit better when composed only of ICE vehicles (Scenarios 3 and 6). In any case, differences are slight, and different effects compensate each other. For instance, the additional vehicles due to battery recharging tend to be compensated by the lower cost of gasoline vehicles, pushing toward a higher fleet. Also, the operative costs of gasoline vehicles are higher, implying a somehow lower optimal demand to serve.

When comparing the recharging options for electric vehicles, overall, the difference is slightly in favor of decentralized charging. This is because the additional repositioning costs force the system to reduce the fleet of cars, resulting in less demand served than the decentralized recharging at stations.

However, that not diminish the positive effect of installing superchargers. The cost increase is compensated by the quicker recharge. It’s their distribution on a central hub what makes them costlier. In case of splitting the superchargers in different installations, their performance gets very close to the domestic recharging at stations.

Parameter		**Units**	**Decentralized (Scn. 1)**	**ONE HUB (Scn. 3)**	**SIX HUBS**
Fleet size	FF	[cars]	314	166	226,03
	SB	[cars]	31	27	36,31
	Total	[cars]	367	214	286,26
Charging points at hub		[parking slots]	-	6	6
Number of repositioning teams		[workers]	6,2	7,6	6,1
Profit	per trip	[€/trip]	2,66	2,69	2,70
	per day	[€/day]	9865,56	9309,48	9635,01

Table 10 – Optimization results. Costs.

4.2.3 Robustness of optimal results

Robustness is a desirable property in optimization frameworks. A robust optimal solution means that small deviations in the selection of the optimal decision variables imply equally small deviations in the result of the objective function. Errors in the analytical definition of the model, or in the estimated parameters, are unavoidable; but the objective should be that these errors do not affect significantly the final objectives (i.e. the design of the system and the results in costs).

This subsection shows that the optimal results obtained, are robust, in the sense that the effects in costs and profit of the system due to sub-optimal selection of decision variables are small, so that the system may be feasible even when its design is suboptimal. Figure 2 shows the variations on the profit and agency cost as a function of variation of decision variables. See, for instance, that variations of 50% with respect to the optimal FF fleet size, m_{FF}, imply variations in agency costs of 10% or less. Also, the effects on the profit of the system are even less, because larger fleets allow to serve more demand, while for smaller fleets the utilization rate of vehicles might increase.

For the other decision variables, especially for the repositioning period, the result is even more robust. The reason is that, after all, the repositioning period is a convenience variable related to the number of repositioning employees. Note that this latter variable results to be small (6-7 employees working simultaneously). Hiring an additional one would imply a small difference on the overall performance, but relatively a bigger increase on the variable.

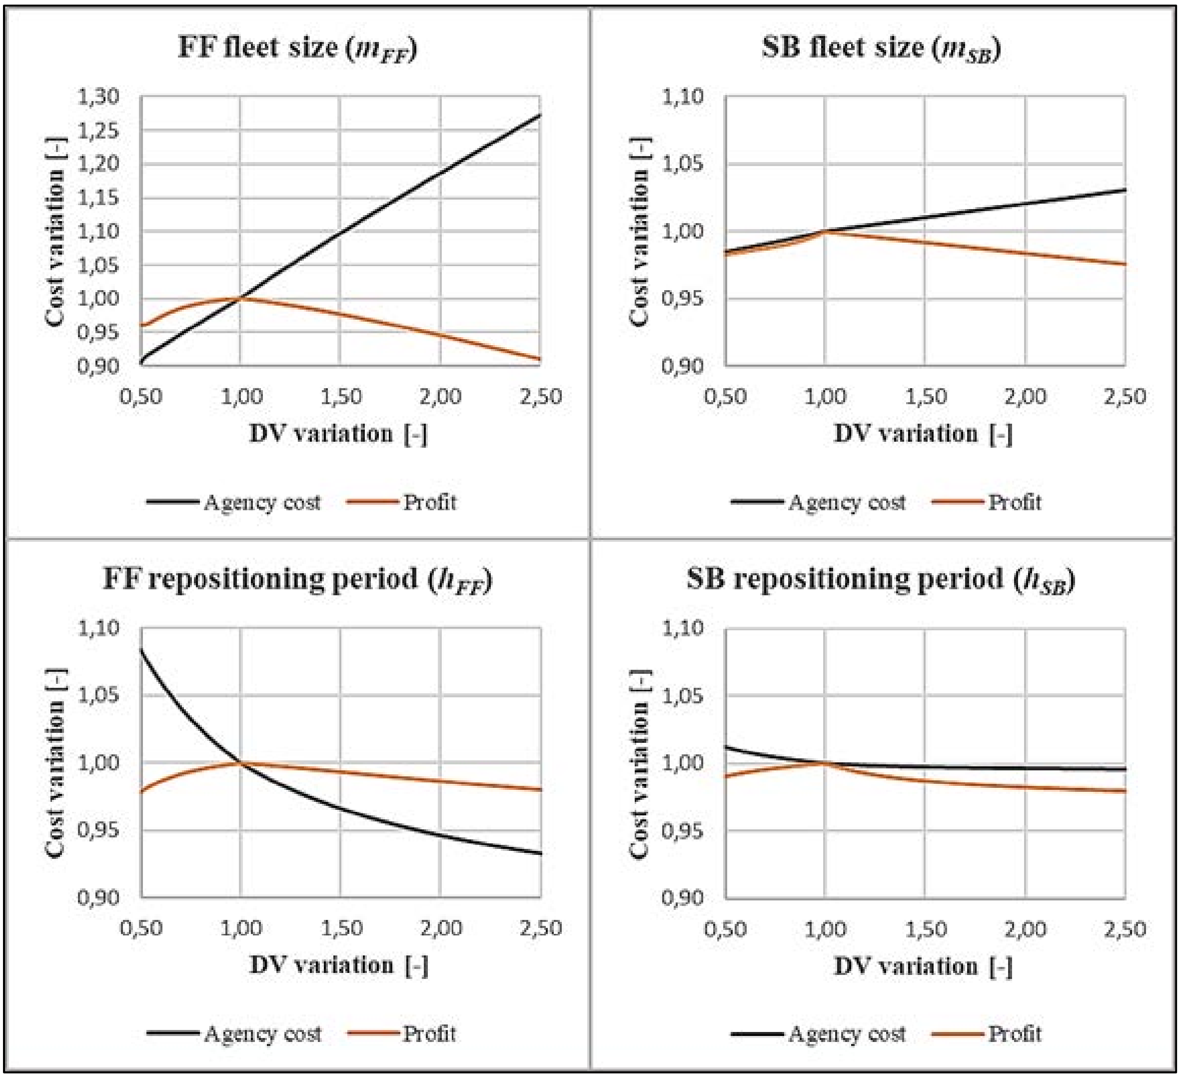

Fig. 2 – Robustness of DVs around the optimum value

5. CONCLUSIONS

An analytical planning model for a one-way mixed FF and SB car-sharing system has been developed. This is based on the modeling of the strategical variables of the system and their relevant trade-offs, using continuous approximations. This analytical approach requires a simplification of the reality (e.g. assumption of spatially uniform demand level) and to obviate some details of operation. However, results provide clear insights, valid in a wide range of contexts and which should be the foundations for further research.

This concluding section summarizes the main findings when the model was applied to a case of study for the city of Barcelona with different scenarios considered. Note that, despite input parameters have been estimated especifically for this case of study, many of them would be very similar for any city of similar size and socio-economical context. So, the insights and considerations to be taken into account would be still valid in many cases if the model is applied in the future in the context of planning a one-way carsharing system.

Take the following bullet points as general conclusions of this document:

- The model gives preference for the FF system. The SB system becomes auxiliary when the difference between SB and FF parking cost is big. A sensitivity analysis of the on-street parking cost would be an interesting point for future research.
- In all scenarios, model shows that it is advisable to leave part of the potential demand not-served (30-35% in case of agency profit maximization and 40-50% in case of minimizing users and agency costs). This allows increasing the vehicle utilization rates and reducing artificial rebalancing. However, the model assumes that potential demand is constant even if a fraction of users is experiencing no-service situations. Further research must be made in order to estimate which is the minimum level of service that must be achieved to maintain that potential demand.
- With respect to the recharging infrastructure, it seems a better option to decentralize the charging points. Superchargers can be as profitable as domestic chargers. Their higher cost gets compensated by their efficiency, which reduces the duration of repositioning tasks.
- The sensitivity of system costs and profit to suboptimal designs is small. This means that the proposed designs are robust, and deviations could be accepted without implying severe penalties. However, it should be noted that this sensitivity is larger when the deployed resources are below the optimal values. This means that special care should be devoted to avoid being excessively conservative in the fleet size deployment, knowing that over-sized fleets almost do not penalize profit.

Bruno Baruque Zanón
Senior Lecturer, University of Burgos, Spain

ABSTRACT

Traffic in urban environments vary significantly depending on the areas of the city and the time of day. Nowadays, thanks to the large number of GPS devices that are integrated in all kinds of devices, it is possible to make a quantitative analysis of traffic. This contribution presents an application developed to analyse this information in a simple way and with a visual representation. One of its main advantages is that it is adaptable to any city in the world, as its internal algorithms adapt to the available data are presenting and adjusting it to the traffic through the city. This is done by extracting information directly from the data provided by GPS devices moving around the city. In addition, an analysis of the execution times of all application processes is presented to determine which parts involve a higher execution cost and determine the overall scalability of the application.

1. INTRODUCTION

Nowadays, the general availability of devices capable of tracking the movements of a subject or vehicle makes movement data collection easier than ever. However, once the data is collected, a more difficult task must be completed to extract relevant information about this monitoring: the data must be cleaned (Chen *et al.*, 2016), organized (de Almeida *et al.*, 2020), aggregated, etc. (Zheng, 2015). This problem grows exponentially when it is necessary to analyse massive amounts of vehicles or people movements at the same time.

This work presents a web application prototype that facilitates the completion of the aforementioned analysis tasks. The tool takes individual regular GPS tracking files and performs operations to filter track errors, detect traffic clusters and nodes, calculate traffic summary indicators between nodes, and display all this information on a dashboard. In addition, it includes an interactive map and additional analytical charts allowing the user to perform exploratory analyses. Additionally, it allows the processed files and their results to be exported in standard format, so they can be used in other software solutions.

The software has been tested with real data obtained from mobility activities in some worldwide cities, obtaining interesting analytical results that will be included in the contribution as examples. These examples are drawn from two datasets. The first one, with a temporal scope of up to one year, including data on up to 442 vehicles and 1,674,141 trips. The second one with a temporal scope of just over one and a half months and 12,695 routes. The geographical scope of the application can be extended to wider areas, not just urban areas, provided the user has the necessary data.

The main capabilities of the presented tool allow us to represent a set of individual GPS files in a graphical environment. It makes possible a global exploratory analysis of the complete dataset. Furthermore, it is possible combine the tool with other analytical software. Finally, the flexibility of its design that makes it easy to extend its functionality with additional data analysis algorithms.

2. STATE OF THE ART

There are three types of commercial solutions on the market. Some are completely focused on the end user and do not allow a general traffic analysis but offer concrete solutions to individual movements (Google Maps, WAZE). The second type of applications are those that allow experienced users to analyse the data in a general way and visualise the results (CARTO, QGIS ArcGIS, and Elastic Maps). The third type are those that allow us to analyse traffic congestion or traffic events with a high level of detail (TomTom Road analytics).

In the literature, there are different techniques to analyse and visualise traffic. One of the most common and simplest method of visualization is the heat maps (Wang, Lu and Li, 2020). It is very common to use groups to classify the regions through which routes pass to analyse the traffic density. The most widespread techniques in this case are grouping by using some characteristic of the location of the data such as neighbourhoods or districts (Ibrahim and Shafiq, 2019). Another option is using clustering techniques that perform an automatic classification of the routes (Bian *et al.*, 2018). These two methods seek to analyse the relationships between the different clusters (Yuan and Raubal, 2014).

There are other analyses with the same type of data that can help us understand traffic and propose improvements. Such as the detection of anomalies and events that allow us to detect anomalous changes in traffic (Donovan and Work, 2017)(Zhong *et al.*, 2020). This also is useful for analysing the resilience of transport systems. And the detection of patterns between routes, which is used to detect which routes are the same or have a high degree of similarity (Barann, Beverungen and Müller, 2017). These techniques are widely used in car sharing services.

Unlike these methods, in this contribution we perform a classification of the route's points. The objective is that the extracted clusters adapt to the distribution of streets and traffic in the city, getting a visual representation of the traffic status through a bidirectional network that is easily understandable.

3. METHODOLOGY

This prototype is based on the methodology described below (and represented on Figure 1), firstly explaining the data structure. Then the application processes are detailed until the graphical representation of the information is obtained.

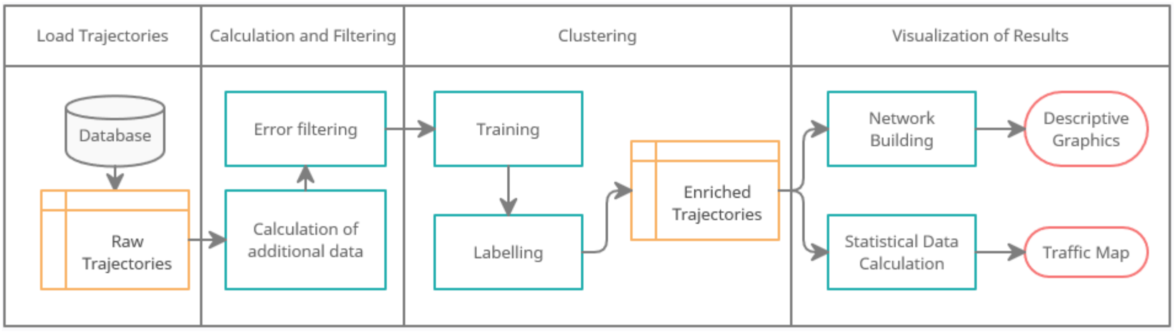

Figure 1 Pipeline of the operations performed by the application

Figure 1 shows the different phases through which the data passes until it is displayed to the user. In the first phase, the data is loaded into the application's memory. In the second phase, data such as distance, speed and time of the registered movements are calculated. This phase includes the elimination of the measurement's errors and outliers. In the third phase, a classifier is trained using this data and the data is grouped according to the geographical distribution. In the last phase, with the data applied and classified, a complex network representing the displacements is generated and the statistics are calculated. Both, the complex network and the statistics are displayed graphically to the user. In the following sections, each step is explained in more detail.

3.1. Trajectories

The basic data used by the application are GPS trajectories or routes. Which are used throughout the execution cycle of the application to perform the analysis.

The trajectories or routes consist of a series of geospatial points ordered chronologically that describe the route of an element. A trajectory T_i is formed by n points P_i that are composed of longitude$x$, latitude y and instant of time$t$.

It is important that the difference between t_n and t_{n-1} has a value small enough to make the path sufficiently descriptive and large enough so that the trajectory is not too bulky. In first data set used, the difference is 15 seconds.

From these simple paths that are stored in a database, it is necessary to calculate other data for processing. First the time intervals and the distance between the points are calculated. This also allows us to calculate the speed at which the movement between these occurs which is crucial for error filtering, as it is described next.

3.2. Error filtering

For (Yan *et al.*, 2013) the trajectories have two types of errors, the first is due to the precession of the GPS itself. These errors produce a loss of accuracy of approximately ± 15 meters. We ignore these types of errors, as they are not very relevant for the analysis. The second type is due to GPS synchronisation failures. This type of error produces failures in the real location of the device recording its location in previous locations or with displacements of kilometres. This causes the speed of an element to be calculated at an unrealistic speed.

To solve these errors, we use the speed, which is the variable that produces the failures. This error detection is context dependent. Since in the experiments we use data from motor vehicles movements in urban environments, to detect if a route contains errors, we filter those that in some intervals exceed 200 km/h. If the context is different, the speed must be adapted to a higher speed than the maximum expected.

3.3. Clustering

Clustering is a data mining technique that is used to separate data into natural groups. For (Mussardo, 2019) this technique has two functions: Summarizing the data allows us to work with a smaller volume of data, which improves processing performance and simplifies visualization. Segmentation of the data allows us to analyse the behaviour of each group. Clustering can be seen as an optimisation problem where the aim is to maximise or minimise a certain variable.

In this study, we compare two widespread algorithms for this task:

- K-means: It tries to minimize the sum of the quadratic distances with the centre of the cluster. It is necessary that we indicate the number of clusters to this algorithm.
- HDBSCAN: It is a variant of DBSCAN, this algorithm reduces the distance that can exist between children until all the points are independent building a hierarchical tree. Then it keeps those branches of the tree that have a greater stability discarding their children. The stability is the number of iterations that a branch maintains the minimum number of points or without dividing. Not all data are classified.

With these techniques, we group each point of a trajectory according to its geographical location. In this way, we can summarize a trajectory as the movement between the areas into which the map is divided, which coincide with the determined clusters. This segmentation of the trajectories allows us to analyse the relationships that exist between the different clusters.

3.4. Visualization of Results

The processing of the information concludes with the creation of an interactive map and additional analytical graphics that allow the user to perform exploratory analyses. Additionally, the application also enables the export of the already processed data.

3.4.1. Map

A complex network is built from the clustering of points, using the centroid of each group as the node of the network. To do this, the number of edges between nodes and the speed at which the movement between nodes takes place are counted. Once the network is built, it is represented graphically on a map. This is represented in a bidirectional way, with a line thickness proportional to the traffic and with a colour that varies between green and red depending on the speed.

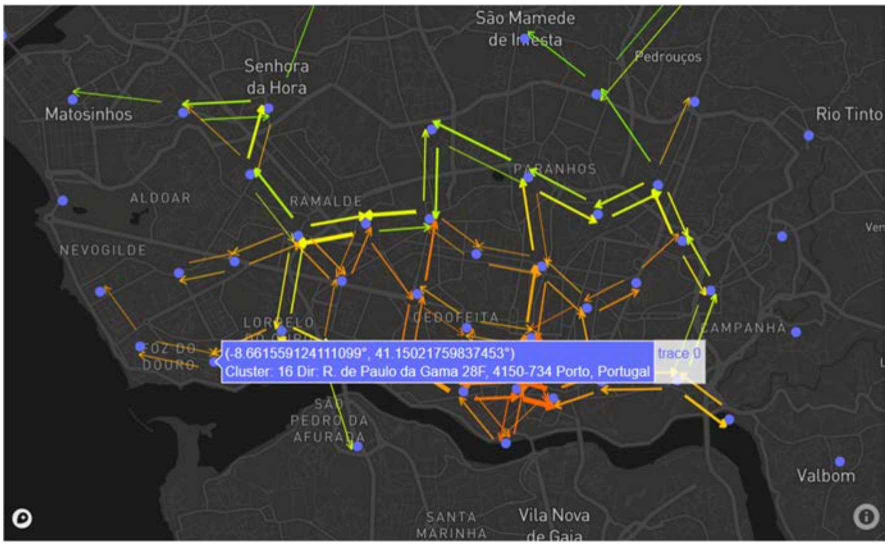

Figure 2 Map with graphical representation of traffic

All the clusters are represented on the map, but only those relationships that have a minimum support are represented. This is done so that the map is as clean and legible as possible, omitting those relationships that have little information. For this reason, there are clusters, especially those on the periphery, which do not have relations represented. As example, we show the traffic flow over the map of Porto (Portugal) can be seen on Figure 2.

3.4.2. Descriptive statistics

A series of statistics and graphs are provided to complement the information on the map. This allows to understand the data used and to analyse other factors not directly related to mobility. It also allows us to analyse the characteristics of the selected data set. As an example, Figure 3 shows a chart representing the frequency of routes completed on each hour of the day, on different days of the week.

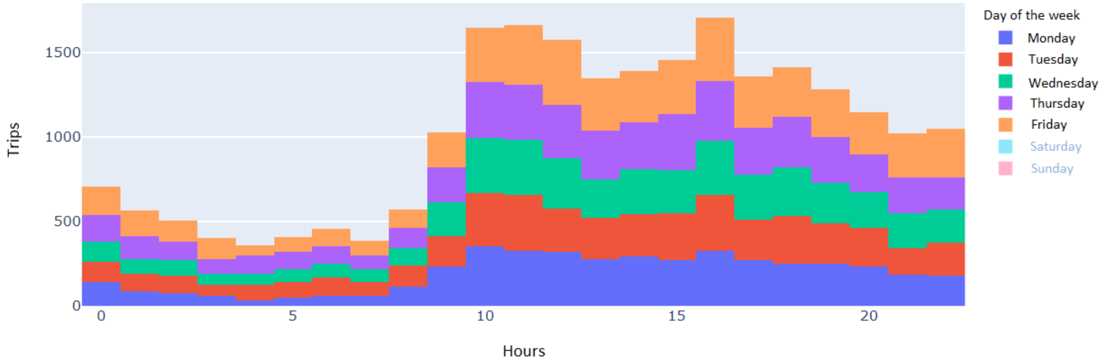

Figure 3 Example of an interactive graphic showing the frequency of routes on each hour of the day

4. EXPERIMENTS

The aim of the experiments is to evaluate the efficiency of the algorithms and them behaviour on different types of datasets. For this purpose, two different datasets are used, the first one is a dataset of taxis from Porto (*Taxi Trajectory Data | Kaggle*, 2018) and the second one is a dataset of taxis from Mexico (*Taxi Routes of Mexico City, Quito and more | Kaggle*, 2017). The difference is that the first one consists of complete routes and has 1,674,141 trips, while the second one only consists of the start and end point of the route and has only 12,695 trips. In the experiments, data loading times, clustering, calculation of the associated data and filtering, network creation and calculation of the statistical data of the routes are measured. These calculations are performed with datasets of different sizes, which allows seeing the growth of the different times. The number of points used for the calculations measures the size. The routes are randomly selected, and the data is split in such a way that there are only the set number of points for each experiment.

For the experiments, we have used a computer with 16 GB RAM, a 2-core 4-threaded processor and an SSD hard disk.

Table 1 and Table 2 show the results for each part of the execution in seconds and are the data used for the graphs in Figure 4.

	5,000	10,000	15,000	20,000	25,000
Data Loading	0.18	0.31	0.53	0.62	0.77
Clustering	0.90	1.78	2.65	3.02	3.91
Calculation and Filtering	0.65	1.33	1.93	2.79	3.13
Network Building	1.36	2.75	4.04	5.64	6.61
Statistical Data Calculation	3.36	6.70	10.21	13.41	16.22
Total	6.45	12.88	19.35	25.49	30.65

Table 1 Mexico taxi execution results. Execution times measured in seconds.

	250,000	500,000	750,000	1,000,000
Data Loading	9.63	16.44	24.08	31.58
Clustering	30.23	59.67	87.91	119.16
Calculation and Filtering	36.00	72.86	106.92	145.59
Network Building	69.88	140.52	207.71	279.83
Statistical Data Calculation	222.34	443.53	653.45	885.08
Total	368.08	733.02	1080.06	1461.24

Table 2 Porto taxi execution results. Execution times measured in seconds.

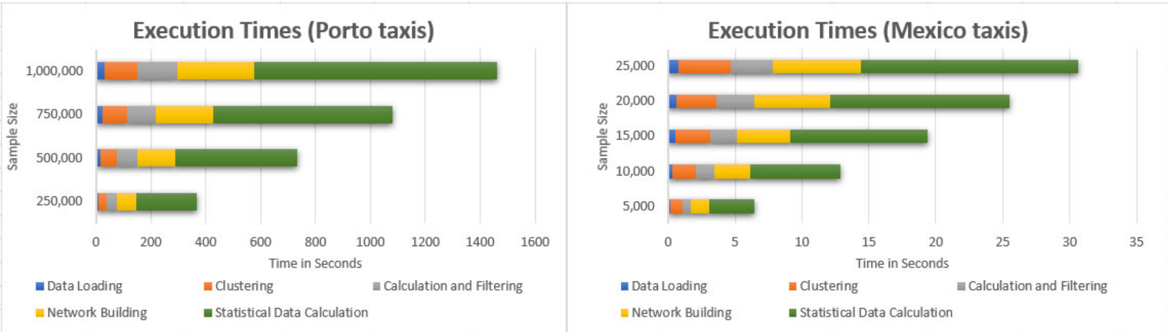

Figure 4 Graphs with the execution times of each experiment differentiating each part of the execution.

5. EXPERIMENT DISCUSSION AND LIMITATIONS

The graphs in Figure 4 show the results of the experiments, indicating the time measured in seconds, for each run and each part of the analysis. The overall time of the runs is linear, which makes it scalable. It can also be seen that all parts of the run maintain their proportionality within the same data set but vary slightly between the two sets. Finally, the runtimes for the network construction and the computation of the statistical data highlight significantly. Unlike the data loading and statistics calculation, which were optimised during the development of the program, these have not been yet optimised. These could probably be optimised or performed concurrently in the future to reduce the waiting time for the user.

The experiments are conducted with two datasets, which are limited to the mobility of two cities. This implies that only the behaviour at the urban level has been analysed. Therefore, we do not yet know the behaviour in other environments.

The application focuses only on data exploration tasks, which allows us to see the behaviour of the data over the time in which they were taken. This allows us to analyse changes in mobility in a simple way. This leads us to think that in specific contexts such as the data set used, it would allow us to make a short-term forecast of mobility.

6. CONCLUSIONS AND FUTURE WORK

The contribution has presented an application for urban traffic analysis. It is oriented towards raw route analysis and exploratory analysis. It is functional and can be used without programming skills.

The performance of the application with small to medium data sets is good using average hardware resources for computing. In the case of large datasets, the use of computing servers should be considered. In addition, the algorithms used show good scalability with linear growth.

The application has proven to be able to adapt to the data and does not need specific information from the environment in which the data was taken. Simply with low-level trajectory data the application can adapt itself to the contour of the city and to show a clear visualisation of the traffic.

The data displayed to the user on the map is clear, based on real traffic information and easily interpretable by any user. In addition, graphs and statistical tables help the user to put into context what is being visualised, giving an analysis of the characteristics of the dataset.

The complex network created from the clustering results is only used for the visual representation of the data. Moreover, it remains as a future line of work to exploit it to obtain information about traffic behaviour.

A future line of work is to improve the performance of those parts of the application that are no optimized yet, such as the calculation of statistical data. This part of the application could even be parallelised to be able to visualise the traffic status, even if this part has not yet finished executing.

RESUMEN

Desde su aparición, el ferrocarril se ha caracterizado por ser el medio más eficiente para transportar tanto viajeros como mercancías a medias – largas distancias. Una de sus principales características, ser un transporte guiado que debe discurrir por una plataforma propia y especifica, hace que sean las estaciones, los nodos de transporte, los puntos donde se presentan fenómenos de congestión que van afectando con el tiempo al conjunto de la red. Actualmente los principales nodos de la red ferroviaria española, particularmente las estaciones de mayor afluencia de tráficos, muestran síntomas de saturación. Debido a esta situación, resulta de especial interés disponer de una herramienta que permita cuantificar la capacidad de estos nodos, entendida como el número de circulaciones que pueden ser atendidas en un periodo de tiempo, bajo unas condiciones de calidad y estabilidad, para dimensionar las insuficiencias de capacidad y proponer las soluciones más adecuadas para cada caso. Este estudio presenta un modelo de cálculo que permite determinar la capacidad de los nodos ferroviarios congestionados, particularmente de las estaciones ferroviarias con gran afluencia de tráficos.

Habitualmente, los estudios enfocados al cálculo de la capacidad de las estaciones han estado centrados en el análisis de las incompatibilidades entre circulaciones y la formación y propagación de retrasos. Sin embargo, en contraposición a estas aproximaciones, el modelo desarrollado se basa en las características de la infraestructura, de los servicios prestados y la experiencia de explotación, obteniendo con ello una aproximación flexible y aplicable a las diferentes configuraciones que presentan las distintas estaciones.

En una situación de congestión en las estaciones se hace necesario realizar actuaciones que permitan devolver a la normalidad la explotación de éstas. En este sentido, el modelo presentado provee de una herramienta de decisión que permite estudiar y optimizar la capacidad para las composiciones de tráfico existentes en las estaciones.. Esto se debe a que el modelo puede ser reconfigurado para cada caso en función de las características de las distintas actuaciones previstas.

1. INTRODUCCIÓN

El ferrocarril es un modo de transporte caracterizado por el seguimiento de un itinerario fijo, guiado y controlado, por lo cual es capaz de aportar una elevada capacidad de transporte, alcanzando elevadas velocidades de explotación sin que ello suponga un elevado consumo energético. Esta amplia capacidad de transporte hace que dicho modo sea propicio para un amplio espectro de aplicaciones, cubriendo desde el transporte a medias y largas distancias de mercancías y pasajeros hasta el transporte de pasajeros en las crecientemente congestionadas urbes. El ferrocarril juega, por tanto, un papel clave en el conjunto del sistema de transporte, por lo que es fundamental prever la saturación de los principales nodos de la red ferroviaria y hacer un análisis de la capacidad que estos son capaces de aportar.

Para comprender la situación actual del sistema ferroviario es necesario analizar su irregular evolución a lo largo del tiempo ya que, desde la puesta en servicio de la línea entre Liverpool y Manchester en 1830 y su consecuente rápida expansión a nivel mundial, la popularización del motor a combustión con el nacimiento del automóvil y la concatenación de guerras durante la primera mitad del siglo XX relegarían al ferrocarril a un segundo plano con gran parte de la infraestructura europea devastada. El inicio de la recuperación de la popularidad del ferrocarril vendría asociado al éxito inmediato de la alta velocidad en Japón. Este hecho derivaría en el inicio de distintos proyectos de alta velocidad a lo largo del mundo, y que en España se traduciría en la línea de Madrid - Sevilla en 1992.

El desarrollo de la alta velocidad ferroviaria española supuso un desafío tanto técnico como tecnológico. Para afrontarlo se hizo necesario mejorar las características de los elementos que condicionan la operación de los ferrocarriles: diseñar nuevos materiales móviles adaptados a las elevadas velocidades, establecer nuevas infraestructuras capaces de proveer de condiciones de circulación seguras y confortables (condicionadas por los mayores esfuerzos impuestos por el aumento de la velocidad), y desarrollar sistemas de protección que permitiesen asegurar la recepción e interpretación de las señales por parte de los maquinistas.

En España supuso la integración de una red ferroviaria de distinto ancho a la previamente establecida, por lo que su establecimiento ha requerido de infraestructuras específicas que han sido el resultado de la adaptación de las existentes o la nueva construcción en casos necesarios. Debido a la diferencia entre anchos de vía la red de alta velocidad tiene una permeabilidad muy limitada con la ya existente, que sólo se da en puntos específicos equipados con cambiadores de ancho de vía o vías de triple hilo adaptadas para la circulación de tráficos de ambos anchos. Dichos equipamientos se encuentran ubicados en el entorno de las principales estaciones de la red, donde conviven tráficos de ambos anchos de vía y se hace necesaria esta permeabilidad para favorecer la accesibilidad a la red de alta velocidad de tráficos que conectan núcleos de población en los que dicha red aún no ha sido desarrollada.

Con la adición de los cambiadores de ancho se produce la reafirmación de la importancia de las estaciones como nodos de la red ferroviaria. Sin embargo, el papel de las estaciones no se limita a este entorno, ya que componen el enlace necesario entre la realidad urbana y la red ferroviaria. Su impacto en el sistema de transporte de las ciudades en las que se enmarcan suele ser considerable: salvo en casos de nueva construcción, las estaciones se ubican en los sectores centrales de las ciudades, requiriendo una amplia reserva de terreno para su establecimiento y ampliación. Estas ubicaciones son privilegiadas, debido a que permiten atraer grandes volúmenes de pasajeros, lo cual hace necesaria una coordinación con el transporte público local que se suele traducir en el establecimiento de grandes nodos intermodales, indispensables para la movilidad diaria en las urbes.

La expansión de la intermodalidad con el modo ferroviario es una de las principales consecuencias de las políticas de transporte impulsadas desde la Unión Europea, encaminadas al impulso de dicho modo en un afán de promover la eficiencia de las redes de transporte de los Estados miembros. Entre estas políticas cabe destacar dos en el plano ferroviario: el establecimiento de una red ferroviaria interoperable y la liberalización de los servicios comerciales de viajeros y mercancías.

En España estas medidas se han adoptado mediante la creación de la red de Alta Velocidad con estándares interoperables y la segregación de Renfe (organismo público que ejercía las veces de operador y administrador de infraestructuras de forma simultánea), en Adif (como empresa administradora de infraestructura ferroviaria) y Renfe Operadora permitiendo con ello el concurso de diferentes operadores por los servicios comerciales.

Debido a la apertura del mercado de servicios comerciales de viajeros se hace necesario armonizar los tráficos a ofertar a los distintos operadores, por lo que la capacidad ferroviaria se debe cuantificar y adjudicar en función de los trayectos a realizar. Tradicionalmente esta capacidad ofertada se limitaba a la reserva del trayecto en las líneas ocupadas, sin embargo, una posible congestión de los principales nodos ferroviarios hace necesario coordinar dichas reservas con el estudio y la adjudicación de la capacidad disponible en aquellas estaciones consideradas como susceptibles de encontrarse saturadas.

Por tanto, el estudio de la capacidad de las estaciones ferroviarias se alza como una consecuencia del aumento de la demanda inducida por la liberalización de los servicios comerciales que introduce nuevos operadores en infraestructuras con una elevada exigencia de puntualidad. Este aumento de la demanda junto con el grado de saturación ya existente puede inducir fallos o errores que desemboquen en retrasos, los cuales a su vez son capaces de transmitirse de tren a tren. Este efecto produce la amplificación de los retrasos, provocando la saturación del nodo y, dependiendo de la importancia del nodo dentro de la red ferroviaria, la totalidad de líneas puede llegarse a ver afectada.

El presente documento es el resultado de una colaboración en forma de prácticas de empresa con Adif, en el contexto de la redacción de un trabajo de fin de máster en ingeniería de caminos, canales y puertos, por lo que los datos empleados para la calibración del modelo son resultado de la operación real y los resultados obtenidos han sido cotejados con la experiencia de explotación.

2. ESTADO DEL ARTE

El funcionamiento de las redes de ferrocarril requiere de una planificación exhaustiva y eficaz, necesaria para asegurar que los servicios prestados tengan unos altos estándares de calidad, medida en puntualidad y seguridad. En escenarios de elevada demanda la necesidad de planificación se intensifica, surgiendo la necesidad de estudiar la capacidad de los elementos de la red más afectados, estableciendo un techo operacional a la oferta planteada a los operadores de la red.

2.1 Concepto de capacidad

Pese a ser una variable clave en la administración de las redes ferroviarias, la capacidad no es un concepto fijo, variando entre los distintos actores del sistema ferroviario (planificadores de infraestructura, planificadores del servicio y operadores). Es por esta situación que, a fin de unificar el concepto, la UIC propone una definición basada en la contabilización del número de circulaciones que pasan por un tramo de red en un periodo establecido, bajo unas condiciones de circulación establecidas (International Union of Railways 2004). De esta forma se reconoce que la capacidad de la red ferroviaria es un ente de cuatro dimensiones, oscilando entre el número de trenes, la velocidad de circulación, la heterogeneidad de servicios y la estabilidad de la red.

Sin embargo, la definición realizada en dicho informe resulta ser insuficiente para la comprensión de la capacidad aportada por la infraestructura, resultando en la necesidad de categorizar la capacidad en función de las condiciones respecto de las que se calcula. En este sentido Abril, Barber, Ingolotti, Salido, Tormos y Lova (2008) definen las siguientes categorías de capacidad:

- Capacidad teórica: representa el máximo número de trenes que podrían utilizar la infraestructura en unas condiciones matemáticamente perfectas, realizando suposiciones como que el tráfico es homogéneo. Por lo general suele constituir el límite superior de la capacidad, pues ignora las ineficiencias que surgen durante la operación real.
- Capacidad práctica: representa el número máximo de trenes que pueden utilizar la infraestructura en unas condiciones aproximadas a las de operación. Para ello se realizan unas suposiciones más realistas a las que emplea la capacidad teórica. En ciertas líneas adquiere una magnitud del 60 – 75 % de la teórica.

- Capacidad usada: representa el número de trenes que circulan realmente por la infraestructura. Es inferior o igual a la práctica.
- Capacidad disponible: diferencia entre la capacidad práctica y la usada.

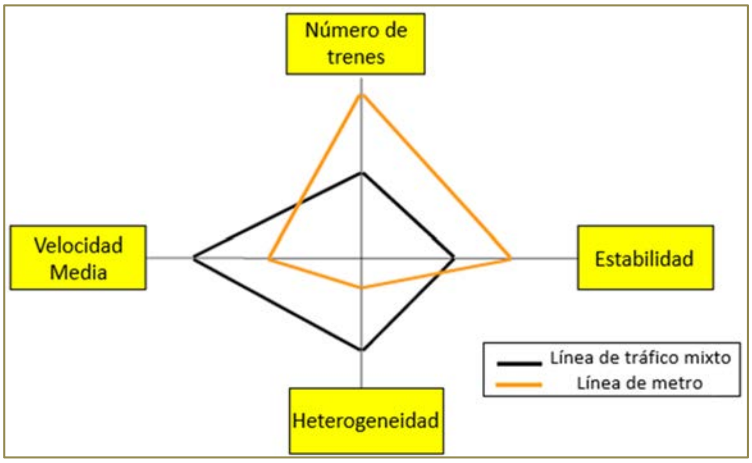

Fig. 1 - Factores que afectan a la capacidad (International Union of Railways 2004)

Estas definiciones se establecen para el estudio de la capacidad de las líneas, que ha sido el objeto tradicional de los estudios de la capacidad ferroviaria, por lo que Liu, Han y Li, (2012) definen la capacidad pasante. Dicha capacidad queda establecida como el número de trenes que se reciben y parten de una estación en un periodo de 24 horas, limitados por las condiciones de operación y de la infraestructura. De esta forma la capacidad aportada por una estación queda limitada por las restricciones impuestas, no sólo por la capacidad inherente a la infraestructura que compone la estación, sino también por la operación a la que se encuentra supeditada y la cual se ha de coordinar con el resto de la red.

2.2 Modelos de capacidad

La determinación de la capacidad y la planificación de su ampliación, son puntos clave en la gestión de las redes ferroviarias, adquiriendo mayor relevancia conforme aumenta la complejidad y la demanda en el sistema ferroviario (Burdett, 2015). El estudio de la capacidad de la red ferroviaria se ha orientado tradicionalmente al estudio de la capacidad de aquellos corredores ferroviarios en los que se detecta una dificultad a la hora de programar circulaciones. Junto con estas líneas de la red, las estaciones han sido tradicionalmente consideradas como generadoras de cuellos de botella (Yuan y Hansen, 2007; Carey y Carville, 2003), pero el estudio de su capacidad ha sido abordado en menor medida. La determinación de la capacidad se aborda mediante la modelización de esta, siendo el modelo más comúnmente empleado en el entorno europeo el establecido por la International Union of Railways (International Union of Railways, 2004; International Union of Railways, 2013). Cabe destacar que, tal como establecen Malavasi, Molková, Ricci y Rotoli (2014), los modelos empleados en la determinación de la capacidad se pueden clasificar a grandes rasgos en dos categorías:

- Analíticos: emplean fórmulas matemáticas generalistas para obtener información y resultados aproximados que puedan ser usados como referencia.
- Simulaciones: permiten obtener una aproximación más precisa de la realidad, replicando las condiciones de la vía. Sin embargo, pese a dar una información más precisa, requieren de definiciones detalladas de los equipos de vía.

Los métodos basados en simulaciones se pueden diferenciar en función del ámbito de aplicación: los modelos microscópicos permiten simular la operación de la estación (Han, Yue, y Zhou, 2014), pudiendo llegar a incluir el impacto de los retrasos y su propagación a lo largo del horario de servicio, cuyo impacto en la determinación de la capacidad ha sido estudiado por Zieger, Weik, y Niessen (2018). Por otra parte, los modelos macroscópicos y mesoscópicos permiten emular y validar las condiciones de funcionamiento de una red; permitiendo los mesoscópicos modelizar puntos clave, como pueden ser los cuellos de botella, con características propias de los microscópicos (Shi, Zhao, Yang, Guo, Zhang, y Feng, 2020) a mayor coste computacional.

La principal ventaja que poseen los modelos analíticos reside en su capacidad de aportar resultados significativos sin tener que recurrir a la simulación, incurriendo, por tanto, en menores costes (Hansen y Pachl, 2008). Los modelos analíticos han evolucionado con el paso del tiempo, pasando de considerar únicamente las incompatibilidades entre movimientos en un nodo, a integrar la teoría de colas y modelos probabilísticos, aumentando su potencia conforme los medios computacionales se han desarrollado (Malavasi et al 2014). En este sentido los modelos analíticos, al permitir realizar una aproximación teórica y puramente matemática, son más adecuados para aplicarse en fases de planificación de infraestructuras. Estos estudios se fundamentan en la optimización de distintas variables de la operación de la estación, como pueden ser las secuencias de tráficos que pasan por la estación (Jovanović, Pavlović, Belošević y Milinković 2020). Así mismo, estos modelos se pueden complementar con métodos de simulación que permitan su validación (Altazin, Dauzère-Pérès, Ramond, y Tréfond, 2020) o su inclusión en una red de mayor entidad. Debido a su naturaleza matemática, el análisis de la sensibilidad de las variables de las que parten estos modelos aporta una herramienta para la toma de decisiones en la expansión de la capacidad (Bevrani, Burdett, y Yarlagadda, 2017).

Como se ha expuesto, la capacidad ferroviaria es un concepto esquivo que varía en función del entorno en el que se considere y de la metodología empleada para su determinación, pero no sólo puede verse afectada por estas variables: El contexto de administración y operación de la infraestructura también resulta determinante. Tal como exponen Pouryousef y White, (2013), las condiciones de contorno del sistema ferroviario varían de una forma muy significativa en los entornos estudiados (Europa y Estados Unidos), resultando en concepciones y metodologías diferenciadas para la determinación de la capacidad. Estas caracterísitcas, reflejadas en la Fig. 2, han propiciado que en estos dos entornos característicos exista una diferenciación clara entre los métodos de determinación de capacidad: En Europa, los estudios de capacidad realizados dependen ampliamente de simulaciones tanto de tráficos como de horarios gracias a la disponibilidad de software como RailSys y OpenTrack, pudiendo combinarse estas simulaciones con métodos analíticos; mientras que en Estados Unidos, debido a su operación no dependiente de horarios, las modelizaciones realizadas dependen de la simulación de los tráficos y, en mayor medida, de métodos analíticos (Pouryousef, Lautala y White, 2015).

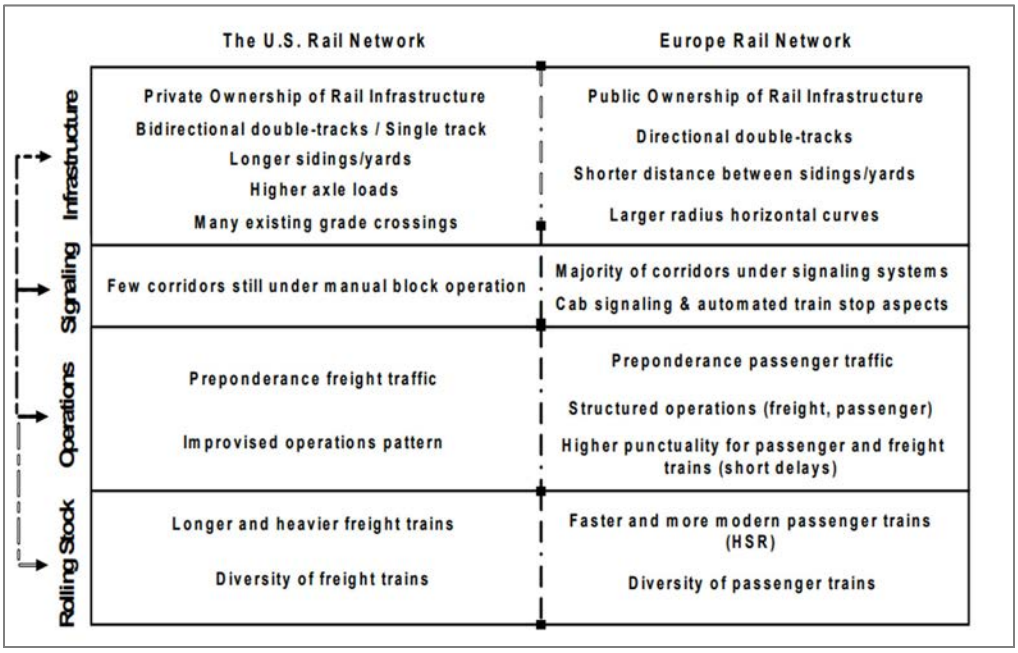

Fig. 2 – Principales diferencias entre los sistemas ferroviarios europeos y de Estados Unidos (Pouryousef y White, 2013).

3. METODOLOGÍA PROPUESTA

Ante la reconocida situación de saturación de los nodos más importantes de la red ferroviaria española se hace necesario estudiar la situación actual y los posibles escenarios derivados de ésta. El estudio de la capacidad asociada a una estación ferroviaria conlleva el estudio de su contexto, su operación y sus características físicas, por lo que resulta necesario desarrollar una metodología que permita establecer dicha capacidad de forma uniforme para los casos presentados, a la vez que conserve una flexibilidad suficiente para reconocer y adaptar sus particularidades.

3.1 Definición de capacidad

Como base la metodología empleada para la determinación de la capacidad de las estaciones ferroviarias se ha establecido el concepto de capacidad definido en las Fichas UIC 406: el número total de trenes que pasan por un tramo de vía en un periodo de tiempo determinado, con una calidad de servicio adecuada y considerando tanto el trayecto empleado como las condiciones establecidas por el administrador de infraestructuras (International Union of Railways 2004).

La definición establecida se hace extensiva tanto para los tramos de vía individuales como para los nodos que formen parte de una red ferroviaria, sin embargo, para su aplicación a las estaciones ferroviarias se va a considerar una puntualización a dicha definición, contabilizando el número de circulaciones comerciales capaces de ser operadas en un periodo de tiempo en las vías de estacionamiento. Esta modificación se sustenta en el hecho de que el complejo de una estación puede poseer vías pasantes por las cuales circulen trenes que no se vean condicionados por el funcionamiento de la misma, no realizando parada y siendo de paso prioritario, por lo que es poco común que sean cizallados (cruces al mismo nivel) por tráficos procedentes de la estación.

La adopción de esta definición conlleva una serie de consideraciones, ya que como se reconoce en la ficha UIC 406 (International Union of Railways 2004), la capacidad ferroviaria es un ente de cuatro dimensiones, interviniendo no sólo el número de trenes, sino la velocidad, la estabilidad y la heterogeneidad. Debido a que tres de estas dimensiones quedan fuera de la cuantificación de la capacidad, se hace necesario integrarlas en el modelo, con el objetivo de que éste sea lo más fidedigno con la realidad presentada en la operación normal.

3.2 Caracterización del tráfico

El tráfico ferroviario que solicita una estación es una pieza clave de la concepción de la metodología al ser el objeto del estudio para la determinación de la capacidad. La modelización del mismo ha de reflejar la heterogeneidad operativa que puede introducir en la estación de estudio, pudiendo variar tanto cuestiones ligadas al propio material móvil, como la longitud, la electrificación o el ancho de vía para el que se encuentran dispuestos (o la capacidad de cambiarlo); como características ligadas a la explotación: el número de circulaciones comerciales que son prestados por una composición a su paso por una estación, si pueden acoplarse/desacoplarse con otros materiales, o si la parada que realizan se produce por cuestiones comerciales o técnicas.

La definición de capacidad adoptada permite homologar los criterios de capacidad contabilizada en líneas a estaciones, pues si bien la definición clásica indica el número de trenes que pasan por una sección de vía, estos trenes a su paso por dicha sección, se encuentran prestando un servicio comercial con un origen y un destino definidos, por lo que se pueden identificar como circulaciones comerciales. La modificación se sustenta en que, si bien una estación puede ser origen o destino de circulaciones, ello no conlleva que sean el origen o el destino final del tren (entendido como el material móvil que presta servicios comerciales), ya que éstos pueden realizar operaciones de rotación, prestando con ello servicios comerciales distintos respecto del prestado al ingresar a una estación. En este sentido, en el presente documento, se referirá un material móvil de distinta forma en función de sus acciones.

- Movimiento: se refiere a la acción de desplazamiento de un material móvil, pudiendo relacionar vías de estacionamiento con vías de apartado, el acceso de la estación u otras vías de estacionamiento. Forman parte de una circulación.
- Circulación: se refiere a la marcha de un tren entre un origen y un destino determinados, prestando un único servicio. Aquellas circulaciones que presten un servicio comercial serán las que permitan definir la capacidad de la estación.
- Tren: se refiere al material móvil, puede prestar múltiples servicios comerciales dependiendo de la ventana temporal observada.

Debido a que la capacidad pasa de ser cuantificada como el número de trenes que pasan por un tramo de la infraestructura en un periodo de tiempo establecido, a la cantidad de circulaciones comerciales que pueden ser prestados en la estación (o la cantidad de trenes que pueden ser operados) en un periodo de tiempo establecido, se hace necesario analizar el tiempo de ocupación de las vías de la estación que es requerido por el tráfico. Debido a que el conjunto del tráfico es heterogéneo respecto a las necesidades de parada de cada circulación planteada, la modelización del mismo requerirá la caracterización de las circulaciones en función de la ocupación de las vías del conjunto de la estación y de la proporción en que se dan.

Así mismo debe de acotarse el periodo temporal en el cual se van a producir los tráficos que van a ser contabilizados. Este período temporal se corresponde con el horario de circulación de los trenes, que contempla dos horas adicionales al horario de servicio contemplado en la Declaración de la Red, de 6:00 a 22:00, de forma que se permita finalizar las circulaciones planteadas al final del mismo y que finalicen su recorrido antes de las 24:00.

Cabe destacar que la consideración de la definición de capacidad adoptada excluye una tipología de movimientos: aquellos que son necesarios para la correcta operación de los tráficos en las estaciones, pero que no forman parte de una circulación comercial. Estos movimientos relacionan la estación con vías de apartado o instalaciones designadas para el estacionamiento y/o mantenimiento de los materiales móviles, donde se realizan de forma parcial o total las operaciones requeridas para la puesta en servicio del material móvil. Estos movimientos se contemplan de forma indirecta, asociándolos a la circulación comercial anterior o posterior que realiza el material móvil.

3.3 Caracterización de la infraestructura

Las estaciones ferroviarias, al igual que en el caso del tráfico, distan de ser homogéneas para cada caso de estudio. En este sentido, las diferencias principales vendrán inducidas por la disposición de las vías, las cuales se pueden diferenciar en tres categorías similares a las establecidas en la ficha UIC 406 (International Union of Railways 2004):

- Vías de acceso: permiten, mediante aparatos de vía, distribuir los trenes entre las distintas vías que conforman el nodo. Un nodo puede tener una o dos zonas de cambio, pudiendo distinguirse con ello dos disposiciones de nodo, el fondo de saco y el pasante.
- Vías de estacionamiento: en las que los trenes pueden realizar las operaciones que requieran, pudiendo variar desde la marcha normal al estacionamiento por razones de limpieza, catering o embarque/desembarque de viajeros.
- Vías de apartado: vías en las cuales un tren puede estacionar pero que no se encuentran conectadas a la terminal de viajeros de la estación. Dependiendo de las características del equipamiento que posean, se podrá dar determinados servicios a los trenes que en ellas se encuentren estacionados. Estas vías no se encuentran diferenciadas como tal en la ficha UIC, pero de encontrarse en el complejo de la estación, permiten acortar el estacionamiento de determinados tráficos en las vías de estacionamiento.

La ocupación de las vías contabilizada para cada circulación será la total, siendo necesario realizar una simulación de marcha desde la señal de entrada de la estación. La caracterización del tiempo de ocupación para cada circulación considerada será el resultado de añadir el tiempo resultante de la marcha a la ocupación de las vías realizada en función de los servicios requeridos en cada caso.

Las características del conjunto de las vías de la estación pueden no ser homogéneas, pudiendo variar su longitud de estacionamiento, la longitud de andén, la electrificación, el ancho con el que se encuentran dispuestas o pudiendo prestar servicio a una composición de circulaciones distinta al resto de vías. Por estas razones será necesario segregar las vías en conjuntos de características similares. La capacidad del conjunto de la estación será el resultado de agregar la capacidad aportada por las distintas agrupaciones de vías que hayan sido consideradas.

En la operación de las propias estaciones se pueden encontrar aparatos de vía que permiten dinamizar la gestión de los tráficos, permitiendo dar servicio a un mayor número de circulaciones de forma simultánea. Los aparatos de vía que se pueden encontrar en las estaciones y que se emplean para este fin son los bretelles, que conectan dos vías paralelas mediante cuatro desvíos simples; y los escapes, que se componen por dos desvíos sencillos y conectan dos vías paralelas en forma de cruz de San Andrés, conformando un escape doble que enlaza dos vías paralelas en ambos sentidos. Se compone por dos diagonales de carriles diferentes superpuestos, contando con una zona singular en la parte central donde tiene lugar la intersección de las dos vías desviadas.

El principal beneficio de los aparatos de vía es que permiten dotar a la infraestructura de una gran flexibilidad de operación, permitiendo cambiar de una vía a la adyacente en los cuatro sentidos de la circulación, todo ello minimizando el espacio ocupado. Su implementación en las vías de estacionamiento de una estación permite dividir dos vías paralelas en cuatro sectores de operación, en los cuales se puede dar servicio de forma individualizada a distintos servicios. Si las vías se disponen en fondo de saco (sólo poseen un acceso) de los cuatro sectores sólo podrán emplearse tres de forma simultánea (dos orientados a las toperas y uno orientado al acceso), dejando el cuarto libre para permitir la salida de todas las circulaciones una vez éstas hayan terminado de realizar las operaciones requeridas. En caso de que las vías de estacionamiento se encuentren dispuestas de forma pasante (pudiendo acceder a ellas desde cualquier sentido de la circulación), se podrían operar hasta cuatro circulaciones de forma simultánea (una por cada sector de vía disponible), sin embargo se trata de un régimen de funcionamiento inestable que no se puede prolongar demasiado en el tiempo (debido a los tráficos pasantes a la estación deben ser acomodados en otras vías en la mayoría de los casos), por lo que lo normal es establecer su funcionamiento dejando un sector libre. La principal ventaja de los bretelles frente a los escapes es que permiten alternar el sector libre, mientras que en los escapes, este sector es fijo.

3.4 Determinación de la capacidad

De manera análoga a lo establecido por Abril et al. (2008), la capacidad teórica puede definirse como el máximo número circulaciones a las que se pueden dar servicio en las vías de estacionamiento de la estación en unas condiciones matemáticamente perfectas. Para su cálculo se requiere caracterizar la estación, estableciendo las vías de estacionamiento y los aparatos de vía que permitan ampliar la capacidad de las vías en las que se encuentren; así como el estudio del tráfico y la ocupación que requiere.

Una vez caracterizado el tráfico que soporta la estación, pormenorizado para cada vía, se procede a agrupar dichas vías en función de sus características, tanto físicas como de demanda. En función de dichas características, se establece la capacidad aportada por cada vía tipo, partiendo de la ocupación requerida por cada servicio planteado y en la proporción determinada que caracterice su tráfico distintivo. Cabe destacar que entre las distintas tipologías de tráfico planteadas pueden encontrarse aquellas que realicen dos servicios independientes entre sí, pudiendo llegar a ser predominantes en las estaciones dispuestas en fondo de saco o que sean el origen o el destino final de los servicios comerciales. Para estos casos la capacidad consumida por cada circulación será la mitad de la consumida por la estancia total del tren.

Una vez obtenida la composición del consumo del tiempo del periodo considerado, establecido en una hora, a su vez determinada por la composición del tráfico considerado para cada vía tipo considerada, se puede determinar la capacidad teórica aportada agregando las distintas capacidades establecidas por cada tráfico y cada conjunto de vías considerado.

Debido a que la capacidad calculada no refleja la capacidad que puede ser operada en la estación, es necesario realizar consideraciones adicionales. El cálculo de la capacidad teórica asume que los tráficos prescritos para cada vía podrán sucederse sin interferir entre sí, por lo cual, la primera consideración debe reflejar el impacto sobre la capacidad que tienen las condiciones de acceso a cada conjunto de vías considerado. Aplicando esta restricción se obtendrían el número máximo de trenes que se podrían operar en la estación, sin embargo, debido a que las estaciones se encuentran sujetas a unas condiciones de funcionamiento garantes de estabilidad, la capacidad que se puede ofertar a las empresas ferroviarias y operadores que en ellas planteen servicios comerciales debe ser estrictamente menor a la resultante del cálculo.

4. MODELO EMPLEADO

La aplicación de la metodología propuesta a un caso práctico se ha realizado mediante el modelo a continuación presentado y resumido en la figura 3. Este modelo, presentado de forma teórica, se ha usado para determinar la capacidad de varios casos de estudio en la red ferroviaria española.

4.1 Cálculo de la capacidad teórica

Como paso previo para determinar la capacidad teórica de la estación se deben definir tanto la infraestructura que la conforma como los tráficos que la solicitan. La caracterización de la infraestructura se puede realizar mediante un esquema de vías, al cual se agregará la información pertinente (datos que permitan la descripción de las vías, tales como el ancho de vía, la longitud de vía, la longitud de andén, la tensión de electrificación…), en función de la cual se agrupan en conjuntos de vía. Para cada conjunto de vía se establece un tiempo de acceso medio, que puede determinarse mediante una simulación de marcha, debiendo realizar un estudio del cizallamiento para aquellos trayectos que puedan verse afectados.

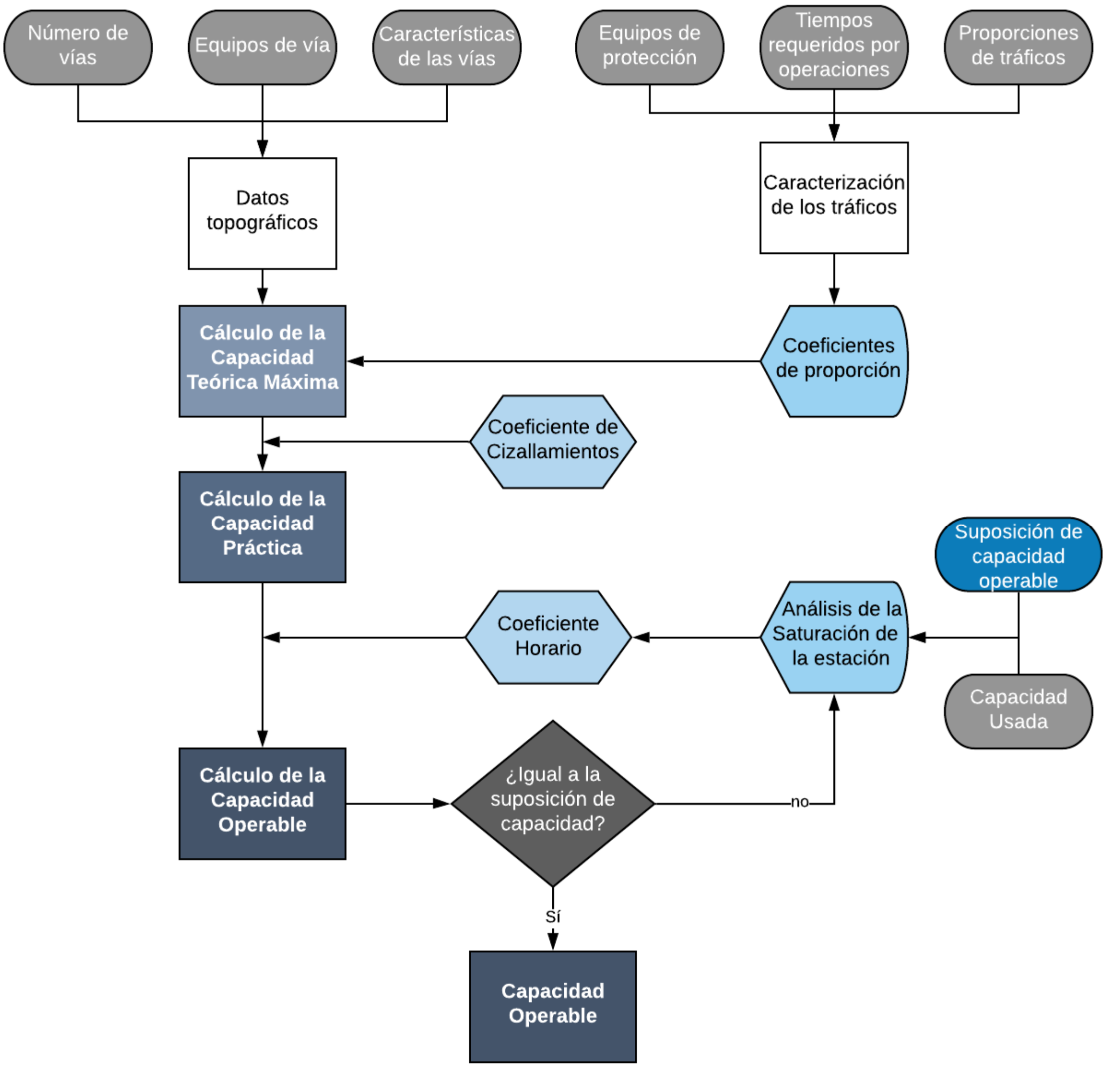

Fig. 3 – Diagrama de flujo del modelo propuesto. (Elaboración Propia)

La caracterización de los tráficos se realiza mediante la observación de las circulaciones que utilizan la estación, en una semana que se considere representativa del funcionamiento normal de ésta. Debido a que el registro de las paradas que realizan las circulaciones refleja aquellas asociadas a las que se realizan por motivos comerciales o técnicos, dicho registro puede resultar insuficiente al no representar el total de las paradas que puede realizar un tren en una estación. La parada no representada es aquella que se realiza al iniciar o finalizar un servicio, pudiendo relacionar dos servicios comerciales o un servicio comercial y un movimiento no comercial a vías de apartado o bases de mantenimiento cercanas. Para el correcto estudio de la ocupación de las vías se debe recurrir a los denominados como Gráficos de Ocupación de Vías (GOV), que permiten visualizar la ocupación de las vías de la estación producida por los trenes. Así mismo, combinando estos documentos con el esquema de vías de la estación se pueden comprender las operaciones de coordinación de tráficos que lleva a cabo el administrador de infraestructuras.

El tiempo de ocupación que requiere cada tren, las circulaciones y los movimientos comerciales serán las variables principales que permitan determinar la composición de tipologías de trenes que utilizan la estación. Una vez determinadas estas tipologías los GOV permiten adicionalmente realizar una segunda fase del agrupamiento de las vías de estacionamiento, estableciendo con ello aquellas que poseen tanto unas características físicas como una composición de circulaciones similares. Este segundo agrupamiento puede realizarse con los propios registros de circulaciones de la estación si a éstas se les ha agregado la vía de estacionamiento real. Con esta información podemos clasificar de forma general los trenes en las siguientes categorías:

- Rotaciones: Son trenes que llegan a la estación prestando un servicio comercial, realizan una parada destinada a la puesta en servicio del tren, realizando operaciones de limpieza, catering…, tras las cuales se procede al embarque de viajeros y parten de la estación prestando un servicio comercial independiente del inicial. Debido a ello, un tren produce dos circulaciones comerciales, que a su vez implican dos movimientos, también comerciales.
- Pasantes: Son trenes que llegan a la estación prestando un servicio comercial y que, tras una parada por razones técnicas o comerciales, parten de la misma prestando el mismo servicio. Por ello, un tren produce una circulación comercial que se traduce en dos movimientos, también comerciales.
- Materiales vacíos: Son trenes que llegan o parten de la estación prestando un servicio comercial, realizando un movimiento complementario (de acceso o salida de las vías de estacionamiento) no comercial, conectando la estación con talleres o vías de apartado. Estos trenes producirán, una circulación comercial y dos movimientos, de los cuales uno de ellos es comercial.
- Acoplados: Son trenes que se encuentran compuestos por dos circulaciones que al llegar a la estación se unen o separan, de forma que una de las circulaciones tiene origen o destino la estación mientras que la otra se comporta como un tren pasante. Por ello, un tren producirá dos circulaciones, ambas comerciales y tres movimientos, también comerciales.

Una vez determinados los conjuntos de vía a analizar y las tipologías de trenes que van a caracterizar el tráfico que las ocupa, se calcula su frecuencia de paso y un coeficiente de ajuste de proporción. Este coeficiente tiene como objetivo establecer el porcentaje real observado de cada tráfico para cada conjunto de vía, permitiendo obtener con ello, los tiempos que de media se consumen por cada circulación en una hora y para cada grupo de vía analizado. Estos tiempos permiten caracterizar la ocupación media que realizaría cada tipología de tráfico en una hora y con ello, las circulaciones que dicha tipología aportaría a la capacidad máxima de las vías estudiadas. La capacidad máxima, por tanto, se calcula en dos fases: en primer lugar, se agrega la capacidad aportada por cada tráfico a la vía tipo de cada conjunto de vías, lo cual permite obtener fácilmente la capacidad aportada por cada grupo de vías. Una vez se ha obtenido la capacidad aportada por cada conjunto de vías, estas capacidades se agregan dando como resultado la capacidad teórica, la máxima a la cual la estación podría dar servicio en unas condiciones ideales.

4.2 Capacidad Práctica y Capacidad Operable

Como se ha establecido el cálculo de la capacidad teórica no resulta representativo de la capacidad que se puede o podría operar en unas condiciones de funcionamiento normales de la estación. Esto se debe a que el cálculo realizado se basa en la suposición de que una vez la vía queda libre otro tren entra para ocuparla, lo cual, pese a poder establecer un margen de tiempo por razones de seguridad, no resulta representativo al no contemplar las posibles incompatibilidades en los trayectos generados por los distintos movimientos requeridos por el conjunto de vías consideradas. Estas incompatibilidades derivan principalmente de la disposición de la playa de vías, que establece las condiciones de acceso a los sectores considerados y particularmente, los tráficos que quedan cizallados entre sí.

A fin de reflejar el impacto que la disposición de las vías de acceso tiene sobre la capacidad se determina el coeficiente de cizallamiento. Dicho coeficiente representa el número de trenes retrasados, cuyo tiempo de ocupación de vía es mayor al estrictamente necesario para realizar las operaciones por cuestiones de indisponibilidad de itinerario. De forma similar a lo establecido por Abril et al. (2008), dicho coeficiente reductor adquiere valores comprendidos entre 0,6 y 0,8 dependiendo de la topología y de las condiciones de explotación de la estación, pudiendo llegar a discriminar el uso de determinadas vías para evitar interferencias entre tráficos. La aplicación de dicho coeficiente a la capacidad máxima teórica permite obtener la capacidad práctica de la estación, representando la capacidad que se podría operar en condiciones máximas, bajo la operación y coordinación de tráficos del día medio.

Tal como se ha establecido, las condiciones de operación de una estación se encuentran sujetas a unas condiciones que han de ser garantes de la estabilidad del servicio, por lo que establecer la capacidad máxima de la estación como la capacidad práctica puede resultar poco representativo de cara al cálculo del estado de saturación de la estación. Debido a ello se introduce el concepto de capacidad operable.

La capacidad operable permite reflejar el funcionamiento de la estación sometida a las condiciones de operación medias. Para ello se estima la ocupación media, que se define como la media de la tasa de ocupación horaria de las vías en un día medio. Se debe a la necesidad de reflejar en el modelo que no todas las horas estarán sujetas a la misma demanda por parte de los operadores. Esta diferencia de demanda permite clasificar las horas de operación en horas valle y horas punta, adaptando como máximo de capacidad horaria la capacidad operable de la estación y la capacidad punta extraordinaria, respectivamente.

La capacidad punta extraordinaria se estima partiendo de los datos de operación de la estación. Mediante un análisis del número de trenes que la estación es capaz de operar en una hora se puede extrapolar o estimar, para un determinado intervalo de confianza la capacidad máxima en la estación. Con el objetivo de que la ley de capacidad sea continua, se establece un modelo de capacidad lineal, permitiendo reflejar cómo varía la saturación de la estación.

El grado de saturación se calculará en función de la clasificación de la hora en hora punta o valle. Para determinar dicha clasificación se comparará el número de trenes que circulan con el número máximo que puede circular por hora, si dicho cociente supera el umbral del 75% (utilizado en el Manual de Capacidad editado por Adif para establecer un tramo como congestionado) la hora se clasificará como punta, en caso contrario, como valle. Aplicando el grado de saturación obtenido a la capacidad práctica se obtiene la capacidad operable, la cual ha de coincidir con la capacidad tomada como base para el cálculo de la saturación. En caso de que no coincida, se debe iterar el proceso hasta llegar a la convergencia de ambos valores. Con el objeto de acelerar este proceso de convergencia, se adopta un factor de iteración igual a la media del valor supuesto inicialmente y el valor obtenido del proceso, llegando a la convergencia en el entorno de la sexta-octava iteración. Tal como se puede apreciar en la figura 4, emplear el valor obtenido puede llegar a suponer la necesidad de llegar a realizar del entorno de 40 iteraciones del proceso.

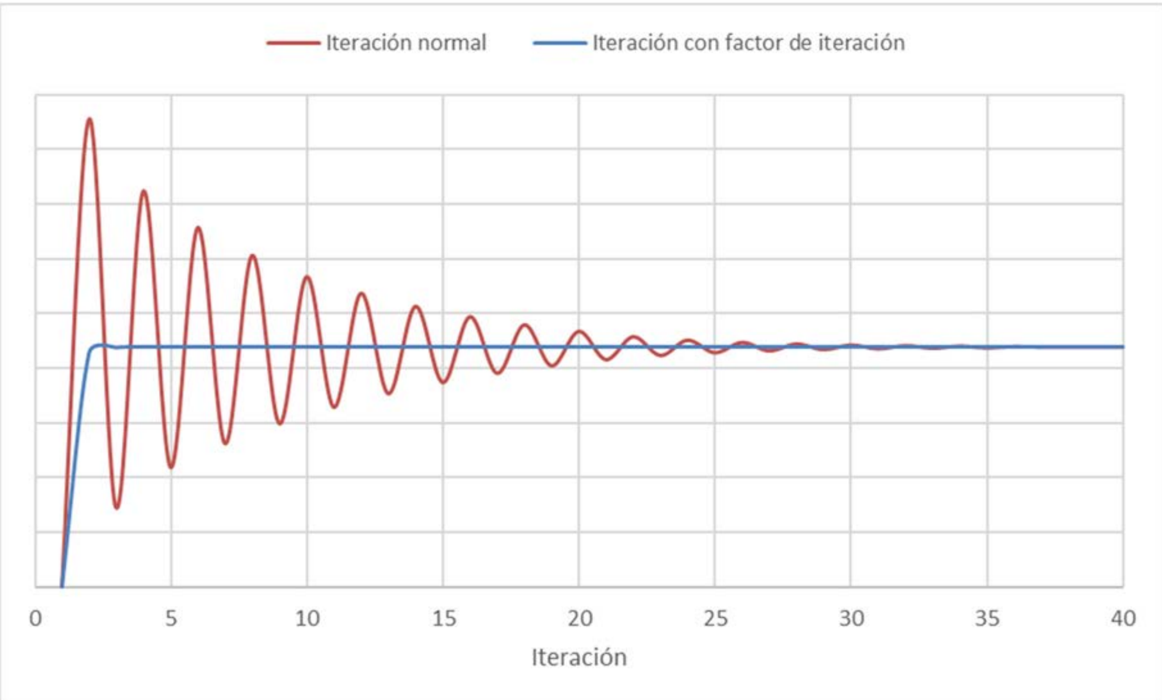

Fig. 4 – Convergencia del valor final de la capacidad operable. (Elaboración Propia)

Tomando como base el grado de saturación horario obtenido se calcula la capacidad operable aplicando la media de dichas saturaciones siempre que sea superior al 60%. En caso contrario la demanda de la estación no es suficiente para adoptar el resultado del estudio de saturación como válido, ya que la reducción consecuente de capacidad no resultaría representativa de la capacidad operable de la estación. De esta forma, el modelo empleado permite discernir entre aquellos casos en los cuales la estación no se encuentra saturada, con un coeficiente igual al 60%; aquellos que poseen una saturación moderada, adoptando un 60% - 75%; y aquellas con una saturación considerable, con un coeficiente superior al 75%.

Como se ha establecido, el tiempo de estudio para la determinación de la capacidad va a ser el del horario de circulación, de 6:00 a 24:00, sin embargo, el horario práctico en el cual una vía puede prestar servicio se puede encontrar limitado por distintos elementos. El principal factor que va a limitar el horario de circulación de las vías son los trenes que las ocupan desde su llegada a la estación, en horas cercanas a la finalización del horario de circulación, hasta su partida a la mañana siguiente, cuya hora puede superar la de inicio del horario de circulación. En estos casos, se dice que un tren duerme en la estación, y para contemplar su impacto en la capacidad, se restringe el horario de circulación en función de la estancia que produzca. De esta forma, las horas en las cuales un tren quede estacionado por estos motivos en una vía, no se tendrán en cuenta a la hora de contabilizar la capacidad aportada por la vía en condiciones de circulación. Así mismo, para contemplar su adición de capacidad, estos trenes se suman a la capacidad operable aportada por cada vía o conjunto de vías, ya que en el tiempo en el cual se encuentren estacionados, se producirá una única circulación comercial.

5. CONCLUSIONES

En general, los métodos aplicables para el cálculo de la capacidad ferroviaria, así como su gestión, se han centrado predominantemente en líneas. Los estudios de capacidad de las estaciones, de gran importancia sin embargo, han quedado relegados a un segundo plano, lo cual se puede asociar a la dificultad de ejecutar modelos basados en el estudio de las incompatibilidades entre tráficos y la generación y propagación de retrasos en nodos ferroviarios complejos. Los modelos comúnmente basados en la simulación microscópica de la estación añaden a la dificultad de la modelización de una estación el elevado coste computacional que suponen, por lo que la aplicación de modelos analíticos resulta más efectiva a la hora de determinar la capacidad global pese a su dificultad de adaptación a los distintos casos.

La metodología y el modelo de cálculo propuestos se basan en la experiencia de explotación y en la configuración de la infraestructura disponible en las estaciones. Estas dos bases dotan al modelo de una gran flexibilidad a la hora de considerar la heterogeneidad de los tráficos y las características particulares de cada caso al que sea susceptible de ser aplicado, pudiendo aplicarlo en concepto de simulación de forma que se puedan evaluar distintos proyectos orientados a la ampliación de la capacidad.

La principal ventaja de la metodología presentada es la facilidad que muestra para la adaptación entre los distintos casos estudiados, capaz de representar las variaciones de capacidad inducidas por distintas variables, como pueden ser la composición del tráfico o la disposición de la infraestructura. Cabe destacar así mismo, que la variable de cálculo empleada, las circulaciones comerciales, permite determinar unos cupos de capacidad, análogos a los surcos establecidos en líneas, por lo que permite a los administradores de infraestructuras dimensionar la oferta de capacidad segmentada en función de las características que estime.

AGRADECIMIENTOS

Este documento ha sido elaborado a partir de un Trabajo de Fin de Máster para el cual fue necesaria la colaboración del administrador de infraestructuras Adif. El desarrollo de esta metodología no hubiese sido posible sin el apoyo del personal de la Dirección de Gestión de Capacidad a los que se agradece su implicación.

DIGITAL SOCIETY AS A DETERMINING FACTOR IN MOBILITY, URBAN DYNAMICS AND CURRENT CITIES STRUCTURE

Victor Manuel Castillo Luna
PhD Student UPM, Madrid

ABSTRACT

The development and evolution of the digital society has brought about relevant changes in the way people experience the city today. In particular, its impact on mobility patterns is evident, especially in the Post-COVID-19 society, where it is possible to access different types of daily activities online (e.g. working, shopping, training, etc.). At the same time, this digital era brings with it new challenges for urban and transport planning, in which information and communication technologies (ICT) can play a relevant role as transformers of traditional urban structures. For this reason, studying and understanding how the digital society is transforming current cities is important and necessary to optimize planning patterns/guidelines and achieve more sustainable and inclusive cities.

To address this challenge, this project has implemented multivariate statistical techniques to characterize the city of Madrid (Spain) at urban level, in order to detect the impact of ICTs on the current urban structure of the city. The methodology incorporated both factorial and cluster analysis with spatial restriction, based on a set of starting indicators referring to urban equipment, demography, socioeconomics, transportation, as well as variables of the digital society (e.g., electronic mailboxes-online commerce, free public and commercial Wi-Fi points, etc.).

The results, among other things, show an optimal classification grouping, as well as the way it was obtained. In this case, the optimal classification grouping is the one conformed by 6 clusters, in which different relationships were detected between the space built, the equipment and aspects of the digital society such as online shopping and the proximity to transport equipment public and physical commerce. These results support a growing influence of the digital society in the urban characterization, suggesting the need to translate this influence into effective planning criteria.

1. INTRODUCTION

The emergence of the digital era in society triggered an unprecedented explosion in the multiple ways in which people experience the city, giving a new direction to its development and modifying urban dynamics, mobility and spaces (Batty et al., 2012). In this sense, the UN´s Agenda 2030 considers digital tools as an essential means in the study and understanding of cities, as well as to promote socioeconomic development, protect the environment, modernize infrastructure and improve human progress (United Nations, 2015). For this reason, there is a tangible need for developing and implementing innovative solutions that use criteria related to digital society in the analysis of the urban form.

The notion of digital society proposes that network infrastructures, as well as information and communication technologies (ICTs), are capable of generating a large amount of data (Butot et al., 2020) and facilitating development processes. Therefore, they can be used to provide solutions to social, economic, urban and territorial challenges (Townsend, 2013) , which guide the progress and growth of cities. On the other hand, urban characterization, defined by its capacity to identify and classify urban typologies through various attributes related to the city, allows the elaboration of quantitative analyses with multiple variables (principal component analysis, factorial, cluster, etc.), using a large amount of information (Song & Knaap, 2007). As a whole, digital society and urban characterization, promote the idea that "increasingly complex" urban processes (Kitchin, 2016), can be made understandable by integrating both concepts. However, ICTs bring new challenges in the planning and development of cities, because by themselves, these new technologies aren´t able to solve problems in a simplistic way (Barbosa et al., 2020). This also generates several inconveniences (e.g. accumulation of power of those who generate and manage a high volume of data) (Sadin, 2013), therefore, their role is and will be fundamental as transformers of traditional urban structures (Elias B., 2020).

Although the impact of the digital society on the structure of cities has been an area of interest in academia in recent years, (Batty et al., 2012; Butot et al., 2020; Elias B., 2020; Reddy & Reinartz, 2017; Ricaurte-Quijano et al., 2017; Townsend, 2013) it has not been widely explored from perspectives of urban characterization through multivariate statistical methods. In previous researches on urban issues and mobility, characterization methodologies have been developed using multivariate analysis that have ignored issues related to the digital society. These methodologies have focused mainly on indicators related to the population structure and its relationship to the metropolitan phenomenon (Martori & Hoberg, 2008; Santos P., 1991; Teoh et al., 2020; Yeh et al., 1995). Other studies have used variables related to the urban built environment (Berrigan et al., 2010; Porta et al., 2006; Song & Knaap, 2007; Vandenbulcke et al., 2009). While some other authors have developed methodologies of multivariate characterization using indicators related to attitudes and urban activities of the population (Balram & Dragićević, 2005; Jacques & El-Geneidy, 2014; Jiang et al., 2012; Steiger et al., 2015). Finally, some have even incorporated attributes with the ability to measure social welfare (Romillo B, 2013).

Furthermore, the influence of digitalization on society has been analyzed from various points of view. The first of these, focusing on the availability and access of the population to the internet, from the logic of those who have it and those who do not (Chen, 2012; El Colegio de la Frontera Norte, 2018; *Schleife*, 2010). The digital society has also been studied through the implementation of ICT´s in the identification of urban activity patterns (location of places of shopping, leisure, employment, study, etc.) using data from social networks (Steiger et al., 2015). Moreover, many studies have been developed without criteria of contiguity, obtaining significant results in relation to the attributes used, but maintaining high levels of fragmentation in these results.

Therefore, the importance of urban characterization methodologies with the capacity to incorporate attributes related to the information society is fundamental. The objective of this study is to apply a quantitative method able to characterize through a multivariate and spatial analysis, the urban typologies affected by the digital society existing in the metropolitan area of the municipality of Madrid. For this purpose, sociodemographic and socioeconomic indicators were used, as well as variables of the built urban space and, specifically, criteria related to ICT´s and spatiality.

2. CONCEPTUAL FRAMEWORK

(Song & Knaap, 2007) emphasize the usefulness of identifying and classifying urban typologies, because this facilitates understanding by organizing ideas and characteristics into defined elements. Likewise, it allows the elaboration of quantitative analyses using a large amount of information, grouping it into a set of components. They also highlight the need to characterize these areas for the development and implementation of public policies. At the same time, (Wu & Sharma, 2012), (Song & Knaap, 2007), agree that in general terms, the classifications referring to the conceptualization of urban areas, are divided into two major categories.

2.1. Descriptive classification

The first category is known as descriptive, and is mainly based on spatial divisions that are readily available or prepared from visual interpretations of maps and images (Jones, Leishman & Watkins, 2005; Thibodeau & Goodman, 2007; Watkins, 2001). Satellite images have played a key role in descriptive characterization and have been used in various approaches. Tapiador, Avelar & Tavares-Correa (2011) applied this type of images to detect the urban morphology of an area of Lima, Peru and to classify it by relating this information to socioeconomic aspects, this allowed them to characterize large areas in social terms and map social inequality. Jun, Jinmei, Guoyu & Jizhong (2011) characterized an urban-rural region of Qingdao with the help of high-resolution satellite images under the criterion of land use properties (such as buildings, roads, pastures, farmland and water).

This type of descriptive characterization has been used in studies of the real estate market to spatially classify housing sub-markets under generic attributes, such as the census blocks into which the dwellings are grouped (Thibodeau & Goodman, 2007), postcodes (Jones et al., 2005) or the physical characteristics of the houses (Basu & Thibodeau, 1998; Watkins, 2001). However, there is a notable lack of descriptive characterizations based on attributes of the digital society (e.g. proximity of the houses to places with public internet access).

2.2. Multivariate classification

The second category is based on the interaction of data from different variables, where the growth of GIS tools and technical innovations has allowed statisticians to process a wide variety of quantitative attributes simultaneously. There are two variations in this category: without and with spatial restriction criteria.

2.2.1 Multivariate classification without spatial criteria

This first modality allows vast amounts of information and attributes to be covered without considering elements of contiguity, so the urban structure can be characterized from different perspectives, although not in a localized manner.

One perspectives is through the urban structure of the population and its relationship with the metropolitan phenomenon using socioeconomic variables and educational level, age indices, diversity and habitability indicators, and using factor analysis (FA), principal components analysis (PCA) and cluster analysis (CA). This reveals that the oldest and most educated population lives in the areas with the highest socioeconomic level (Martori & Hoberg, 2008; Santos P., 1991; Teoh, Anciaes & Jones, 2020; Yeh et al., 1995).

Likewise, urban characterizations have been studied using the built environment through building type indicators (size of homes, apartments and building, number of levels, building density, etc.), section widths, accessibility to public transport, etc. (Berrigan et al., 2010; Porta et al., 2006; Song & Knaap, 2007; Vandenbulcke et al., 2009). This group does not included any built-environment attribute related to the digital society either.

City characterizations have been developed with attributes associated with the population´s activities (work, study, leisure, etc.) and travel behavior using origin and destination indicators, travel distances, schedules, mode of transport, activities during the trip, etc. (Balram & Dragićević, 2005; Ettema & Verschuren, 2008; Jacques & El-Geneidy, 2014; Jiang et al., 2012; Steiger et al., 2015; Varghese et al., 2018). This type of study analyzes the relationship between the digital society and travel behaviour, but with the aim of identifying the influence of digital media on multitasking and rather than as an attribute for effectively contributing to urban characterization.

Some authors have used social indicators (percentage of active population and rates of: unemployment, divorce, infant mortality, life expectancy, etc.) in PCA and CA to group the sectors of an urban area according to territorial structures of social welfare (Romillo B, 2013), but without including parameters related to the digital society in their classifications.

Characterization with this technique has also been extremely useful in explaining the phenomenon or urban expansion, identifying sub-centers in urban areas (Cai, Huang & Song, 2017; Thomas, Riguelle & Verhetsel, 2007) and studying the effects of the compact vs. dispersed city (Thinh, Arlt, Heber, Hennersdorf & Lehmann, 2002). Or simply studying the phenomenon of sprawl by characterization the structure of the built environment and its connection with the growth of cities (Batty, Longley & Fotheringham, 1989; Piron, Dureau & Mullon, 2004).

2.2.2 Multivariate classification with spatial criteria

In the second mode, spatial restrictions can be incorporated simultaneously to the data being classified using criteria of location, distance or contiguity in the variables, or by including additional indicators that restrict the spatiality of the results.

Many studies incorporating contiguity restrictions have been undertaken in the real estate market, and include characteristics related to dimensions, costs, building heights, number of rooms etc. This allows similar areas to be identified and grouping geographically (Bates, 2006; Bourassa et al., 2007; Clapp & Wang, 2006; Tu, Sun & Yu, 2007; Wilhelmsson, 2004).

Figure 1. - Area of study – Municipality of Madrid

However, there are very few studies with the capacity to characterize urban areas incorporating spatial restrictions, and there continue to be considerable gaps in the methodology. As mentioned by Wu & Sharma (2012), authors that include spatial contiguity in their methodologies (Bates, 2006; Bourassa et al., 2007; Clapp & Wang, 2006; Tu et al., 2007; Wilhelmsson, 2004; Wu & Sharma, 2012), were successful in achieving some levels of restriction, although the groupings generated lack contiguous boundaries and their results didn´t coincide with the actual division of urban space. In addition, by focusing on spatial contiguity, the studies fail to highlight the importance of the attributes analyzed with respect to the complexity of the urban space (Wu, Wei & Li, 2019). This complexity is often addressed through features alien to the digital society, leading to significant gaps when incorporating spatial criteria and information society indicators.

This highlights the need for a feasible solution for the classification of urban areas, and suggests that an optimal procedure would strike a balance between the importance of emphasizing the required urban attributes (of the built space, the conditions and habits of the population and incorporating digital society variables) and including spatial restriction criteria. This balance would make it possible to achieve a homogeneous classification without mitigating the original attributes.

3. METHOD AND RESEARCH DESIGN

3.1. Case of study

The municipality of Madrid, in the metropolitan area of Madrid, Spain, was selected for this study (Fig. 1), as it is considered to fulfil many of the characteristics that exemplify the influence of the use of new ICT´s in Spain and Europe.

According to the survey *"Equipamiento y Uso de Tecnologías de la Información y Comunicación en los Hogares de la Comunidad de Madrid. TIC-H(2019a)"* 94.5% of the homes in this community had access to internet, and it is also in second place in the province of Madrid, in terms of internet users with 94.1% of people connected (Instituto Nacional de Estadística, 2019b).

In addition to this, a digital transformation has been developed in various areas of the urban structure of Madrid, with transport being one of the main ones by focusing its attention on four lines of action. The traveler´s experience, security, intelligent platforms and routes (automating a wide variety of services, and offering digitally information related to trips, waiting times, routes, etc.) and finally from the line of environmental impact, addressing urban space management strategies to reduce congestion and environmental pollution (Public Sector Observatory, 2018).

3.2. Description and data

Our analysis was performed using indicators from the municipality of Madrid, created according to the urban and digital characteristics of the study area, and classified into six groups as shown in Table 1.

VARIABLES			
GROUPS	**VARIABLE**	**No.**	**UNIT**
1.- Socio-demographic variables	Housing Density	**1**	(Inhab / dw)
	Employment Density	**2**	(Inhab/Emp)
	% of population without education	**3**	%
	% of population with "University Studies"	**4**	%
	% of population dedicated to the "Industry" sector	**5**	%
	% of population dedicated to the "Construction" sector	**6**	%
	% of population dedicated to the "Services" sector	**7**	%
	Housing rental levels by neighborhood	**8**	(Euros /m2)
	Housing price levels by neighborhood	**9**	(Euros /m2)
2.- Diversity Variables	Youth Index	**10**	Index
	Ageing Index	**11**	Index
	Index: Structure of the working population	**12**	Index
	Shannon Diversity Index	**13**	Index
3.- Design and urban structure variables	Density of public transport stops and stations	**14**	(Stops/1000inhab)
	Proximity of the population to public transport stops (bus, metro, suburban)	**15**	Distancia
	% of land use dedicated to "Residential"	**16**	%
	% of land use dedicated to "Green areas"	**17**	%
	% of land use dedicated to "Tertiary services"	**18**	%
	% of land use dedicated to roads (streets and sidewalks)	**19**	%
	Number of intersections per unit of analysis	**20**	No.
	Density of intersections per neighborhood	**21**	Intersec./1000inhab
4.- Physical commerce variables	Density of basic physical stores	**22**	Physical stores/1000inhab
	Proximity of the population to physical commercial activities of daily use	**23**	Distance
	Number of shopping centers per unit of analysis	**24**	No.
	Number of municipal markets per unit of analysis	**25**	No.
	Number of supermarkets per unit of analysis	**26**	No.
	Density of supermarkets per unit of analysis	**27**	Superm/1000 inhab
5.- Information society variables	Density of electronic mailboxes	**28**	Elec. Mail./1000 inhab
	Density of Free Public Wifi Points	**29**	(F.W.P. / 1000 inhab)
	Density of Commercial Public Wifi Points	**30**	(W.P.C./1000 inhab)
	Proximity of the population to electronic mailboxes	**31**	Distance
	Proximity of the population to free public wifi points per unit of analysis	**32**	Distance
	Proximity of the population to public wifi points of stores per unit of analysis	**33**	Distance
	Number of electronic mailboxes per analysis unit	**34**	No.
	Number of points with free public wifi per unit of analysis	**35**	No.
	Number of points with public wifi of stores per unit of analysis	**36**	No.
6.- Location variables	Distance to the centroid	**1**	Distance
	District of belonging	**2**	No.
	Geographic coordinates	**3**	Coordinates
	Cluster of belonging	**4**	No.

Table 1. - Variables

These variables were developed using the 131 neighborhoods in the 21 districts in the municipality of Madrid shown in Figure 1 as units of analysis. They were obtained with the help of different official databses, as well as various digital platforms (NOMECALLES, NavegaPorMadrid, GoogleMaps, QGis, etc.), websites of official national agencies or of the Madrid regional government (INE, website of the Madrid City Council and the Madrid Transport Consortium, the open data portal of the Municipality of Madrid, etc.), websites of stores, parcel services, supermarkets, tourism, digital services, among other sources.

A data based urban characterization model was applied through factor analysis (FA) and cluster analysis. This methodology without spatial contiguity parameters has been previously tested in several studies focused on urban structure and metropolitan phenomena (Jacques & El-Geneidy, 2014; Martori & Hoberg, 2008; Piron et al., 2004; Santos P., 1991; Song & Knaap, 2007; Thinh et al., 2002; Thomas et al., 2007; Yeh et al., 1995). Including criteria of contiguity and spatial constraints some of them, mainly focused on the analysis of the housing market (Bates, 2006; Bourassa et al., 2007; Clapp & Wang, 2006; Tu et al., 2007; Wilhelmsson, 2004).

4. RESULTS

4.1. Factorial analysis (FA)

The application of FA allowed seven factors to be extracted that can reproduce approximately 71% of the total variation of our original 36 variables, given their scores. Principal component analysis was used for factor extraction. Varimax with Kaiser Normalization was applied as the rotation method in the analysis, as this combination explains the greatest variation in the data by maximizing the loading squared for each component (Campos, Pitombo, Delhomme & Quintanilla, 2020; Khan, Ahmad & Bano, 2020; Wu & Sharma, 2012).

The results of the FA are shown in Table 2, where the variables are listed in the order of magnitude of their factor loadings sequentially for each factor. This shows the seven dimensions (factors) of the attributes originally proposed (socio-demographic, diversity, information society, etc.) resulting from the analysis.

The first factor reflects the dimension “*Information Society: Proximity and distribution of equipment*”. It mainly highlights the variables of the information society and then, those related to public urban equipment’s. The high correlation between ICT variables and public equipment’s (public transportation stops and physical commerce) is a clear indicator that there aren´t physical barriers that interfere with the user´s choice to make purchases and develop activities in a traditional way or using digital media.

The second factor includes variables of "*Diversity and surplus value of urban areas*", with high positive loads existing among the variables related to the cost of renting, the indices of the active population and of Shannon´s diversity.

The third factor reflects the "*Socioeconomic*" level. High positive loads among the variables: percentage of population with university studies (PPUNS) and housing costs per m^2, and high negative loads in the variables: percentage of population without studies (PPWS), percentage of population dedicated to the service sector (PPSS) and employment density.
The fourth factor is related to the variables of "*Density of urban and digital equipment*". Maintaining high positive loads between the density of physical commerce, density of wifi points in stores (WPC), density of supermarkets and density of public transport stops (DPTS). Thus corroborating the capacity of this factor to represent aspects related to the public equipment's in the analysis units.

Table 2. - Matrix of components/factors

The fifth factor incorporates variables of “*Digital Society as a function of Land Use*”, keeping mainly high factorial loads between the number and density of free wifi poins (FWP) and the percentage of land use dedicated to green areas (PLUGA). Highligthing the capacity of this factor to cover information regarding the sites where there is greater possibility of finding FWP according to the type of land use present in each unit of analysis.

The sixth factor reflects interesting parameters among the variables related to “*Online Shopping vs employment density*”. With high positive factorial loads among the variables: number and density of electronic mailboxes, and relatively high negative factorial load with the variable employment density.

Finally, the seventh factor includes variables related to the “*Structure of the population*”. Having high positive factorial loads between the youd index and the land use dedicated to services, with a high negative factorial load focused on the aging index. This allows us to differentiate the areas where the young population predominates, and in which of them, on the contrary, there is an aging population structure.

4.2. Cluster analysis (CA)

One of the main objectives of the research is to understand the dimension, variation and influence of the characteristics described in the previous factors incorporating spatial restrictions. It was therefore necessary to identify the optimal number of groups in which to incorporate our units of analysis. However, due to the lack of previous studies specific to the metropolitan area under the characteristics considered, a hierarchical cluster analysis was used to determine the appropriate k-value (number of groups).

With the factors extracted in FA, the variables of spatial constraints and the number of cluster (k-value) defined, six k-means cluster analysis (CA K-means) with 125 units of analysis were performed. To form clusters with the influence of spatial contiguity from smallest to largest measure, a sequence of incorporation of spatial constraints variables was assigned for each cluster analysis.

Table 3 shows the number of cases grouped in the clusters formed. It was observed that the number of cases is more homogeneously distributed in the clusters with a greater number of spatial constraints variables.

The results were reviewed to select the optimal classification method according to the objective of the study. The result was that Group V, comprising seven FA factors and four spatial constraint variables, is the cluster that best defines the structure of the metropolitan area of the municipality of Madrid according to the characteristics considered (Fig. 2).

Clúster #	**7 Factors** **Group I**	**7 Factors +** **1 Var. Restriction** **Group II**	**7 Factors +** **2 Var. Restriction** **Group III**	**7 Factors +** **3 Var. Table 3. - K-means cluster analysis (K = 5)

The map represents the 131 units of analysis (Fig. 2). Except for the atypical cases that make up cluster six, the formation of homogenous sub-groups can be seen with units that maintain a contiguous boundary with another unit belonging to the same group, or at least have a location close to the subgroup. Achieving with this, an adequate level of spatial integrity and a balance between the location parameters used, the characteristics of urban structure and the variables of digital society considered (Table 4).

Fig. 2. - Group V – 4 Spatial constraints variables (Best grouping)

CLUSTER´S	
CLUSTER	**Main features**
1	Central zone with ederly population
	High ICT services (electronic mailboxes, Wifi Points Commerce)
	High urban services (public transport stops, basic retail outlets, municipal markets)
	High rent and housing cost and high socioeconomic level
	High percentage of population with university studies
	Shorter travel distances to access digital society services
	Lower number of free wifi points.
2	Northeast zone with young population
	High number of electronic mailboxes
	Low density of public services and low active population and Shannon diversity indices
3	Mixed zone with High percentage of land use dedicated to green areas
	High number of free wifi points
	Longer travel distances to acces digital society services
	Structure population is mainly young
	Electronic mailboxes is relatively low
4	Southwest zone with low socioeconomic level and ederly population
	Minimum density of urban and digital services
	Low quantity of electronic mailboxes
	Low rental and housing costs with high percentage of population without studies (PPWS)
5	Peripheral zone to the center with few free wifi points and green areas
	Low density of urban and digital services
	Relatively low travel distances to access digital society services
	Above-average diversity and surplus value according to the high values of the Shannon and active population indices.
	High rental and housing costs.
6	These units are that they are located on the periphery of the study area,
	Urbanized land of less than 50%, few public and digital amenities

Table 4. - Clusters formed

5. CONCLUSIONS

The multivariate and spatial analysis developed allowed the identification of the typologies existing in the metropolitan area of Madrid based on sociodemographic, socioeconomic, urban structure and diversity criteria, and specifically relating to the digital society. A classification methodology was successfully developed with two levels of spatial restrictions: the first was incorporated into the FA, where it reduced the dimension of 36 attributes in seven factors that explained over 70% of the total data; and the second involved four more contiguity variables that were gradually incorporated in the cluster analysis.

The results suggest that 125 of the 131 units of analysis considered can be assigned to one of the five typologies, while the six remaining units were classified in a specific group of atypical cases due to their extreme characteristics. The largest group comprises 43 units of analysis (Cluster 4) and includes neighborhoods with a low socioeconomic level, minimum density of urban and digital services, and a relatively low number of electronic mailboxes, meaning that they have limited access to both physical and online shopping.

The second largest group consisted of 32 units of analysis (Cluster 1) located in the central zone. They have an elderly population and a high level of digital and urban services, with the shortest distances to these facilities. The third largest cluster comprises 27 units of analysis (Cluster 5), and contains the neighborhoods with a low density of urban and digital services located on the periphery of the central zone, thus maintaining a significant diversity and surplus value with high rental and housing costs and a representative number of Wi-Fi point commerce (WPC).

The fourth (Cluster 2) and fifth (Cluster 3) clusters in order of size included 16 and 7 units of analysis respectively. Cluster 2 contains neighborhoods with a young population structure, a high number of electronic mailboxes and low densities of public amenities, while Cluster 3 is a mixed zone with extensive green areas and free Wi-Fi points (FWP), and a low proportion of housing areas.

Although the central area is closer to digital society services, this is not the area with the most digital public amenities; these are cluster 3 and 2, which have a greater number of FWP in relation to the population. Likewise, cluster 2 and 5, despite not having an high number of electronic mailboxes like other groups, maintain a considerable proportion of these facilities, pointing to the importance of online shopping in these areas, even though Group 5 has a mainly elderly population and Group 2 has a high percentage of population without studies (PPWS).

The results show the potential usefulness of obtaining a classification of urban areas using attributes of urban complexity, with spatial limits and restrictions that do not significantly affect the quality of the data, and of measuring this complexity through the structure and services of the areas analyzed. This characterization also offers a detailed view of how digital society attributes strongly influence cities, and how these indicators are capable of modifying urban structures, the inhabitants’ activities and behavior, and the general development of the urban form.

Public and private organizations can use classifications of this kind to carry out/adapt urban development plans and identify specific urban areas. This methodology can also be updated for various periods with current information, or with data from previous years to provide knowledge of the urban structure in specific years. As mentioned by Song & Knaap (2007), these classifications can be used in regression analysis to select sampling strategies, for the specific design of urban areas, and to measure progress in the implementation of urban development plans that incorporate information society criteria.

ABSTRACT

As data quality and quantity increase, the prediction of future events using machine learning (ML) techniques across engineering disciplines grows by the day. Air transportation cannot be an exception. Delay prediction is paramount in the aerospace industry, since air traffic delays are responsible for millions of dollars in losses to airlines and passengers, along with negative impacts on the environment. In this contribution, we leverage recent signal processing and ML advances to put forth a processing-and-learning pipeline for the prediction of air traffic delays. The proposed approach is executed in several steps. Firstly, we apply signal processing and data science techniques to filter and denoise the original information. Secondly, we run a descriptive analysis of the data and design new features tailored to the prediction problem. Thirdly, we implement a scheme to select the most informative of those features, contributing to a better generalization performance, and offering useful insights. Two algorithms are used to that end: one based on random forests and one employing a sparse logistic regression approach. Finally, once the features are selected, we implement, analyse, and compare several ML architectures (from classical classifiers to deep learning) to predict the delay. While the focus of the comparison is prediction accuracy, metrics such as sample and computational complexity are also discussed. Numerical experiments are drawn from the US domestic market for the year 2018, when more than 7 million flights between 358 airports were flown. The designed processing/learning pipeline reveals interesting insights and achieves better prediction results than the state of the art. The results confirm that air traffic delay prediction is a challenging problem, mainly because the delay is extremely airport-dependent and the data is highly unbalanced (i.e., only a small percentage of flights are noticeable delayed), and identify worth-pursuing future lines of work.

1. INTRODUCTION

During the year 2018, 46.1 million flights were operated in the world, with more than 4.4 billion passengers being transported (The International Air Transport Association (IATA), 2020), which represents 3.5% more flights and 6.4% more passengers than during the previous year. More importantly, traffic predictions for the next decade foresee that the growth of traffic will persist, further stressing the air traffic system and challenging its efficient operation. With these numbers in mind, and given the role that the aerospace system plays in our lives, initiatives targeted at a more efficient operation of the system can generate remarkable social and economic benefits. A particularly challenging aspect is that of air traffic delays. To illustrate the importance of this point, let us focus on the US domestic market. During 2018, the 7 million domestic flights connecting US cities experienced an average delay of 9.9 minutes, yielding an aggregated delay of more than 133 years. According to Eurocontrol, each minute of delay costs more than 100€ to the system (Mulligan, 2019), including all the stakeholders. The Federal Aviation Administration (FAA) and the Nextor consortium in the US estimated the delay cost to be greater than 28 billion dollars in 2018 (Airlines for America, 2019). From this point of view, being able to predict air traffic delays before they take place would provide substantial benefits in the context of daily operations. Although the costs associated with delays would not be fully eliminated, airlines could probably mitigate them by taking proactive actions, such as rescheduling or cancelling some flights in advance.

Using past and current information to predict future flight delays is, however, not an easy task. Precise mathematical models describing the delay dynamics are to be had, the available information is noisy and oftentimes incomplete, and the historic delays seem to depend heavily on the particular airport and time of the year. Hence, rather than pursuing a model-based approach, this paper puts forth a data-based approach that combines recent advances in signal processing (SP) and machine learning (ML) to address the problem of air traffic prediction using historical information. In recent years, ML and artificial intelligence algorithms have excelled in a number of engineering problems (from image recognition to language processing) beating the state of the art in areas where well-established model-based approaches had been used for decades, and providing a feasible alternative in areas where model-based designs were inexistent or poorly accurate.

The approach implemented in this paper proceeds in three steps. In the first step, we design SP and ML algorithms to identify, aggregate and extract relevant features from a database containing past information about air traffic delays. In the second step, we use the output of step 1, together with information of actual flight delays, to train different supervised ML architectures. The third step consists in using the trained ML architectures to predict current delays. The final goal is threefold: 1) providing a delay prediction accuracy that beats the state of the art, 2) testing and comparing a broad range of ML architectures that exploit different levels of information structure, and 3) gaining insights on the key factors and trade-offs that govern the problem of air-traffic delay prediction.

The number of works dealing with the prediction of air traffic delays is limited, which is likely a testament to the complexity of the problem. To the best of our knowledge, Rebollo (2012) was the first publication that addressed the problem of flight delay prediction over origin-destination (OD) pairs using ML algorithms, a problem further explored in Rebollo & Balakrishnan (2014), Hanley (2015), and Gopalakrishnan & Balakrishnan (2017). These works recast the delay prediction as a binary classification task, so that the problem reduces to estimating if the delay is going to be below or over a given threshold in a specific OD pair. Addressing the delay prediction as a decision task, which is also our approach, brings a number of advantages, but it also generates some challenges, being the so-called "unbalance" between the positive class (i.e., flights where delay exists) and the negative class (i.e., flights where delay does not occur) the most challenging one (see Section 4 for details). Regarding the ML architecture to predict the delay, those works rely mostly on decision trees (DT) and Random Forest (RF) classification algorithms, with Gopalakrishnan & Balakrishnan (2017) exploring other architectures and concluding that the best results were achieved by Neural Networks (NNs).

Relative to those works, our contributions are the following. Firstly, we predict not only delays at OD pairs but also at airports. Secondly, we implement several SP and data-science techniques for pre-processing the raw data, extracting relevant knowledge, and designing new features to serve as input to the classification problem. Thirdly, we design a problem-tailored feature-selection scheme to identify the most relevant features. Fourthly, we employ a range of (classical and modern) ML algorithms to address the classification, comparing pros and cons, and assessing their accuracy and computational complexity. Finally, we consider rebalancing training techniques to counteract the severe lack of balance present in the dataset. Regarding the ML algorithms implemented, it is also important to remark that some of the proposed architectures account for the specific structure of the data at hand, namely its temporal variation by using Long-Short Term Memory (LSTM) networks (Hochreiter & Schmidhuber, 1997), and the topology of the air-traffic network (specifically, the graph connecting the different airports) by using Graph Convolutional Neural Networks (GCNN) (Gama et al., 2019). Our numerical tests, which are based on the US domestic market for the year 2018, reveal that the proposed processing and learning pipeline yields a better prediction performance -namely better precision, recall and f1-score (Geron, 2017)-, than that achieved by the state-of-the-art air-traffic delay prediction algorithms.

Section 2 details the problem to solve and introduces notation. Section 3 designs the schemes to select the most relevant variables for the prediction. Section 4 describes the ML architectures and assesses their delay prediction performance.

2. PROBLEM DESCRIPTION, DATASET, AND DELAY-SIGNAL GENERATION

Given a planned (departure or arrival) time, the delay of a flight is defined as the difference between the originally planned time and the actual time when the event happens, namely the departure or the arrival. Air traffic delay can be due to different causes that may be grouped in five categories (US Department of Transportation, 2020) corresponding to delays caused by: a) the airline carrier, or circumstances under the control of the airline; b) elements in the National Aerospace System (NAS) (airport operations, high traffic, etc.); c) other flights arriving late and thus making the plane that must operate the flight unavailable; d) severe weather conditions; and e) security reasons. Clearly, the effects of a particular delay have impacts beyond the time and element for which the delay first takes place and, hence, the entire network must be considered.

The air transportation network may be regarded as a system composed of different elements, including airports and OD pairs. We will use E to denote the set of elements of interest (i.e., either the set of airports or the set of OD pairs), e to denote a generic element of E, and G to denote a graph capturing the connections between the elements in E. Rather than predicting the delay of a particular flight, our focus is on predicting the aggregated (average) delay experienced by a particular network element e (airport or OD pair) and a particular time t'. To be more specific, let $d(e,t)$ denote the delay that element e is experiencing at time t. Then, we aim at designing ML architectures that, after properly trained, at time t use as input global network information and the values of $d(e,\tau)$ for $\tau \leq t$ to predict if $d(e,t')$, the delay of element e at time $t'=t+h$, will be greater than a prespecified threshold δ. Hence, $h>0$ can be viewed as the horizon of the prediction (typically between 2 and 6 hours) and $d(e,t')\geq\delta$ (with the delay threshold δ typically set to 60 minutes) as the condition to trigger the delay alarm.

Note that $d(e,t)$, which constitutes the essential piece of information of our model, can be viewed as a spatiotemporal signal that varies both across time and across the nodes of the network graph G. Regarding the construction of G, when dealing with the "airports graph", we consider two nodes to be connected by an edge if there is any flight between them. When the nodes of G represent OD pairs, we use as graph G the line graph associated with the graph of airports; see Harary (1972) for details on the definition of a line graph. From this "delay-signal" point of view, one can reasonably expect $d(e,t_1)$ and $d(e,t_2)$ to be close if the difference between t_1 and t_2 is small, and $d(e_1,t)$ and $d(e_2,t)$ to be related if e_1 and e_2 are neighbouring nodes. Last but not least, we will handle (and predict) arrival and departure delays separately, since their causes can be different. However, to simplify the discussion and notation, in the following sections we will generically refer to a single type of delay.

Dataset: To train and test our architectures we use a database provided by the Bureau of Transportation Statistics from the US Department of Transportation, whose website publishes data for different means of transport in the US. Our focus is on the database for domestic flights, whose entries provide information for individual flights, including scheduled and actual departure and arrival times, origin and destination airports, delays and their categories, deviations, and cancellations. For 2018 only, this database features more than 6,000 OD pairs, 358 airports, and more than 7 million flights.

Pre-processing: One-third of the OD pairs show a frequency lower than 1 flight per day. These samples add computational complexity, without providing meaningful (generalizable) knowledge for a data-based delay-prediction approach, hence we only consider airports and OD pairs featuring more than 10 flights per day on average. Also, we remove cancelled flights, as we consider that they do not exhibit a causal relationship with the considered variables (departure and arrival times, delay, etc.).

Definition of the state signal $d(e,t)$: Time is slotted into one-hour intervals, with t denoting the slot index. Inspired by Rebollo (2012), the process to obtain $d(e,t)$ is as follows. For each hour t (say 3PM of Today), we consider a 120-minutes window that considers the previous and current hour (i.e., from 2:00PM to 3:59PM). Furthermore, let $F_{(e,t)}$ denote the subset of flights that took place within the 120-minutes window around t and involved element e. Then, the value of $d(e,t)$ is simply defined as the average of the delay experienced by the flights in $F_{(e,t)}$. Following this procedure, we obtain a first version of the signal $d(e,t)$ for all e and t. However, there are instances of (e,t) for which there was no flight within the considered two-hour interval (i.e., $F_{(e,t)}$ was empty) and, hence, the value of $d(e,t)$ is not defined. To deal with those, we implemented the following approach: if the number of consecutive hours where $d(e,t)$ is not defined is less than six, then we set $d(e,t)$ using linear interpolation based on the values of $d(e,t')$ for $|t-t'| < 6$. If the number of consecutive empty windows is larger than six, we do not consider $d(e,t')$ with $|t-t'| \geq 6$ to be informative and set $d(e,t)$ to zero, which is considered as the default delay value.

3. DESIGNING THE INPUT VARIABLES

This section details the design and selection of variables that will be used as input for our classification algorithms. This is an important issue oftentimes overlooked. For a data-based approach to succeed in the context of air-traffic delay prediction, a balance between the number of data points (samples) in the dataset and the dimensionality and complexity of the input variables needs to be reached. ML architectures that use the raw data as input will require many more training samples than those that use a reduced dimensionality (possibly quantized) representation of the data where relevant knowledge has been extracted. We split this design into two steps. Firstly, we extract (create) new variables from the dataset. Secondly, we implement a feature selection scheme to identify the subset of the most relevant variables for the prediction problem.

The input variables are split into two groups: time variables (hour, day, month, and year) and network delay-state variables (aggregating/encapsulating delays of one or several (e,t) pairs). When running a descriptive analysis of the data, we observe a seasonality pattern on the delays. For that reason, we generated a new categorical variable ***"season"***, which takes three values: low (September to November), medium (January to May) and high (June to August, and December). Similarly, to account for the congestion of the overall network we define two new variables: one accounting for the network delay in the last hour and another one accounting for the network delay in the last 24 hours. Rather than using an average across elements of the network, we rely on a (K-Means) clustering algorithm to split the delay levels into (six) different groups and use those to define a ***"network delay congestion index"*** for each hour and day. Lastly, when modelling the delay in an element *e*, it is reasonable to assume that the delay experienced by the neighbours of *e* is relevant. Since considering the delay of each of the neighbours can lead to a very high dimensional signal, we define a continuous variable that, for every (*e*,*t*) pair, aggregates (sums) the value of the delays *d*(*e'*,*t*) for all elements *e'* that, according to the graph *G*, are neighbours of *e*. Moreover, since the relation between delays of neighbouring nodes seems to depend strongly on the particular cause generating the delay, we define 5 different ***"neighbour-aggregated delay variables"***, each of them associated with one of the 5 causes of delay listed at the beginning of Section 2.

The information of the dataset with the addition of the variables described above yields more than a thousand input features (variables) for our classifier. Since this large number challenges learning and incurs a high computational-complexity cost, we put forth a feature-selection mechanism to identify the most informative variables. Two options are considered: one based on RF techniques and one based on lasso-regularized logistic regression (LR); see (Hastie et al., 2009). While not implemented in the context of air-traffic delay prediction, these two feature-selection techniques have been recently used in a number of ML approaches. The variable selection is carried out based on a "level of information" that depends on the effect/usefulness of the variable on the delay to be predicted. This guarantees that the fact of the goal being delay prediction is accounted for when running the proposed feature-selection mechanism.

The selection is run only for network-delay state variables (time variables are deemed informative, and their number is small, hence, they are preserved); it is carried out separately for each element of the network (delays seem to depend heavily on the airport, so we do not want to force the selected variables to be the same across the entire network); and it proceeds in two steps. Firstly, we run a single-shot selection step, where we reduce the number of features to 100. Secondly, we further reduce those 100 features to 10. That is achieved by running $I=10$ different instances of the feature selection algorithm. Each of those instances identifies the 10 most important variables, and the ones we finally select correspond to the 10 most important ones obtained after averaging the results across the $I=10$ instances.

As an illustration of the feature selection results, Figure 1 shows the selected variables by the two algorithms for the "O'Hare (ORD) to LaGuardia (LGA)" OD pair, which is the route with the highest number of flights. As we can see, the two methods assign the highest importance value to the NAS delay in the neighbours. They also assign a high importance to the current departure delay of the ORD-LGA pair (the one under analysis) and LGA-ORD. The arrival delay variable in ORD airport is also selected by both algorithms, with the remaining ones being different. Analysing these differences is certainly meaningful but beyond the scope and page limits of this paper.

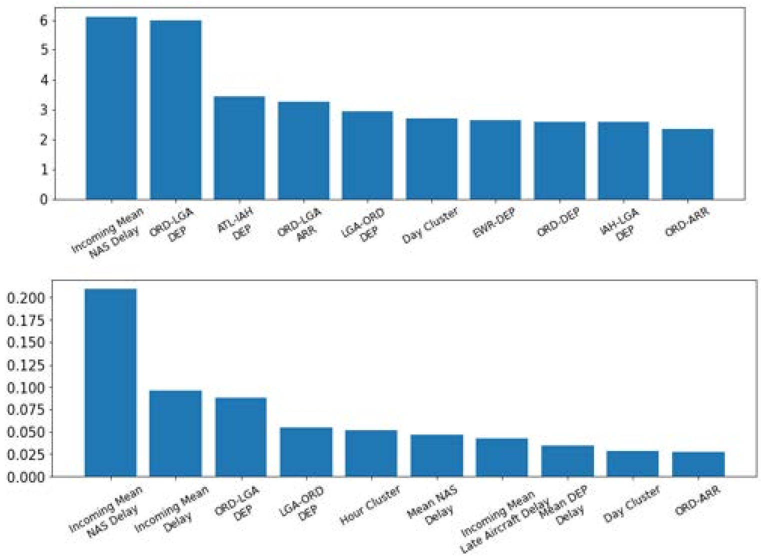

Figure 1: Features selected by the RF (top) and LR (bottom) schemes. The x-axis represents the selected features and the y-axis the "information level" given by the scheme.

4. ML ARCHITECTURES, TRAINING, AND TESTING RESULTS

Let x and y denote, respectively, the input and output variables of our classifier. The input x is a vector with as many dimensions as input features and y is a binary $\{0,1\}$ number. Suppose that: a) $\mathcal{T} = \{x^s, y^s\}_{s=1}^{S}$, where s denotes a sample index, is the set of training samples and b) $f(x|\theta) \rightarrow y$ is the input-output mapping implemented by a (nonlinear) parametric ML architecture whose parameters are collected in θ. The approach in a supervised ML setting is to use $\mathcal{T}$ to estimate $\hat{\theta}$, the value of θ, and then use the (learned) function $f(\cdot\,|\hat{\theta})$ to estimate the output associated with inputs x not included in $\mathcal{T}$ as $\hat{y} = f(x|\hat{\theta})$.

Recall that, at time t, our goal is to predict if $d(e,t+h)$, the delay of element e at time $t'=t+h$, will be greater than a prespecified threshold δ. The approach that we put forth to achieve that is to: i) train a different classifier per element e (so that the parameters can depend on the airport or OD-pair); ii) use as input the features described in Section 3; and iii) try a range of architectures defined in more detail soon. For the results presented in this paper, we set the prediction horizon to $h=2$ hours (so that time correlation is likely to exist, and companies have sufficient time to take mitigating actions) and the delay threshold to $\delta=60$ minutes (so that the incurred delay is meaningful). By recasting the prediction of a continuous variable as the prediction of a (quantized) binary version of it, the complexity of the output is reduced, rendering data-based learning more likely. The main drawback associated with this approach is that, for most (e,t) pairs, the associated output label is zero. That is, for the vast majority of the samples the network is not saturated and the continuous delay is less than 60 minutes.

The next step is to describe how the training of the ML architectures is carried out. The two key aspects are i) the definition of the training set and ii) how to deal with the unbalancing of the labelled data. Regarding the first aspect, we use the data of the US domestic market from the year 2018 to train, and test the results using the data from January 2019. More specifically, if the focus is on predicting the delay for the element e, we: i) select the samples of the dataset related to e; ii) compute the features introduced in Section 3; iii) associate each input sample with the corresponding value $d(e,t+h)$; iv) remove all the samples for which $d(e,t+h)$ is exactly 0 minutes; and v) compute the binary label y associated with the input by checking if $d(e,t+h)\geq\delta$. The reason for iv) is threefold: 1) many of those samples correspond to cases where $d(e,t+h)$ was not defined and set to zero, 2) if $d(e,t+h)$ was an actual measurement, an exactly zero value represents a stress-free scenario were predictable 1-hour delays are very unlikely to take place, and 3) it contributes to balance the dataset, reducing the number of samples whose label is $y=0$. Indeed, the second aspect to be handled is the lack of balance in the data. A descriptive analysis of the dataset reveals that 97% of the samples satisfy $d(e,t)<\delta$, so that the associated label y is zero. This is a significant challenge because it means that a (useless) classifier that always predicts zero and misses all the delays would have an accuracy of 97%, likely beating all other classifiers that try to find a balance between false alarm and miss detection errors. Indeed, if accuracy is the metric chosen to train the ML architectures and the original data is used as the training set, then the optimal ML classifiers always yield a zero prediction. To bypass this problem, we use an *undersampling and oversampling balancing approach* during the training phase (Chawla, 2010). More specifically, we train the ML architectures using 3,000 samples but, rather than choosing them uniformly at random from $\mathcal{T}$, which is the standard approach in balanced setups and in our case would yield 90 samples with $y=1$ and 2,910 with $y=0$ on average, we pick the samples as follows. We split $\mathcal{T}$ into two subsets, from the subset with $y=0$ we pick 1,500 samples uniformly at random and from the subset with $y=1$ (which contains less than 1,500 samples), we build a larger set with synthetic copies of the original samples (to obtain a set with more than 1,500 samples) and then pick 1,500 of those “original and synthetic” samples with $y=1$ uniformly at random. This *undersampling and oversampling* approach balances the data and exposes the classifiers to a large number of samples where delay took place, so that they are able to learn the patterns in the input data that are related to those events. To render the learning process more robust and less sensitive to the subset design, we construct 10 instances of $\mathcal{T}$, train the classifiers for each instance, and average the results.

ML architectures: To tackle the classification task, we consider eight different ML architectures. Six of them correspond to “traditional” classification algorithms with an increasing level of complexity: LR, DT, RF, K-Nearest Neighbours (KNN), Gradient

Boosting Trees (GBT), and Multi-Layer Perceptrons (MLP) (Hastie et al., 2009). The other two are more advanced classification architectures that account explicitly for the domain structure of the delay signal $d(e,t)$, either its time structure (using an LSTM-based classifier) or its graph structure (GCNN-based classifier).

Prediction results over the testing dataset: Once the architectures have been trained and the corresponding (element-and-architecture dependent) parameters $\hat{\theta}$ have been learned, we assess the classification performance using the data on the test set (January 2019). Let N_{ab} be the number of samples where the predicted output is $\hat{y} = a$ and the actual label was $y = b$, and note that, for binary classification, the cardinality of $\{N_{ab}\}$ is 4. Based on those values, we report the classification performance of each of the trained architectures using the following metrics: accuracy $Acc=(N_{00}+N_{11})/(N_{00}+N_{01}+N_{10}+N_{11})$, precision $Prec= N_{11}/(N_{11}+N_{10})$, recall $Rec=N_{11}/(N_{11}+N_{01})$, and f1-score $F1=2 \cdot Prec \cdot Rec/(Prec+Rec)$.

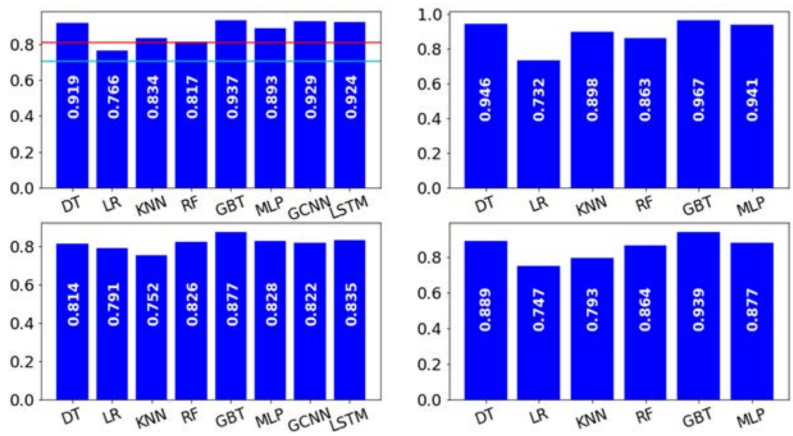

Figure 2: Comparison of the accuracy for OD Pairs (on the left) and airports (on the right), using balanced (on the top) and unbalanced (on the bottom) data.

Figure 2 shows the classification accuracy of our ML architectures both for the prediction of delays on OD-pairs (two panels on the left) and airport delays (two on the right), using balanced (top) and unbalanced (bottom) testing data. To facilitate comparisons with the state of the art, the results in Figure 2 only consider the 100 most delayed airports and the figures correspond to the averages across all the elements in the network. In addition to the results of our architecture, the top-left panel shows two horizontal lines: the red line corresponds to the accuracy of the approach in Rebollo & Balakrishnan (2014) and the blue one to that in Gopalakrishnan & Balakrishnan (2017). To keep the comparison fair, these two lines are not shown in the other panels because the state of the art addressed neither predicting airport delays nor testing on unbalanced data. The main observations are as follows: 1) The accuracy levels are relatively high but, as expected, below the 97% level achieved by the dummy all-zero classifier. 2) Our architectures (7 out of 8) beat the state of the art, in some cases by more than 10%. Since some of our classifiers are fairly simple, this outperformance confirms the importance of the pre-processing steps. 3) Predicting delays at airports is easier than at

OD pairs. 4) The results deteriorate when (actual) unbalanced testing sets are used. 5) Classifiers with a higher degree of sophistication seem to give rise to better results at the price of a higher computational and training complexity (which is the reason for not reporting the results of the GCNN and LSTM algorithms in plots on the right).

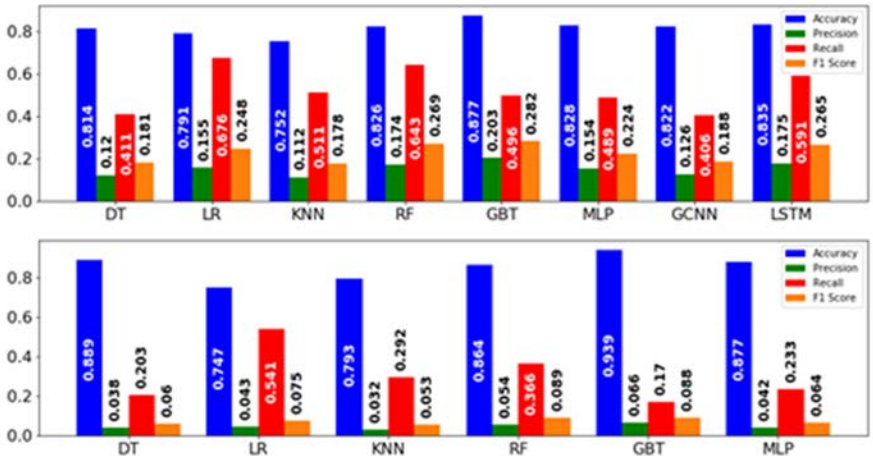

Figure 3: Accuracy, precision, recall, and f1-score for OD pairs (top) and airports (bottom) using unbalanced test data.

The reason for reporting accuracy was to establish a fair comparison with the state of the art. However, as already discussed, in unbalanced classification setups, accuracy must be complemented with precision, recall and f1-score metrics, with the last one being typically used as the main figure of merit to analyse. Figure 3 reports the four metrics for OD pairs (top) and airports (bottom) for our architectures using unbalanced test data. We observe that the results are noticeably worse, confirming that: a) most of the accuracy observed was due to the “trivial” prediction of non-delay scenarios and b) as expected, early prediction of a significant percentage of future delays based on present and past data is a challenging task. Interestingly, the results also show that better precision/recall/f1-score are obtained for OD pairs, suggesting that the higher accuracy in predicting delays at the airport level was associated with a larger number of zero labels. Regarding the ML architectures, the highest recall is achieved by the simple LR algorithm. However, the highest f1-score (which is typically viewed as the most important classification performance indicator) is achieved by the GBT, with RF and LSTM also showing a good performance.

To gain further insights, Figure 4 reports classification results in two additional scenarios dealing with OD-pairs and unbalanced test data. In the first scenario (top panel) we constrain the prediction to the 25 busiest OD-pairs (largest number of flights). The motivation here is to focus on elements with more data and, also, a higher likelihood of a delay, to check if under those conditions, learning from past and previous data is more feasible. The second one corresponds to a classifier that proceeds in two steps. In the first step if $d(e,t)=0$ the “deterministic” prediction is that $d(e,t')<\delta$ and, hence, that $y=0$. If $d(e,t)>0$, we then use the output of the ML classifier as the predicted y. Note that, under this approach, $\mathcal{T}$ needs to be modified accordingly, so that all the training samples whose input contains *d(e,t)=0* are removed. The idea behind this scenario is to identify the "trivial cases" first and then let the classifier focus on the non-trivial ones. The results corroborate that in both cases, the accuracy and, most importantly, the f1-score improve, suggesting that our intuition was correct and motivating further research of "hierarchical" classifiers that focus on the elements where delay is more likely and more data exists.

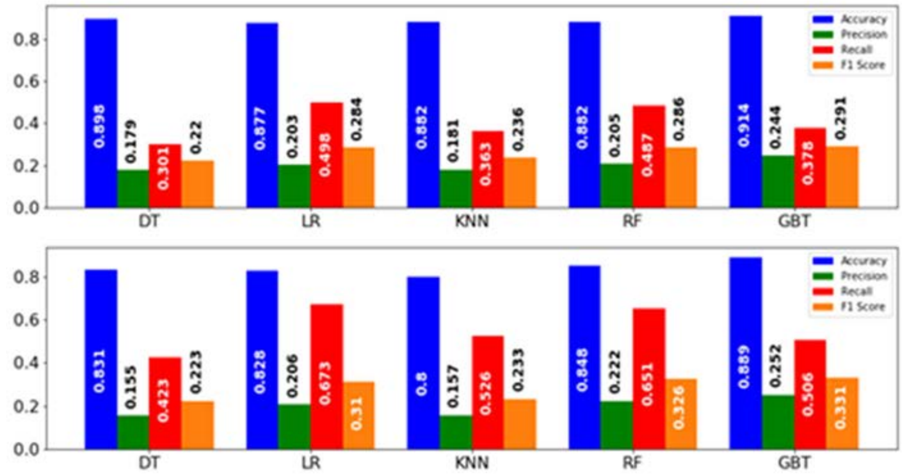

Figure 4: Accuracy, precision, recall, and f1-score for OD pairs using unbalanced test data for two additional scenarios (top and bottom). See the main text for additional details.

5. CONCLUSIONS

We put forth a data-based processing and learning pipeline to predict the delays in an air transportation network. Key novelties of our approach included the prediction of the delay not only across OD pairs but also across airports, the consideration of feature selection schemes, accounting for the (graph) structure of the network and the correlation of the delays across time, and the incorporation of rebalancing schemes to foster recall and precision performance. Our schemes were trained and tested using real data from the US domestic market in 2018 and 2019. The results outperformed the state of the art by more than 10% and confirmed that air-traffic delay is an inherently complex problem. Future research includes the prediction of delays for individual flights along with the implementation of network-segmentation schemes that enable tailoring the prediction to segments of the air transportation network that exhibit related delay dynamics.

ABSTRACT

It is well known that one of the most efficient ways of moving goods is the combination of two freight transport systems, rail and road. The purpose of this study is to evaluate factors that affect the competitiveness of intermodal rail-road transport (IRRT). Previous research has focused on the definition of a multi-criteria framework to identify and prioritize the determining factors. However, the assessments have been done before the coronavirus pandemic, but after the quarantine and post-quarantine period of the virus, the prioritization of these criteria has definitely changed in the view of experts and customers. The appearance of a drastic change in some of the influencing factors during this period, e.g. political decisions that affect regulation and operations, as well as changes in technology and the use of infrastructure, have make it necessary to reevaluate the IRRT.

In order to carry out this evaluation, a combination of two methods has been performed: (i) Laboratory-based hierarchical structure to test and evaluate the gray decision (gray-DEMATEL), and (ii) Network Analysis Process (ANP) to carry out the evaluation of the IRRT system in Spain. As a result of this work, an ex- ante and ex- post analysis of the evaluation of the criteria is shown, with respect to the evaluations made by decision makers during the post-pandemic.

This work shows how the importance and necessity of the criteria have changed as the world has changed due to Covid-19, and what factors have changed the priorities of customers, experts and operators based on the current situation. This research also provides theoretical and managerial insights for policy makers and researchers in this field.

1. INTRODUCTION

An intermodal or multi-mode transport system is a combination of two or more modes of transport (Steadieseifi et al., 2014). For achieving the most economical, efficient, and environmentally friendly way to transport goods and passengers to a destination (Kumar& Anbanandam, 2020).

To minimize the environmental impact of transportation, switching from roads to more sustainable modes such as railways and waterways is required (Eng-Larsson & Kohn, 2012). It is necessary to identify inter-model rail barriers (IRR) to transfer part of the road transport to rail transport (Tsamboulas et al., 2007).

Roso (2013) to reducing the negative impact on the environment and social activities, the government usually tries to change the mode from single-model transportation to inter-model transportation of goods. Therefore, managers must identify organizational challenges to increase the prosperity of inter-model transportation services and face the complexity of the supply chain network (Monios & Bergqvist, 2016).

The analyze of barriers in several dimensions such as economic, technical, environmental, social, and political is needed to develop an inter-model freight system (Tsamboulas et al., 2007). In this sense, Kumar & Anbanandam (2020) identify IRR criteria in various decision dimensions (policy, operating regulations, technology and infrastructure, knowledge, organization, and government).

For this purpose, the grey-DEMATEL method (Gabus & Fontela, 1972) is used to identify the mutual relationships of criteria and handle dependencies among criteria. Its dimensions are taken by ANP (Saaty, 1996). The DEMATEL technique is introduced and combined with ANP in can make up for the equal weighting assumption of ANP (Büyükeozkan & Güleryüz, 2016). Kumaer & Anbanandam (2020) develope an evaluation framework from multiple user perspectives and perform an integration of grey theory-based decision-making trial and evaluation laboratory (grey-DEMATEL) and Analytic Network Process (ANP).

While at the end of December 2019, China reported several cases of an acute respiratory infection in Wuhan City, Hubei Province, China. The World Health Organization (WHO) named the previously unknown virus severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and called the disease caused by the virus coronavirus disease (COVID-19) (WHO 2020).

This virus has disrupted global production lines, supply chains, international trade, and the world's maritime and aviation networks. Araz et al. (2020) emphasize that the COVID-19 outbreak constituted one of the crucial disruptions experienced during the half-century, “breaking many global supply chains.” (Other authors,e.g Dolgui, Ivanov& Sokolov 2020; Golan et al.,2020; Haren&Simchi-Levi 2020; Hobbs, 2020; Linton &Vakil, 2020; Remko, 2020, (consider theCOVID-19) as a global catastrophe that affects human life and economic activities such as production operations, supply chain and logistics, and several other sectors.

The constraints of this epidemic lead to labor shortages, followed by logistical disruptions, and ultimately supply shocks to the supply chain (Hobbs 2020). The current global supply chain has weaknesses that have led to a loss of revenue, demand, and supply shortages in the

Covid-19 situation (Linton & Vakil, 2020). Following the various destructive effects of this epidemic, the prioritization and impact of intermodal transportation indicators have also been affected by this situation.

This article aims to identify the different types of intermodal transportation criteria which are related to geographical location by reviewing the papers. We then turn to the changes resulting from the ranking of these clear criteria before and after the coronavirus epidemic. To analyze criteria interactions. we use the combined Gray Theory and Decision Making Test and Evaluation Laboratory (DEMATEL) method, e.g., Gray-DEMATEL.

The rest of the paper is structured as follows. Section 2 presents the background of the study. Section 3 shows the method that has been applied. Section 4 analyses the main results, and finally, Section 5 concludes the main findings.

2. BACKGROUND

2.1 Framework

Identifying the influencing factors to analyze the relationship between multiple criteria and appropriate measures to promote them has broadly been addressed in literature. In this sense, the most common factors for selection decisions are economic (Eng-Larsson&Kohn, 2012). To reduce the negative impact of road transportation, some modal shift measures, such as the promotion of intermodal freight transport, mitigation of intermodal freight transportation adoption barriers, and improving the utilization of rail and water-based transport systems have been adopted (McKinnon et al., 2015).

Most freight industries in developing countries face many challenges in obtaining real-time data on environmental, social, legal, and organizational factors for intermodal services.
For this purpose, a literature review and expert opinions are carried out to identify the relevant factors. Next, they are divided into five main dimensions: Operational, Technology, and infrastructure of organizational knowledge of government policy and regulations (Kumar & Anbanandam, 2020).

Kumar & Anbanandam (2020) illustrated operational indicators to relate to the factors that hinder the supply chain and the logistics performance of the inter-model transport system. The author concluded that freight shippers have not adopted intermodal services for short hauling to the additional cost of pre and post-haulage. Road freight is often the priority of transportation because inter-model freight transport does not exist in the underdeveloped rail transport infrastructure and hinders the popularity of inter-model freight (Lindholm & Behrends, 2012). Intermodal rail transport infrastructure factors point to the lack of physical infrastructure and the technology available for the intermodal transport system (Kumar & Anbanandam, 2020). Most of the criteria for purchasing transportation services focus on the economic aspect and quality of business delivery, while the environmental side is less advertised (Elbert & Seikowsky, 2017; Lammgård, 2012). Knowledge is one of the most critical factors to improve the organization's competitiveness by developing products, processes, and people (Cheng et al., 2008). Organizational barriers refer to the organizational structure of the organization and its relationship with other organizations. In the age of digitalization and information technology, sharing shipping information with other companies is an essential criterion for choosing a mode (Truschkin & Elbert, 2013). The lack of government policies and environmental regulation hinders the modal shift (Islam & Zunder, 2014). Monios & Bergqvist (2016) concluded that a poor modal balance between rail and road mode reduces the adoption of intermodal services. Policy Makers to improve the intermodal services, might assess incentives that enable the use of intermodal services (Elbert & Seikowsky, 2017; Tsamboulas et al., 2007).

2.2 DEMATEL & ANP method

Multiple criteria decision-making (MCDM) methods are prevalent methods to deal with the complicated problems, including conflicting objectives, hierarchical structure, and involvement of various stakeholders (Demirel et al., 2010).

The Decision-Making Trial and Evaluation Laboratory (DEMATEL) method is used to find the cause-effect interdependencies of the factors and measure in relation values. The relative importance is measured by the prominence value of factors (Geolcük & Baykasoı, 2016). The priority weight of factors cannot be determined by the DEMATEL method; however, ANP method help to compute the structural dependency of the decision problem (Büyükeozkan et al., 2017; Büyükeozkan & Çifçi, 2012). The integration of DEMATEL with the ANP method reduces the complexity of the problem and helps to identify the global influence strength of factor (Büyükeozkan & Güleryüz, 2016). In the DANP method, the DEMATEL method is used to collect the data, identify interrelationships, and measure interdependences. In contrast, the ANP method is used to drive the unweighted supermatrix, weighted supermatrix, and the limiting matrix for computing the influential weights of the factors (Ju-Long, 1982). This method can combine grey's theory with different MCDM methods to improve the accuracy of the decision-making process (Xia et al., 2015). The benefit of the grey systems idea over the fuzzy approach is that it does not need any robust fuzzy membership function (Xia et al., 2015).

2.3 Impact of Covid-19 on the supply chain

According to World Trade Organization (WTO) figures, the worldwide economy gross domestic product (GDP) is projected to consent 2020 sharply by up to eight, and global trade will decrease by up to 32% in 2020 thanks to the COVID-19 pandemic (World Trade Organization, 2020). Supply chain disruptions cause significant challenges and may affect organization performance (Hendricks & Singhal, 2003). Pettit et al., (2019) offer a review of the literature on supply chain resilience that predates COVID-19. The severity of the business disruption of the COVID-19 pandemic has challenged much of our previous understanding of what constitutes a resilient supply chain. Recent research has indicated that this crisis has led to the rapid deterioration of several business and economic indicators, including productivity and global GDP (Harris, 2020). These impacts are due to the imposition of travel and trade restriction (Baveja et al., 2020) and the shutting down of workplaces. Ivanov (2020), considered the pandemic and the respective supply chain risks, provided a simulation model for global supply chain disruption, and predicted the severity of COVID-19 impact on supply chain performance.

In summary, COVID-19 has put some significant and unprecedented strain on global supply chains across most product categories. Past literature has provided some indication of the factors that may cause disruption on the supply chain. However, at the same time, it has exposed a number of challenges related to identifying and responding to significant changes within the demand patterns during an outbreak. However, the power to forecast excess demand during the pandemic early could have substantial implications for supply chain managers and policy makers.

3. METHOD

The proposed method consists of three steps to solve the interrelationships and prioritize the problem of IRR criteria.

3.1 The grey-DEMATEL methodology

The gray-DEMATEL decision matrix usually uses a gray 5-digit spectrum that includes the expressions without impact (0.25 and 0), very low impact (0.25 and 0.5), low impact (0.5 and 0.25), high impact (0.75 and 0.5), impact is very much (1 and 0.75). Therefore, the first step of the gray DEMATEL method is forming a direct communication matrix. In the next steps, the normalization operation is performed, the matrix is determined, the matrix is multiplied, and finally, the total communication matrix (T) is obtained.

As indefinite numbers, we have the operations of multiplication, division, and addition. In gray numbers, these relations are also established.

The gray-DEMATEL method is a decision-making method for performance and a way to help visualizing a complex causal relationship using useful matrices and diagrams. Matrices or diagrams depict the relationships between system components with the strengths of the relationships within these quantitative relationships. The gray-DEMATEL consists of four main steps, including developing a direct pairwise relationship matrix between system components through the evaluator or decision-maker inputs, the determination of the initial impact matrix through the normalization of the natural relationship matrix. Determining the matrix (impact) of total relationships and finally determining causal relationships (causal-salient diagrams) are among the components and relative strengths. A summary of the steps is shown next:

Step 1: Form a group of experts to gather their group knowledge to solve the problem.

Step 2: Determine the criteria to be evaluated and design language scales. In this step, experts' opinions, research factors and indicators are the main outcomes.

The criteria to be evaluated will be selected according to the areas under study. The gray numbers used in this study are of the fuzzy triangular type. As can be seen, this spectrum is the same as the spectrum of the DEMATEL method, except that gray numbers are used.

Step 3: Create a gray matrix of direct initial communication with the collection of expert opinions.

To measure the relationships between criteria, we need to put them in a square matrix and ask experts to compare them in pairs based on how much they affect each other. In this survey, experts will express their views based on gray numbers. Assuming we have n criteria and p experts; we have a gray matrix, each of which corresponds to the opinions of an expert with gray numbers as its elements.

Step 4: Normalize the direct connection gray matrix.

For this purpose, linear scale conversion is used as a normalization formula to convert benchmark scales to similar criteria.

Step 5: Calculate the matrix of the total connection. In this step, first, calculate the inverse of the standard matrix and then subtract it from the matrix I, and finally multiply the standard matrix by the resulting matrix.

Step 6: Create and analyze the causal chart.

For this purpose, we first calculate the sum of the elements of each row (Di) and the sum of the elements of each column (Ri) of the gray matrix. The sum of the elements of each row (D) for each factor indicates the extent to which that factor influences other factors in the system. The sum of the column (R) elements for each factor indicates the degree to which that factor is affected by different factors in the system.

Then we get the values D + R and D-R. To draw a causal diagram, we must de-fuzzy these two values, like the definitive DEMATEL method. Therefore, the horizontal vector (D + R) is the influence of the system's desired factor. In other words, the higher the D + R vector, the more it interacts with other system factors. The vertical vector (D - R) indicates the power of each aspect. In general, if D - R is positive, the variable is causal, and if it is negative, it is a disability. After deactivating the numbers, a Cartesian coordinate system is drawn. The longitudinal axis shows the values D + R, and D-R is the transverse axis in this device.

Therefore, the horizontal vector in the coordinate system is the degree of impact of the desired factor in the system. In other words, the higher the value for an aspect, the more the factor interacts with other system factors.

The vertical vector of the coordinate system shows the effect of each factor.

3.2 DANP

This approach is one of the newest techniques for combining gray-DEMATEL with ANP, known as fuzzy DANP.

As mentioned, the degree of importance of each element under the control of the other component was measured using the ANP method. Because of facilitating the work and reducing the number of pairwise comparisons required, the internal connections and the degree of influence of the elements on each other are measured by the DEMATEL method. The number of even comparison matrices and the volume of calculations are reduced, the speed of calculations is increased, and its complexity is reduced. In this technique, after forming the total gray-DEMATEL communication matrix, the threshold value is no longer calculated, i.e., no relation is eliminated. From this matrix, the ANP supermatrix is formed with a series of other steps, and then it is possible to converge. The converged matrix is the limit supermatrix that represents the final weights of the factors.

In the integration of gray digital technique and network analysis process in the first phase, the external weight coefficients required to form the initial heterogeneous supermatrix are obtained from matrices pairwise comparisons of elements to the target cluster.

Yang & Tzeng (2011) expansion analysis technique can be used to determine the weighting coefficients of factors in this section. In the second phase, the internal weighting coefficients required to form the initial unbalanced supermatrix are obtained from the diffuse communication matrix of the DEMATEL technique at the level of clusters and elements. In this method, the initial heterogeneous supermatrix is formed according to the defined pattern and finally converges. This method was invented by Tezang and has been used by many people, including (Kahraman et al. 2014). Due to its positive features and capabilities, this method is used in this research.

3.3 gDANP

Step 1. We formulate the effect matrix of all the criteria. Gray-DEMATEL method is used to calculate the total effect of the matrix from each dimension or inhibitory measure with different degrees of effective relationship.

Step 2. Formulation of the weightless supermatrix. After obtaining the standard matrix, the normalization of the initial matrix with the degree of overall effect will be accepted.

Step 3. Calculation of supra-matrix weight matrix of total dimension relations matrix obtained by the gray-DEMATEL method.

Step 4: Limit the supermatrix. As with the conventional ANP method, limiting the supermatrix to power provides a stable weight of criteria. Likewise, the proposed gDANP supermatrix must reach sufficient power. Therefore, the effective weights of each criterion can be obtained.

4. EXPECTED RESULTS

In this study, the gray network analysis method will be used to determine the weight of the criteria and model indices.

Railway policymakers will be able to develop the proposed gDANP evaluation framework between models and logistics operations organizations to evaluate IR more effectively. IRR upgrades and having a strategic plan to upgrade their barriers. Managers can gain valuable managerial insights from many charts

Use the above convergent cause, effect, and criteria to identify insightful decisions.

If procurement and transportation policymakers want to reach the highest level of performance, they will be advised to pay more attention to "deterrence". This level is because factors have a significant effect on the criteria.

The findings of this study will provide a list of priority criteria before and after the spread of coronavirus. By prioritizing impact indicators in both pre- and post-virus situations, logistics policymakers will be able to revise transportation policies. Logistics policymakers can use the proposed framework to analyze the impact of IRR factors on future IRR system development. This study will also provide the next important IRR metrics that may suggest that adequate policy action be taken.

5. CONCLUSIONS

The rail-based freight system has become essential to policymakers in recent years due to its commitment to a sustainable strategy.

Therefore, road freight transportation towards rail transportation and their integration have been given priority. In a complex process of decision and evaluation, many criteria include subjective and qualitative judgments. In such circumstances, MCDM methods can be an effective solution for calculating the barriers to cross-communication of priority importance.

The proposed framework analysis was considered by using an integrated MCDM method, for example, DEMATEL-ANP gray (gDANP), to validate the proposed framework. Experts from different departments of freight organizations are considered.

It is hoped that the results of the post-searcher computational results will confirm that the proposed model will help transport policymakers and stakeholders to improve them.

The decision-making process improves the share of intermodal services, especially in cases where many criteria are interrelated.

The results of future calculations will be presented in the form of ranking and correlation of all criteria.

RESUMEN

Public transport modes in urban peripheries have a twofold function: buses provide the territorial capillarity, while the suburban rail acts as the backbone of mobility. Despite its relevance there, suburban rail usually runs on pre-existing tracks for heavy rail services. Moreover, in the current context of rail liberalization in Europe, the infrastructure manager and the rail operator are separate organizations with impacts on suburban rail. Therefore, it is important to discern the responsibilities of both agents in providing a better service, to promote a more sustainable mobility. This work aims to explore how the perceived quality of service (QoS) of suburban rail services can be influenced by the rail network infrastructure. The suburban rail network of Madrid (Cercanías) has been selected as case study because of the combination of pre-existing and new tracks as well as having a total of 9 regular lines, enough to perform this analysis. Data is gathered from the 2019 annual Cercanías traveler satisfaction survey. First, different aspects of the lines are thoroughly examined, such as the travel time between stops, shared sections or the location of the different sections within the metropolitan area. These factors are transformed into indicators to ease comparison. Based on the main indicators and the average QoS, lines are classified into 4 groups. The joint analysis of the infrastructure indicators and the attributes from the traveler satisfaction survey suggests that lines with similar QoS also have features common regarding to infrastructure and operation such as line length or travel time between stations.

1. INTRODUCTION

In the last decades, cities have greatly increased their population that overgrow the cities' limits and settling in nearer population centers, thus configuring metropolitan areas. As an instance, 55% of citizens of main European metropolitan areas dwells in metropolitan rings, which remarks the incoming importance of these areas (EMTA, 2020). Compared with urban centers, these metropolitan peripheries have often lower population densities and less land use mix. That clearly conditions the current metropolitan mobility, since citizens must travel longer for both their daily home-to-work commuter trip and their non-obliged trips (shopping, leisure, etc.). For that reason, mobility policies should go towards a sustainable mobility not only in main cities but also in the whole metropolitan areas, as the European Commission's new Sustainable and Smart Mobility Strategy states (European Commission, 2020).

Currently, mobility in metropolitan rings highly relies on cars (Wolny, 2019). The lower population density and lack of land use mix difficult public transport agencies and operators to provide a high frequency public transport, consequently reducing its competitiveness. Nevertheless, metropolitan areas get configured through corridors given the existing transport infrastructures that previously connected the city with some others: roads upgraded to highways and railway tracks. This is because inhabitants aim to reduce their transport cost living close to these infrastructures (Müller et al., 2010). Public transport can profit from these infrastructures to serve the population in these peripheries. Two main services emerge there: metropolitan buses and suburban railways, using each type of infrastructure. Metropolitan bus services provide the territorial capillarity and accessibility, reaching most of dwellers, and may benefit of high-capacity roads to provide faster connections. However, with great capillarity and low density comes lower frequency, and traffic jams – out of control of bus operators – clearly also affect bus regularity. Suburban rail often provides more frequent, reliable, and higher-capacity services, connecting metropolitan passengers with the main urban transport hubs, thus becoming the backbone of metropolitan mobility.
Furthermore, the previous stages in the liberalization of the railway sector in the European Union has caused, for suburban rail services, the coexistence two agents: the infrastructure manager (IM) and one railway undertaking (RU). Unlike metro networks, where a single company manages both infrastructure and rolling stock, for suburban railways the transport service is offered by the RU, whose rolling stock runs on tracks and stops at stations under the control of the IM. Some key variables for RU such as the track layout, the distance between stations or the maximum speed of each stretch are determined beforehand. In addition, under a railroad disruption to be fixed by the IM, trains cannot take an alternative route. Therefore, this situation can compromise the overall quality of the rail service provided by the RU despite not being its direct responsibility.

The concept of Quality of Service (QoS) in PT is oriented to fulfil the requirements of passengers. With this aim, the EN 13816 Standard (CEN, 2002) proposes 8 categories that comprise the criteria from the user's point of view: availability, accessibility, information, time, customer care, comfort, security and environmental impact. The most widely method used to evaluate QoS in PT is the Traveler Satisfaction Survey (TSS), whose questionnaire is often based on the aforementioned categories. It must be stressed, however, that QoS and satisfaction are not the same concept – user satisfaction may be interpreted as the comparison between the expectations and the perception of the provided service (Mouwen, 2015). These TSS not only make it possible to measure the most highly valued attributes, but also to estimate their relative importance on the overall satisfaction.

Most studies about quality of PT services are focused on bus services or subway systems, which have different characteristics compared to suburban rail services. Nevertheless, several studies estimate the most important service attributes for suburban railway passengers: main factors are related to service supply (e.g. regularity and punctuality), vehicle cleanliness service supply, information and station accessing (de Oña et al., 2015, Weinstein, 2000). When working with TSS in PT services, two consideration must be bear in mind. First, the existence of a psychological “rail factor”, which makes rail services more attractive than buses. In terms of TSS, it results in a better valuation of train services than bus services (Scherer & Dziekan, 2012). Second, there are socio-economic and spatial differences on the perception of the quality of public transport services. As an instance, Grisé and El-Geneidy (2017) found an inverse relationship between socially deprived neighborhoods and passengers’ satisfaction with bus services. Besides, Eboli et al. (2018) found that areas with lower density of rail network leads to lower perceived QoS of Milan’s regional and suburban rail.

To the best of our knowledge, only Eboli et al. (2018) find a relationship between suburban rail network characteristics and perceived QoS. Furthermore, the studies analyzing the QoS on suburban rail does not focuses on the effects of both infrastructure manager and railway undertaking. This work aims to explore how the perceived quality of service of suburban rail services can be influenced by the rail infrastructure characteristics, taking into account the different responsibilities of both infrastructure manager and railway undertaking..

2. CASE STUDY: CERCANÍAS MADRID

We have chosen as a case study the Madrid Region’s suburban rail service, Cercanías Madrid. Madrid Region, located in the center of Spain, had about 6.7 million inhabitants in 2019, of those 3.3 million live in Madrid, the capital of Spain, and about other 3 million live in its metropolitan ring. GDP per capita in Madrid Region was 35,041 euro in 2018, 36 % over the national average (INE, 2020). However, Madrid Region presents a southwest-northeast line of social inequality, with lower incomes and higher unemployment in the southeastern half of the region (Leal & Sorando, 2015).

The public transport network in Madrid is composed by 440 metropolitan bus lines, 205 urban bus lines, 13 Metro lines and 4 light rail lines, 5 multimodal interchange stations – managed by the regional Public Transport Authority (PTA) – and 10 Cercanías lines. Cercanías is the suburban rail division of Renfe Operadora, the Spanish national railway undertaking. Cercanías Madrid was first put in service in 1985 using the long-distance, pre-existing railroad tracks. Currently, their trains run on ADIF tracks, the Spanish national IM. In addition to the pre-existing tracks, some sections specifically designed for suburban rail have also been built. It is noteworthy that Cercanías Madrid manages most stations (access, furniture, etc.) although they are owned by ADIF.

Cercanías Madrid has 9 regular lines and 1 touristic line. The infrastructure network lengths 370 km and has 90 stations. Cercanías Madrid also follows a clear radial structure, with a central area in the inner center of Madrid. That includes a main trunk section with two tunnels connecting the most important rail stations in Madrid (Atocha and Chamartín) and a partially tunneled section from Atocha to Principe Pío (Green Railway Corridor) based on the 19th century railroad track. A more in-detail scheme of the network can be found in Figure 1, including the southwest-northeast line of social inequality and the central area.

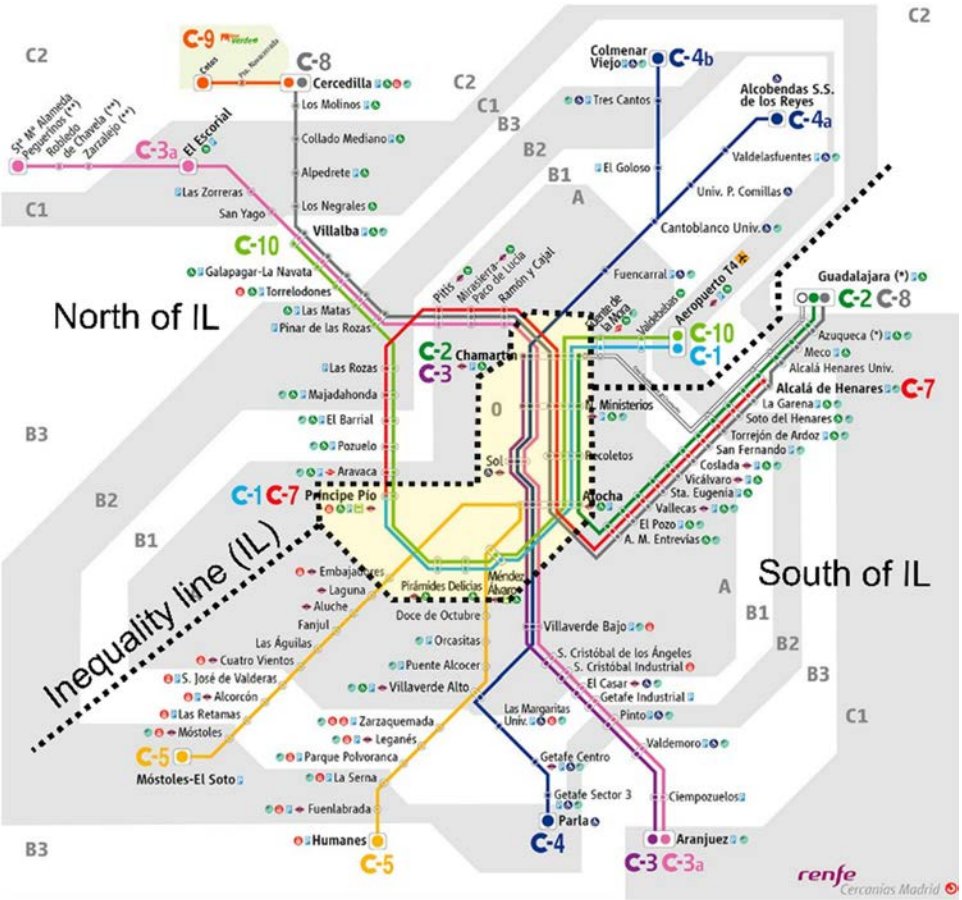

Fig. 1 – Cercanías Madrid network, with the inequality line and the central area (shaded in yellow).

3. METHOD AND DATA SOURCES

The analysis framework is divided in two steps. First, a description of the lines based on several key variables of railway infrastructure and operation. Then, a grouping of the different lines based on the passengers' satisfaction that leads to a comprehensive analysis considering the previous infrastructure and operation variables. This section presents the data acquisition and next it explains the method of each step.

3.1 Data sources

This study needs to compile two different type of information for each line: infrastructure and operation key variables and data about quality of service. First, data on infrastructure and operation has been gathered from several sources. Travel times have been manually collected from Renfe Operadora website. Last, length of lines is obtained from Madrid Region PTA open data portal and the average commercial speed at peak hour and the number of train circulations in peak and off-peak hour are taken from Madrid Region PTA annual report (CRTM, 2021).

On the other hand, data about quality of service derive from the 2019 annual TSS carried out by Renfe Operadora. The survey was conducted in November and December 2019 to about 2,600 passengers, what means that about 200 – 250 surveys per line. The survey questionnaire includes general questions about trip habits (trip frequency, access and dispersion modes…) and passenger characteristics. It also asks to rate a list of service attributes on a scale of 0 to 10. For this work, there were only available the average values for each line.

3.2 Indicators

To properly describe the lines, a set of indicators are selected. Following Alonso et al. (2015), the indicators should ideally meet seven requirements: target relevance, validity, transparency, sensitivity, standardized for comparison, unambiguity, and data reliability and availability. In this case, we prioritize the last criterion over the others. Based on Nicholson et al. (2015) railway evaluation KPIs and public availability of data, 6 indicators are chosen: line *length*, number of *stations* per line, percentage of *shared sections* with other line/s, average *travel time between stations* (i.e. between two consecutive stations), operational *speed* at peak hour, and number of daily *services* per line. The indicators *stations* and average *travel time between stations* have been divided in 3 parts, based in the Madrid Region's southwest-northeast line of social inequality: north (N), central (C) and south (S). That is expected to help in the comparative analysis. Table 1 contains the values of the indicators for each of these lines, which are analyzed in detail in Section 4.

3.3 Grouping

In this step, lines are grouped according to passengers' satisfaction and some key infrastructure characteristics for better understanding the similarities and differences in QoS among lines. Furthermore, it will allow discussing which variables drive the perception towards the different services' attributes. It would be preferable to aggregate the infrastructure attributes into composite indicators. Nevertheless, to the extent of our knowledge, there are not composite indicators of railway infrastructure at line level which may serve as a reference. The solution taken here is to obtain the relative importance of the previous variables on the QoS by using the Pearson's correlation coefficients (Weinstein, 2000). Although it does not provide a direct relationship between these variables, it serves to rank the relative importance of service variables.

Then, groups are compared taking into account their infrastructure and operation characteristics as well as the different variables included in the Cercanías TSS: train supply, regularity and punctuality, travel time, information to passengers, easiness of access to station, station comfort, train comfort, station and train cleanliness, staff attention, customer relationship, security and fares. In the Cercanías Madrid case, the responsibility for train supply, regularity and punctuality, travel time and easiness of access can be shared between ADIF (the IM) and Renfe Operadora (the RU), while the rest of attributes lie predominantly with Renfe Operadora.

4. DESCRIPTIVE ANALYSIS OF LINES

Prior to the analysis of the lines of Cercanías lines, it is pertinent to point out some operational peculiarities of certain lines which may affect to the proper comprehension of the results. First, lines C3 and C3a are commercially two different lines although they run as a single line up to Chamartin, with some services ending at Chamartin (C3) and a few others running northwest. In this paper we have opted to consider it as a single line. Second, lines C4a and C4b operate as a single line with two branches in the north side, with different infrastructure characteristics.

The main variables of the lines are shown in Table 1 (infrastructure) and Table 2 (operation). The average length of lines is 70.5 km. However, it varies considerably from more than 120 km for lines C3a and C8 to just over 20 km for line C1. This clearly affects to the commercial speed: on average it is 50.1 km/h at peak hour, overpassing 55 km/h in the two longest lines and being lower in shorter lines (C1, C5). Despite that, C1 and C5 are the lines with lower average travel time between stations, along with the lines C4a and C4b. On the other side, C3a presents the longest travel time between stations (4.7 minutes), almost a minute above the average (3.8 minutes). It is also noteworthy to glance at the travel times between stations in the central area, since most lines share some sections. More in detail, travel time between Atocha and Chamartin is longer via Recoletos (4.3 min/section) than via Sol (3.7 min/section).

It is also interesting to point out the spatial distribution of lines (Figure 1): C2, C3 and C5 only connects the southern areas of the region with the center of Madrid, while C1 and C10 are exclusive-northern lines. The remaining half of lines links north and south, among them the two longest lines (C3a and C8) are found.

Line	Length (km)	Stations				Shared sections (%)
		Total	S (%)	C (%)	N (%)	
C1	24.5	11	0	73	27	100
C2	64.2	19	79	21	0	100
C3 + C3a	128.9	24	38	17	46	85
C4a	48.2	15	40	27	33	73
C4b	59.2	15	40	27	33	73
C5	45.0	23	87	13	0	0
C7	79.4	24	46	21	33	100
C8	122.4	32	47	13	41	82
C10	62.3	21	0	38	62	100
Avg.	70.5	20.4	46	25	29	79

Table 1 – Main infrastructure variables of Cercanías lines

Line	Travel time between stations (min)	Speed (km/h)	Services (% peak h.)	Average QoS
C1	3.6	38.2	75 (37%)	7.21
C2	4.1	53.9	211 (45%)	7.01
C3 + C3a	4.7	58.9	160 (46%)	6.57
C4a	3.7	51.7	285 (49%)	7.08
C4b	3.3	46.4	302 (54%)	7.03
C5	2.5	46.4	302 (54%)	7.40
C7	4.0	50.2	101 (57%)	7.36
C8	4.4	55.4	46 (50%)	6.64
C10	4.3	39.2	165 (51%)	7.26
Avg.	3.9	49.5	149 (49%)	7.13

Table 2 – Main operation variables of Cercanías lines

5. COMPARATIVE ANALYSIS OF LINES BASED ON THE PERCEIVED QUALITY OF SERVICE

The descriptive analysis of the lines provides a general overview of the lines, with clear differences on length, operational speed at peak hour or travel time between stations. This may give a broad idea of the service offered, but it does not relate to the QoS perceived by travelers. To that extent, the relative importance of each service attribute is obtained using Pearson’s correlation coefficient. Then, the most important variables are line length (-0.79) and travel time between stations (-0.68). The negative sign implies that the longest the line and the travel time, the worst QoS. These three variables (QoS, line length and travel time between stations) are displayed in a scatter plot (Figure 2) where four groups of lines can be extracted. This analysis based in groups was carried out to ease the description of the results, without aiming to provide a statistically consistent classification of lines.

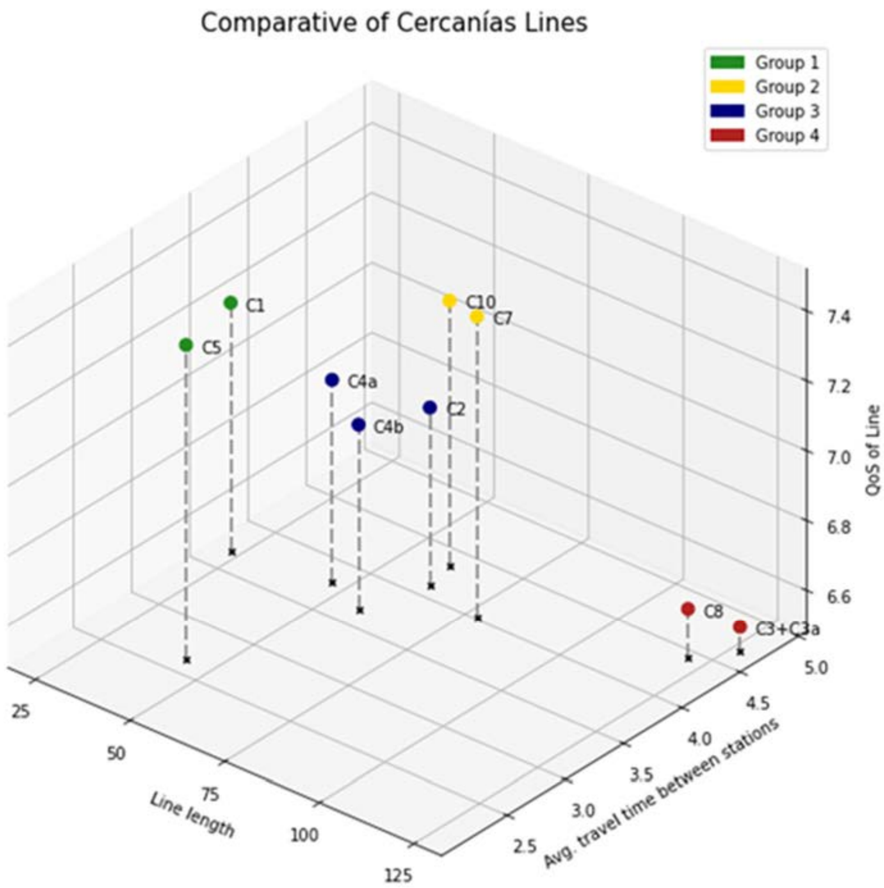

Fig. 2 – Grouping of lines according to the passengers' satisfaction and key infrastructure satisfaction as defined in Section 3.2

The four resulting groups are sorted based on their average QoS, resulting in Group 1 (C1, C5), Group 2 (C7, C1, C10), Group 3 (C4a, C4b, C2) and Group 4 (C3, C8). Hereby, Group 1 has the higher overall perceived quality (+0.27 above average), followed by Group 2 (+0.18). At this stage, we include into the analysis the passengers' perception towards the different service attributes mentioned in Section 3.3. To ease comparison, Table 3 shows the difference, for each attribute, between the groups' rating and the network average and also the highest difference between groups. Overall perceived quality is also included in Table 3 to facilitate the discussion. Below the four groups are analyzed in detail, followed by some considerations on infrastructure issues.

Attribute	Group 1	Group 2	Group 3	Group 4	Max. difference among groups
Supply	0.19	0.25	0.09	-1.06	1.31
Regularity	0.33	0.00	-0.09	-0.69	1.01
Travel time	0.41	0.12	-0.29	-0.56	0.97
Information	0.11	0.29	-0.06	-0.47	0.76
Access to station	0.11	0.17	-0.11	-0.38	0.55
Station Comfort	0.15	0.09	0.06	-0.53	0.68
Train Comfort	0.16	0.09	-0.08	-0.26	0.41
Cleanliness	0.11	0.08	0.00	-0.39	0.50
Staff attention	0.08	0.22	-0.19	-0.13	0.40
Customer relationship	0.19	0.31	-0.08	-0.60	0.91
Safety	0.11	0.36	-0.05	-0.29	0.65
Fares	0.11	0.09	-0.04	-0.32	0.43
Overall perceived quality	0.22	0.18	-0.09	-0.54	0.76

Table 3 – Attribute rating among clusters. Difference between value of group and Cercanías Madrid average.

5.1 Group 1: Short, well-perceived lines

The first group consists of C5 and C1. This is the group with less travel time between stations (3.0 min on average) and with more daily circulations (188 on average), although its operational speed is lower than the average. This situation clearly impacts to the satisfaction results. In addition to being the highest-rated group, the service's attributes where the group overperforms are regularity and travel time, which seems to be in consonance with the operational characteristics of the lines.

5.2 Group 2: Long, well-perceived lines

The second-best rated group comprises lines C7 and C10: two long lines (70.8 km on average) that connect the city of Madrid with one edge of the metropolitan area. They share a common section at the northwest of the inequality line, and they mostly serve to the northern half of the network, which could explain why this group is perceived as the most secure (+0.36) and with the best customer relationship (+0.31)). This group is also well rated at train supply (+0.25) – while they are below average in daily services (11% below average), this is the group that most concentrates its supply during peak hours (53% of services) and furthermore two or more lines stop at every station of this group, so passengers may perceive a greater supply than other groups.

5.3 Group 3: Balanced lines

The third group includes the lines C2, C4a and C4b. While C4a and C4b lines share most of the route and only split at the north, line C2 does not have any section in common with the former lines. Their most distinctive feature is the number of daily services, 10% above average, while the other attributes are quite close to the network average. In addition, this group has most of their service attributes rated just a bit below the average: only station comfort (+0.06) and train supply (+0.09) overperform; the latter having a meaning given the high volume of daily services.

5.4 Group 4: Underperforming longest lines

The remaining lines C3 and C8 form the last group. This group has the lowest overall perceived quality (0.52 below average) and being the worst rated group in every attribute except for the "staff attention" (-0.12). In contrast to the Group 2, train supply (-1.06), regularity (-0.69) and travel time (-0.56) are three of the most underperforming attributes. As already mentioned, they are the longest lines. In addition, they are the lines with the highest number of stations and the longest travel time between stations, despite being the lines with highest operational speed.

5.5 Effects of rail infrastructure on QoS and stakeholders' responsibilities

It is also possible to perceive some effect of the infrastructure on QoS, based on similarities and differences of attributes ratings among groups, with data extracted from Table 3. The attributes with the least variation among groups are train comfort (0.41), staff attention (0.40) and fares (0.43), which are independent of the infrastructure characteristics. Conversely, the most divergent attributes are train supply (1.31), regularity (1.01) and travel time (0.97), in which both the infrastructure manager and the railway undertaking are involved.

6. DISCUSSION AND CONCLUSIONS

This study aims to obtain an overview of the quality of service in suburban rail considering general infrastructure and operational parameters. To achieve that objective, we take a line-based approach and apply a two-steps procedure to the Cercanías Madrid case study. We first analyze the general characteristics of that lines and then we classify the lines in four groups according to the average passengers' satisfaction and key characteristics of lines, leading to a comprehensive examination of the service considering both sides.

The most relevant line attributes seem to be the travel time between stations and the total line length. In fact, the best rated group (Group 1, 0.22 above average) has the lower travel time between stations (3.0 min), which may be coupled with a much higher ratings of regularity and travel time. On the other hand, the worst rated group (Group 4, 0.54 below average) only comprises the longest lines, having the higher average speed but also the higher average travel time between stations. We find that the most constant attributes from the TSS depend solely on the RU, while the most varying ones depend both on RU and IM, thus having the infrastructure some sort of effect on the perceived QoS. Last, as for the socioeconomic or territorial effects on the service, we can only suggest a slight positive relationship with perceived security in north-based lines, but that deserves to be analyzed more in depth.

Future work should be directed at quantifying the effect of the different parameters of infrastructure (e.g. length, travel time) on passengers' satisfaction and, more specifically, on some attributes such as the passengers' satisfaction with regularity or travel time. There is also room for exploring the responsibility of IM and RU by including variables related to railroad capacity and/or blocking. That gained knowledge will help both agents to enhance certain aspects of the service, leading to the identification of areas for individual and joint improvements. In the end, it will result in an increase in satisfaction and a potential increase in the ridership of the suburban railroad, promoting a more sustainable mobility in metropolitan areas

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the Spanish Ministry of Transport and Renfe Operadora for their support in the preparation of this article by providing us with data related to the annual passenger satisfaction survey.

RESUMEN

El presente estudio tiene por objetivo comparar los tiempos de viaje en autobús con los tiempos de recorrido del tráfico general en A Coruña. Esta comparación permite, por una parte, determinar la relación existente entre la velocidad de circulación de los autobuses y el tráfico general a lo largo del mismo trayecto y sentido de la calzada, y por otra, determinar y cuantificar otros factores que influyen en la misma. Esta información puede ser útil para la planificación de nuevas líneas o la determinación de la necesidad de implantación de plataformas reservadas.

Para llevar a cabo el estudio se han utilizado, por un lado, datos de llegada de autobuses urbanos a cada una de las paradas situadas dentro del tramo a analizar. Esta información se obtiene a partir de la base de datos del Sistema de Ayuda a la Explotación de la Compañía de Tranvías de La Coruña. Por otro lado, el tiempo de recorrido del tráfico general se obtiene explotando los datos recogidos por el Ayuntamiento de A Coruña mediante sensores localizados en diferentes puntos de la ciudad, que detectan dispositivos bluetooth activos y registran la información cada 3 minutos.

Por el momento, el análisis se ha centrado en la relación entre los tiempos de operación de los autobuses urbanos y el tiempo de recorrido del tráfico general en los días naturales del mes de febrero de 2019, en un corredor en concreto, que constituye una de las principales vías colectoras de la ciudad: Ronda de Outeiro entre la Estación de Tren y la intersección con la Tercera Ronda en A Coruña, con una distancia recorrida de 2400 m.

1. INTRODUCCIÓN

El tiempo de recorrido del transporte público urbano, así como su relación con el tráfico general, ha sido objeto de análisis en numerosos estudios desde hace décadas. En Levinson (1983) se calculan las velocidades de tránsito y demoras del autobús en una muestra representativa de varias ciudades de Estados Unidos. En este mismo estudio se concluye que la velocidad del coche es entre 1.4 y 1.6 veces más rápida que la del autobús, utilizando como variables la distancia entre paradas, congestión del tráfico, embarque y desembarque de viajeros, y número de aceleraciones y deceleraciones.

En estudios posteriores se ha continuado con el objetivo de relacionar ambos tiempos de recorrido, utilizando modelos de regresión lineal y añadiendo nuevas variables para llevar a cabo la comparación (McKnight *et al.*, 2004). Estos modelos se han perfeccionado en los últimos años con la incorporación de datos GPS (Bertini y Tantiyanugulchai, 2004; Mazloumi, Currie y Rose, 2010), favoreciendo la creación de marcos teóricos de predicción de tiempos medios de recorrido, hora de llegada a parada o velocidades del transporte público a partir de datos de entrada como el tráfico general (Chien, Ding y Wei, 2002; Chakroborty y Kikuchi, 2004; Mazloumi et al., 2011).

Los teléfonos móviles proporcionan gran cantidad de información que puede ser utilizada para estimar la demanda de viajes de autobús a través de la utilización de aplicaciones como Twitter que geolocaliza las publicaciones (Liao *et al.*, 2020). Por otro lado, estos dispositivos con bluetooth activo pueden ser localizados por sensores que calculan y registran las velocidades y tiempos de recorrido del vehículo en el que se encuentran (Imam, Bhaskar y Chung, 2017), y permiten comparar estos datos con los del transporte público (Kieu, Bhaskar y Chung, 2015). En Banik, Vanajakshi and Bullock (2020) el tiempo de recorrido de los vehículos de tráfico general en Chennai (India) se registra a partir de sensores Wi-Fi y se compara con el tiempo de recorrido del autobús equipado con GPS.

En Liao et al. (2020) se concluye que el transporte público tarda de media entre 1.4 y 2.6 veces más que el automóvil privado en recorrer la misma distancia en cuatro ciudades diferentes. En el presente estudio se analizará la relación entre tiempos de recorrido de autobús y tráfico general en la ciudad de A Coruña.

La ponencia se estructura de la siguiente forma: tras este primer apartado introductorio se presenta la metodología seguida para realizar el análisis, en el tercer apartado se exponen los resultados obtenidos y, en el cuarto, se presentan las primeras conclusiones y futuras líneas de investigación a desarrollar a partir de este estudio inicial.

2. CASO DE ESTUDIO Y METODOLOGÍA

En el presente estudio se analizará la relación entre el autobús urbano de A Coruña y el tráfico general durante el mes de febrero de 2019 en la Ronda de Outeiro a lo largo de un corredor de 2400 m de longitud, entre la Estación de Tren y la intersección con la Tercera Ronda. La Ronda de Outeiro es una de las arterias principales de A Coruña: todas las vías de salida y entrada a la ciudad se conectan con esta Ronda. Además, comunica con el Polígono de la Grela, con más de 500 empresas instaladas en una superficie de 1.400.000 m^2, por lo que el tráfico es elevado en hora punta. El tramo objeto de estudio consta de dos carriles de circulación y 10 paradas de autobús a lo largo de su recorrido pertenecientes a diferentes líneas regulares de la Compañía de Tranvías de La Coruña: 5, 7, 12A, 14, 20 y BUH (nocturna). De las líneas diurnas solo la 12A y la 14 recorren el corredor completo. Para el presente estudio se ha tenido en cuenta la línea 14, que comunica los barrios de Los Rosales y Castrillón. La ubicación de las paradas y de los sensores en el tramo se muestra en la Figura 1.

Para analizar la relación entre tiempos de operación de autobuses urbanos en A Coruña y los tiempos de recorrido de tráfico general se han utilizado dos fuentes de datos. Por un lado, se obtienen los tiempos de llegada del autobús a las paradas seleccionadas, entre las 7:00 y las 23:45 horas, a partir de la base de datos del Sistema de Ayuda a la Explotación de la Compañía de Tranvías de La Coruña. Por otro lado, el tiempo de recorrido del tráfico general se obtiene a partir de los datos recogidos por el Ayuntamiento de A Coruña a través de sensores localizados en diferentes puntos de la ciudad. Estos sensores detectan los dispositivos bluetooth activos, los codifican y registran la información cada 3 minutos. Obteniendo esta información de varios sensores se deduce la procedencia de los vehículos y se conocen los tramos por los que han circulado, así como sus tiempos medios de recorrido cada 3 minutos.

Figura 1. Paradas de autobús y sensores bluetooth en el tramo objeto de estudio. Fuente: Elaboración propia a partir de mapa de paradas de autobús y sensores en A Coruña.

El primer paso para llevar a cabo el análisis será obtener el tiempo total de recorrido de los autobuses urbanos a partir de los tiempos de llegada de los mismos a cada parada durante los días naturales del mes de febrero de 2019. El tiempo total de recorrido se calcula como la diferencia entre el instante de llegada a la parada final (559) y el instante de llegada a la parada inicial (119). En la Tabla 1 se presentan los datos obtenidos para uno de los días estudiados.

No se han considerado para el análisis los tiempos de viaje de autobuses con situaciones anómalas, como inexistencia de registros del instante de paso por alguna parada del tramo, o servicios con cambios de turno de personal en alguna de ellas que dan lugar a aumentos adicionales del tiempo de viaje no atribuibles a las condiciones de tráfico ni de operación normal.

El siguiente paso para realizar la comparación entre ambos tiempos de recorrido será calcular el tiempo que tarda el tráfico general en recorrer el mismo corredor. Este corredor se encuentra delimitado por cuatro sensores de detección bluetooth (numerados en la Figura 1), que forman, entre cada par, tres vectores:

- Vector 44. Tramo entre sensores 1-2.
- Vector 62. Tramo entre sensores 2-3.
- Vector 23. Tramo entre sensores 3-4.

Tabla 1. Tiempo de recorrido del autobús en el corredor durante el día 03.02.2019.

Para el cálculo del tiempo de recorrido del tráfico general se considerarán los tiempos de recorrido de los vectores en los intervalos temporales en los que el autobús estuvo circulando por dichos vectores. De esa forma solo se tendrán en cuenta las condiciones de tráfico de cada vector que realmente han podido influir en la velocidad del autobús. Tal y como se representa en la Figura 1, los sensores no coinciden de forma exacta con las paradas del autobús urbano. Para considerar que el autobús ha salido de un vector se tiene en cuenta la parada inmediatamente posterior a la posición del detector de bluetooth que determina su fin. Se ha utilizado este criterio porque el sistema de ayuda a la explotación (SAE) de la operadora registra el instante de llegada a la parada cuando el autobús se encuentra a una distancia de alrededor de 30 m de la misma. Por tanto, considerando la parada inmediatamente posterior se ajusta de forma adecuada el tiempo de estancia en el vector para tomar datos del tráfico general.

Por tanto, para cada vector se considerará el tiempo medio del tráfico general en los períodos en que el autobús se encuentre entre las siguientes paradas:

- Vector 44. Paradas 119 a 122.
- Vector 62. Paradas 122 a 124.
- Vector 23. Paradas 124 a 559.

Como se ha mencionado anteriormente, los datos obtenidos de los dispositivos bluetooth activos se registran cada 3 minutos. En cada instante temporal se registra el tiempo medio que han tardado en recorrer el vector los vehículos que han llegado al segundo sensor del mismo en los 3 minutos anteriores. Por lo tanto, no se obtiene el dato de tiempo de recorrido medio del tráfico general en un vector a la hora exacta de llegada del autobús a la parada. Para llevar a cabo la comparación de datos de forma rigurosa, se empezarán a considerar los datos de un vector desde el instante de registro inmediatamente posterior a la llegada del autobús al mismo, de manera que se obtendrán los tiempos de tránsito de los vehículos que han estado simultáneamente con el autobús en ese tramo. En la Figura 2 se muestra un ejemplo del registro de tiempos de recorrido del tráfico general mediante sensores bluetooth a partir del recorrido del autobús urbano.

Una vez hecha la aproximación a los instantes de registro inmediatamente posteriores a la llegada del autobús a la parada final e inicial de cada vector, se procede a calcular el promedio de tiempos de recorrido del tráfico general en los vectores 44, 62 y 23 a partir de los datos recogidos por el Ayuntamiento de A Coruña. Si el autobús urbano llega a la parada 119 a las 11:02:50 y a la parada 122 a las 11:05:30, se hará el promedio del tiempo de recorrido del tráfico en el vector 44 para los registros de las 11:03 y 11:06. Calculando el promedio de estos dos tiempos registrados se obtiene el tiempo de recorrido medio del tráfico general en el vector 44 en el período en el que el autobús circuló por el mismo. Este procedimiento se repite de forma análoga para los vectores 62 y 23. Por último, la suma de estos tres promedios será el tiempo medio total de recorrido del tráfico general para el corredor considerado.

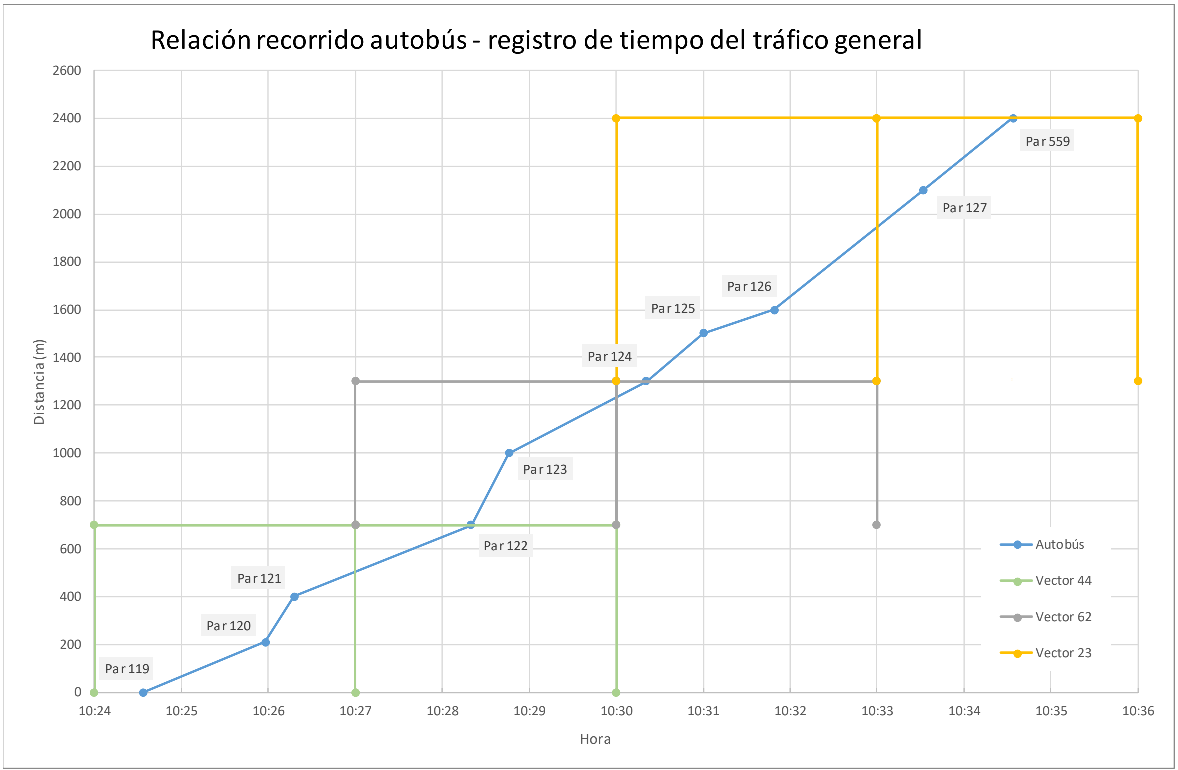

Figura 2. Representación del recorrido del autobús y el registro de tiempo de recorrido medio del tráfico general mediante sensores bluetooth activos. Ejemplo del día 03.02.2019.

3. RESULTADOS Y DISCUSIÓN

A partir de los tiempos de recorrido del autobús urbano y el tráfico general durante el mes de febrero de 2019, obtenidos siguiendo la metodología descrita en el apartado anterior, es posible conocer el ratio entre ambos en el tramo objeto de estudio.

En la Tabla 2 se presentan los tiempos totales de recorrido del tráfico general correspondientes a cada uno de los autobuses considerados para una fecha concreta. En la tabla se incluye también esta proporción entre el tiempo de recorrido del autobús y el tiempo medio del tráfico general, así como el intervalo de paso con respecto al autobús anterior de la misma línea.

Hora llegada autobús Parada 119	Tiempo de recorrido total autobús (s)	Tráfico general				Proporción autobús - tráfico	Intervalo entre autobuses (min)
		Promedio tiempos de recorrido (s)			Total tiempo recorrido (s)		
		Vector 44	Vector 62	Vector 23

Tabla 2. Tiempo de recorrido medio del tráfico general durante el día 03.02.2019.

Como se puede apreciar en la Figura 3, cuanto mayor es el tiempo de recorrido del tráfico general, mayor es el tiempo de recorrido del autobús urbano, observándose en el gráfico cierta correlación entre las dos variables. En la primera semana de febrero, representada en la Figura 3, se han analizado un total de 452 autobuses correspondientes a la línea 14. Durante estos primeros 7 días analizados se concluye que el transporte público tarda entre 1.04 y 3.64 veces más que el tráfico general en recorrer la misma distancia, con una proporción promedio de tiempos de recorrido de 2.03. De forma visual, se puede apreciar en la Figura 3 que la mayoría de registros se sitúan entre los límites marcados por las rectas que representan, por un lado, el tiempo de recorrido de autobús equivalente al del tráfico general (y=x) y, por otro lado, el tiempo de recorrido del autobús triplicando el valor del tráfico general (y=3x). Para los días considerados en la Figura 3, el tiempo de recorrido medio del autobús urbano es de 773 s mientras que el del tráfico general se sitúa en 381 s.

Se ha considerado como umbral de condiciones de tiempo medio mínimo del tráfico general, aquel valor en minutos enteros con al menos 10 valores por debajo. De la misma forma, se ha considerado el umbral de tiempo máximo como el valor con al menos 10 valores por encima. En condiciones de tiempo de tráfico general mínimo, menores que 300 s (5 min), el tiempo de recorrido medio del autobús es de 662 s (11 min). Si se consideran los tiempos máximos del tráfico general, mayores que 480 s (8 min), se obtiene un promedio de tiempo de recorrido del autobús de 1020 s (17 min). Por consiguiente, se puede observar que, entre la situación más y menos favorable para el autobús urbano respecto a la presencia del tráfico general, existe un aumento de tiempo medio de recorrido de 1.54 veces.

Por otro lado, analizando los tiempos de recorrido mínimos y máximos del autobús, por debajo del percentil 5 y superior al percentil 95 de los datos, se obtienen tiempos de recorrido promedio de 487 s y 1162 s respectivamente, produciéndose un ratio de aumento de 2.39. Este dato contrasta con el ratio de 1.94 en el caso del tráfico general, ya que el rango de tiempo de recorrido entre ambos casos extremos es de 5 a 9 min mientras que el autobús se mueve entre los 8 y 19 min, aumentando el tiempo de recorrido máximo en 10 min.

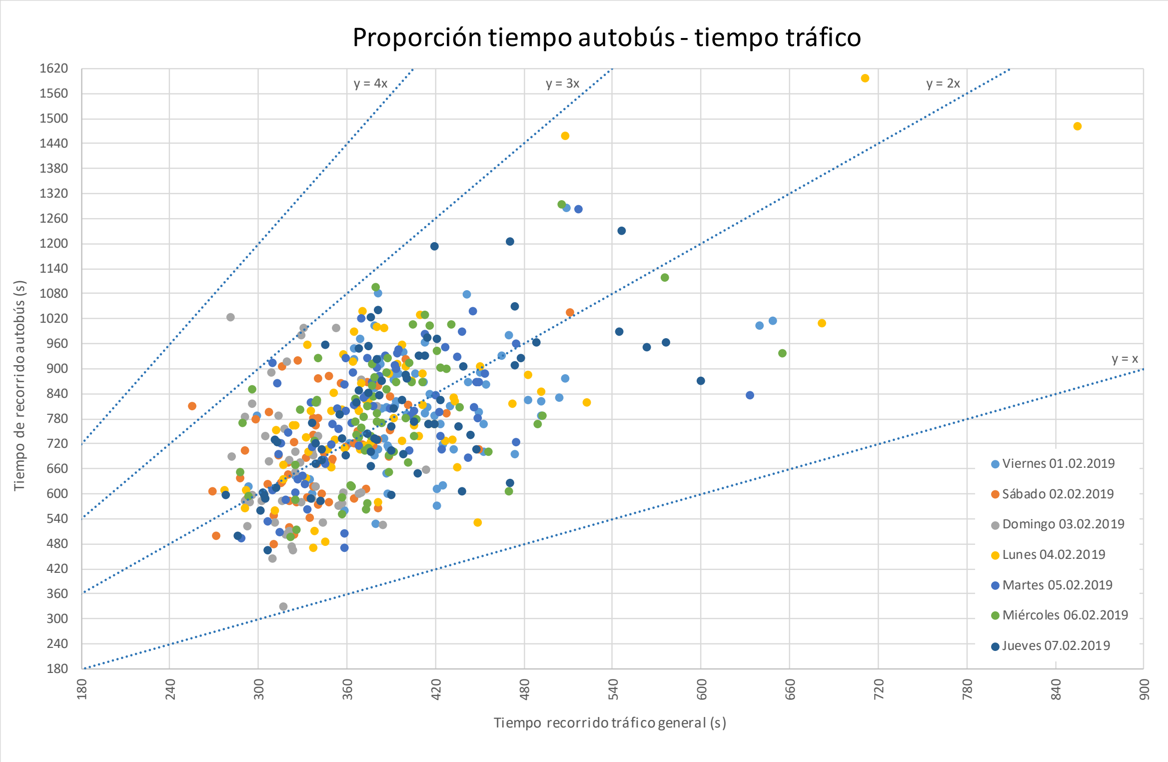

Figura 3. Proporción entre tiempo de recorrido del autobús urbano y tráfico general durante la primera semana de febrero de 2019.

En la Figura 4 se representan los datos calculados para el mes completo. Se observa que el autobús tarda en promedio 2.08 veces más (entre 1.04 y 3.64) que el tráfico general en recorrer el corredor completo, obteniendo resultados similares a los expuestos en Liao et al. (2020), donde se establece una proporción de tiempos entre 1.4 y 2.6. Para llevar a cabo el análisis del mes de febrero de 2019 se han tenido en cuenta 1855 autobuses de la línea 14.

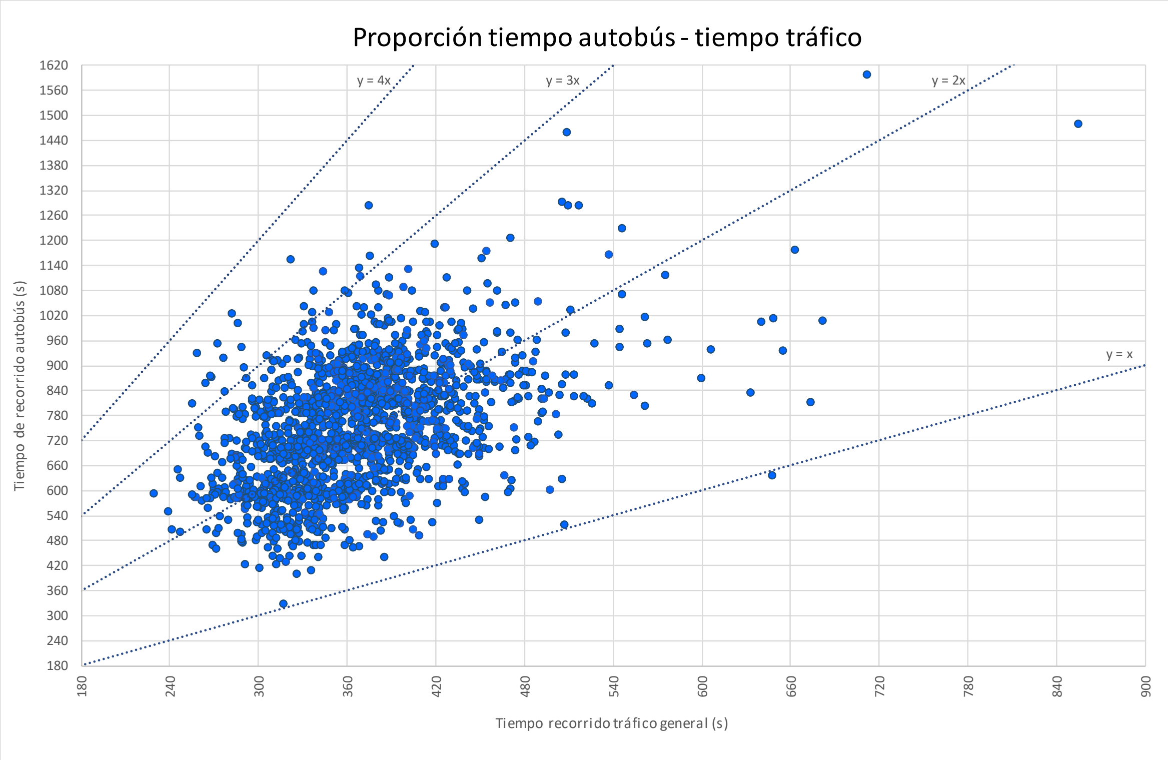

Figura 4. Proporción entre tiempo de recorrido del autobús urbano y tráfico general durante el mes de febrero 2019.

La correlación observada pone de manifiesto la influencia del tráfico en el tiempo de viaje en autobús, pero, sin embargo, la variabilidad de dicho tiempo de viaje para un mismo valor de tiempo de tráfico general indica que existen otros factores que influyen en el tiempo del autobús, como pueden ser la distancia entre paradas, el número de subidas y bajadas en la parada, los ciclos semafóricos, la tipología de paradas o la climatología.

Además de la presencia del tráfico general, los tiempos de operación del transporte público se ven afectados por la frecuencia con la que llegan a la parada los autobuses de la línea. La acumulación de viajeros por el aumento del intervalo entre los vehículos de la Compañía de Tranvías de La Coruña aumentará el tiempo de parada y, por consiguiente, el tiempo de recorrido total. Este hecho se muestra en la Figura 5, que presenta los tiempos de recorrido del autobús y del tráfico general para un día concreto, así como el intervalo entre autobuses en cada momento.

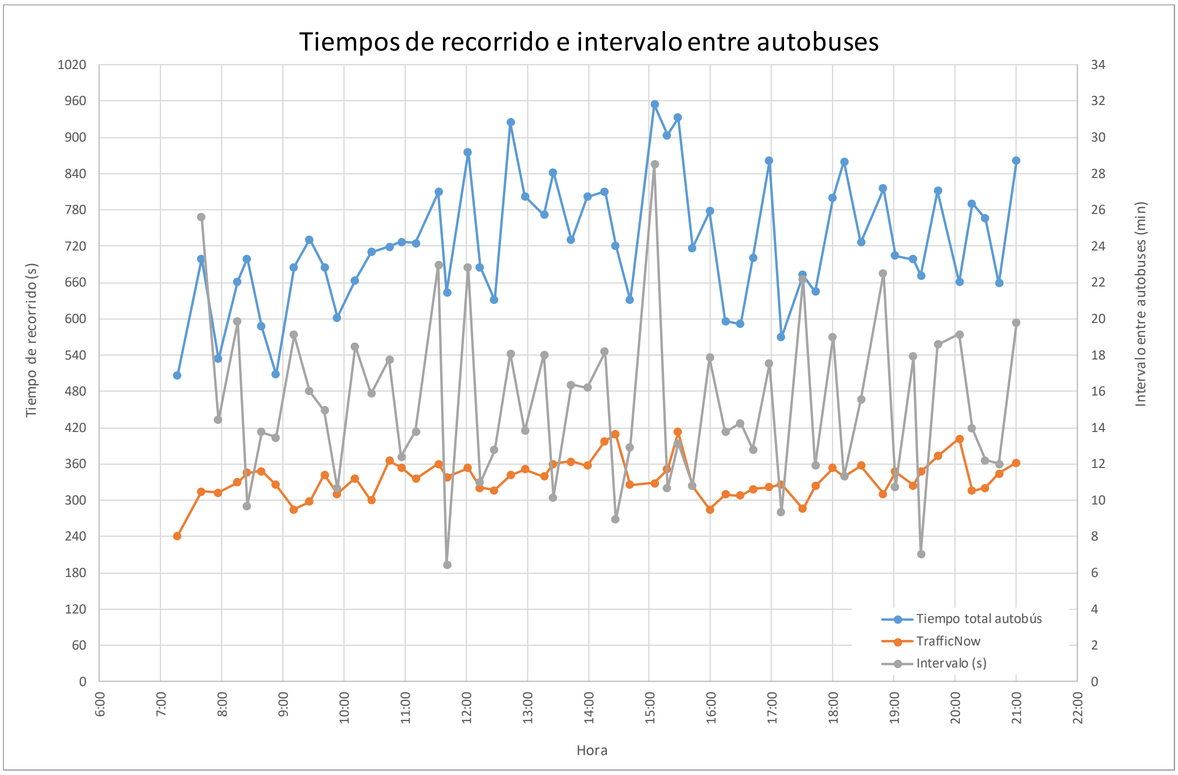

Figura 5. Relación entre tiempos de recorrido e intervalo entre autobuses el día 16.02.2019 en Ronda de Outeiro.

Como se aprecia en la Figura 5, a determinadas horas del día, el aumento en el tiempo del autobús urbano no se justifica con el incremento del tiempo de recorrido del tráfico general. A las 9:10:59 horas del 16 de febrero de 2019 se observa una disminución del tiempo del tráfico y un aumento considerable del tiempo de recorrido del transporte público. Una vez incluida la variable del intervalo entre autobuses, señalada en color gris en la Figura 5, se puede explicar el aumento del tiempo de operación del autobús a las 9:10:59 horas debido al incremento del intervalo. Por otro lado, en el autobús de las 9:41:17 ocurre lo contrario: aumenta el tiempo del tráfico general en el tramo analizado y, sin embargo, el tiempo de recorrido del autobús disminuye. En este caso, el intervalo entre autobuses también puede explicar esta variación, aumentando a la vez que lo hace el tiempo de recorrido del transporte público.

4. CONCLUSIONES Y FUTURAS LÍNEAS DE INVESTIGACIÓN

Los resultados presentados en la ponencia han sido las primeras conclusiones obtenidas de una línea de trabajo que se encuentra en estado inicial. Se espera trabajar en el futuro con un mayor número de registros, considerando para el análisis un período temporal más largo, así como diferentes tramos de diferentes líneas en calles con características diferenciadas, para tratar de determinar la influencia de ciertas variables en el ratio entre el tiempo de viaje en autobús y en transporte público. Están en curso otros trabajos para cuantificar los tiempos empleados por el autobús en las paradas y para estimar el número de viajeros que descienden en cada parada a partir de registros históricos de subidas. Esto permitirá diferenciar la influencia del tráfico, tanto en las maniobras de salida de las paradas como en la propia circulación de los autobuses, de la influencia de la demanda del autobús.

En el presente estudio se ha puesto de manifiesto la variabilidad de la relación existente entre el tiempo de recorrido del tráfico general y el autobús urbano. A partir de los resultados obtenidos y replicando este análisis para otros tramos de la ciudad, se puede considerar la implantación de plataforma reservada en aquellas zonas en las que la influencia de los vehículos sobre el autobús sea mayor. Con esta medida disminuirá el tiempo de recorrido del autobús y no se verá repercutido por atascos ocasionados en el tráfico general.

Por otro lado, se ha evidenciado que el intervalo de tiempo entre autobuses es otro factor que influye sobre el tiempo de recorrido. La información proporcionada por estas dos variables consideradas será útil para la planificación de nuevas líneas de transporte público.

En análisis posteriores se intentarán determinar y cuantificar nuevas variables que influyan en la relación entre el tiempo de recorrido del tráfico general y del autobús, como pueden ser, entre otras: el número de viajeros que suben y bajan en las paradas, el número de intersecciones en el corredor, así como los ciclos semafóricos en las mismas, la sección de la calle (número de carriles, anchura), la tipología de las paradas (bahía, bahía invertida), la meteorología o la intensidad de tráfico medida mediante espiras.

Todos los resultados tienen por objetivo conocer y analizar el comportamiento del autobús urbano y sus causas para así realizar mejoras y conseguir un transporte público más eficiente y más atractivo para los usuarios no cautivos.

AGRADECIMIENTOS

Esta ponencia forma parte del proyecto “Paradas, transbordos y reserva de plataforma. Análisis experimental y modelización de su influencia en sistemas de autobús (IMPROVEBUS)”, de referencia RTI2018-097924-B-I00, financiado por: FEDER/Ministerio de Ciencia e Innovación – Agencia Estatal de Investigación. El primer autor es beneficiario de una beca predoctoral (FPI) PRE2019-089651 incluida en proyecto RTI2018-097924-B-I00, financiado por el Ministerio de Ciencia e Innovación y cofinanciado por el Fondo Social Europeo.

Los autores agradecen al Ayuntamiento de A Coruña el acceso a los datos registrados mediante sensores bluetooth en la ciudad, y a la Compañía de Tranvías de La Coruña (operador del sistema de autobuses urbanos) el acceso a los datos de su Sistema de Ayuda a la Explotación.

ABSTRACT

Connected and Autonomous Vehicles (CAV) is the developing summit of the integration between artificial intelligence (AI), robotics, automotive design and information technologies. Many researchers are investigating their effects on traffic safety. This study tries to quantify the volume of incidents when sharing the road human-driven vehicles and fully CAV. After modeling the geometry of 4.5 km of motorway and the parameters of connectivity and automation using Aimsun Next platform, several scenarios of the percentages of CAV (0%, 25%, 50%, 75%, and 100%) were driven in microsimulation runs. Then the microsimulation generated vehicles trajectories that are used to identify conflicts using the Surrogate Safety Assessment Model (SSAM). The results of this analysis confirm previous research in that the reduction of number of conflicts will be up to 35% with low and moderate penetration rates of CAV and more than 80% if the road is operated only with CAV.

1. INTRODUCTION

The proposed advances in Connected and Autonomous Vehicles (CAV) will widely change the traffic system to make it more efficient. CAV's most common positive effects discussed in the literature are reducing traffic congestion, delay time, and vehicles emissions (Poczter & Jankovic, 2014; Fagnant & Kockelman, 2015) to the way in which CAV are expected to operate in traffic flow. In addition, ongoing CAV manufacturers' field trials expect that CAV are capable to enhance traffic safety. Theoretically, NHTSA (2008) expected that vehicle automation (i.e. limiting human controls and performing the bulk of driving tasks without the need for a human) can play an important role in achieving the target of zero collisions as the majority of traffic conflicts are due to human errors. Connectivity goes besides and strengthens automated vehicle capabilities by enabling them to share their location and other relevant data with nearby vehicles and infrastructures for safer repositioning and streaming (Petit & Shladover, 2015).

The Society of Automotive Engineers (SAE, 2014) developed a scale for manufacturing levels of CAV from zero to five to define their progression. Level 0 indicates that there is no driving automation. Level 1 is equipped with lateral or longitudinal system for driver assistance. Level 2 uses partial driving automation upon driver request. Level 3 represents the conditional driving automation (i.e. the car transfers the control to the driver and the driver should respond to the car request). Level 4 is with high driving automation and full responsibility for driving task. Finally, Level 5 is with full driving automation and able to operate the car everywhere.

In the last five years, the volume of work evaluating the safety gain hypothesis has increased (e.g. Xie et al., 2019; Papadoulis et al., 2019, Morando et al., 2018). Almost all the related research contend that the safety impact is primarily governed by market penetration rates of CAV. Due to a lack of enough real data, simulation-based microscopic, stochastic methods have been used. These methods involve the CAV penetration rates in car-following and lane changing driving models to reflect the individual vehicles interaction with other vehicles, geometry, and other road elements (HCM, 2016). Consequently, the potential traffic conflicts resulting from vehicles interaction is the measure to evaluate the safety impacts of CAV involved in microsimulation.

Traffic conflicts are situations in which vehicles travel close in time and space in such a way that they could potentially end up in a crash (Hydén & Linderhonm, 2012). To identify these risky situations (traffic conflicts), the vehicle trajectories resulting from simulation are scrutinized using surrogate safety measures indicators (e.g. time-to-collision (TTC), post-encroachment time (PET), etc.).

This study expands the insight into the dynamics of CAV and their impact on safety. It provides a connectivity and automation modeling with the microsimulation platform that enables the modeler to deal with driving dynamics with more details, control, and reliability. In this platform (Aimsun Next platform with V2X extension) many penetration rates of CAV are operated on the case study (motorway segment). Later, the Surrogate Safety Assessment Model (SSAM) is used to quantify the effect of CAV on the corridor safety and compare the results with previous research.

The paper is organized as follows: next section, identifies the most relevant literature on CAV safety evaluation. A detailed description of the motorway segment drawn in Aimsun Next platform guided by Open Street Map, and modeling the car-following and lane-change behavior of the CAV are introduced in section three. The fourth section of the paper presents the results obtained from the simulation, and discusses them with previous literature. Finally, the last section summarizes the conclusions of the research, presents the study limitations and proposes future directions for CAV simulation research.

2. LITERATURE REVIEW

Most prior research performed traffic efficiency assessment of connected and/or automated vehicles (e.g. Guériau et al. 2016; Talebpour & Mahmassani, 2016; Stanek et al., 2018; Makridis et al., 2018) , but few safety evaluation studies exist (e.g. Morando et al., 2018; Papadoulis et al., 2019; Rahman; 2019). To these studies: introduction of CAV would increase the throughput of highway facilities and improve traffic flow stability (Talebpour & Mahmassani, 2016). CAV can also make about 20% of speed improvement (Stanek et al., 2018) and increase the road capacity with the increase in the CAV-penetration rate within even a heterogeneous flow (Ye and Yamamoto, 2018).

The initial work on CAV was based on stability analysis and simulating CAV using a proposed simulation framework (e.g. Talebpour & Mahmassani, 2016, Pereira & Rossetti, 2012). These studies created an integrated multi-level simulation framework that includes traffic, sensors (robotics), and network simulators in order to achieve detailed CAV simulation. Nevertheless, the results of these one-of-a-kind models were less reliable and difficult to compare.

Further studies started to use a traffic microsimulation platform and its internal/external extensions. This approach showed a considerable ability to model a large scale networks and gave reasonable results (Roncoli et al., 2015; Park et al., 2012). However, since the operational behaviour of CAV is described differently in each study, their results are not always comparable.

Particularly, most of researchers in this approach chose VISSIM to simulate CAV. ATKINS (2016) provided a milestone in simulating the CAV in VISSIM when they use the COM interface to change the CAV-related parameters, penetration rates, time headways that end up with changing driving behaviour when applying the driver model of VISSIM (Wiedemann 99 flow model). Following the criteria of ATKIN (2016) report, Jeong et al. (2017) improved an algorithm to control the longitudinal movement and gave powerful insights with micro safety results. But they still have a weakness since they did not develop a lateral movement control. Meanwhile, Stanek et al. (2018) changed the default VISSIM driver models parameters to show the effect on traffic behaviour. Similarly, Papadoulis et al. (2019) and Gueriau & Dusparic (2020) followed the mentioned approach for analyzing traffic safety.

In microsimulation-based studies, they used to apply the Surrogate Safety Assessment Model (SSAM) developed by the Federal Highway Administration for CAV traffic safety evaluation. Rahman et al. (2019) investigated the safety effect of vehicles with low levels of automation and vehicle-to-vehicle (V2V) and infrastructure-to-vehicle (I2V) connectivity technologies. From SSAM indicators, they integrated several measures (e.g. time exposed time-to-collision (TET), time integrated time-to-collision (TIT), lane changing conflicts

(LCC), etc.) to quantify the conflict risk on an intersection. They found that there is a significant safety enhancement resulting from introducing CAV.

Papadoulis et al. (2019) used the VISSIM API's External Driver Model to develop a decision-making CAV control algorithm and then SSAM time-to-collision indicator was used to measure the number of conflicts. A comprehensive safety evaluation study showed the percentage of conflicts reduction with different CAV market penetration rates: daily, in space, and by conflict type. A fully-CAV-operated motorway showed an extreme reduction in number of conflicts (about 94%) which is very close to the theoretical expectation made by NHSTA (2008).

Moreover, Gueriau & Dusparic (2020) studied the effect of CAV on both efficiency and safety in three types of networks (urban, national, and motorway), simulating different penetration rates of vehicles with various levels of automation. Their results showed that lower penetration rates result in a 30% rise in conflicts, but higher penetration rates result in a 50-80% reduction in conflicts, with steady growth of the increased penetration.

On the other hand, Zhang et al. (2020) developed a platoon control algorithm to represent the cooperation of CAV. To assess the safety impact of setting exclusive lanes for CAV, four surrogate safety indicators were used, including both longitudinal and lateral safety risk indexes. In high-truck ratios scenarios, setting exclusive lanes improves longitudinal and lateral protection up to 55% and 85% respectively.

Finally, it could be shown that safety evaluation of CAV depends primarily on the assumptions of CAV's simulated behaviour in movement. Once there is lack of information about CAV and Human Driven Vehicles (HDV) contact, a special and direct platform of calibrating CAV is need. To this intention this study uses the Aimsun Next API with new versions and extensions that are made especially to model CAV behaviour.

3. METHODOLOGY

The procedure was to design fully CAV (i.e. totally depending on the technology in driving process). This begins with understanding the driving behaviour difference between HDV and CAV. Accordingly, different parameters values affecting car following and lane-changing models used in Aimsun Next platform are applied to CAV and HDV.

3.1 Connectivity between vehicles

Vehicles connection was conducted by building the connection network using V2X Aimsun Next extension. This network includes: On Board Unit (OBU) in each CAV, that represents the receiver and transmitter in a vehicle; Channels, which is the simulated representation of the radio hardware and protocols that provide communication between vehicles; and Cooperative Awareness Messages (CAM), that provide information about the presence, activity and position of CAV. Channel design depends basically on the number of probable CAV in the channel range, their speed, and the channel reliability. This is expressed using three characteristics:

- *Latency*: The delay in packet transmission,
- *Range*: The range of transmission, and
- *Packet Loss*: The percentage of packets which are not received.

Following many research works (Teixeira et al., 2014; Mir and Filali, 2014; Ahmadvand et al., 2016; Chen et al., 2019) and based on our case (higher than 125 connected vehicles in the channel range if the speed is about 100km/h), the selected channel was: *IEEE 802.11p (250 m range) with 2100 ms latency and 0.75 packet loss.*

3.2 Automation parameters

As many studies did, vehicle full automation was modeled by calibration of all needed parameters that control both longitudinal and lateral movements on the road and distinguish the CAV over HDV. The traffic flow model used in Aimsun Next API is Gipps model, so the parameters discussed below are those entering the model' equations.

Specifically, vehicles parameters are modified according to vehicle behavior models: "Car-Following" and "Lane-Changing" as they move through the network.

Gipps (1981) car-following model was created by incorporating the parameters that are influenced by local parameters such as: the "type of driver" (speed limit acceptance of the vehicle), the geometry of the section (speed limits on the section, speed limits on turns, etc.), and the impact of vehicles on adjacent lanes.

However, acceleration and deceleration are the two main elements of Gipps model. The first reflects a vehicle's willingness to reach a certain desired speed, while the second simulates the restrictions imposed by the preceding vehicle when attempting to travel at that speed. The maximum speed that a vehicle (n) can accelerate during a time period (t, t+T) is given by this model:

$$V_a\,(n,\, t+T) = V(n,t) + 2.5a(n)T\left(1 - \frac{V(n,t)}{V*(n)}\right)\sqrt{0.025 + \frac{V(n,t)}{V*(n)}} \quad (1)$$

Where:

$V_a(n,t)$ is the speed of vehicle n at time t;
V*(n) is the desired speed of the vehicle (n) for current section;
a(n) is the maximum acceleration for vehicle n;
T is the reaction time.

At the same time, the maximum speed that the same vehicle (n) can reach during the same time interval (t, t+T), according to its own characteristics and the limitations imposed by the presence of the lead vehicle (vehicle n-1) is:

$$V_b\ (n,\ t+T) = d(n)\ T + \sqrt{d(n)^2T^2 - d(n)\left[2(x(n-1),t) - s(n-1) - x(n,t)) - V(n,t)T - \frac{V(n-1,t)^2}{d'(n-1)}\right]} \quad (2)$$

where:

d(n) (< 0) is the maximum deceleration desired by vehicle n;
x(n,t) is position of vehicle n at time t;
x(n-1,t) is position of preceding vehicle (n-1) at time t;
s(n-1) is the effective length of vehicle (n-1);
d’(n-1) is an estimation of vehicle (n-1) desired deceleration.

Gipps (1986a and 1986b) lane-change is modelled as a decision process, analyzing the *necessity* of lane change (such as for turn maneuvers determined by the route), the *desirability* of lane change (to reach the desired speed when the leader vehicle is slower, for example), and the *feasibility* of lane change (using forward, backward, and adjacent gap evaluation) depending on the position of the vehicle in the road network with respect to the lane geometry and adjacent vehicles.

			HDV		CAV	
Parameters	**Definition**	**References**	**mean**	**s.d.**	**mean**	**s.d.**
Main parameters						
Speed acceptance	How much vehicles could take a speed greater than speed limit	Atkin (2016), Stanek et al. (2018), Ye and Yamamoto (2019)	1.1	0.1	1	0.05
Clearance (m)	Distance that vehicle keeps with the preceding one when stopped	Atkin (2016), Stanek et al. (2018)	1	0.3	0.2	0.2
Max give-way time (sec)	Give-way time at a Yield or stop junction or an on-ramp	Atkin (2016)	10	2.5	7.4	0.5
Guidance acceptance (%)	The probability that a vehicle will follow the recommendations	Stanek et al. (2018)	70	10	100	0
Reaction time (sec)	The time to react in general	Zhang et al., (2020)	0.8	-	0.6	-
Reaction time at stop	The time to react at stop	Zhang et al., (2020)	1.2	-	1	-
Max acceleration (m/s²)	The highest value that the vehicle can achieve under any circumstances	Atkin (2016), Stanek et al. (2018), Karjanto et al. (2017)	3.28	0.2	3.72	0.15
Normal deceleration. (m/s²)	The maximum deceleration that the vehicle can use under normal conditions	Atkin (2016), Naujoks et al. (2016), Karjanto et al. (2017) Zhang et al., (2020)	3.27	0.25	4.12	0.18
Max deceleration (m/s²)	The most severe braking can be applied under special circumstances	Atkin (2016), Naujoks et al. (2016), Karjanto et al. (2017), Zhang et al., (2020)	5.39	0.5	6.2	0.3
Safety margin factor	a multiplier of a normal range of gap acceptance range	-	1	0	1.5	0.2

Table 1- Gipps models parameters affected by the type of driver

			HDV		CAV	
Parameters	**Definition**	**References**	**mean**	**s.d.**	**mean**	**s.d.**
Car-following model						
Sensitivity factor	How much the vehicle could be sensitive to the deceleration of the leader	-	1	0	1.5	0.5
Gap (sec.)	How much override the headway calculated by car following model	Karjanto et al. (2017)	0	0	0.6	0.1
Headway aggressivenes s	How much vehicles could enter with shorter gaps without forcing the rear vehicle to brake	Stanek et al. (2018)	0.8	0.2	0	0
Lane-changing model						
Overtake speed threshold	The threshold that delaminates an overtaking maneuver	Stanek et al. (2018)	90	-	95	-
Percentage staying in overtaking lane	The probability that a vehicle will stay in the faster lane instead of recovering to the slower lane after an overtake maneuvers	Naujoks et al. (2016)	40	-	20	-
Imprudent lane change	Defines whether a vehicle will still change lane after assessing an unsafe gap	Naujoks et al. (2016)	Ticke d	-	Non ticked	-
Cooperate in creating a gap	Vehicles can cooperate in creating a gap for a lane changing vehicle	Stanek et al. (2018)	non ticked	-	ticked	-
Aggressivenes s Level	The higher the level, the smaller the gap the vehicle will accept, being a level of 1 is the vehicle's own length	Stanek et al. (2018)	0-1	-	0-0.75	-
Distance Zone Factor	To modify the distance zones used in the Lane Changing Model to adjust where lane changes start to be considered and, if a range is given, to randomize behavior	Stanek et al. (2018), Talebpour and Mahmassani (2016)	0.8-1.2	-	0.6-1.5	-

Table 1 (cont.) - Gipps models parameters affected by the type of driver

Consequently, while default values in most of the model's parameters are supposed to represent HDV, CAV tend to keep smaller standstill distances, accelerate and decelerate faster and smoother, keep constant speed with no or smaller oscillation at free flow, form platoons of vehicles and follow the leader, perform more co-operative lane change as lane changes could occur at a higher speed co-operatively (Stanek et. al, 2018).

Table 1 shows the specific parameters that are affected by automation in Gipps' car following and lane-change models depending on previous research (Atkin, 2016; Stanek et al., 2018; Zhang et al., 2020; Karjanto et al., 2017; Naujoks et al., 2016) and logic. Parameters definitions are summarized from Aimsun user manual. Table 1 presents both mean and standard deviation (s.d.) values that were defined before microsimulation. The values follow a normal distribution as it is proposed in Gipps' model. The discussion about the values for both HDV and CAV is provided below.

3.2.1 The main parameters

It is supposed that CAV will respect the speed limits. CAV's clearance is directly adopted from ATKINS (2016) report as minimum space headway. Stanek et al. (2017) showed lower deviation values because of full-dependence on technologies. Maximum give-way time is suggested to be the same to the minimum time gap in ATKINS (2016) report. The report also showed lower deviation for CAV. Guidance acceptance is proposed to be 100% with no deviation in fully CAV.

No previous research has directly detailed CAV's reaction times and it is not a parameter considered in VISSIM car following model (Wiedemann 99). Also, in Aimsun Next old versions, it was considered a global parameter (i.e., with fixed value in the simulation). Recently, since version Aimsun Next 4.3, this parameter is subjected to calibration depending on the type of vehicle that allows the change for CAV. However, Zhang et al. (2020) suggested a hint value that was depending on Adaptive Cruise Control (ACC) platoons applied on the field.

In general, connection-automation technologies are supposed to show higher speed in reaction. Thus, it should be significantly lower when the driving is fully connected and automated (Zhang et al., 2020). The same behaviour will be on unexpected stops, that requires highly connection technology or referring to the driver.

For acceleration and deceleration**,** ATKINS (2016) and Stanek et al. (2017) suggested that CAV will be accelerating and decelerating faster and smoother, resulting in higher values. Besides, the deviation will be lower than in HDV values by 25% according to achieving higher uniformity in dynamic driving process (Stanek et al., 2017).

As CAV will be more cooperative in gap acceptance, a multiplier of 1.5 is proposed for safety margin factor.

3.2.2 Car-following parameters

It is supposed that CAV will be more sensitive to leader action. Thus, a multiplier of 1.5 is proposed for sensitivity factor. In addition, it could override the headway calculated by car following model by 0.6 sec (Karjanto et al., 2017), but without any aggressiveness (Stanek et al., 2017).

3.2.3 Lane-change parameters

As CAV show more co-operation in considering maneuvers, a slight increase of percentage of vehicles that travel at less than Overtake Speed Threshold is suggested. Moreover, they cooperate in creating a gap (Stanek et al., 2018). However, CAV prefer to go back to the original lanes and will not make a lane-change if the gap is not safe (Naujoks et al., 2016). Furthermore**,** in Stanek et al. (2017), CAV showed a reduction of 0.75 of human vehicle driven gap acceptance in lane changing. As a result, the zones that are considered as lane-change distance will be modified by the same factor (Stanek et al., 2017; Talebpour & Mahmassani, 2016).

3.3 Simulated scenarios

After adjusting car following and lane-change models' parameters, five scenarios were considered with different sharing percentages of both HDV and CAV (100/0, 75/25, 50/50, 25/75, and 0/100). The developed models, were calibrated for the times of the real-world trips; between 10:00 and 12:00 am (off-peak hours) in a regular day. The number of replications for each scenario needed in order to achieve a 90% confidence interval level for the simulation output was calculated using Shahdah et al. (2015) equation (Eq. 3). It was shown that 15 runs is a sufficient sample.

$$N = \left(\frac{t_{(1-\alpha/2),N-1} * \sigma}{E}\right)^2 \quad (3)$$

Where, N equals the required number of simulation runs, σ equals the sample standard deviation of the simulation output, t is the student's t-statistic for two-sided error of a $\alpha/2$ with $N-1$ degrees of freedom and E equals the allowed error range, where $E = \varepsilon * \mu$; μ is the mean of the number of simulated conflicts based on the initial set of simulations runs and ε is the allowable error specified as a fraction of the mean For example in 100% CAV scenario we tested a 15 runs trial (with $\sigma = 28.06$, t = 2.14 (with α = 0.05 and degree of freedom =14), E = (0.10*305) and it was a sufficient sample. Likewise, 15 runs were a sufficient value for all scenarios.

3.4 Safety evaluation

As expected, the model does not generate any crashes in the simulation. So, the model cannot be used to explicitly calculate collisions or traffic safety. In order to assess the safety, the outputs of vehicles trajectories from Aimsun microsimulation runs have to be analyzed using SSAM. The trajectories at each time step of simulation (0.2 s) are examined to check the existence of traffic conflicts instead of crashes.

The indicator that has been applied in most studies (Gueriau & Dusparic, 2020; Papadoulis et al., 2019; Rahman et al. 2019) to assess traffic safety is the time-to-collision (TTC). It is defined as the time that remains until a collision could occur if two successive vehicles maintain a speed difference (Hayward, 1972). The TTC of vehicle i with respect to a leading vehicle i + 1 at time step t can be calculated with:

$$TTC\ (i,t) = \frac{d\ (i,t)}{v\ (i,t) - v\ (i+1,t)} \quad \forall\ v(i,t) > v\ (i+1,t) \quad (4)$$

Where d(i, t) and v(i, t) denote the real space gap and the speed of vehicle i at time step t, respectively.

Following the recommendation of Papadoulis et al. (2019) and after a sensitivity analysis, we used a threshold value of TTC equal to 1.5 to identify conflicts.

4. RESULTS AND DISCUSSION

Safety assessment of CAV in this study is conducted on a modeled motorway segment in Aimsun Next platform. Imported Open Street Map was used as a background to create the geometry (i.e. curves of the road segment, lane width and the length of links, merging and diverging areas) of the segment using drawing tools and overlapping the sections created with the map. As case study, a three-lane motorway section was chosen of the GR-30 freeway, close to Granada city in Spain. The designed corridor was 4.57 km long, with fourteen on and off-ramps and nine vehicle input points (seven ramp entrances and two major entrances from south and north) After including the segment geometry, many information from the network has also been modeled, including speed limit, detectors location, and traffic volume. Directional traffic flow (pc/hr) was obtained from several detectors managed by the Dirección General de Tráfico (DGT) in Granada.

Firstly, this section provides a check of the simulation performance by presenting the distribution of TTCs, velocity difference, and acceleration during simulation steps along the five scenarios modeled. Then a sensitivity analysis of TTC thresholds is laid out. Afterwards, the resulted conflicts are discussed among scenarios.

4.1 Traffic flow dynamics

4.1.1 TTC distribution

The introduction of low CAV penetration rates increases both low and high TTC values due to non-consistent flow dynamics (Figure 1). Under high CAV penetration rates, smoother traffic flow reduces large TTC values while reducing the gaps by CAV increasing the ratio of small TTCs. This distribution is logic and agrees with Ye and Yamamoto (2019) research work.

4.1.2 Acceleration distribution

Figure 2 shows that under low penetration rates scenarios, acceleration ratio about 0 slightly decrease due to the lack of harmony in traffic flow, but with high penetration rates the ratio of acceleration rate about 0 increases obviously that indicates smoother dynamic flow. Similarly, this distribution is logic and agrees with Ye and Yamamoto (2019).

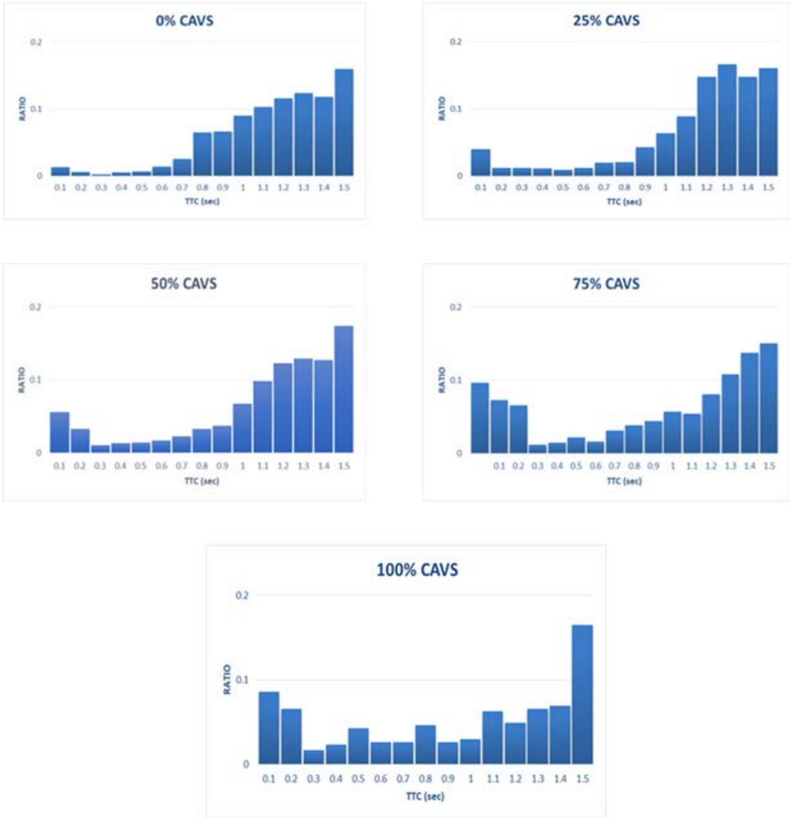

Fig. 1- TTC distribution under the proposed scenarios

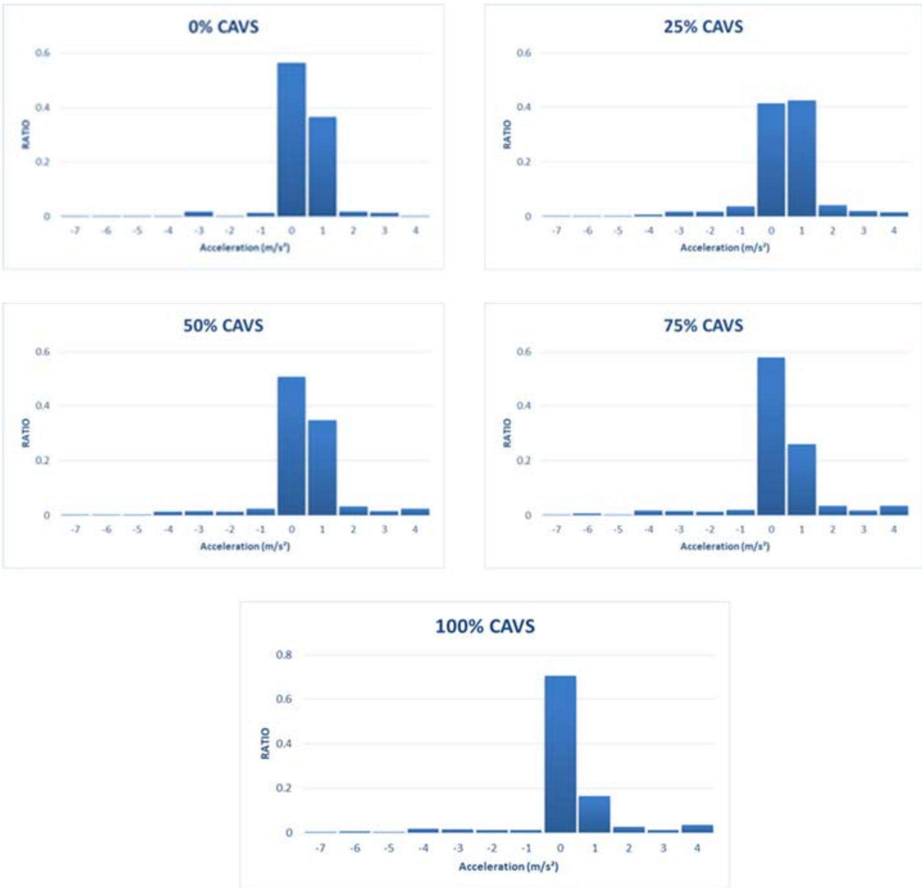

Fig. 2 - Acceleration distribution under the proposed scenarios

4.1.3 Velocity difference distribution

The distribution of difference between the vehicle and its leader velocities for each scenario are shown in Figure 3. A bell shape with a lower peak is present in the distribution of low penetration rates and covers a wider range. The velocity difference ratio of the bell peak slightly increases at high sharing percentages of CAV. The difference in velocity tends to cluster around small values (0, 1). This phenomenon shows that the velocity difference between vehicles is reduced and traffic flow is harmonized with the rise in the CAV penetration rate which is logic and agrees with Ye and Yamamoto (2019).

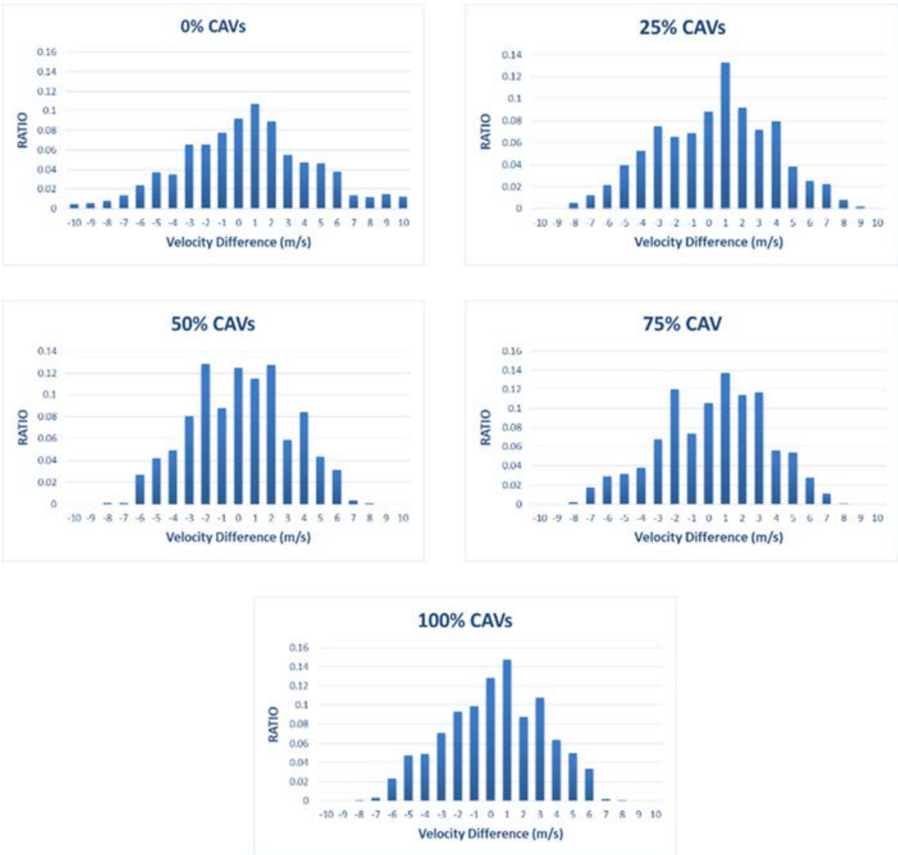

Fig. 3 – Velocity-difference distribution under the proposed scenarios

4.2 TTCs sensitivity analysis

TTC threshold is critical in analyzing traffic conflicts and it is more questionable for CAV. Thus, CAV traffic safety studies used to make a sensitivity analysis to check the effect of changing this value and chose a proper threshold (Zhang et al., 2020; Papadoulis et al., 2019; Morando et al., 2018). In this study, a sensitivity analysis for TTC thresholds of 0.5, 1.0, 1.5, 2.0, and 2.5 seconds has been conducted for CAV introduction scenarios (25% CAV, 50% CAV, 75% CAV and 100% CAV). Using the analysis of variance (ANOVA), the change in percentages of conflicts between each CAV penetration scenario and the HDV scenario was not significantly different in most cases when comparing 1.5 seconds and both 1.0 and 2.0 seconds. But 0.5 and 2.5 seconds (the lowest and the highest thresholds) were statistically significant from the other values (Table 2). Graphical illustration (Figure 4) of mean and standard deviation for the change in percentages of conflicts also showed the same results in variance. The significant values in 0.5 and 2.5 values is normal since the potential conflicts will noticeably change with such extreme time to collision thresholds. Meanwhile Papadoulis et al. (2019) have found non-significant variance even with extreme values; Zhang et al. (2020) have used just 1.0, 1.5, and 2.0 values in their analysis and found the same results of this study. Consequently, both studies used 1.5 seconds as a threshold value.

	Time-to-Collision (TTC)				
	0.5 s	1.0 s	1.5 s	2.0 s	2.5 s
Scenario 25% CAV	39.50 a	-21.54 b	-2.56 c	1.84 c	34.08 a
Scenario 50% CAV	11.39 a	-39.26 b	-35.90 b	-29.81 b	-3.67 c
Scenario 75% CAV	-9.57 a	-54.53 b	-60.83 b	-55.75 b	-29.01 c
Scenario 100% CAV	-47.07 a	-77.16 b	-82.66 c	-80.53 b,c	-68.42 d

For each scenario, a, b and c values denote differences statistically significant ($p < 0.05$). Two or more TTC values with the same letter denote a homogeneous subgroup.

Table 2-The percentage of change in the number of conflicts for each TTC value

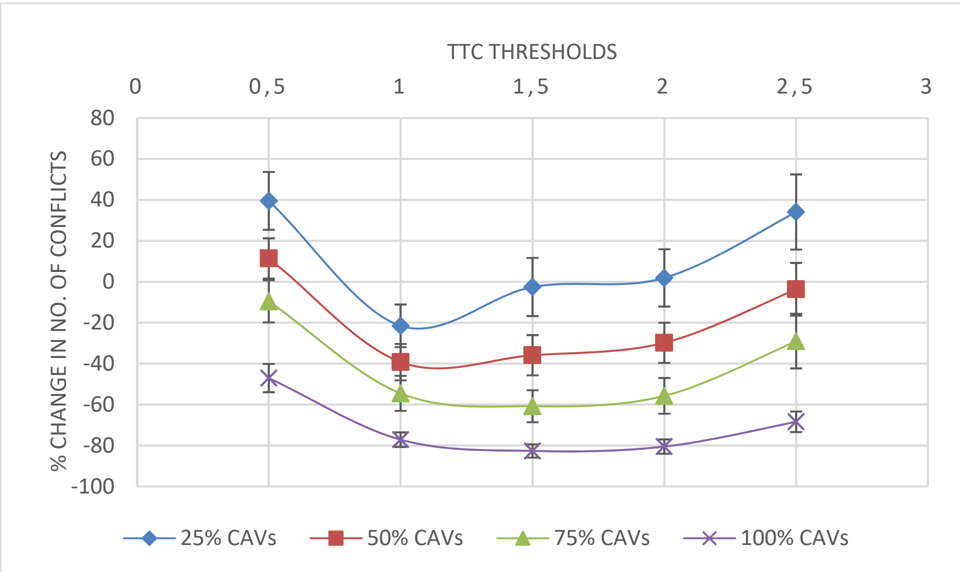

Fig. 4 – Sensitivity analysis of TTCs thresholds under the proposed scenarios

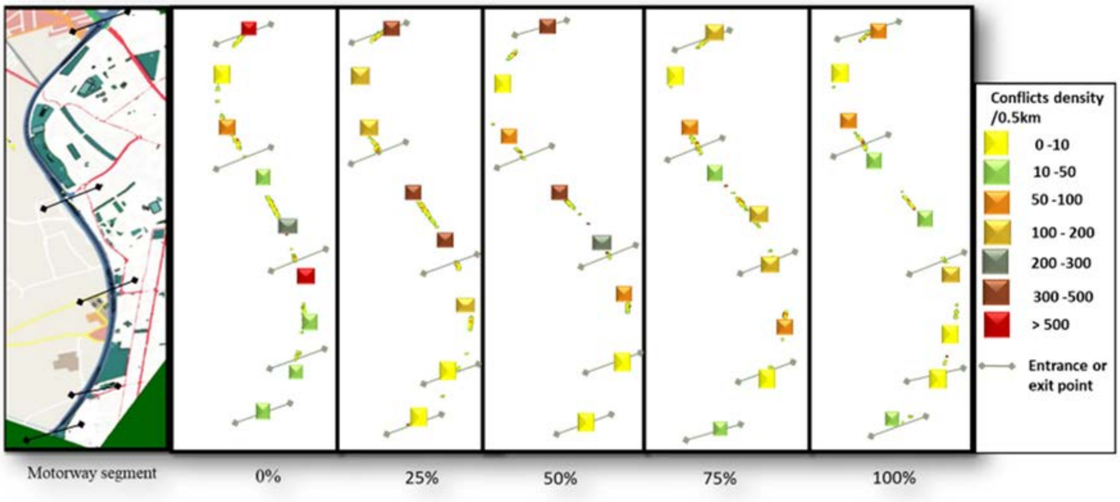
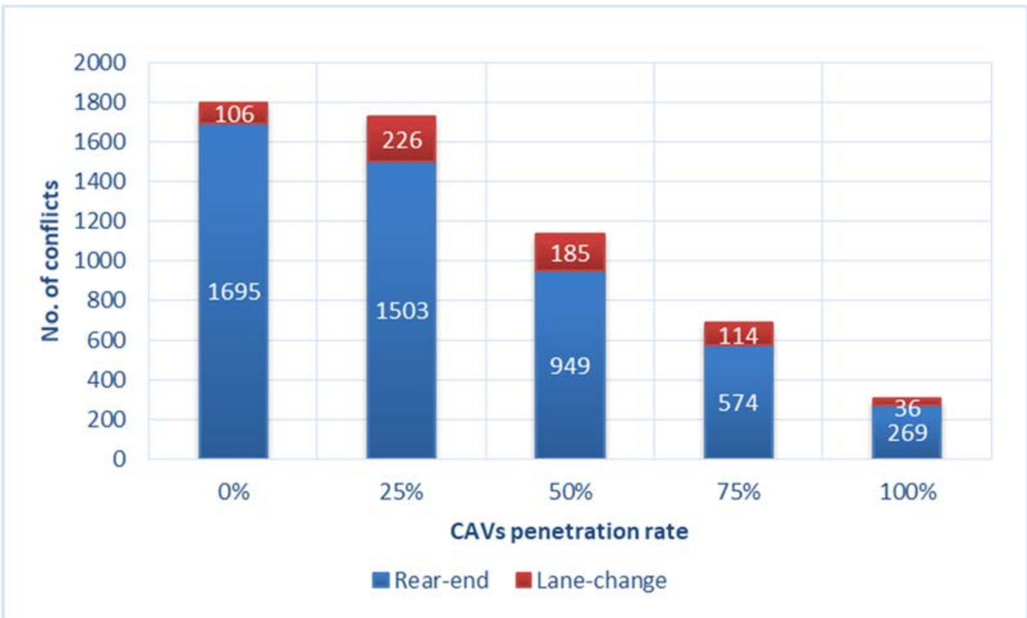
4.3 Quantifying the safety impact of CAV penetration

Using 1.5 s as TTC threshold, the average results of the conflicts tried out of microsimulation runs are shown in Figure 5. Increasing the penetration rates of CAV has positive effect on decreasing the number of possible conflicts. The reduction percentages of conflicts for 25%, 50%, 75% and 100% CAV scenarios are 2.56%, 35.9%, 60.83%, and 82.66% respectively. These results agree with Papadoulis et al. (2019) for motorways and Morando et al. (2018) for intersections. On the other hand, Gueriau & Dusparic (2020) and Xie et al. (2019) have shown that low levels of automation could increase the potential conflicts especially in low penetration scenarios.

Figure 5 (a) shows the previous main result by density of resulted conflicts within the segment at the conflicts distribution map. The density representative points of each 500 m range show decreasing in the number of conflicts by increasing the percentages of shared CAV that agrees Papadoulis et al. (2019) results. In addition, the figure shows that the probable conflicts are near to the entrances and exits of the motorway as it was observed in Gueriau & Dusparic (2020). This is due to speed differences at these points that affect the possibility of resulting conflicts.



(a)



(b)

Fig. 5 – Conflicts resulted by the proposed scenarios: (a) Conflicts density representative points. (b) Number of conflicts by type

Figure 5 (b) shows the effect of penetration rates of fully CAV on conflict type. The resulting conflicts at this motorway are mostly rear-end conflicts in the base scenario (only HDV scenario). While rear-end conflicts are probably to be 93.95%, 86.9%, 83.64%, 83.37%, and

88.12% of overall conflicts, lane-change conflicts will be of much lower percentages (5.96%, 13.09%, 16.32%, 16.59%, and 11.89%).

Whereas rear-end conflicts had the same direction of reduction of the total conflicts, the effect was different in the case of lane-change conflicts. Even sharing just 25% of CAV can over duplicate the percentage of lane-change conflicts. This is related to the significant difference in behaviour between HDV and fully CAV in lane-change process (imprudent lane change, cooperation in create gap, and aggressiveness level) (ATKINS, 2016; Stanek et al., 2018). After that the percentage of lane-change conflicts was not affected significantly with increasing CAV ratios.

5. SUMMARY, CONCLUSIONS AND LIMITATIONS

In this paper, it was applied a simulation-based safety assessment of introduction of fully connected and automated vehicles. It was conducted on a motorway segment with free flow condition. The modeling of CAV was done using Aimsun Next API by building connection network and calibration the automation behaviour of both longitudinal and lateral movements. This platform enables the user to calibrate the behaviour parameters with a range rather than fixed value (i.e. mean, min, max, deviation values) that improve the calibration to be realistic and reliable. Moreover, the used models (Gipps models) in this platform deal with parameters that reflect a direct and explicit driving behaviour such as reaction time, speed and guidance acceptance, driving aggressiveness.

Traffic flow dynamic was configured by drawing the distribution of some indicators (TTCs, acceleration and velocity-difference) resulted after traffic microsimulation. These distributions demonstrate that increasing the penetration rates of CAV will make the flow dynamics more harmonized and smooth.

The potential conflicts were detected by calculating the time to collision (TTC) indicator using SSAM. To test the proposed value of TTC threshold (1.5 s), a sensitivity analysis was applied for a range around this value (between 0.5 and 2.5 seconds) and the results showed a significant difference in case of extreme values (0.5 s and 2.5 s) but non-significant difference between the values 1.0, 1.5, and 2.0 seconds on the impact of CAV.

The effect of introducing the fully CAV is through with the theoretical and experimental exist research. The positive effect (i.e. the reduction in the total number of conflicts) reached about 35% for medium penetration rates and 80% for fully operated motorway of CAV.

This work is limited to various circumstances: it considers only HDV and fully CAV vehicles, while in the real world several type of vehicles, with several automation levels will be circulating simultaneously; and it considers only one type of road section. Further studies could deal with different levels of automation. Also, many types of road sections, traffic conditions, and vehicles could be simulated.

AKNOWLEDMENTS

Financial support from the Spanish State Research Agency (Research Project PID2019-110741RA-I00) is gratefully acknowledged. The authors are also grateful to the Spanish General Directorate of Traffic (DGT) for providing the traffic flows from several GR-30 sections. Tasneem Miqdady appreciates Aimsun to provide their postgraduate student license to make this work.

ABSTRACT

In recent years, Intelligent Transportation Systems are leveraging the power of increased sensory coverage and available computing power to deliver data-intensive solutions achieving higher levels of performance than traditional systems. Within Traffic Signal Control (TSC), this has allowed the emergence of Machine Learning (ML) based systems. Among this group, Reinforcement Learning (RL) approaches have performed particularly well. Given the lack of industry standards in ML for TSC, literature exploring RL often lacks comparison against commercially available systems and straightforward formulations of how the agents operate. Here we attempt to bridge that gap. We propose three different architectures for RL based agents and compare them against currently used commercial systems MOVA, SurTrac and Cyclic controllers and provide pseudo-code for them. The agents use variations of Deep Q-Learning (Double Q Learning, Duelling Architectures and Prioritised Experience Replay) and Actor Critic agents, using states and rewards based on queue length measurements. Their performance is compared in across different map scenarios with variable demand, assessing them in terms of the global delay generated by all vehicles. We find that the RL-based systems can significantly and consistently achieve lower delays when compared with traditional and existing commercial systems.

1. INTRODUCTION

Traffic Signal Control (TSC) can be used to ensure the safe and efficient utilisation of the road network at junctions, where traffic can change directions and merge, having to manage conflicting individual priorities with the global needs of the network. Traffic congestion has a major financial impact. A study by (INRIX 2019) shows that traffic congestion in 2019 cost £6.9 billion in the UK alone, with similar patterns being observed in other developed countries.

Cities around the globe are starting to explore the deployment of smart Urban Traffic Controllers (UTCs) that use real time data to adjust their stage schedule and green time duration. Traditionally, fixed time plans have been used. Those fixed time plans can be managed by systems that try to optimise the green time splits in a deterministic manner such as TRANSYT (Robertson 1969). These types of systems require costly site-specific knowledge of the traffic lights placement and typical demand profiles to be able to provide effective control. These methods are not easily scalable and deteriorate over time as the traffic demand changes as explained by (Bell and Bretherton 1986). With the development of induction loops, real time actuated UTCs were created in two variants: those that optimize single isolated intersections with systems such as MOVA (Vincent and Peirce 1988), and those that cover multiple intersections such as SCOOT (Hunt et al. 1982). To remedy the scalability problem, other systems based on local rules that generate self-organising area traffic controllers were developed, such as SurTrac (Smith and Barlow 2013), which solves a forward implementation of Dynamic Programming.

With the recent breakthrough of Deep Reinforcement Learning (DRL) on complex problems such as Atari games or Go (Mnih et al. 2013; Silver et al. 2017; Hessel et al. 2018), attention has turned towards adapting these approaches to generate industry-grade controllers for traditionally noisy and difficult to control systems such as TSC.

The purpose of this paper is to reproduce some of the results of the main and most successful RL approaches on intersections of increasing complexity, while comparing different architectures of DRL TSC agents, since, given the complexity of their implementation, most available literature only deals with a single class.

2. STATE OF THE ART

2.1 Previous Work

Reinforcement Learning (RL) is an area of Machine Learning that tries to imitate how biological entities learn. In it, an independent agent evolves in an unknown environment and learns how to perform a task for which no prior information is given based on its interactions said environment via a set of allowed actions. The agent aims to maximise the total reward signal it receives as a feedback for each of its actions.

RL methods have been applied to TSC in experimental setups. A good review of early methods can be found here (Mannion, Duggan, and Howley 2016). More recent works (Liang et al. 2018; Genders 2018; Liu, Liu, and Chen 2018) use neural networks as function approximators to avoid the dimensionality and computing time limitations of table based methods in large state-action spaces, and show that DRL TSC can be more efficient than some earlier methods.

While there is a variety of approaches in the literature that craft successful RL-based TSC systems, most of them do no present direct comparisons against commercial systems that are the concern of this paper. Gao et al. (2017) used a Convolutional Neural Network (CNN) and discrete cell encoding with a Target Network for a value-based agent. The results were compared against a fixed time and a heuristic system (longest queue first), finding RL to perform better. In Mousavi, Schukat, and Howley (2017), raw pixels were used as input for a CNN that parametrises two agents: a policy-gradient agent and a value-based agent. The variation in the delay between actions was used as reward, and while both agents were found to have near-identical performance, they were not compared against any reference system. Later, in Wan and Hwang (2018) a DQN using discrete cell encoding as state was implemented. It used a CNN architecture and a delay-based reward. It was compared against a fixed time system, obtaining better performance. Liang et al. (2018), used the same approach and included speed information in the state, using a reward based on variations on aggregated wait time for all vehicles. It compared against two different fixed-time systems, ranking better than both and providing some early evidence of the benefits of using Double DQN, Duelling architecture and Prioritised Experience Replay. In Genders and Razavi (2018) different state spaces were evaluated using a policy-gradient algorithm, including: occupancy and speed for each incoming road, queue and a measure of density of incoming roads, and Discrete Cell Encoding, partitioning the incoming roads into cells of fixed lengths, in this case 2.5 metres. Genders found little difference in the performance of the agents as a result of the change in the magnitudes observed, but it could be argued that a discrete cell encoding would greatly benefit from a Convolutional Neural Network (CNN) architecture in the agent, which is not used.

Regarding comparisons with established systems, in Stevanovic and Martin (2008) the authors compare SCOOT with a Genetic Algorithm-based control method. It is shown that SCOOT's performance can be surpassed by more adaptive Genetic Algorithms that, in turn, tend to be less effective at learning than RL methods.

Despite these previous works, most results are hard or impossible to reproduce given the lack of industry standards in terms of simulators, performance metrics, the lack of availability of commercial algorithms for comparison and the fierce protection of their internal workings, and the lack of open-source code of proposed RL models.

2.2 Commercial Traffic Signal Control Optimisers

MOVA (Microprocessor Optimised Vehicle Actuation, (Vincent and Peirce 1988)) is a traffic controller designed by TRL Software. It aims to reduce delay on isolated junctions. The basic functioning of MOVA involves two induction loop detectors estimating the flow of vehicles in each lane. The system makes a virtual cell representation of the lanes within MOVA, and then it computes a performance index based on the delays calculated. If the index results lower than a certain threshold, the signal is changed to the next stage, otherwise the stage it is extended.

Surtrac (Scalable URban TRaffic Control, (Smith and Barlow 2013)) is an adaptive TSC system published in 2013. A real-world deployment on 20 intersections in Pennsylvania showed a performance improvement of 20-40% in performance. Its operation is decentralised, each intersection allocates green time independently and asynchronously based on incoming flows. Each intersection is controlled by a local scheduler and communicates projected outflows to the downstream neighbouring junctions, modelling vehicles as a sequence of clusters. This communication allows for locally balancing competing flows while creating larger "green corridors" by finding an optimal sequence such that the input jobs (ordered clusters) are cleared while minimising the joint waiting time of all vehicles.

3. METHODS

3.1 Traffic Control as a Markov Decision Process

The control problem can be formulated as a Markov Decision Process (MDP) defined in terms of a 5-tuple:

- A set of possible environment states $s \in \mathcal{S}$.
- A set of available actions to the agent $a \in \mathcal{A}$.
- A stochastic transition function $\forall a \in \mathcal{A}, \mathcal{T}_{s,s'}^{a} \triangleq \mathbb{P}(s_{t+1} = s' | s_t = s, a_t = a)$.
- A scalar real valued reward function $R(s_t, s_{t+1}, a_t)$ providing a performance measure to the transition generated by progressing into the state s_{t+1} after taking action a_t while in state s_t
- A discount factor γ that will provide the balance between immediate exploitation and approaches that aim to maximise returns over time.

Each time an action is required, the agent will receive a state vector s_t from the environment. Based on this state, the agent will produce an action a_t, which will be implemented in the simulator. The environment will then advance time until a next action is required, according to its dynamics represented by $\mathcal{T}_{s,s'}^{a}$. At this point, the next state s_{t+1} will be observable. Both states will be used to generate a reward r_t to serve as feedback to the agent. The agent will receive the state observation s_{t+1} and the cycle will start again.

In the case of TSC, the MDP is modelled as partially observable, following an unknown stochastic transition function. From here on, it is assumed that the traffic environment displays the Markov property, i.e. the process is memoryless, with the next state only depending on the current state and the action taken.

3.2 Reinforcement Learning

The goal of the agents will be to maximise their future discounted return, $G_t = \sum_{t=0}^{+\infty} \gamma^t \, r(s_t, a_t)$ with $\in [0,1]$. This is done by learning a policy π, parametrised by the weights θ of the neural network performing the approximation of the reward function and mapping states to actions: $\pi: f_1(s) \to a$. The reward function maps an action given a state to a reward scalar value: $r: f_2(s, a) \to \mathbb{R}$. The action-value function or Q-value is $Q_\pi(s, a) = \mathbb{E}_\pi[G_t | s_t = s, a_t = a]$. It represents the total episodic return by following policy π after being in state s and taking action a.

3.3 Value-based Reinforcement Learning Methods - DQN

Tabular value-based methods, such as Q-Learning, attempt to learn an optimal policy $Q_\pi^* = \max_\pi \mathbb{E}[r_t | s_t = s, a_t = a]$ by iteratively performing Bellman updates on the Q-values of the individual state-action pairs:

$$Q_\pi(s_t, a_t) \leftarrow Q_\pi(s_t, a_t) + \alpha\big(y_t - Q_\pi(s_{t+1}, a_{t+1})\big), \quad (1)$$

where α is the learning rate and y_t is the Temporal Difference (TD) target for the value function

$$y_t = r_t + \gamma \max_{a_{t+1}} Q_\pi(s_{t+1}, a_{t+1}, \theta'). \quad (2)$$

Deep Q-Network (DQN) agents are an evolution of Q-Learning. The purpose of the agent is to find an approximation of Q_π^* by tuning the weights θ of a neural network. The agent keeps a second neural network, the target network, parametrised by the weights vector θ' which is used to generate the TD targets:

The experience replay memory is used to increase training stability, obtaining samples that cover a wider number of situations. It can also increase the data efficiency since the same transition can be used several times for gradient descent. Three additional modules have been applied to the basic agent to improve performance, Double Q Learning (Hasselt 2010), Prioritised Experience Replay (Schaul et al. 2016), and Dueling Architecture (Wang et al. 2015).

Two variants of the DQN agent have been implemented, being described on the algorithms displayed in Figs. 1 and 2. The agents implemented used the hyperparameters described in Fig. 4.

Algorithm 1 Operation of the implemented Dueling DQN Agent with PER

```

3.4 Policy Gradient Reinforcement Learning Methods - A2C

Policy Gradient in RL is based on the idea that obtaining a direct policy $\pi(s)$ mapping states to actions can be easier than estimating the value function or the state-action values. It has an added benefit in that it can learn stochastic policies, generating a probability distribution over the potential actions. The goal is to find the policy that maximises the reward. To do so one has to perform gradient ascent on the performance measure $J = \sum_a [Q(s_0, a)\pi(a|s)]$. The Synchronous Advantage Actor Critic (A2C) method tries to reduce the variance in the policy method by combining the direct mapping from actions with the value-based approximation method. The goal is to learn an actor

$$\pi_\theta = \mathbb{P}_\theta[a_t = a | s_t = s], \quad \text{and a critic} \quad V_\pi^\theta(s) = \mathbb{E}_\theta[G_t | s_t = s], \tag{3}$$

both of which are parametrised by the neural network weights vector θ.

Algorithm 3 Operation of the implemented Advantage Actor Critic Agent

Initialise actor network with random parameters θ_a,
Initialise critic network with random parameters θ_c,
for *each episode* **do**
  reset gradients $d\theta_c = d\theta_a = 0$ measure initial state s_0
  choose action $a_t = \pi(s_t)$ according to $\pi_\theta(a_t|s_t)$,
  while *episode not done* **do**
    implement action a_t,
    advance simulator until next action needed,
    measure new state s_{t+1}, and calculate reward $r_t = V_{\theta_c}(s_t)$,
    choose action $a_{t+1} = \pi(s_{t+1})$ according to $\pi_{\theta_a}(a_{t+1}|s_{t+1})$,
    update actor $\theta_a = \theta_a + \alpha\nabla_{\theta_a} \ln \pi_{\theta_a}(a_i|s_i)Q_{\theta_c}(s_i, a_i)$,
    calculate TD error $\delta \leftarrow r_t + Q_{\theta_c}(s_{t+1}, a_{t+1}) - Q_{\theta_c}(s_t, a_t)$,
    update critic $\theta_c = \theta_c + \alpha\delta\nabla_{\theta_c}Q_{\theta_c}(s, a)$,
  end
end

3.5 State, Action and Rewards of the agents

The experiments presented in the following sections all use the same descriptions for simulator state and reward calculation, although they differ in the number of actions available to them.

The state of an intersection of l lanes will be presented to the agents as a state vector $s \in \mathbb{R}^{l+1}$. Each component will contain the length of the queue of vehicles measured upstream from the traffic light in metres. The last component will be the numeric ID of the current stage that the agent is implementing.

While marginal improvements in performance can be obtained by using different variables for reward (Cabrejas Egea et al., 2020.; Cabrejas-Egea and Connaughton 2020b), as per the discussion of Heydecker (2004), queues can be a reasonable choice for states and rewards, being able to transmit useful information to the agent relative to the mean rate of delay of the system. Based on this, the reward after an action will be calculated as the negative sum of the length of the queues of all lanes immediately upstream from the intersection:

$$r_t = -\sum_l q_l^t \, . \qquad (4)$$

The agent has a set of actions $\mathcal{A}$ that varies depending on the intersection being controlled. Once the agent chooses an action a, the stage corresponding with the ID of a is implemented. Green stages are set to a minimum of 6 seconds. Once this time has passed, the agent is requested a new action. If the agent chooses the same action again, the current stage is extended for a further 3 seconds. There are no inbuilt limitations as to how many times an agent can extend a stage, leaving it for the agents to learn. If the agent chooses a different action than the currently active one, a 3 seconds amber stage is implemented in the lights that were green, after which, the new stage is implemented.

3.6 Agent Benchmarking

In order to compare the agents' performance, a testing framework was defined. For each model, a demand profile will be created, following the shape found in a typical day as described by using the methodology introduced in (Cabrejas Egea, De Ford, and Connaughton 2018) and expanded in (Cabrejas-Egea and Connaughton 2020a). The profile will be split on 10 segments of length 6 minutes. Each of these segments will correspond with a level of demand. The levels of demand are obtained by setting out what will be the maximum demand the intersection will suffer, setting that magnitude to coincide with the peaks of the distribution that could be found on said typical day and are specified in each experiment's section.

Random seeds are changed and updated after every simulation episode, training or testing. The quantitative metrics on which the system will be evaluated are the Global Cumulative Delay (accounting for any deviations from the maximum speed) and the Average Queue Length generated by all vehicles during the execution of the evaluation.

4. EXPERIMENTAL RESULTS

4.1 Experiment 1: Cross Straight

The first test is conducted on the simplest junction, shown in Fig 5. The junction referred to as Single Cross is composed on 4 lanes distributed in 4 arms coinciding with the cardinal directions of the model. The controller for the junction has two stages, a north-south stage and an east-west stage, and turning is not allowed. The testing aim was to perform an initial performance comparison of DRL algorithms against MOVA, SUTRAC, and a cyclic controller. Here the goal for the agent was to exert fine adaptive timing control while extrapolating, rather than using complicated transitions between stages that would rarely, if ever, appear in sequence in cyclic control. MOVA was configured using loop detectors set in accordance to its manual, the implementation of Surtrac follows the work of Xie et al. (2012), and the cyclic controller was set on a 56 second cycle following both the methodology presented in (Salter 1996) and a parallel optimisation process, reaching the same result.

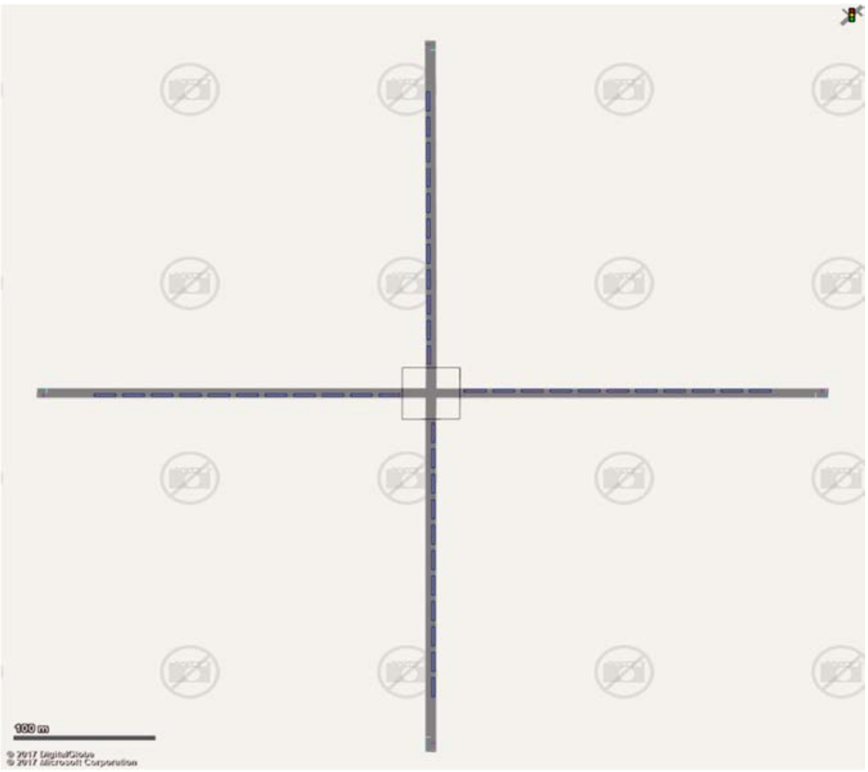

Figure 5 - Cross Straight Map.

The agents were trained using a fixed vehicle demand of 400 vehicles per hour on each of the incoming lanes. Both DQN variants were trained for 400 episodes, using an ϵ geometrically annealed from 1 to 0.001. The A2C agents were trained for 100 episodes until they converged. Best performing agents in each class were selected for benchmarking and evaluated in scenarios lasting one hour, as described in the previous section with the demands shown in Table 1. During evaluation, an average of 2120 vehicles are inserted in the model, with 2 peaks of demand of 3000 vehicles/hour for 6 minutes each. Figure 6 and 7 and Table 2 show the Global Cumulative Delay and average queue length for the network. As expected, the cyclic solution is outperformed by all adaptive controllers. The different controllers are on a par with a slight advantage for the DuelingDDQN which saves the community an average of 3000 seconds compared to MOVA on this hour of simulation, which represents on average 1-2 seconds per vehicle. RL agents also seem slightly more robust against changes in demand, producing lower slopes in the delay graphs in sections of extreme demand.

Time period [min]	North	East	South	West
0-6	200	200	200	200
6-12	400	400	400	400
12-18	900	500	900	500
18-24	1000	500	1000	500
24-30	700	500	700	500
30-36	500	700	500	700
36-42	500	1000	500	1000
42-48	500	900	500	900
48-54	400	400	400	400
54-60	200	200	200	200

Table 1 - Demand in vehicles/hour per cardinal direction over the benchmark in Cross Simple.

The cyclic controller resulted in saturated lanes during both peaks and queues in excess of 150 metres during a great part of the simulation. MOVA suffered two moments in which at least a sensor was saturated coinciding with the peaks in demand, however the queues were close to lengths of around 50 metres during the most part of the simulator. Surtrac followed a similar pattern, having a single lane saturated coinciding with the second peak in demand. RL agents as suffered no saturation in any of their lanes during the length of the evaluation. They all managed a more balanced distribution of queues in their respective lanes, displaying a higher ability to balance loads during peak times.

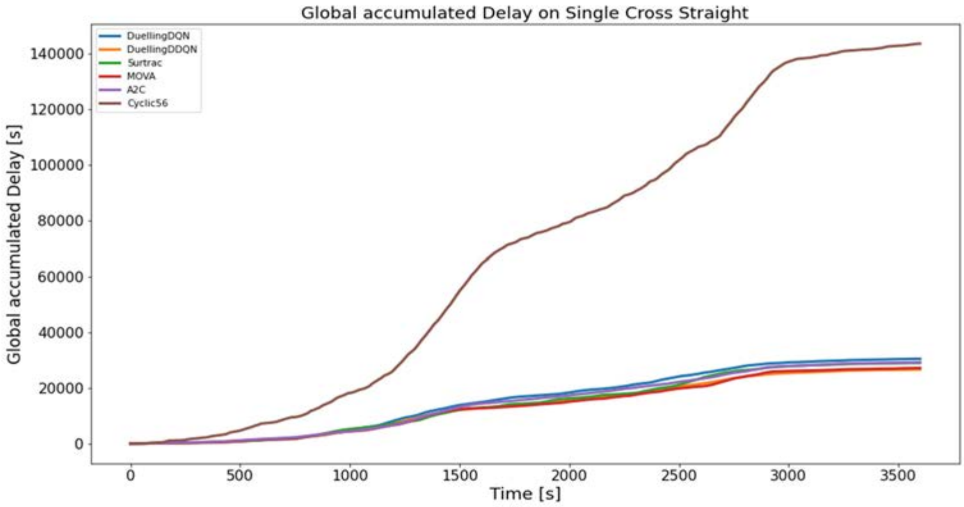

Figure 6: Global Cumulative Delay in Single Cross for DQN variants, A2C, Surtrac, MOVA and the reference Cyclic controller.

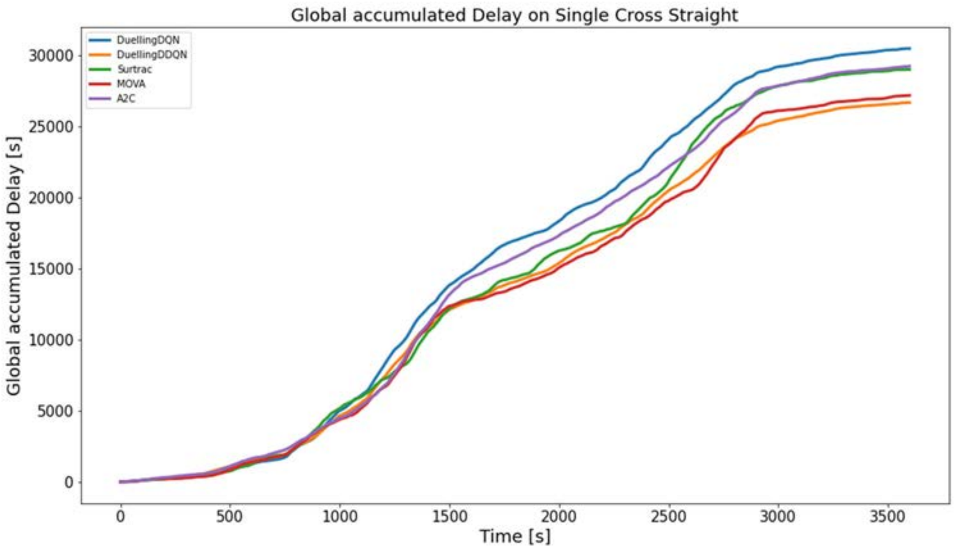

Figure 7: Global Cumulative Delay in Single Cross for DQN variants, A2C, Surtrac, MOVA and the reference Cyclic controller.

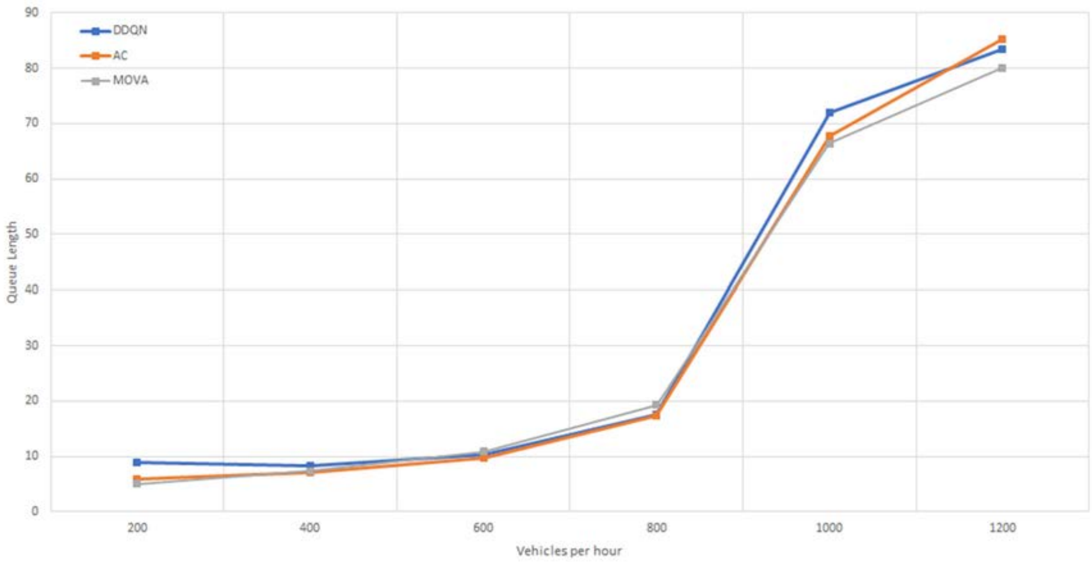

Figure 8: Queue length by demand level in Single Cross

When comparing the systems that obtain the best performance, RL agents and MOVA, across different constant demand profiles, we observe that MOVA obtains a small advantage at the extreme low and high demand levels, but this difference is overcome by the RL based systems in the middle demand levels. This gives another indication that while MOVA can obtain really good results, especially at constant demand, it is not optimal, having room for improvement in the control exerted while in situations of varying demand.

Controller	Cumulative Delay [s]	Average Sum of Queues [m]
Cyclic	143660.50	132.37
MOVA	27187.53	60.59
SURTRAC	29008.36	72.41
A2C	26382.14	56.07
DDQN	28303.94	50.11
DDDQN	21286.86	49.42

Table 2 - Cumulative Delay and Cumulative Stop Delay in seconds across Controllers on Single Cross Straight.

Because of the simplicity of this 2 actions intersection, there is not a lot of delay difference between adaptive UTCs. As it will be appreciated shortly, these results will change when we consider more complex junctions.

Given the difference in performance between the adaptive and cyclic controllers, which is expected to become greater on more complex intersections, and the increasing difficulty in setting them in large intersections, the cyclic controller will be omitted for the next examples. Given that the A2C agent has been clearly outperformed in this experiment by those based on the DQN architecture, the following experiments will focus on the performance of this last architecture compared with commercial systems.

4.2 Experiment 2: Cross Triple - 4 actions

This junction, as shown in Fig. 9, displays a much higher complexity than the intersection presented in the previous section. It is composed of 4 incoming links of 3 lanes each. In each incoming link, the left lane serves a dedicated nearside turning lane, the central allows for forward travel and the right lane allows for both offside turning and going straight. Due to limitations in how Vissim internally treats the queues, it is not possible to obtain a straightforward measurement of the lane queues in links that have more than one lane. To mitigate this, the first experiment was run with agents that would take 4 queue inputs (one for each incoming link), plus the state of the traffic signal as state input. The action set was consequently limited to 4 different actions, being allowed only those that set to green the 3 traffic lights serving the lanes of the same incoming link. This allows for turning vehicles but prevents more sophisticated stages from happening.

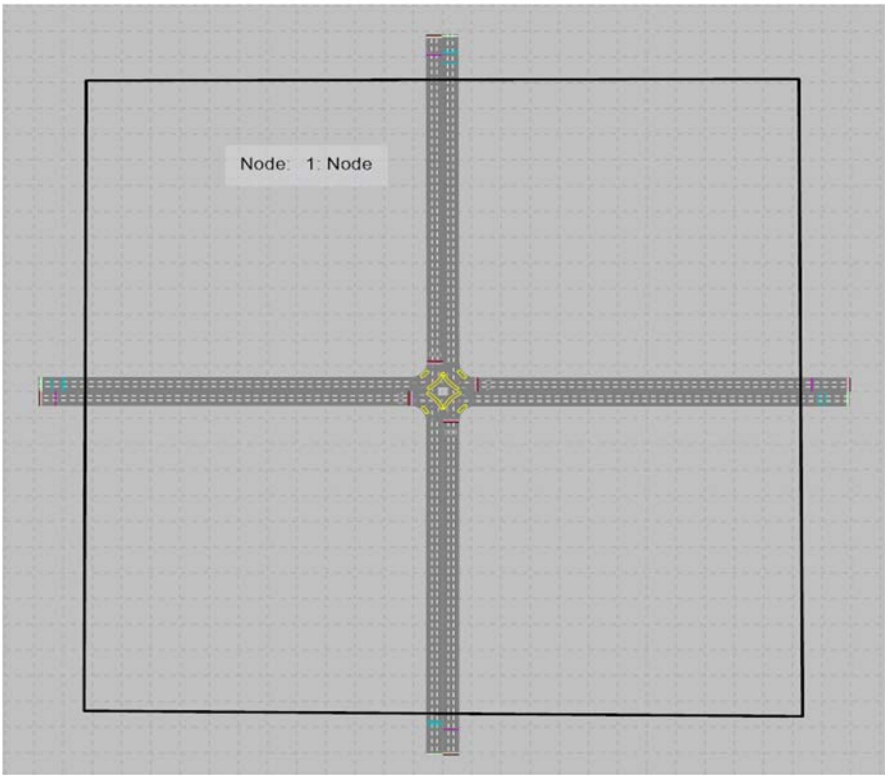

Figure 9 - Cross Triple Map.

The agents were trained on a fixed demand of 400 vehicles per hours on each incoming link. The DQNs were trained for 400 episodes of one hour of simulated time, with ϵ annealed geometrically between 1 and 0.001. A2C agents were trained for 100 episodes until they converged. During the hour of evaluation, the demand profile from the last experiment was used with a scaling factor of 1.5, an average of 3180 vehicles were introduced to the model, with 2 peaks of demand of 4500 vehicles/hour for 6 minutes each, as shown in Table 3.

As it can be seen in Figure 10 and Table 4 the UTC using MOVA performs poorly compared to the DQN-based agents. During this hour of simulation RL agents halve the cumulative delay, saving over 27 hours of travel time for all vehicles involved, an average of over 32 seconds of per vehicle. The length of the queues in those intersections controlled by RL agents during the test scenario were lower than the ones controlled by MOVA. Additionally, it can be seen that the agent using Dueling Q-Learning has a better performance than that Dueling Double Q-Learning.

Time period [min]	North	East	South	West
0-6	300	300	300	300
6-12	600	600	600	600

Controller	Cumulative Delay [s]	Average Max Queue Length [m]
MOVA	260257.65	179.27
DDQN	135220.91	153.58
DDDQN	155563.22	128.20

Table 4 - Cumulative Delay in seconds and Average Sum of Max Queue length in meters on Single Cross Triple - 4 actions.

4.3 Experiment 3: Cross Triple - 8 actions

In order to allow the use of a higher variety of stages in the controllers the map was reworked. All original lanes were partitioned into their own independent links, allowing extra space for lane changes. While these modifications allowed using information from all lanes in an akin manner to what modern sensors would achieve, due the limitations to lane changing, direct comparisons with Experiment 2 must be handled with care. Both models share name and rough geometry, but the layout of lanes is changed and so are the routing possibilities open to the vehicles.

The results presented below, use DQN agents taking 12 queue length inputs plus the state of the signal. Here, 8 different stages are available as represented in Fig. 11. No specific stage order is enforced, and the agents are free to change between any combination of stages.

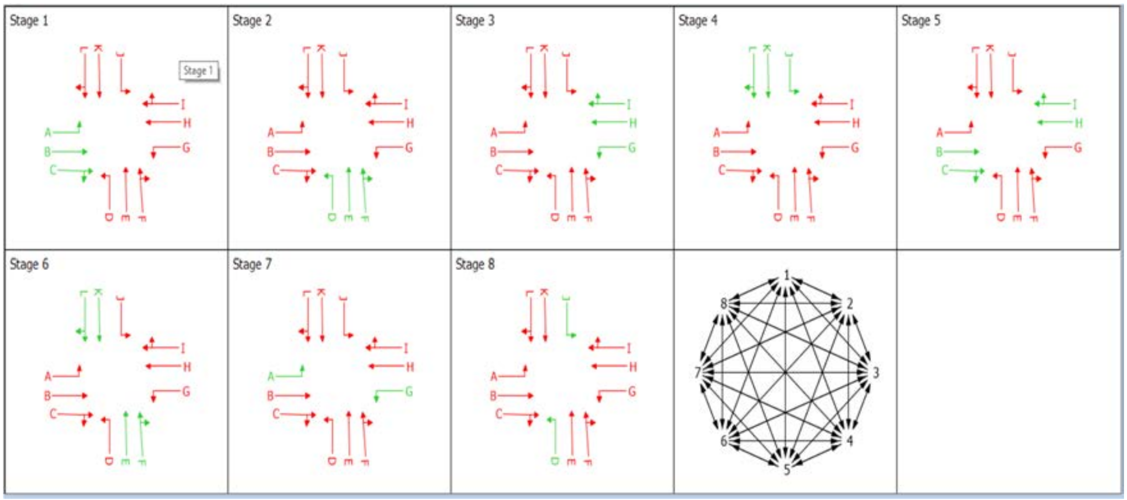

Fig 11 - Allowed stages of the Single Cross Triple model and allowed transitions between stages.

The RL agents display a similar, yet wider gap in performance with MOVA as in the previous experiment, with both classes benefiting from the increased actions pool. RL agents manage to generate about a third of the delay produced by MOVA. While this appears to be a great success, these results must be put into context. MOVA has a lot of internal parameters meant to be fine-tuned by a traffic engineer with site-specific knowledge. Our settings did produce a successful control loop, operating in line with what was expected of the configuration process. None of the RL agents has been fine tuned to the level that would be expected during commercial operation. The layers and neuron distribution weren't optimised, nor were the activation functions, meaning that the RL agents can still be improved upon.

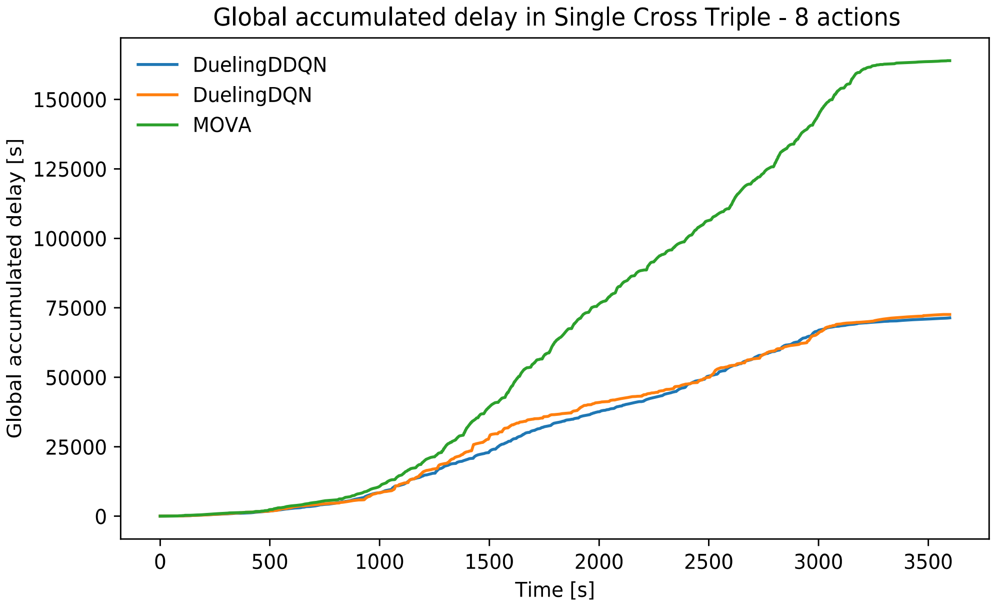

Figure 12 - Global Cumulative Delay in Cross Triple - 8 actions.

When we look at how the performance of the different systems scales as the demand increases, we can observe in Fig. 13 that in the complex intersection where the RL agents have the ability to freely switch between stages, they obtain better performance than MOVA across the board. In the scenarios covering low demand levels, where in simple intersections MOVA was obtaining marginally better performance, now the situation is reversed, mostly due to the previously mentioned ability to switch to the most suitable stages in absence of a predefined order, which was not the case in the intersection with 2 stages.

As the demand increases, the performance gap becomes wider, reaching a very significant advantage for the RL agent at high demand levels. This is consistent with the results presented in Fig.12 and Table 5.

Controller	Cumulative Delay [s]	Average Sum of Queues [m]
MOVA	165456.44	339.41
DDQN	72642.59	123.52
DDDQN	71245.61	119.86

5. DISCUSSION AND FUTURE WORK

Several neural network architectures for RL controllers were tested. The agents did not require extensive or complex configurations to adequately control traffic junctions, outperforming the commercial controllers in terms of average queue length and delay, calculated as deviation from free-flow times. RL agents showed great stability and robustness to control situations within their training envelope as well as outside of it. Additionally, agents trained on relatively low uniform demand showed they can perform better than commercial systems during evaluation tests that included variable demand 5 times higher than anything experienced during training.

Experiment 1 provided evidence that fixed time systems perform worse than adaptive and RL UTCs in simple intersections. In this case, MOVA and the RL agent following a DuelingDDQN architecture obtained very similar results, with a slight advantage for the RL agent.

Experiment 2 provided similar evidence about a smaller number of controllers, in a situation where queues were measured on a per-link basis rather than per-lane. This implies less granularity in the data and makes the control task more challenging. The results followed the same pattern with a DuelingDQN agent obtaining the best performance, despite the lower quality of the input data.

Experiment 3 required modifications of the map in order to obtain said per-lane queues. This model saw the introduction of a much more complex intersection, with a multitude of actions available to the agent, some of them serving the same lanes in different ways, and letting the agent decide on the sequence of actions. Once again RL agents obtained better results than MOVA, with the DuelingDDQN agent obtaining the lowest global delay and average queue length. The gap between the performance of MOVA and RL agents is increased here with respect to the last experiment. Most likely reasons are higher granularity in the data and extra actions being available to the agent, allowing it to display more complex sequences of actions.

Reinforcement Learning applied to UTC keeps demonstrating that it can be a real-life solution to improve traffic conditions in urban environments, even though the sensors required are more sophisticated than simple induction loops. These experiments provide further evidence that Reinforcement Learning based UTCs could be the next generation solution for reducing traffic congestion.

ABSTRACT

Since the container ship was born, we have seen an impressive increase in order to get advantage of the economies of scale. In the last two decades, the capacity of vessels has been trebled. Currently, vessels of 23,000 TEU (20-foot equivalent unit) sail the seas.

Despite the exponential growth experienced in this sector, individuals question if it is possible to reach a peak capacity, as has occurred with bulk cargo vessels and, recently, aircraft. This paper aims to predict the possible size and dimensions of a new generation of mega container ships. Based on economy of scale, port infrastructure, demand and environmental trends and naval design criteria the limit ship size has been estimated. The results suggest that it is still possible additional increases of the ship size. This paper allow Port Authorities to understand the needs of shipping container industry and to figure out the expansion and investment necessary.

1. INTRODUCTION

Fuelled with the Industrial Revolution in the nineteenth century, globalization and international trade started to take off. After a period of stagnation and decline during the First World War, Great Depression and Second World War, global trade boomed again around the 1950s with the introduction of container boxes. The container shipping market was born, significantly reducing transport costs. In the following decades, container ships became an important part of the global logistics chain. An increase in efficiency and ship size followed. UNCTAD (2018) estimated that 752 million TEUs were moved at container ports worldwide in 2017.

The global trade growth experienced in the last decades has had an impact on container ship size, resulting in six waves of substantial changes, each represented by a new generation of container ships.

The first generation of container ships were primarily modified bulk vessels with a capacity up to 1,000 TEU. Rapid evolution followed. The ships continued to upsize in capacity and size until the Panama Canal limitations came into effect in 1985, with a maximum capacity of around 4,000 TEU. Accordingly, these ships came to be known as the Panama generation. In 1988, a beam of 32.3 meters was first exceeded and the generation of Post-Panama container ships began. This new generation created infrastructure problems for most ports worldwide, as they had to invest in wider gantry cranes and dredge to accommodate those ships.

At the beginning of the 2000s, demand and volume were still growing. From 2001 to 2006, growth in trade volume was, on average, three times higher than the growth of GDP.

Therefore, the top shipping lines, which started to form strategic alliances, saw the need for a new generation of container ships. In 2006, the introduction of Emma Maersk, the first very large container ship (VLCS), marked a new generation. Bigger container ships reduced the cost per TEU even further, which in turn increased demand and therefore incentivized bigger ships. This positive feedback loop ended in 2008 with demand decreasing due to the financial crisis.

However, the market power of alliances and the rise of emerging markets like China stimulated the growth of container ships even further, despite demand not yet catching up.

Therefore, around 10 years later in 2013, ultra large container ships (ULCS) with capacities above 20,000 TEUs were introduced. The current biggest container ship, in terms of capacity, reaches 23,000 TEU, 400 meters of length, 61.5 meters of beam and 16.5 meters of draught. Even though the capacity has noticeably risen, the dimensions of the newest container ships has not changed significantly in recent years. In the last 15 years capacity has been trebled and length increased 20%, beam 43% and draught only 10%.

It is a consensus that both maximum capacity and ship size will increase over the next years (Malchow, 2017; Saxon and Stone, 2017; Park and Suh, 2019). But how long these increases will take remains unclear. In this paper, potential ship dimensions are studied from the point of view of naval design principles and regulations.

The most modern cranes currently available can reach 23/24 rows across the vessel. If this limit is exceeded, then one must either load cargo for another port in the extra rows or take time to turn the vessel around part way through the operation. This is both costly and time-consuming and thus not a practical option if required in every port.

If container ships' capacity increases, some ports will struggle to handle their cargo because of container yards' limitations. Adding extra length to the container yard is often limited by the surrounding infrastructure. According to the International Transport Forum, bridges can become an obstacle if the height of container ships continues to grow. It is important to note that the increase in the capacity of container ships can congest ports that do not have sufficiently fast logistics chain.

By the light of all this, this paper aims to analyse the future evolution of container ship size and dimensions. It is analysed if the exponential growth that the sector has experienced in the last decades is approaching to a peak.

This paper is structured as follows: Section 2 contains a literature review of existing research related to the evolution of the container ship size and influencing factors. Taking into account state-of-the-art technologies, a methodology is proposed in Section 3 to estimate the container ship size of the future, identifying possible limits in growth as viewed through naval design principles. In Sections 4 and 5, we analyze the past evolution of container ship size, according to the Lloyds database, and we define a set of future optimal alternatives according to naval design restrictions and capital costs. In Section 6, we analyze the economies of scale of running bigger ships, considering vessels from the past and a set of alternatives for the future. Finally, we analyze the impact of world economic and demand trends on ship dimensions in Section 7. General results, discussion and conclusions are drawn at the end of the paper in Sections 8 and 9.

2. STATE OF ART

The exponential growth in the last decades of container ship size has motivated several authors to model the industry's evolution and the possible limits for upsizing vessels.

According to Malchow (2017), container ships with a capacity of 30,000 TEU are expected to be launched in 2025, with approximately 20 m draught, which should be the ultimate limit due to the depth constraint of the Malacca Strait. But Malchow questions if we are following this path and compares it with the development in the tanker sector, where a counter movement had happened after hitting a certain tanker ship size. Malchow conclude that container lines will not benefit from further upsizing of container ships, and, moreover, other stakeholders, like ports and terminals, will suffer the consequences of additional investments.

The International Transport Forum (Merk, 2105) points out that the current generation of container ships can be marginally optimized by adding a top layer or an additional container row. Beyond that, however, a new generation of container ships will be needed, with bigger dimensions to generate sufficient cost reduction. This new class could start with a maximum capacity of around 24,000 TEU and require a length of 456 m as well as a beam of 65 m.

The authors (Merk, 2105) question if further ship size increase would be desirable if the potential cost savings to carriers will be outweighed by high infrastructure costs. An introduction of a new generation with 24,000 TEU capacity would require substantial investments for the ports where they will operate first (Far East, North Europe, Mediterranean). In addition, due to the cascading effects, 19,000 TEU ships should be operated in North America and 14,000 TEU ships in South America and Africa, where investments will eventually have to take place.

In a similar way, Tran N.K. (Tran and Haasis, 2015) research concludes that bigger vessels could help container shipping lines to get more revenue, but at a lower ratio than capacity growth. Nevertheless, the paper shows evidences that the scale economies at sea create scale diseconomies at port. A comparison of port’s operating cost shows that serving Post Panamax vessels of 18,000 TEU is 17% more expensive than serving 4,000 TEU vessels (Saanen, 2013). Taking into consideration external costs, S. Veldman (Veldman, Glansdorp, and Kok, 2011) shows that economies of ship size exist for vessels above 15,000 TEU capacity. For existing fleet up to 15,000 TEU the economies are lower than expected.

The upsizing of container ships is mainly restricted by sailing routes. Charchalis and Krefft (2009) point out that the length and beam of a container ship for current mega vessels, from an engineering point of view, are limited by the expected sailing route.

In the long term, Saxon and Stone (2013) conclude that the upsizing of container ships is limited by three main factors: the decline of the return of investment, the physical constraints of the sailing routes and the port infrastructure. However, they hypothesize that container ships with 50,000 TEU are possible for the next half-century. Even though in the next 5 to 10 years the development could slow slightly because of overcapacity, the upsizing could continue when demand catches up.

Gomez Paz et al. (2015) use the Delphi method to determine which factors will slow down the growth of the container ships in the long term. Interviews of experts across the logistics’ chain led them to conclude that the port infrastructure and the canals would be the limiting factors.

The fact that environmental factors will become increasingly important could favour bigger ships. On the one hand, upsizing the ship could reduce the environmental impact by using less energy per TEU (Charchalis and Kreft, 2009). On the other hand, from ports’ point of view, a bigger ship has more air pollution emissions than a smaller ship. If ports are starting to charge container ships based on their emissions, at one point it could become uneconomical to operate those bigger vessels (Helmy and Shrabia, 2016). Therefore, the regulatory framework of ports could also have an impact on further ship size development (Lam and Notteboom 2014).

Tran & Haasis (2015) suggest that because of the interdependencies of stakeholders, we should not make decisions looking from only one side of the problem. Instead, we need a more holistic view when decisions about ship size are taken. For example, besides shipping costs, we should also look at port costs, inventory costs, inland transportation costs, etc.
O. Merk (2018a) concludes that port relocation due to bigger container ships could favour non-urban ports with deep sea access. Nevertheless, a port relocation is consequential for existing ports and inland connections. Thus, these decisions must be carefully considered.

Ports will have to react to the constant upsizing of container ships and to the shipping alliances trends. O. Merk (2016) suggests that ports should coordinate more to build their own alliances in order to balance the power in the container market in their own favour. This could lead to a slower ship size growth.

Related to the container ship size, the relationship between carrying capacity and ship dimensions has been studied in several research projects. Predictions of megaships' dimensions are formulated via regression analysis by Kristensen (2013). The author analyses container ships from the IHS Fairplay database and creates regression formulas, which are used to calculate further length, beam, and draught based on capacity. However, this analysis is based on data from the past and does not consider that, for example, technological disruption or a dramatic ship redesign could change the evolutionary trajectory. Park, Nam K. et al. (2019) and the Korea Maritime Institute (KMI, 2012) construct similar regressions with updated data to predict the tendency toward mega container ships.

Literature suggests that bigger container ships are still possible, with a range capacity size between 30,000 and 50,000 TEUs. Regarding the ship dimensions, authors indicate that, depending on capacity, the length estimated is between 453 and 517 meters; beam between 65 and 72 meters; and draught, between 17 and 20 meters.

3. METHODOLOGICAL APPROACH

In order to study the evolution of container ship size and define the possible limits on growth, various approaches or criteria have been considered at the same time: the evolution of the principal dimensions of container ships; the naval design restrictions and regulations; the geographic and port restrictions; the economies of scale of container shipping lines; the CO2 emissions of vessel; and finally the world economic, demand and global trends.

This paper contributes to the state of art because it defines a methodology to design alternatives of possible bigger container ships according to naval design regulations. Additionally, different criteria are analysed in order to identify the boundary restrictions of growth.

Several studies predict the future ship size dimensions with regressions, based on data of the world existing fleet. Nevertheless, in this paper we predict the container ship capacity and its dimensions by identifying alternatives of possible bigger vessels and selecting the optimal ones. Figure 1 describes the main steps of methodology used.

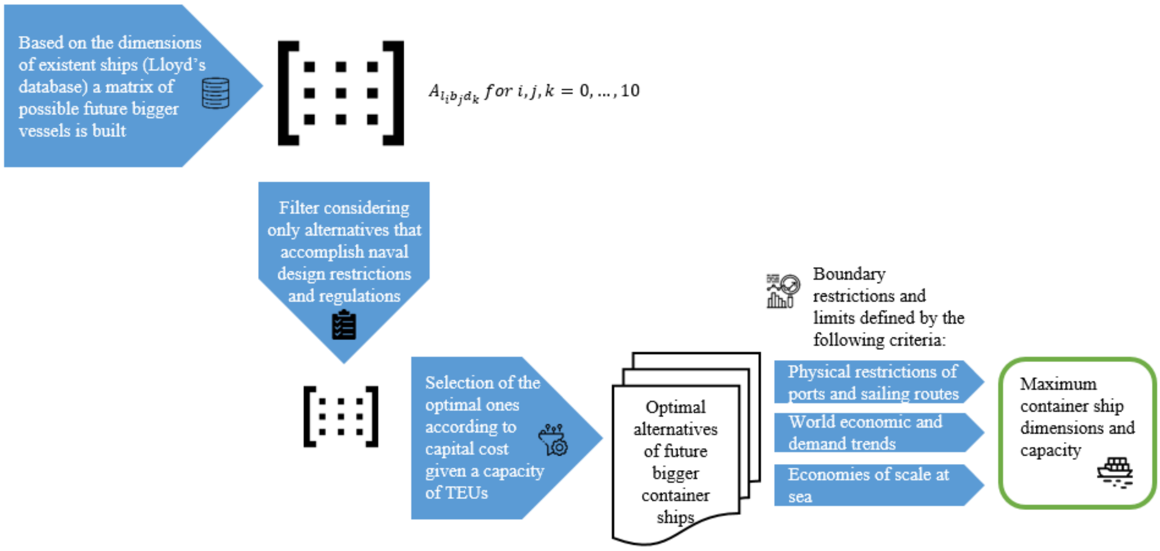

Figure 1. Simplified methodology approach

4. EVOLUTION OF THE DIMENSIONS OF CONTAINER SHIPS

To predict further development, firstly we analysed, based on Lloyd's Database, container ship dimensions from the past. Figures 2, 3 and 4 illustrate the evolution of the length, beam and draught in relation to the capacity of all container ships built since 1944. Analysing the relationships, some comments can be pointed:

- Draught does not significant change once a limit of 12,000 TEU is passed. In fact, draught for these larger ships seems to be stabilized around 16-16.5 meters.
- Length is stabilized around 400 m for vessels bigger than 15,000 TEU.
- Beam is the dimension that experiences the largest proportional growth. Currently, the bigger vessels are 60 meters in length.
- Increase in capacity for VLCS and ULCS is logically related to changes in length, depth and beam, but significantly more so for beam than for the other two. Regarding draught, it is the least-affected dimension for the new mega vessels.

Higher capacities are being achieved without a substantial increase in vessel dimensions. According to the recent vessel developments, the beam is the dimension that best accommodates extra TEU capacity when compared with the other measured dimensions.

5. POSSIBLE ALTERNATIVES FOR BIGGER VESSELS ACCORDING TO NAVAL DESIGN REGULATIONS AND PHYSICAL CONSTRAINTS (PORTS AND SALING ROUTES)

In this section, different scenarios of possible container ship sizes are represented according to different restrictions. Beam (B), length (L), depth (D) and draught (T) intuitively grow by intervals according to the new rows of TEUs added in each direction. For that reason, a matrix of alternative possible larger vessels has been built adding new rows in each direction to the current biggest container ship of 23,000 TEU (L=400, B=61.5, D=33.2, T=16.5). The matrix of alternatives is defined as:

$$A_{l_i b_j d_k} \; for \; i, j, k = 0, \ldots, 10 \quad (1)$$

Where,

$l_i = 400 + i * 5.9$, is the length and increases accordingly to the length of a TEU (5.9 m)
$b_j = 61.5 + j * 2.4$, is the beam and increases accordingly to the wide of a TEU (2.4 m)
$d_k = 33.2 + k * 2.4$, is the depth and increases accordingly to the height of a TEU (2.4 m)

To calculate draught, we assume the same ratio of the current 23,000 TEU, T=0.48*D. For example, the alternative $A_{l_0 b_3 d_1}$ is a container ship with 400 m length, 68.7 m of beam, 35.6 m of depth and 17,08m of draught.

The set of alternatives is calculated following Alvariño formulation (Alvariño et al, 1997). The formulation to define the load capacity considers, aside from the main ship dimensions, the power of the ship, the service speed at 85% of the Maximum Control Rate (MCR) and displacement of different vessels generated. The stability is verified using the assumptions defined by the International Convention for the Safety of Life at Sea (IMO, 2019). To ensure that the alternatives generated are feasible, the initial stability of each of them has been calculated, by making sure that the metacentric height (GM) of the vessel is greater than zero.

$$GM = (KB - BM) - KG \quad (2)$$

Where K is the intersection point between the ship baseline, the creaking plane and the transversal section; B is the center of buoyancy where the thrust is concentered; G is the gravity center of the vessel; and BM the metacentric radius which can be defined as the ratio between the total inertia of and the total volume of the ship.

$$BM = \frac{C_2 * B^2}{12 * C_b * T} \quad (3)$$

KB is the ratio between momentum of the volume in relation to the plane K and the total volume of the ship; $C_b$is the block coefficient which is the ratio of the volume of displacement at that draft to the volume of a rectangular block having the same overall length, breadth, and depth.

$$KB = C_1 * T \quad (4)$$

Where C_1 and C_2 are constants obtained of Riddlesworth's and Normand's expressions (Alvariño et al, 1997). KG depends on the ship's displacement and the distribution of loads. It is estimated using weighted ratios obtained from Alvariño (Alvariño et al, 1997).

The set of alternatives defining future ship sizes was filtered, with selection of the vessel designs that optimize for capital costs of construction given a capacity. This decision is made due to the fact that construction costs represent 42% of major costs associated with running ships, according Stopford (2009).

The capital cost formulation is defined in Section 6. Figures 2, 3 and 4 illustrate the historic dimensions of ships (length, beam and draught) and the set of alternatives selected. The figures show that the alternatives selected follow the historic tendencies for all the dimensions.

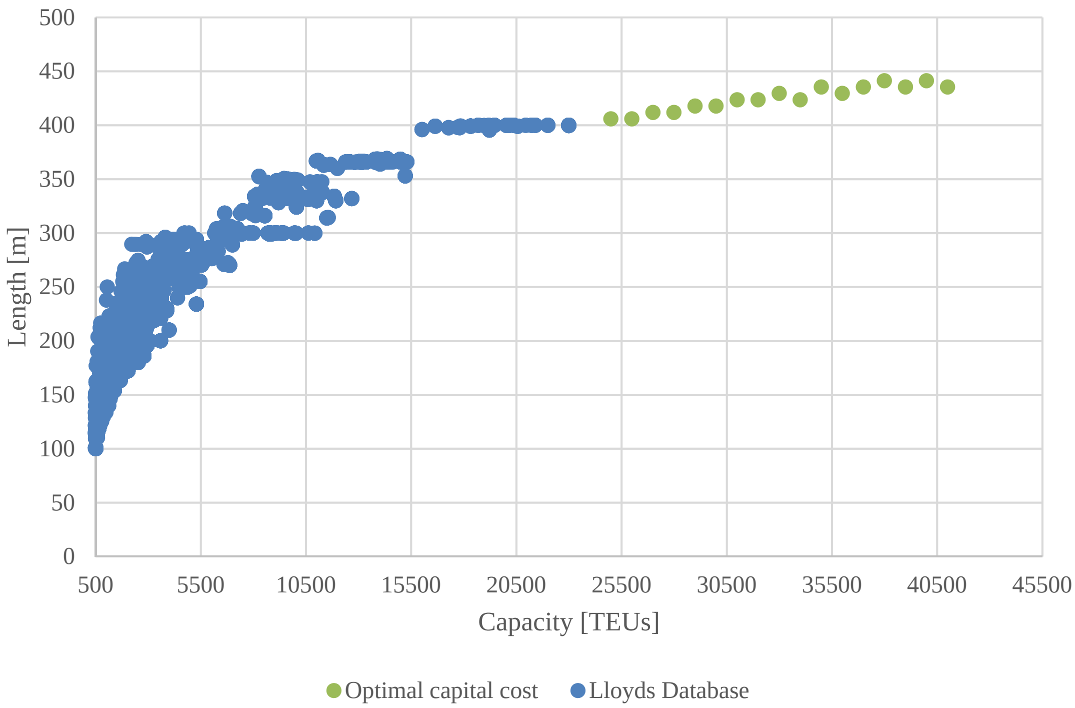

Figure 2. Relationship between the length and capacity of container ships built, with optimal alternatives selected according to capital cost.

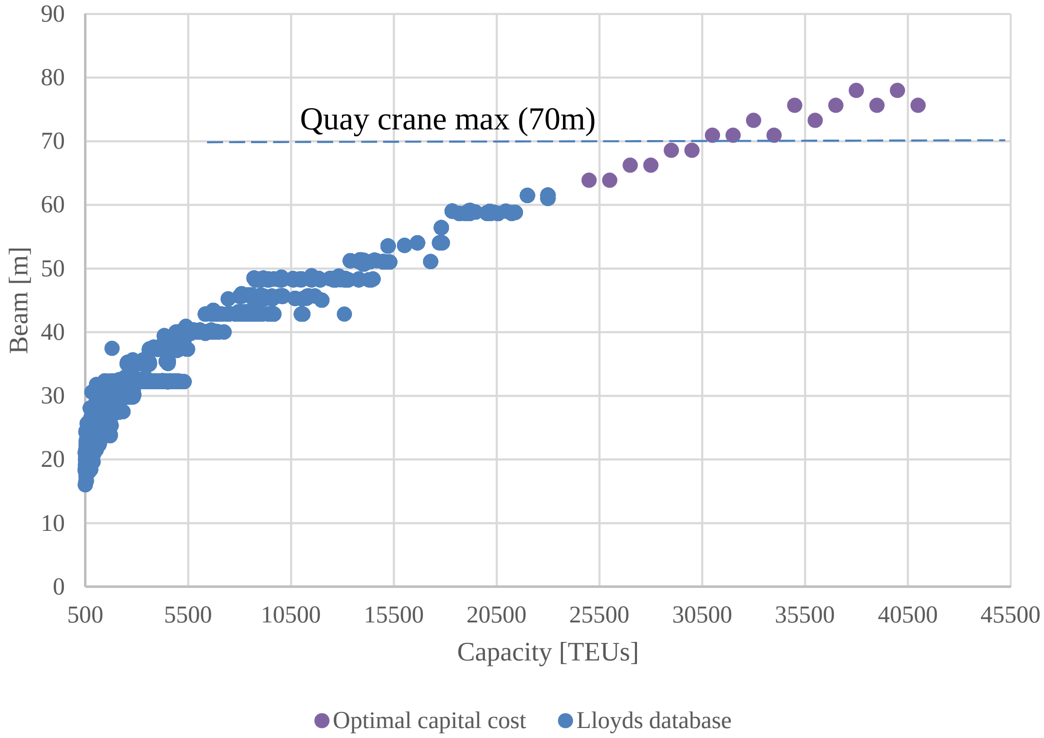

Figure 3. Relationship between the beam and capacity of container ships built, with optimal alternatives selected according to capital cost.

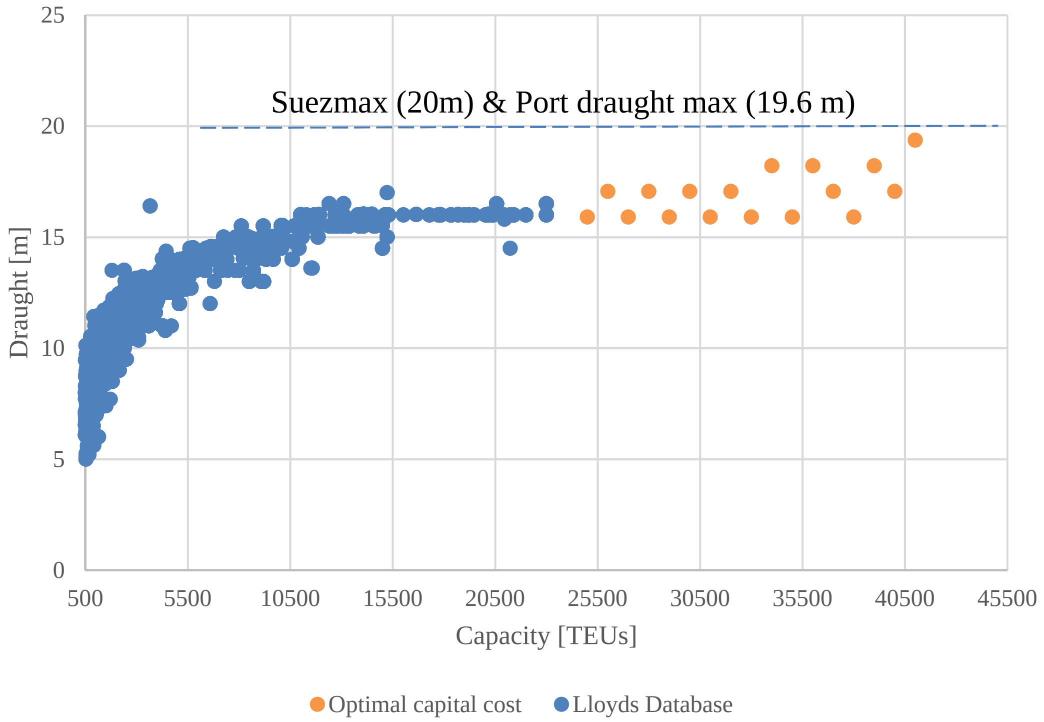

Figure 4. Relationship between the draught and the capacity of container ships, with optimal alternatives selected according to capital cost.

The constraints of the port's infrastructure limit ship size development as well. Draft deepness, the limited arm-length of gantry cranes and the limited space for container yards make it impossible for some ports to handle the ever-growing vessels. The traditional outreach of quay cranes in most container terminals is less than 70.4 m (represented in Figure 3); automatic container terminals opened after 2015 have a length of berth of over than 1.000 m according to Park and Sub (2019). Draft deepness of main ports of the world is contained in Table 1. As shown, the draught port is limited to 20m, and the range is from 16 m to 19.65 m.

Region	Country	Port	Draught [m]
South-Eastern Asia	Singapore	PSA Singapore	18
	Indonesia	New Priork (Jakarta)	16
North-Eastern Asia	China	Dalian	17.8
	South Korea	Busan	17
Middle East & South Asia	India	Bharat Mumbai	16.5
	Saudi Arabia	Saudi Global Port	16
North Europe	Belgium	Antwerp	17
	Hollande	Rotterdam	19.65
	Germany	Hamburg	17.4
Mediterranean Sea	Italy	Savona	17.25
	Portugal	Sines	17.5
	Turkey	Mersin	15.8
	Spain	Algeciras	18.5
	France	Marseille	16
	Morocco	Tanger	18
America	Panama	PSA Panama	16.3
	Colombia	Buenaventura	16.5
	United States	Los Angeles	16.7

Table 1. Draught of the main ports across the world sorted by region and country. Own elaboration based on the ports' website data

Relative height of mega ships or how high containers are stacked could be a limiting factor of growth, especially for maritime routes that need to cross bridges to access to the ports.

The actual relative height is around 17.50 meters for the current biggest container ships, and according to the results shown in Figure 5, it could be stabilized around 20 meters.

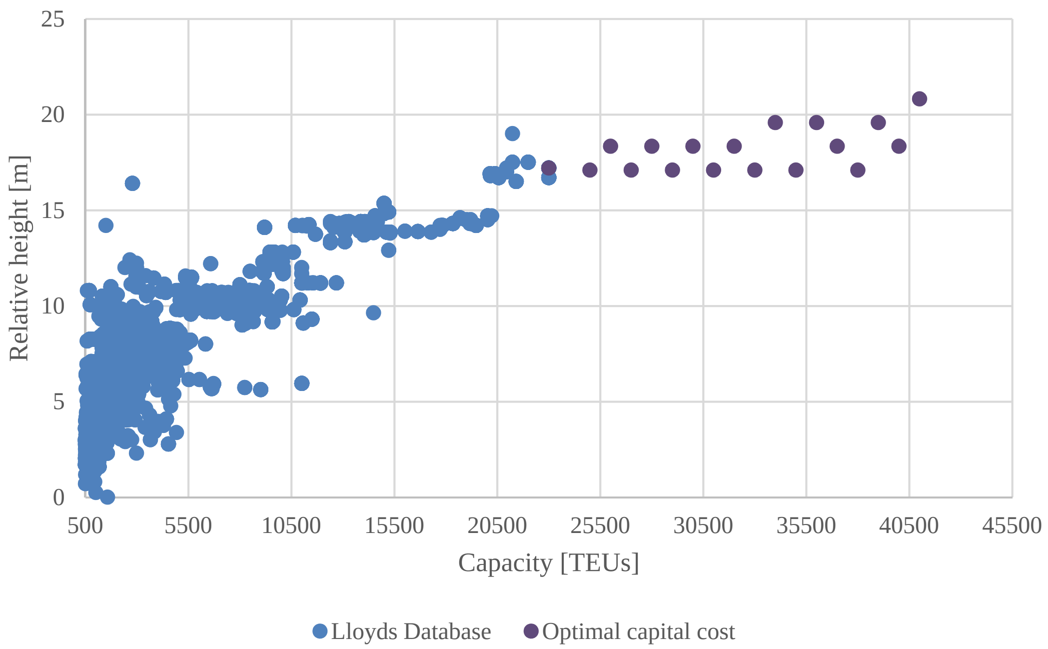

Figure 5. Relationship between the relative height and the capacity of container ships, with optimal alternatives selected according to capital cost.

Ship size development is also limited by the physical constraints of sailing routes. The Panama Canal route is the most restrictive, with a limited length of 366 m, a beam of 49 m and a draught of 15.2 m. For the Asia-Europe route through the Suez Canal, which is the shortest path for this itinerary, there is no limitation of length, a beam limitation of 50m and a draught limitation of 20m or, eventually, 77m of beam and 12.2m of draught (SCA, 2019). It is important to note that, in accordance with the Suez regulations, as we increase the beam, the draft decreases because of the trapezoidal cross section geometry of the canal. For example, for the actual biggest container ship of 23,000 TEU capacity, with a beam of 61.5 meters, the draught restriction is 16.28m. It thus becomes clear that today's container ships should optimize their dimensions to increase capacity according to the Suez Canal's navigation regulations. Nevertheless, this paper aims to study future ship size and accordingly assumes that the cross section of the Suez Canal could be increased, despite the high investment costs required. For the alternate Asia-Europe route, through the Cape of Good Hope, the only limitation is for draught in the Malacca Strait, which is constrained to 25 meters. Finally, due to the global warming, we have considered in a long term the Arctic Route, but according to a study by the Copenhagen Business School (2016) the Northern Sea Route will not be commercially viable until 2040.

Analysing the set of alternative physical and geographic restrictions of sailing routes and ports, we can conclude that:

- According to capital cost optimisation, ship length can grow up to 450 meters, with no boundary restriction on this dimension.
- According to Figure 3 the beam can increase up to 80 meters. This is due to the fact that the beam is the cheapest dimension for increasing capacity. However, the canal and quay crane boundary restrictions could limit this dimension to around 70 meters, which corresponds to a container ship of 30,000 TEUs.
- Finally, draught is the dimension that experiences less increase, growing up to 20 meters for vessels larger than 40,000 TEU. Nevertheless, for vessels with capacity under 35,000 TEUs, draft fluctuates between 16 and 17 meters. Current canal and port restrictions operate at around 20 meters in depth.

In summary, draught or beam limitations could form the natural limit to further ship growth.

6. ECONOMIES OF SCALE AT SEA

One of the main drivers for bigger container ships is the economy of scale. Historically, increased capacity per vessel reduced the cost per TEU, so shipping lines strove over the last decades to enlarge their vessels. However, returns of scale are declining with increasing size. Therefore, it is not clear if the unitary cost will keep declining with the ship size.

Due to the fact that container ship maritime trade is strongly dependent on the economies of scale, in this section we study the main influencing costs of Container Shipping Lines: Capital, Fuel and Operational costs (Stopford, 2016).

6.1 Capital costs

Capital costs are defined as the ship yard building price. To analyse capital costs according to the size of the vessel, we have used the methodology elaborated by Junco O. (2003). The following costs have been taken into account to calculate a ship's total capital cost (CC):

$$CC = CMg + CEq + CMo + CVa \tag{5}$$

The bulk material cost (CMg) considers the materials used and their qualities, as well as the utilization coefficient. Junco O (2003) uses series of coefficients to take into account not only the steel of the ships' hull, but also all the metallic elements included in the structure (superstructure, metallic equipment, etc.)

The ship equipment costs (CEq) have been calculated as a sum of the labour costs of assembling the equipment and facilities, cargo handling equipment, cost of equipment calculated as the cost per power units of propulsion and auxiliary equipment for the total propulsion power. Here we take into account the cost of propulsion equipment, calculated as 350 €/kW for the power installed in the vessel, as well as the cost of crew members' quarters and the price of the remaining equipment calculated by their weight.

General labour costs of the ship (CMo) considers the costs of personnel necessary to carry out the construction in the ship yards, calculated as the hours needed to build the ship by weight of steel.

Other construction costs (CVa) include the costs of the International Association of Classification Societies, insurance, channel tests, etc., where a value of 10% of the total construction cost has been assumed based on Junco O (2003).

Due to the fact that we calculate fuel costs based on the EU-MRV (UE, 2015; EU-MRW,2019) database for 2018 container ships, we analyse only these same vessels' capital costs. We assume the operating life of ships to be 20 years, with an operating time of 365 days per year.

6.2 Fuel costs

To determine fuel costs based on ship dimensions, the Lloyds database has been used in conjunction with the available data from European Union (EU-MRV, 2019) data, which reports ships' fuel consumption of 2018 according to EU Regulation 2015/757. Despite the fact that alternatives fuels are currently emerging, we assume that container ships will continue to use traditional petroleum fuel throughout the next 30 years according to the World Energy Outlook of 2018 (IEA, 2018). We address the impact of new ECA and SECA regulations of the IMO for the next years building three scenarios that consider Marine Diesel Oil and Very Low Sulphur Fuel Oil.

In order to determine daily fuel costs based on the EU-MRV database, we have applied the following formulation:

$$Daily\ Fuel\ Cost_{2018}\ \left[\frac{€}{TEU}\right] = \frac{Total\ fuel\ consumption_{2018}}{Total\ time\ spent\ at\ sea_{2018} * TEU\ capacity} \tag{6}$$

The total fuel consumption cost and the time spent at sea is obtained from the EU-MRV (2019) database.

To estimate the fuel costs of the predicted ships of the future, we use Alvariño's (Alvariño et al, 1997) methodology. The following formulation is used to calculate the ship's fuel consumption:

$$Consumption\ \left[\frac{m3}{hour}\right] = \frac{Power\ (kw) \cdot Specific\ consumption}{Fuel\ density} \qquad (7) \qquad (7)$$

Where, specific consumption is 0,189 $\frac{kg}{kWh}$ and fuel density is 991 $\left(\frac{kg}{m^3}\right)$.

We have assumed a constant cost of $571/tonne of Heavy Fuel Oil, which represents the average cost during the first quarter of 2018 according to Energy prices in selected OECD countries by the International Energy Agency (IEA, 2019). We assume a US dollar to Euro exchange of 1.1534, the 2018 average according the European Central Bank.

It is important to remark that the new generation of Maersk’s Triple E, which practically doubled the capacity of its predecessors, achieved a cost reduction of 40-50%. However, in recent years, it has been found that 60% of the reduction is given more by the efficiency of the engines than by the scale effect (Merk, 2015).

6.3 Operational costs

Operational costs include manning, insurance, stores, spares, lubricating oils, R&M, dry docking, management and administration. They are estimated according to the 2015 regressions of Tran N.K. (Tran, 2015), which are based on Drewry data from 2012. The estimated regression model with respect to TEU capacity is:

$$Daily\ operational\ cost\ \left[\frac{€}{TEU}\right] = \frac{22{,}89 * TEU\ capacity}{r} \tag{8}$$

Where, r is the US dollar to Euro exchange of 1.1534.

Operating cost is the category that presents the least variation for ship size capacity. Doubling vessel capacity increases overall cost by only 32% while decreasing unit operating costs by 34%.

Finally, it is important to point out the inventory cost. Arrival of a mega-ship in a port is associated with higher yard occupancy, more feeder traffic, truck and train movements that could increase the inventory costs due to the delay (Merk, 2015). Tran N.K. (2015) defined the inventory cost as $20 per TEU carried. Inventory costs are excluded from the analysis due to the dependence on the sailing routes and port calls.

6.4 Total costs of running container ships

Given the set of alternatives selected in the previous section, we estimate shipping unitary costs in order to study economies of scale. Figure 6 illustrates the evolution of running costs of all 2018 ships as well as the prospective costs of future vessels.

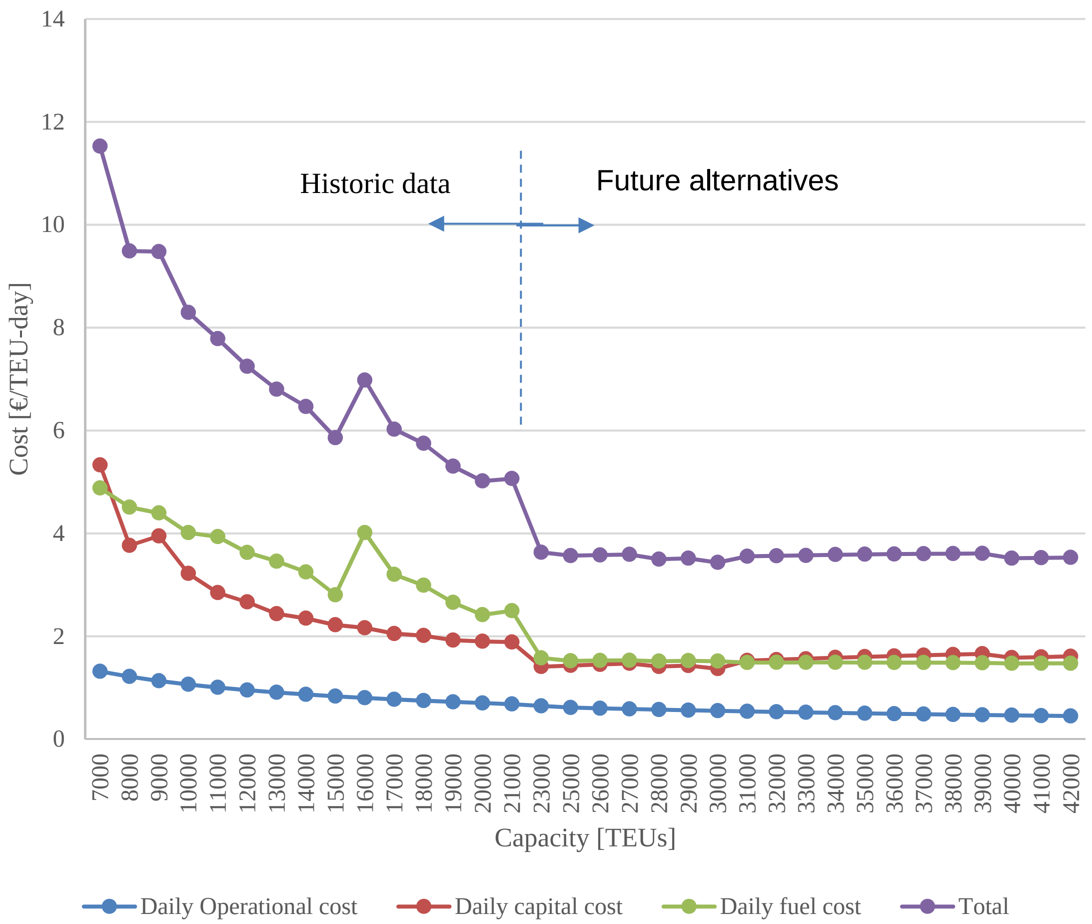

Figure 6. Fuel, capital and operational costs of container ships in 2018 (7,000-21,000 TEU). Prospection for vessels bigger than 23,000 TEU. Own elaboration with Lloyds and EU-MRV databases.

Some comments can be arisen from Figure 6:

- The total unitary cost is stabilized container around 30,000 TEUs. Figure 7 details the relative lifetime costs for a vessel of this capacity.
- For vessels larger than 20,000 TEU, the reduction in operational costs is negligible.
- From the point of view of construction and fuel costs, we observe a stabilization of costs per TEU for vessels over 25,000-30,000 TEU.
- There is a downtick in total costs around 21,000 TEU ships, especially due to the fuel costs. However, if we consider historic ships (2018) up to 15,000 TEU the trend of the historic data follows the one of the future alternatives, drawing a potential stabilization curve.
- The gap detected in the economies of scale that appears in Figure 6 is derived from the EU-MRV database, because 16,000 TEU ships present higher consumptions of fuel.

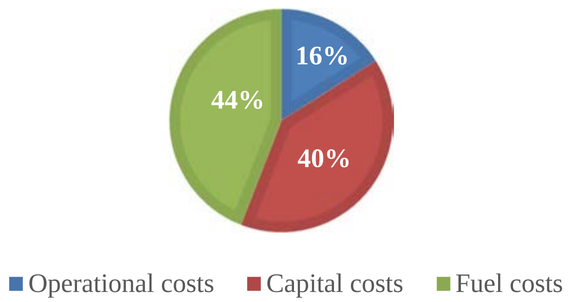

Figure 7. Detailed relative lifetime costs (fuel, operational and capital) of running a container ship of 30,000 TEU

In order to analyse the possible influence of the IMO 2020 regulation, Figure 8 represents the fluctuation of total costs, comparing the High Sulphur Fuel Oil (HSFO) with the Very Low Sulphur Fuel Oil (VLSFO) and the Marine Diesel Oil (MDO), that have respectively +70% and +50% higher cost in relation to the HSFO (Ship & Bunker, 2020). Analysing the results we can assume that in the three scenarios there is a stabilisation of total economies of scale. Costs for running container ships bigger than 25,000 TEU fluctuates between 4 and 6 €/TEU-day.

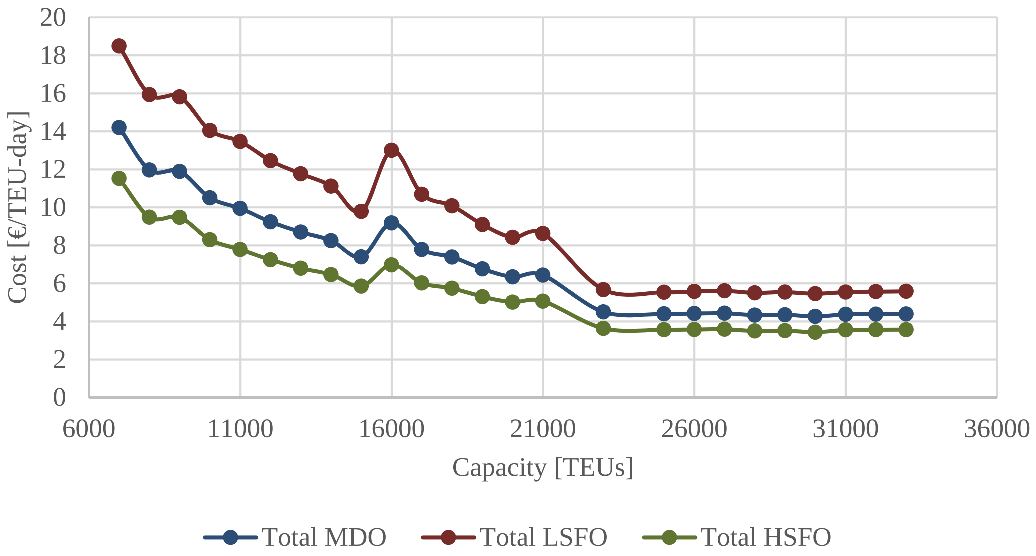

Figure 8. Total costs of container ships in 2018 depending on the type of Fuel Oil used (7,000-21,000 TEU). Prospection for vessels bigger than 23,000 TEU. Own elaboration with Lloyds, EU-MRV databases and Ship&Bunker data prices.

In light of climate change, it is worthwhile to analyse the evolution of CO2 emissions produced by container ships. We have estimated the evolution of CO2 emissions related to container ship capacity.

This is done using Lloyds database as well as data available from the EU-MRV system, which reports ships' CO2 emissions according to EU Regulation 2015/757. Figure 9 illustrates that there is a trend of reducing CO2 emissions as we increase container ship size. Even though there is a small uptick for container ships of 15,000 TEU, it can be assumed that environmental scale economies could favour an increase in ship size.

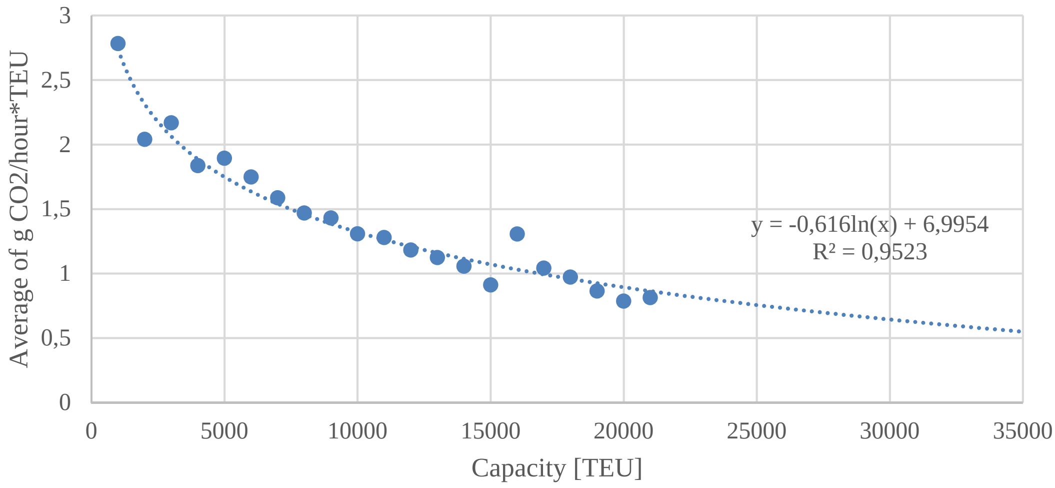

Figure 9. Evolution of CO2 emissions per hour and TEU transported according to ship size. Own elaborations with the EU-MRV database.

7. WORLD ECONOMIC AND DEMAND TRENDS

GDP is usually a valuable indicator to anticipate future trade volume. From 1997 until 2007, the growth of the container trade was almost three times higher than GDP growth. Since the 2008 crisis, the volume of goods traded has increased approximately in line with GDP, with a ratio of TEU growth to GDP of 1.7 (Saxon, 2017). Current estimates show global trade to be growing slightly quicker than GDP but to be on a downward path (Saxon, 2017). Figure 10 illustrates the positive relationship between world container port traffic and the largest ship, in terms of capacity, in each year since 2001.

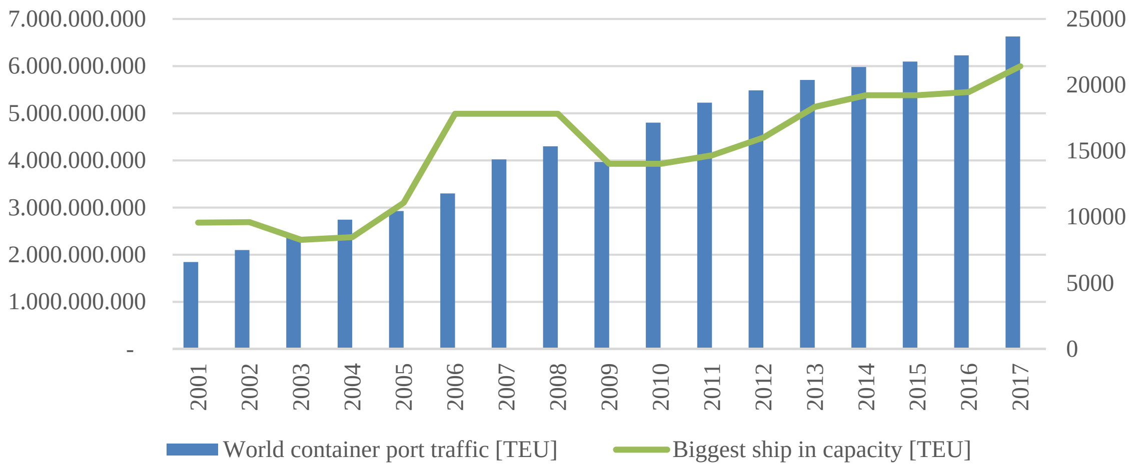

Figure 10. Global TEU trade evolution and biggest current container ship in capacity. Source: Own elaboration based on Lloyds and the World Bank Database.

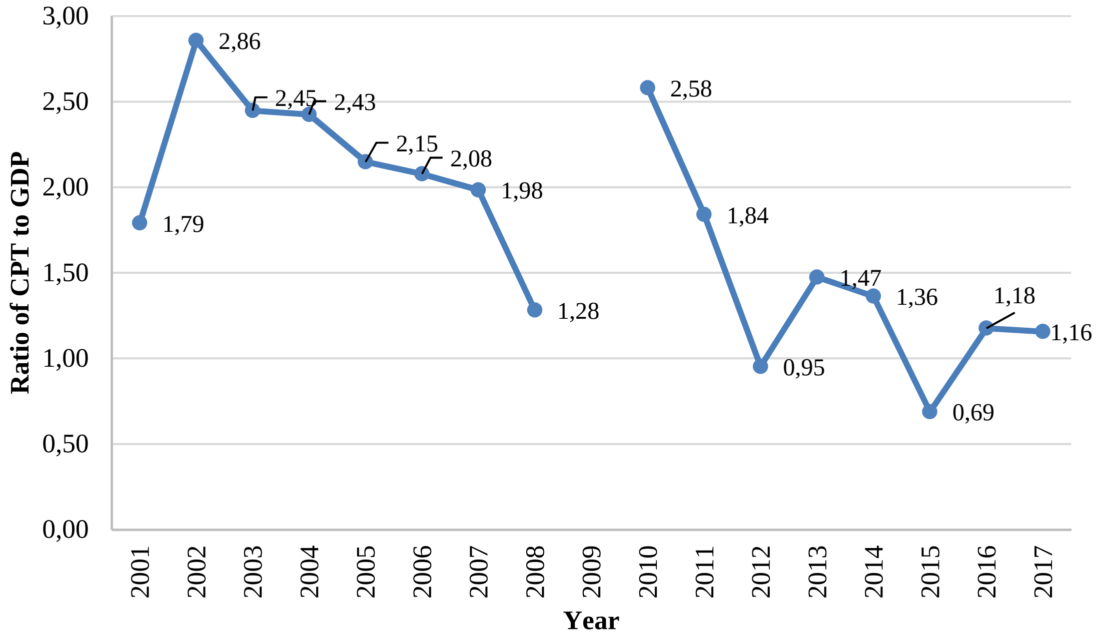

Figure 11. Ratio of annual container port traffic to Annual GDP growth excluding 2009 due to the financial crisis. Source: Own elaboration with World Bank Database.

Figure 11 indicates that the average ratio of Container Port Traffic to GDP is decreasing from two to one. Moreover, in 2012 and 2015, the ratio was under one, which means that world container traffic is growing proportionally less than the global economy.

According to Figure 10, we can assume that, if the global container trade is growing in a similar to GDP (as can be concluded from Figure 11), ship size is going to act in the same proportion. ITF (2019) has estimated that the Compound Annual Growth Rate in the World 2015-2050 is 2.9%. Thus, if the biggest container ship in the world in 2015 was 19,000 TEU, in 2040 we could estimate a container ship of 39,000 TEU, based only on demand forecast and past ship size evolution. In addition to that, the downward trend in TEU growth to GDP growth could be an indicator of stabilization of container ship size.

Another way of favoring bigger container ships and reinforcing a 39,000 TEU capacity ship, is the shipping alliances phenomena. Three global alliances represent the eight largest container carriers of the world. Together, the three alliances represent around 80% of overall container trade and operate around 95% of the total ship capacity on East-West trade lanes (Merk, 2018b). Such alliances have allowed carriers to acquire and operate mega-ships, thereby reducing unit costs.

However, even ever-larger ships are increasing supply, but demand is not catching up. This creates overcapacity in the container market. Although demand has increased since the financial crisis 2007-2009, it is not keeping pace with supply. The supply/demand imbalance will persist, we predict, with revenue and pricing remaining under pressure as container ship sizes increase and global GDP only moderately grows. To take just one example, in 2016, supply total fleet was 23% over the world demand (Saxon, 2017).

In addition to the supply and demand unbalance, some additional trends can slow down the ship size increase. Firstly, 3D printing could decentralize a bigger part of the global production, which would have a negative impact on global trade. At the moment, nonetheless, the impact of new technologies on global trade is expected to be marginal: one analysis, by Irene J. Petrick and Timothy W. Simpson (2013), estimates that TEU volumes will fall less than 1 percent by 2035. Another trend is the slowdown of the Chinese market, which is moving away from a development-based model centered on the export of physical goods and toward a consumption- and services-based model, is negatively affecting world demand and therefore also the evolution of container ship size.

Finally, emerging companies like Amazon and Alibaba could heavily impact the ship size developments by prioritizing time-to-market over cost per TEU. This would result in a push for smaller vessels with more direct port-to-port connections, the opposite trend of that observed in recent years.

8. RESULTS AND DISCUSSION

From the combination of the limiting factors described in the previous sections, it can be concluded that:

- Increases in capacity does not have a large impact on vessel dimensions. Beam is the dimension experiencing proportionally the biggest growth. In the last 15 years capacity has been trebled and beam has increased 43%, while length and draught only a 20% and 10% respectively.

- Draught or beam limitations of ports and sailing routes could form the natural limit to further ship growth. The results suggest that this limit will be reached with a container ship of 30,000 TEU capacity due to the physical restrictions of the sailing routes and port infrastructure (quay crane maximum reach of 70 m).
- From a point of view of the economies of scale, there is possible stagnation, with an eventual increase foreseeable for ships over 30,000 TEUs.
- The overall growth of world GDP and global trade favour the container ship upsizing beyond 30,000 TEU capacity. This is especially true as the container shipping market has become increasingly consolidated, with just a few shipping-line alliances controlling most trading routes. These alliances continue to use their market power to increase container ship size and capacity in order to achieve economies of scale. We predict the possibility of 39,000 TEUs capacity ships in 2040 according to the GDP and traffic trends. However, the decline evidences of the world global trends in relation to the GDP indicates a possible peak of the container ship size. Other global trends like the 3D printing or the overcapacity of the world container fleet could reduce the expectation of a 39,000 TEU capacity ship. In addition to that, according Figures 2, 3 and 4, dimensions of a 39,000 TEU ship are of 435 m of length, 76 m of beam and 18 meters of draught, which will limit the number of feasible port calls and a beam larger than the current quay cranes.

It is necessary to note that from the point of view of CO2 emissions, there is no stagnation of economies of scale as we increase ship size. If environmental scenarios are prioritized by the regulatory frameworks, larger container ships are more sustainable if the transport model is from hub to hub. These findings are consistent compared to Veldman et al. (2011) that estimates that for a 6,000 TEU ship the external costs vary from 5.9% to 29.3%, while for a 25,000 TEU vessel they decrease slightly from 5.2% to 26.2%.

To sum up, the results suggest that there is a stabilization of ship growth around a capacity of 30,000 TEU. Malchow (2017) and Park, Nam K. (2019) predict that 30,000 TEU capacity ships will appear in the shipbuilding market in 2025. However, in the light of the global economic trends analyzed in this paper the findings suggest that the 30,000 TEU ship could appear in 2030. In the long-term Saxon & Stone (2017) hypothesize 50,000 TEU container ships for 2050.

The results of this study are consistent and contribute to the state of art by defining a methodology to predict future optimal vessel dimensions and capacity according to the naval design regulations (1997) and considering different criteria to fix upper and down limits.

Under the assumption of 30,000 TEUs vessel, the results indicate that optimal ship size according the capital costs is of 418 m of length, 69 m of beam, 35 m of depth and 17 m of draught. In order to verify accomplishment of naval design criteria, GM value is calculated. For the alternative selected this value is 3.01 meters and, expressed as percentage of beam, 4.36%. A reasonable value would be between 4-5% (1997), in order to avoid stability problems.

Our predictions are similar to those predicted in 2019 by Park, Nam K: 453 m in length 72 m of beam and 17.3 m of draught. However, they differ from the ones predicted by the Korea Maritime Institute for a ship of 30,000 TEU: 517 m in length, 65 m of breadth, and 19.4 m of draft (KMI, 2012). A similar approach was built by Kristensen (2013) that estimated a hypothetical container ship with a capacity of 30.000 TEU would have 483 m of length, 71.5 m of beam and 18.7 m of draught. Malchow (2017) estimates that a 30,000 TEU ship will have 20 m draught, while our results suggest that this dimension will be around 17 m.

This paper contributes to the state of art of the evolution of container ship size offering some strategic key points in order to evaluate the need investment in new port infrastructures to fit mega ships, considering also the possible unbalanced externalities. Nevertheless, the three existing shipping alliances (2M, Ocean Alliance, The Alliance) represent 80% of all container trade, and they control the driver of ship size optimisation more than ports.

9. CONCLUSIONS

This paper deals with the possible growth path of container ships. A limit on capacity is estimated at around 30,000 TEUs. Analysing historical container ships data, it is apparent that an increase in capacity does not have a large impact on vessel dimensions, with the exception of the beam, which has experienced the biggest growth in the last decades. If no technological disruption drastically changes container-ship design, the results suggest that the world's largest vessel of 30,000 TEUs will have approximately 418m of length, 69m of beam and 17m of draught. It has been assumed that the cost of construction will prevail, to the detriment of fuel costs, as the dominant shaping force, since it is expected that technological development will reduce fuel consumption as a result of increases in engine’s efficiency.

ACKNOWLEDGEMENTS

This research has been conducted as part of a research grant from the Port of Barcelona. The authors would like to thank the staff of its Department of Innovation and Strategy, for its support in this paper.

RESUMEN

Las infraestructuras de transporte, como los puertos, se enfrentan al desafío de latransición hacia prácticas de gestión sostenible en un contexto de cambio climático. El nexo Energía y Agua es clave para ese propósito como lo señala la Organización Europea de Puertos Marítimos (ESPO) en el informe "*Prioridades de los puertos europeos para 2019-2024*", centrándose en la necesidad de coherencia y coordinación entre la política de transporte y otras políticas a nivel de la Unión Europea (UE) (Medio Ambiente, Aduanas, Competencia, Energía, Asuntos Marítimos, Investigación). En 2019, 94 puertos de 19 distintos países miembros de la ESPO, han tomado iniciativas de sostenibilidad para reducir la contaminación de agua en los puertos y de este modo proteger la calidad del agua y respetar las normas impuestas por la Directiva Marco del Agua. Los SistemasUrbanos de Drenaje Sostenible (SUDS) se han convertido en las técnicas de drenaje másutilizadas para adaptar con éxito las áreas urbanas a los escenarios climáticos presentes yfuturos. Sin embargo, se han realizado pocas investigaciones sobre la aplicación de SUDS en la infraestructura de transporte relacionada con los puertos, lo que representa una brecha clave en el campo de la gestión de la infraestructura de transporte. Algunos trabajos previos sobre pavimentos permeable (PP) mostraron el potencial para implementar SUDS en terminales portuarias, capturando y filtrando la escorrentía superficial, permitiendo el control del volumen y el tratamiento de contaminantes. Esta investigación presenta un nuevo enfoque para la ubicación y selección del drenaje en lospuertos, considerando todos los aspectos del diseño de SUDS dentro de un marco multicriterio (ej.: control de la cantidad de agua, tratamiento de la calidad del agua, biodiversidad y servicios). A su vez, esta investigación demuestra que tipos de SUDS podrían diseñarse y utilizarse en puertos bajo un análisis multicriterio, presentando las principales limitaciones para su implementación.

1. INTRODUCCIÓN

Los puertos son infraestructuras de transporte que, debido a sus características y serviciosque ofrecen, generan una alteración de las condiciones naturales preexistentes a su implantación, tanto en el área donde se ubican como en sus zonas adyacentes. Además, actúan como lugares de punto de encuentro entre el transporte terrestre y marítimo (Bravoet al. 2006). Este último, es el medio más eficaz de transportar mercancías debido a su bajo costo, gran capacidad de transporte masivo de mercancías y movimiento en largas distancias (Bobadilla y Venegas 2018). Actualmente, representa casi el 90% de la gestióndel comercio mundial (Zahed, 2015). De esta manera, los puertos se convierten en un factor indispensable para el comercio y desarrollo económico de un país, siendo puntos nodales en las cadenas de suministro mundiales (Martí et al. 2015). Sin embargo, generan una serie de impactos negativos al medio ambiente como consecuencia de las actividadesinherentes a su función y a una gestión deficiente en esta materia. Además, debido a su ubicación, son susceptibles de recibir la contaminación proveniente del entorno del puerto(Goulielmos, 2018). Muchos puertos en países altamente industrializados están experimentando una grave degradación de sus entornos. En consecuencia, la protección del medio ambiente se está volviendo cada vez más un aspecto importante en la gestióny desarrollo portuario y, en general, para la gestión de zonas costeras (Tubielewicz, 1995).Existen numeras investigaciones que estudian esta problemática, como la realizada por lainiciativa medioambiental EcoPorts, integrada en la Organización Europea de Puertos Marítimos (ESPO), la cual ha identificado y monitorizado aquellos riesgos ambientales que presentan los puertos integrados en la red EcoPorts a lo largo de estos últimos años. Además, han establecido las principales prioridades ambientales de las autoridades portuarias europeas.

Los resultados del "*Informe medioambiental ESPO 2018*", establecen como la primera prioridad medioambiental la calidad de aire (ESPO 2018). Esto se debe a que es el principal riesgo para salud humana en Europa, causante de aproximadamente 400.000 muertes prematuras por año (European Environment Agency,2018). La segunda es el consumo de energía, estrechamente relacionada con las emisionescontaminantes, entre otros factores por la correlación directa entre el consumo de energíay la huella de carbono de los puertos, así como el cambio climático (Raptis, 2019). La contaminación acústica es la tercera prioridad, principalmente la provocada por los motores de los barcos y la maquinaria portuaria (Puig et al. 2015). Es interesante observarque la mitigación y la adaptación al cambio climático se encuentran entre los diez factoresclave, indicando que los puertos ya comenzaron a actuar para adaptarse a los efectos del cambio climático (Raptis, 2019).

La calidad del agua, a pesar de no encontrarse entre las primeras prioridades, se trata del indicador ambiental que ha sufrido un mayor aumento de monitorización desde 2013 (ESPO 2018). Esta circunstancia se ve motivada porque los estados miembros de la UE están realizando esfuerzos para alcanzar los objetivos planteados por la "*Directiva marcosobre la estrategia marina*" (DMEM) (Unión Europea, 2008). Principalmente, los relacionados con alcanzar un buen estado ambiental de las aguas marinas, perseverando en su protección y conservación, así como en evitar su deterioro.

Las autoridades portuarias españolas están actuando en esta materia siguiendo las recomendaciones propuestas en la ROM 5.1-13 (Ministerio de Fomento, 2013). Estas recomendaciones propuestas se basan en el establecimiento de métodos y procedimientos para la tipificación de las unidades de gestión del medio acuático portuario y para la gestión de la contaminación marina accidental. Además, establecen recomendaciones para la evaluación y gestión de riesgos ambientales de las actividades realizadas en el entorno portuario y el análisis de la calidad ambiental de las unidades de gestión del medio acuático portuario.

No obstante, los enfoques actuales para regular los impactos en la calidad del agua no son suficientes (European Environment Agency, 2018).

La gestión de esta problemática en los puertos presenta una gran complejidad dada la diversidad de focos devertido de contaminantes que tienen lugar en las áreas portuarias (Fred Lee y Jones-Lee,2003). La calidad del agua está intrínsecamente relacionada con los factores que influyen en el desarrollo portuario (la ubicación del puerto, su construcción y las operaciones portuarias que se desarrollan en el mismo) (UNESCAP, 1992).

Una de las principales causas de este problema ambiental es que, con demasiada frecuencia, se permite que fluya la escorrentía superficial de las áreas portuarias hacia a la ribera del mar o de las rías, sin ningún tipo de tratamiento (Fred Lee y Jones-Lee, 2003).Las aguas pluviales que precipitan sobre estas áreas no tienen presentes gran cantidad decontaminantes. Sin embargo, cuando estas aguas pluviales arrastran los contaminantes como escorrentía sobre las superficies impermeables del puerto, pueden ir acumulando distintos tipos de contaminantes (depósitos de contaminación del aire, fluidos automotrices, sedimentos, nutrientes, pesticidas y otros tipos de contaminantes) (Bailey et al. 2004). Esta contaminación difusa se ve acentuada a causa de las operaciones de limpieza con baldeo y riego para atenuar emisiones a la atmósfera que se realizan con frecuencia en los puertos (Ministerio de Fomento, 2015). Las escorrentías superficiales que se vierten a la masa de agua de los puertos españoles es, según un gran número de Autoridades Portuarias Españolas (Ministerio de Fomento, 2012), el foco de vertido mássignificativo que repercute sobre la calidad del agua. Numerosos estudios científicos han demostrado repetidamente una correlación directa entre esas superficies impermeables yla contaminación de la escorrentía (Shueler, 1994). Por ejemplo, un aparcamiento de 4.000 m^2 produce 16 veces más de escorrentía que una superficie permeable (Shueler, 2000). Por lo tanto, se puede considerar que en un puerto las superficies impermeables son generadoras de contaminación y consecuentemente de efectos ambientales adversos.

Este estudio tiene el objetivo de reducir esta problemática mediante la implantación de SUDS en áreas portuarias, ya que una de las características de estos sistemas, es su capacidad de disminuir los volúmenes afluentes de pluviales mediante su captación en origen (Lerer et al. 2015). Estas técnicas de drenaje, tienen además la funcionalidad de retener en gran medida los contaminantes arrastrados en la escorrentía superficial, así como otros beneficios de índole social, de biodiversidad y económicos (Stormwater Committe, 2006). Como ya se mencionó, se han realizado pocas investigaciones sobre laaplicación de SUDS en la en los puertos, lo que representa una brecha clave en el campode la gestión de la infraestructura de transporte. Existen estudios y manuales de técnicas específicas, como es el caso de los pavimentos permeables (Sieglen y Langsdorff, 2004), (Knapton y Smith, 1997) y los depósitos de infiltración (Gray et al. 2010). Sin embargo,no existen investigaciones como la realizada en este caso, en la que se presenta un nuevoenfoque para la ubicación y selección eficiente del drenaje en los puertos, teniendo en cuenta todos los aspectos del diseño de los SUDS dentro de un marco multicriterio, comoel que se corresponde con una infraestructura de transporte de tanta complejidad.

2. METODOLOGÍA

La metodología desarrollada para determinar el potencial de implementación de los SUDS en áreas portuarias es el resultado de la recopilación y análisis de metodologías dediferentes artículos, manuales y guías internacionales para la implementación de SUDS en áreas urbanas (CIRIA, 2017), (NCDEQ Stormwater Design Manual, 2017). A consecuencia de las diferencias que presentan las áreas portuarias respecto a las urbanas, también fue necesario estudiar con detalle toda la información disponible relativa a las características que presentan dichas áreas y su legislación correspondiente (Ministerio deFomento, 2011).

2.1 Evaluación del emplazamiento

El primer paso para estudiar la implementación de este tipo de técnicas de drenaje en áreas portuarias es realizar una evaluación del emplazamiento donde se pretende instalar el sistema. Esto se debe, a que la evaluación de la localización en el proceso deplanificación y diseño adquiere importancia para identificar las restricciones que pudieranlimitar o reducir la capacidad de funcionamiento de este tipo de técnicas (Port of Oakland,2015). Llevar a cabo este paso en el proceso de planificación, reduce la posibilidad de tener que rediseñar las medidas adoptadas y/o su ubicación. Por consiguiente, se requiere realizar una revisión exhaustiva de toda la información existente del lugar y recopilar todos los datos específicos que puedan influir en el establecimiento de estas técnicas. Concarácter general, en este tipo de proyectos hay que identificar la siguiente información:

- Ubicación, tipología y tamaño del puerto.
- Condicionantes de la localización (geológicos y tipología del suelo, hidrológicos tanto superficiales como subterráneos, geotécnicos, topográficos y los relativos a la existencia de contaminantes en el suelo y aguas subterráneas).

- Superficie del área portuaria, delimitando los espacios y usos portuarios e indicando la cantidad de superficie impermeable antes de la introducción de las medidas a adoptar.
- Diseño actual del sistema de drenaje de aguas pluviales y residuales del puerto. Señalando con claridad la ubicación de los puntos de descarga de escorrentía de aguas pluviales.
- Las distintas operaciones portuarias que se desarrollen en el puerto, así como, su localización. En concreto, aquellas que sean susceptibles de ser una fuente potencial de contaminantes.
- Indicar la variedad de los potenciales contaminantes que afectan de manera directa o indirecta a la calidad de las aguas litorales en la zona portuaria, determinando su tipología y estimando su cantidad.
- Otras consideraciones y restricciones particulares del sitio.

2.1.1. Geología y geotecnia

El tipo de suelo y las condiciones geológicas y geotécnicas del área portuaria influyen directamente en la elección del tipo de SUDS y su diseño, así como en su ubicación más adecuada. A la hora de analizar la geología de la zona de estudio puede ser de gran utilidad consultar la web del Instituto Geológico y Minero de España (IGME). Uno de los parámetros más importantes en el análisis de la geología y geotecnia es la capacidad de infiltración que posea el terreno, por lo que identificar los principales materiales de los que está compuesto el suelo y su permeabilidad es clave a la hora de alcanzar un funcionamiento óptimo del sistema (Port of Tacoma, 2015). Los suelos pueden tener un comportamiento drenado, no drenado o la posibilidad de ocurrencia de ambas situaciones.Con el objetivo de tener una orientación previa acerca de la capacidad de infiltración de un determinado suelo característico en áreas portuarias, la normativa española en proyectos portuarios recoge los valores típicos de distintas formaciones de suelos y rellenos (Ministerio de Formento, 2005).

En esta primera evaluación de la capacidad de infiltración del terreno, es recomendable revisar toda aquella información existente relativa a la permeabilidad de la zona de estudio, a partir de la literatura existente del lugar y de los ensayos realizados previamente, con el objetivo de obtener unos mejores valores de referencia. Seguidamente, en la fase de proyecto es aconsejable realizar ensayos “in situ” para obtener unos valores más fehacientes sobre la permeabilidad de la zona, así como otros parámetros geotécnicos, especialmente los relativos a la resistencia al corte y compresibilidad. Algunos de los ensayos utilizados con más frecuencia son los de *Lefranc*y *Lugeon*, dependiendo del tipo de suelo, también se realiza con frecuencia el piezocono“CPTU” u otros equipos de ensayo como los permeámetros autoperforadores (Ministeriode Formento, 2005). Además, existen ensayos normalizados para medir la capacidad drenante de algunos sistemas específicos, como es el caso de los pavimentos permeables,en el que es usual utilizar el permeámetro LCS (NLT-327/00).

Con el objetivo de realizar un estudio geotécnico completo, y en concreto de la permeabilidad, los ensayos de laboratorio son muy aconsejables como el realizado a partirde permeámetros de carga constante (UNE 103403:1999) o variable (Ministerio de Formento, 2005). Un ensayo de laboratorio recomendable para evaluar la capacidad de infiltración de los pavimentos permeables es el infiltrómetro CF (Castro-Fresno et al. 2013). Cabe mencionar que, para el almacenamiento y gestión de los datos de la zona deestudio, diseñar una base de datos implementada en un Sistema de Información Geográfica (SIG) puede resultar de gran ayuda.

Coeficiente de permeabilidad (cm/s)	**Viabilidad de infiltración**	**Tipo de suelo**
$k>10^{-2}$	Muy permeable	Gravas
$10^{-2}>k>10^{-4}$	Buena	Arenas y mezclas de arenay grava
$10^{-4}>k>10^{-6}$	Mala	Limos y mezclas de arena, limo y arcillas.
$k<10^{-6}$	Impermeable	Arcillosos

Tabla 1 - Estimación del coeficiente de permeabilidad en función del tipo de suelo. (Fuente: Ministerio de Formento, 2005)

Se puede considerar la viabilidad de infiltración del sistema al terreno a partir de una conductividad hidráulica mayor de 10^{-6} cm/s, pero es necesario tener en cuenta otros factores como son: la proximidad del nivel freático, el grado de contaminantes del suelo y la proximidad a infraestructuras adyacentes (Checa y De Pazos, 2018).

- Como norma general el limitante geométrico del nivel freático hasta la subbase del sistema en el que se desea permitir la infiltración al terreno ha de ser como mínimo de un 1 m (CIRIA, 2017).
- La proximidad a los cimientos de infraestructuras adyacentes varía en función del sistema que se pretenda implantar. Cuando se proponga la infiltración al terreno y esta distancia sea menor de 5 m será necesario estudiar con detalle las especificaciones técnicas del sistema (CIRIA, 2017).
- Si la escorrentía superficial está contaminada, existe el riesgo de que los sistemas de infiltración puedan introducir contaminantes en el suelo y finalmente en el agua subterránea. Se deben realizar verificaciones para confirmar que los suelos debajode cualquier componente de infiltración propuesto sean adecuados para proporcionar una protección adecuada a las aguas subterráneas. El diseño de SUDS también debe garantizar un tratamiento adecuado de la escorrentía antes dela infiltración (NCDEQ Stormwater Design Manual, 2017).

Un aspecto clave también es comprobar que la explanada sobre la que se asentará el SUDS, conste de las condiciones mínimas respecto del índice CBR. Este análisis de la capacidad portante del suelo, así como su clasificación es recomendable hacerlo según lanorma PG-3 (Ministerio de Fomento, 2015).

2.1.2. Topografía

La topografía es un factor muy importante a la hora de analizar los patrones de flujo sobrela zona de estudio y, por consiguiente, para determinar que técnica de SUDS será la más conveniente para el sitio donde se desea implantar. Para realizar este análisis se debe estudiar previamente toda la información cartográfica existente del lugar (Checa y De Pazos, 2018).

Por otro lado, al igual que en el análisis geotécnico de la zona, los SIG permiten el almacenamiento, procesamiento y análisis de toda la información topográfica. Una herramienta muy usual para almacenar y procesar esta información son los modelosdigitales de terreno (MDT), concretamente en formato ráster, es decir, una matriz de celdas en la que cada cuadrícula contiene una información cartográfica que puede ser de gran ayuda para la modelización hidrológica y geomorfológica. A partir de este MDT, se determinan las direcciones de drenaje y seguidamente se obtienen parámetros clave comoel área de drenaje y la pendiente del terreno, las cuales serán de gran ayuda para definir la red de drenaje de la zona estudio y la estimación de variables geomorfológicas (Ramírez, 2002).

2.1.3. Hidrología

El primer paso para el diseño hidráulico e hidrológico es determinar la pluviometría del área de estudio. En este estudio se propone la siguiente metodología, en la que en primerlugar hay que obtener las precipitaciones diarias máximas. Para ello, se puede acudir a los registros de la pluviosidad de la zona en la que se van a implantar, tanto los valores normales como los anómalos. Para la obtención de los datos históricos de dicha variablese van a utilizar los recogidos en la página web de la Agencia Estatal Meteorología (AEMET), concretamente los correspondientes a la estación meteorológica más próximaa la zona de estudio. En caso de que dicha estación no tenga un registro amplio, otra opción es utilizar la monografía “Máximas Lluvias en la España Peninsular” (Ministerio de Fomento, 1999). En este documento se describe un proceso operativo para la obtención de la precipitación diaria máxima para un periodo de retorno seleccionado.

El siguiente paso es calcular el caudal máximo que le va a llegar al sistema correspondiente al periodo de retorno elegido. Si no se dispone de información sobre loscaudales máximos que proporciona la Administración Pública, se debe calcular a través del método racional de la normativa IC-5.2 (Ministerio de Fomento, 2016). En el procesooperativo recogido en esta normativa es muy importante definir y delimitar correctamentela cuenca drenante, así como sus principales parámetros. Un aspecto clave es calcular correctamente el coeficiente de escorrentía, para lo que hay que definir la cantidad de superficie impermeable que hay en el área drenante. Con el objetivo de conseguir unos parámetros característicos fehacientes de la cuenca, es muy recomendable apoyarse en las herramientas SIG comentadas con anterioridad (Checa y De Pazos, 2018).

También es necesario determinar los puntos de descarga de los volúmenes efluentes del sistema. Este proceso de evacuación depende de la modalidad de SUDS que se esté estudiando, así como de la operación portuaria o uso del suelo que se desarrolle en su ubicación y de la permeabilidad del subsuelo (en caso de que se pretenda la infiltración al terreno). Existen recomendaciones sobre cómo realizar la evacuación de aguas pluviales, como las recogidas en la ROM 4.1-94 (Ministerio de Formento, 1994).

Cabe mencionar que, en algunos casos, puede ser recomendable reutilizar este volumen efluente para requerimientos de agua no potable, como la limpieza con baldeo. O en el caso, por ejemplo, de las terminales portuarias de graneles sólidos, reutilizar dicho volumen para el riego con la misión de atenuar las emisiones a la atmósfera (Ministerio de Fomento, 2015).

2.1.4. Principales focos de contaminantes

Como se mencionó anteriormente, las operaciones portuarias y determinados usos de suelo que habitualmente se suelen dar en los puertos, pueden causar daños significativosen la calidad del agua y, consecuentemente, a la vida marina y los ecosistemas, así comoa la salud humana (Herz y Davis, 2002).

Por tanto, es necesario examinar los principales focos de vertidos de contaminantes a la escorrentía superficial que se pueden dar en las áreas portuarias. Para ello, hay que estudiar con detalle las operaciones portuarias y usos del suelo que pueden causar daños significativos en la calidad del agua y, en consecuencia, a la vida marina, los ecosistemasy a la salud humana. Dada la heterogeneidad que presentan los puertos, en especial los deuso de comercial, en función de las actividades que realizan y el tipo de mercancías que manipulan, se realiza un análisis de los usos de suelo de las áreas portuarias. En este estudio, se distinguen las zonas de operación y las de almacenamiento, así como las vías de comunicación y las zonas complementarias.

Una de las instalaciones que se consideran como la razón de ser de los puertos son las terminales portuarias. Se entiende por terminal portuaria aquellas instalaciones que constituyen la interfase entre los diferentes modos de transporte (Ministerio de Fomento, 2005). Los tipos de terminales portuarias que han sido objeto de estudio son las siguientes: contenedores, graneles sólidos (almacenamiento a la intemperie), mercancía general y de buques Ro-Ro. La posible gama de contaminantes que llegan a las aguas de los puertos de este tipo de terminales es muy amplia, destacando los sedimentos, metales, productos químicos, combustibles diésel, gasolina y aceites hidráulicos, siendo estos últimos el mayor contribuyente individual en volúmenes (Gómez et al. 2015). Es posible que las descargas en la costa y ríos no parezcan ser tan graves, pero los vertidos crónicos persistentes reducirían la pesca y los recursos acuáticos, además de disminuir la diversidad de vida vegetal y reducir seriamente la calidad del agua (Davis, 1990). Estos vertidos aumentan la contaminación bacteriana y viral de peces y mariscos comerciales, disminuyen la cantidad de oxígeno en el medio, y generan una bioacumulación de ciertastoxinas en los peces (Herz y Davis, 2002).

Cabe destacar que el principal foco de emisiones en los puertos, según las autoridades portuarias españolas, se da en la manipulación y almacenamiento de gráneles sólidos a la intemperie (Ministerio de Fomento, 2015). En este tipo de terminales portuarias los principales contaminantes son la lixiviación de productos químicos derivados de equipos y productos, vertidos accidentales derivados de las operaciones de mantenimiento y almacenamiento (escorrentía con alta carga de sedimentos y escombros) (Port of Tacoma, 2015).

Existen otros usos de suelo en las áreas portuarias como las zonas complementarias (zonas urbanizadas, de paseo o aparcamiento) o los viales de comunicación, que también son puntos de vertido de contaminantes (principalmente hidrocarburos y metales pesados), así como los derivados de los movimientos de los vehículos (deposiciones atmosféricas, desgaste de neumáticos y frenos) (Port of Oakland, 2015). Pero, dadas sus característicasintrínsecas, se asemejan en gran medida a las áreas urbanizadas donde la viabilidad de implantación de SUDS está contrastada, aunque con algún limitante mayor como son lascargas actuantes sobre el pavimento (Ministerio de Fomento, 1990). Otro uso de suelo que puede ser un potencial foco de contaminantes son las áreas de limpieza y mantenimiento.

Estas áreas conllevan un riesgo de vertidos accidentales de fluidos contaminantes y de aguas contaminadas con hidrocarburos, disolventes y pinturas principalmente (Cedre, 2007).

Por último, también se han considerado como foco de contaminantes las cubiertas de edificios (de más de 45 m^2 (Port of Tacoma, 2015)), ya que estas superficies generan contaminantes, entre los que destacan las deposiciones atmosféricas (CIRIA, 2017).

2.1.5. Normativa

Es necesario revisar y cumplir todas las legislaciones que afecten al ámbito portuario, en especial aquellas que se refieren a su transformación física y que repercutan de manera directa e indirecta en la gestión de las aguas litorales en áreas portuarias. Para ello, se debe conocer quiénes son los organismos con competencias, así como los agentesimplicados en la gestión, la coordinación y el control de eficiencia del sistema portuario (Port of Oakland, 2015). Es necesario conocer todos aquellos Marcos y Directivas legalesrelevantes de la UE (Directiva 2014/89/UE 2014 y 2008/56/CE 2008), así como aquellaspolíticas nacionales y marcos legales para la regulación del estado del agua, tanto los de alcance territorial (Real Decreto Legislativo 1/2001), como los relativos al dominio público hidráulico (Real Decreto 849/1986 y 927/1988), a las demarcaciones hidrográficas (Real Decreto 125/2007 y 126/2007), los planes hidrográficos (Ley 10/2001, Real Decreto 907/2007, 650/1987 y 1/2016) y calidad del agua (Real Decreto 817/2015 y 1341/2007) y otros actos legales relevantes a la hora de estudiar la normativaexistente en el ámbito estatal (Real Decreto 903/2010, 2090/2008, 2/2011, 17/2012 y lasleyes 22/1988, 2/2013 y 1/2018). Algunas de las preceptivas reglamentarias en proyectosdel sistema portuario español de interés general del Estado, también pueden ser de gran ayuda a la hora de implantar estas técnicas de drenaje (ROM 5.1-13, 1.0-09, 2.0-08, 0.5-05, 0.2-90 y 4.1-94). Para la elaboración de este estudio, el equipo investigador también se apoyó en otras normativas y guías (IC-6.1 y IC-5.2).

2.2. Selección de SUDS

A continuación, se describen las distintas técnicas de SUDS que han sido objeto de estudio en esta investigación con el fin de evaluar su posible implementación en áreas portuarias.

Cabe mencionar que hay algunos métodos que, debido a sus características propias y de la ubicación donde se van a implantar, se han descartado desde el inicio. Estos SUDS, se han desechado por la falta de espacio para su instalación, o por motivos de funcionalidad y normativos. Los SUDS seleccionados para lograr reducir y mejorar la calidad del volumen efluente de escorrentías superficiales que se localizan en los puertos de la manera más eficiente posible, se describen a continuación en la Tabla 2.

Nombre del SUDS	Definición	Funcionesprincipales
Depósitos de infiltración (Biorretención)	Se trata de una excavación que es posteriormente rellenada con un materialfiltrante permeable y en cuya superficie suele tener una determinada vegetación. Almacena el agua hasta que se produce su infiltración, para su posterior evacuación mediante un sistema de drenaje subterráneo o su almacenamientoen el propio sistema (Sañudo-Fontaneda,et al. 2012).	Infiltración, detención y almacenamiento.
Pavimentos permeables (Adoquines impermeables en disposición permeable, PICP)	Suelen ser de hormigón y se agrupan de tal manera que dejen ranuras entre cada adoquín. De este modo, se permite la infiltración vertical del agua. Las ranuraspueden ser cubiertas por gravilla o dejarse libres (Sieglen y Von Langsdorff,2004).	Captación, infiltración, detención y almacenamiento.
Cubierta verde (Extensivas)	Elemento constructivo que cubre parcial o totalmente la parte superior de un edificio, mediante un sistema multicapa, en el que la superficie en contacto con el aire está compuesta por una capa delgadade vegetación. Esta vegetación se cultivaen una capa de sustrato de pequeño espesor. La parte inferior debe estar siempre impermeabilizada para de este modo evitar el paso del agua a la estructura (NCDEQ Stormwater Design Manual, 2017).	Captación, infiltración ydetención.
Depósitos de almacenamiento (RHW)	Estructuras cerradas que admiten multitud de diseños y que recogen el agua, para su posterior reutilización enrequerimientos de agua no potable (CIRIA, 2017).	Almacenamiento.
Drenes filtrantes	Son zanjas poco profundas, generalmentelineales, que están compuestas por un material de relleno filtrante granular o sintético(Sañudo-Fontaneda et al. 2012).	Captación y transporte.

Tabla 2 – Técnicas de SUDS para su uso en zonas portuarias. (Fuente: elaboración propia)

Dentro de todas las modalidades de pavimentos permeables se ha seleccionado lamodalidad de adoquines impermeables en disposición permeable (ver Tabla 2), debido principalmente a que, tras realizar un análisis de las categorías tráfico actuantes en las superficies portuarias consideradas, se observa que se obtiene una tipología de A y B paralos distintos usos del suelo (Ministerio de Fomento, 1990). Esta tipología, excederá la capacidad portante de la mayoría de modalidades de este tipo de SUDS, en especial los clasificados como pavimentos permeables de superficie continua (Rodríguez-Hernández et al. 2011). Además, existen estudios y aplicaciones de los adoquines impermeables en disposición permeable en áreas portuarias (Gray et al. 2010), que han demostrado los beneficios que presentan su aplicación. Destacan por su mayor flexibilidad y capacidad portante, menor necesidad de mantenimiento y gran poder de reducción de la carga contaminante.

Por otro lado, también existen modalidades de los depósitos de infiltración y drenes filtrantes que pueden ser muy aconsejables para su implantación en áreas portuarias. Es el caso de los depósitos de infiltración, en los que hay diseños estructurales que se adaptan al espacio disponible y los requerimientos funcionales de las terminales de contenedores(Gray et al. 2010). Además, hay empresas especializadas en el drenaje de puertos como *Polypipe*, que han desarrollado diseños de componentes de estructurales de SUDS(Permavoid system) (Polypipe, 2016), que han sido implantadas en áreas portuarias con éxito (Polypipe, 2017). O la empresa ACO, que también ha implementado modalidades novedosas en áreas portuarias (ACO, 2012).

3. RESULTADOS

Una vez analizadas las características de las zonas portuarias que pueden repercutir en la investigación y las alternativas de SUDS, que por sus propiedades intrínsecas pueden ser viables su implementación, se realiza una tabla multicriterio. Ésta, recibe el nombre de "*Selección de SUDS en función de la operación portuaria o uso del suelo*", la cual puede proporcionar apoyo a los organismos con competencias en infraestructuras portuarias. Igualmente puede servir de guía a su personal técnico para planificar, implementar, diseñar y mantener un control efectivo de este tipo de técnicas de drenaje. Cabe mencionar, que las columnas relativas a los tipos de terminales portuarias que se puedenencontrar en un puerto hacen referencia a sus zonas de almacenamiento (ver Tabla 3). Laszonas de operaciones de este tipo de terminales se han unificado en una única columna, teniendo en cuenta las características específicas de cada una de ellas a la hora de estudiar la viabilidad de implementación de SUDS en ellas. Para los resultados de este análisis, fue necesario tener en cuenta el grado de implementación de cada técnica en función de las limitaciones que pueden presentar los distintos usos portuarios. Las justificaciones generales por las que las técnicas de SUDS no son aplicables o se verían condicionadas en su uso, son las siguientes:

- Cargas: significa que las cargas actuantes derivadas de las actividades que se desarrollan en esos usos de suelo excederán la capacidad portante del método convencional en cada caso.
- Sedimentos: significa que las altas cargas de sedimentos que generalmente están asociadas con esta actividad provocarían que sea incompatible o condicionada su implementación con el funcionamiento normal y el rendimiento efectivo de este método.
- Espacio: significa que este método puede que no sea compatible con la disponibilidad de espacio en el uso del suelo correspondiente.
- Calidad: significa que la calidad del volumen afluente que recibe el sistema debería ser tratada por otro método específico no englobado dentro de los SUDS.

Tabla 2 - Selección de SUDS en función de la operación portuaria o uso del suelo. (Fuente: elaboración propia)

A partir de las limitaciones comentadas, se establece el grado de implementación de las distintas técnicas mediante la siguiente nomenclatura:

- PR (Puerto Requiere): los SUDS en esta categoría deben usarse para las actividades especificadas, siempre que existan condiciones físicas apropiadas.
- PA (Puerto Admite): los SUDS en esta categoría también deben considerarse y es recomendable su uso siempre que sea posible.
- C (Condicionantes): esta categoría es para los métodos SUDS en los que su implementación se vería afectada por las actividades especificadas. Sin embargo, el método puede ser aprobado con alguna variante respecto a su diseño convencional.
- P (Prohibido): el puerto no permitirá el uso de estos SUDS para las actividades especificadas.
- n/a (No aplicable).

Si se analizan las funciones principales de las técnicas de SUDS para su uso en zonas portuarias, mostrados con anterioridad (ver Tabla 3)**, s**e observa que estas difieren en función del sistema. Por esta razón, en ocasiones si los condicionantes del emplazamiento lo permiten será viable combinar algunas de estas técnicas formando un esquema secuencial denominado usualmente tren de drenaje (Ariza et al. 2019). La combinación de SuDS, con el objetivo de alcanzar un sistema de drenaje multifuncional con un rendimiento óptimo, ha sido contrastado con éxito en áreas urbanas (Edmonton, 2014). Las funciones físicas e hidrológicas principales desarrolladas por los SUDS seleccionados son las siguientes: captación (C), infiltración (I), detención (D), transporte (T) y almacenamiento (A). En la siguiente tabla, se propone un esquema secuencial para las distintas técnicas estudiadas, en la que el primer componente indica el proceso relacionado con la fila y el segundo componente el proceso relacionado con la columna (Ariza et al. 2019).

FINAL INICIAL	Depósitos de infiltración	Pavimentos permeables	Cubierta verde	Depósito de almacenamiento	Drenes filtrantes
Depósitos de infiltración					
Pavimentos permeables	C.D.I.A			C.I.D.A	C.I.D.A.T
Cubierta verde	C.I.D.A	C.I.D.A		C.I.D.A	C.I.D.T
Depósitos de almacenamiento					
Drenes filtrantes	C.T.I.D.A	C.T.I.D.A		C.T.A	

Tabla 3 - Esquema secuencial entre los distintos SUDS (tren de drenaje). (Fuente: elaboración propia a partir de Ariza et al. 2019)

Al analizar los resultados de la anterior tabla, se observa el potencial que presentan diversas técnicas SUDS para ser utilizadas como elementos multifuncionales. Es el caso de la combinación de drenes filtrantes en la primera etapa con depósitos de infiltración en la etapa final. Esto se debe a que el objetivo principal de los drenes filtrantes es el de captar y filtrar la escorrentía superficial de áreas impermeables con el fin de transportarlas a otros puntos de tratamiento o de vertido, como en este caso son los depósitos de infiltración (RHW) (NCDEQ Stormwater Design Manual, 2017). En estos depósitos, se logra retener casi en su totalidad la mayoría de la contaminación difusa, mejorar la laminación del volumen afluente y conferir funciones de reutilización del volumen efluente a través de su almacenamiento y posterior bombeo. Si se quiere optimizar esta reutilización de agua, implantar los RHW en la etapa final puede ser muy aconsejable. En especial en aquellas áreas portuarias donde haya una alta carga de sedimentos, ya que, este sistema tiene modalidades en las que se realizan procesos de decantación, como los sistemas bombeados o compuestos (CIRIA, 2017). Si la etapa inicial son las cubiertas verdes o los pavimentos permeables, los RHW también presentan gran potencial como etapa final en un tren de drenaje.

Aunque, si la etapa inicial son cubiertas verdes y la final los RHW, hay que prestar especial atención a los contaminantes que llegan al depósito, debido a que si la escorrentía contiene elementos comocobre, zinc, fungicidas y herbicidas, puede no ser adecuada la reutilización del volumen efluente (dependiendo del propósito para el que se va a utilizar) (CIRIA, 2017).

4 CONCLUSIONES

En base al estudio realizado en la presente investigación sobre la implementación de SUDS en áreas portuarias, se puede concluir que este tipo de técnicas se presentan como un nuevo paradigma y una oportunidad para mejorar la gestión de agua pluvial en los puertos. Es decir, se trata de un conjunto de técnicas que deben complementar, y en algunos casos sustituir, al drenaje convencional en las áreas portuarias. A la par, será ineludible su implantación en los puertos de nueva creación, con la finalidad de evitar todos los indeseables problemas que se generan a consecuencia de mala gestión de la escorrentía superficial.

En relación, a los resultados particulares del estudio realizado, se puede concluir que existen algunas zonas portuarias que presentan una gran idoneidad para la implementación de este tipo de técnicas de drenaje, como es el caso de las zonas complementarias. Son fundamentalmente las zonas urbanizadas, tales como edificios, dependencias administrativas, zonas de paseo y esparcimiento o áreas de estacionamiento, ya que, al compartir características con las áreas urbanas, presentan grandes ventajas desde el punto de vista de funcionalidad de los SUDS que se puedan implantar en ellas.

Por otro lado, en las vías de comunicación también puede ser recomendable su uso, aunque habrá que prestar especial atención en algunos sistemas, como el de los pavimentos permeables, a la hora de seleccionar la modalidad y realizar su diseño para que las cargas actuantes y presiones de contacto con el pavimento no superen la capacidad portante del sistema.

En las zonas de operación, la aplicación de los SUDS estudiados se verá principalmente condicionada por algunos criterios como los normativos, de acumulación de sedimentos o de disponibilidad de espacio, así como por las cargas actuantes en ellos.

En las zonas correspondientes al almacenamiento que se realiza en las distintas terminales portuarias estudiadas, los principales condicionantes se van a dar en las terminales de graneles. Por un lado, en las de graneles líquidos, a consecuencia de su necesidad de tratamientos específicos para la gestión de los vertidos y descargas, y en las de graneles sólidos con almacenamiento en la intemperie, ya que las cargas actuantes en ellos son menores en comparación con otras terminales. Estas terminales presentan la gran desventaja de la cantidad de sedimentos que transporta la escorrentía superficial que se genera en ellos, lo que provocaría una rápida colmatación del sistema. Esto se debe a que uno de los principales inconvenientes de los SUDS es la vulnerabilidad que presentan a ser obstruidos por los sedimentos, por lo que la implantación de las técnicas estudiadas (con la excepción de los depósitos de almacenamiento), conllevaría numerosas tareas de mantenimiento con una periodicidad muy corta y el riesgo de empeorar el funcionamiento correcto del sistema y llegar, incluso, a inutilizarlo.

AGRADECIMIENTOS

El equipo investigador de este proyecto agradece al Instituto Universitario de Tecnología Industrial de Asturias (IUTA), la Fundación de la Universidad de Oviedo (FUO) y el Ayuntamiento de Gijón, la financiación recibida a través del proyecto SuDS-Ports con referencia SV-19-GIJÓN-1-03; así como a la Fundación para el Fomento en Asturias de la Investigación Científica Aplicada y la Tecnología (FICYT) la financiación con fondos FEDER de la Unión Europea del proyecto con referencia IDI/2018/000221.

RESUMEN

Esta investigación busca el objetivo de plantear un escenario de gestión portuaria, para el actual Sistema Portuario español, analizándolo y comparándolo con el actual.

Mediante el empleo del Análisis Envolvente de Datos (DEA) y sumándole el análisis de competitividad, se elabora un escenario, en base a criterios técnicos, y bajo la definición de "fachada marítima", sobre la cual analizar la eficiencia operativa y financiera.

La metodología del modelo DEA ha venido evolucionando, ya que actualmente se tienden a modelos orientados en input o en output, lo que favorece el uso de análisis Bootstraping. El cual corrige los sesgos que puedan producirse en el análisis DEA tradicional.

Los resultados del análisis DEA-Bootstrapping muestran una serie de resultados que favorece a este escenario frente a la situación actual, ya que tanto la eficiencia operativa como la financiera mejoran respecto al escenario actual o escenario 0.

1. INTRODUCCIÓN

1.1 El Puerto

En su origen etimológico, la palabra puerto proviene del latín, *portus,* significando puerta o entrada, y, a esta a afección hacen referencia las múltiples definiciones de puerto empleadas en la actualidad. Por citar dos de las más empleadas, Rodrigue et al. (2013) definen los puertos como puntos de convergencia entre dominios geográficos (terrestre y marítimo) de circulación de mercancía y pasajeros. Por otro lado, Martagan et al. (2009) establecen que los puertos son las instalaciones intermodales por excelencia, ya que centralizan múltiples medios de transporte.

El transporte marítimo, ha sido durante toda la historia de la humanidad, el modo de transporte de mercancías por excelencia, siendo los puertos enclaves vitales para el control de dichas mercancías. Tal consideración se ha mantenido en el tiempo incluso tras la revolución industrial y el desarrollo de la automovilística (transporte terrestre) y la aeronáutica (transporte aéreo). Según Rodríguez et al. (2013) los puertos siguen centralizando de forma masiva el tráfico de mercancías debido al elevado coste del transporte aéreo, sólo viable en transacciones urgentes y de productos de tipo tecnológico, cuya relación precio de mercado-peso hace que sea económicamente conveniente. Rodrigue et al. (2013) añade también, que el transporte terrestre no puede competir con el marítimo, en cuanto a la movilización de grandes volúmenes de mercancía, debido a la falta de infraestructura ferroviaria y la rigidez de esta.

La clasificación de los puertos es variable, y depende en gran medida de la perspectiva con la que se analice el mismo. Depende, por ejemplo, de la especialización en cuanto a tipo de tráfico, volumen de tráfico, infraestructura, superficie de ocupación, etc. Además, según López (2018) en numerosas ocasiones es necesario identificar los elementos constituyentes del puerto por separado, pudiendo pertenecer dos terminales de un mismo puerto a clasificaciones diferentes, según el criterio empleado.

1.2 El Sistema Portuario Español: desde sus orígenes hasta hoy

Hasta finales del siglo XIX, los puertos se regían por sistemas más o menos heredados de la Edad Media, tales como los Consulados del Mar y similares, y no es hasta los años 70 de ese siglo cuando se promulga la Ley General de Obras Públicas, por medio de la cual se comienza a ordenar administrativamente las infraestructuras y su explotación. A continuación, se desarrollan las leyes específicas, de aguas, ferrocarriles, etc. que regulan las distintas áreas.

En 1880 se promulgó la primera Ley de Puertos, continuación natural de esa Ley General de Obras Públicas. Prácticamente era más una ley de costas que de puertos, ya que regulaba fundamentalmente el dominio público marítimo terrestre y su aprovechamiento.

De cómo se debían explotar los puertos, no se establecía más norma que la atribución de las operaciones náuticas al Capitán de Puerto, que era el comandante de Marina, y las terrestres al director del Puerto, que era un Ingeniero de Caminos, Canales y Puertos del Estado.

Esta ley estuvo vigente hasta la promulgación de la Ley de Puertos y Marina Mercante de 1992, es decir, 112 años. Naturalmente, si bien no tuvo más que pequeñas correcciones en el año 1928, se fue complementando con otras leyes que regulaban aspectos propios de los puertos, como la ley de Juntas de Obras del Puerto, la ley de Régimen Financiero o la de Juntas de Puertos y Estatutos de Autonomía.

El modelo de 1992 fue modificado por la ley de 1997 que aumentó la participación de las Comunidades Autónomas en el funcionamiento y gestión de los puertos y una mayor liberalización de las tarifas.

La incorporación de las Comunidades Autónomas en la gestión de los puertos de interés general se orientó hacia su participación en el nombramiento de los órganos de gobierno de las Autoridades Portuarias. De este modo, la ley concedió una mayor participación a las Comunidades Autónomas donde estén ubicados los puertos, tanto en su estructura de cargos como en su gestión, a través de la designación de los miembros de sus órganos de gobierno. Se garantizó que en el Consejo de Administración estuvieran también representadas las Administraciones Municipal y Central, la Cámara de Comercio, Industria y Navegación, y las organizaciones empresariales y sindicales de los sectores económicos más relacionados con el comercio marítimo.

Además, con esta reforma legislativa, no sólo aumentó la autonomía las Autoridades Portuarias en relación al Ente Público Puertos del Estado, sino que también el Ente Público Puertos del Estado, ganó autonomía respecto del Ministerio de Fomento (Transportes, Movilidad y Agenda Urbana. Así, por ejemplo, los objetivos generales que aquel fije como guía para los programas de actuación de las Autoridades Portuarias ya no tienen por qué estar de acuerdo con la política de transportes definida por el Ministerio de Fomento (Transportes, Movilidad y Agenda Urbana). Como consecuencia de estas y otras características, es posible afirmar que la Ley 62/1997, crea un nuevo modelo de gestión portuaria: el modelo español.

La Ley 27/1992, de 24 de Noviembre, de Puertos del Estado y de la Marina Mercante (LPEMM), modificada por el Texto Refundido 2/2011, de 5 de septiembre, distingue entre los puertos de titularidad autonómica (básicamente los puertos pesqueros, deportivos y de refugio), que dependen del Gobierno de la Comunidad Autónoma donde están ubicados, y los puertos de titularidad estatal, es decir, los puertos calificados como de interés general.

2. ESTADO DEL ARTE

2.1 Gobernanza portuaria

La gobernanza portuaria se define, según Comtois y Slack (2003), en función de dos fuerzas: las fuerzas centrípetas y las fuerzas centrífugas. Las fuerzas centrípetas tratan de definir, en términos políticos, los controles de orden jurisdiccional y geográfico de las dinámicas territoriales de un puerto. Es decir, enfatiza sobre los distintos roles de los agentes privados y públicos, profundizando en el ámbito de la gestión y de las operaciones portuarias desde la perspectiva de una economía de mercado. Las autoridades portuarias buscan adoptar aquellas medidas que permitan aumentar la eficacia, como la mayor descentralización administrativa y los mayores campos de libertad para la economía privada, adaptándose a las reglas de mercado. Por tanto, los cambios estructurales en la gobernanza enfatizan hacia una mayor liberalización y desregulación. Producto de esta dinámica es la creación de plataformas multimodales, que buscan captar y atraer tráficos, mejorar el posicionamiento de las infraestructuras portuarias en el mercado mundial y, por tanto, una nueva definición intraportuaria, que supone una ampliación de los servicios logísticos y del desarrollo de redes globales alentadas por las economías locales (Nottebom y Rodrigue, 2005). Los puertos constituyen un elemento más de la cadena multimodal entre productor y consumidor, aumentando los vínculos entre el transporte marítimo y el transporte terrestre. Bajo esta fuerza centrípeta asistimos a un crecimiento de la capacidad de oferta de las terminales; a una adaptación de los flujos y de los sentidos de las rutas de transporte marítimo; a una nueva concepción de los índices de performance y del beneficio empresarial; y a una reducción del riesgo y aumento de la seguridad en el transporte “puerta a puerta”. Las autoridades portuarias combinan las actividades de los transportistas y los operadores de terminales, buscando las mayores economías de escala y el desarrollo de actividades de marketing. Las autoridades portuarias operarán en situaciones de mayor complejidad e interdependencia; con mayor participación en la definición de estrategias marítimas en lo que atañe a acuerdos entre puertos y selección de rutas; y finalmente en lo que concierne a los sistemas de tecnología de información.

Las fuerzas centrífugas, por su parte, hacen referencia a las trayectorias de la gobernanza portuaria. Fuerzan, por lo tanto, a una nueva redefinición de las funciones tradicionales de las autoridades portuaria. Es decir, enfatizan sobre aquellas actividades complementarias de las funciones estrictamente marítimas y portuarias, para reforzar las integraciones verticales y horizontales; en suma, para responder a las nuevas demandas y necesidades de incrementos del comercio. En consecuencia, buscan aprovisionamiento y gestión del espacio; conexiones con otros modos de transporte; y desarrollos logísticos (Laxe, 2008).

2.2 Los nuevos modelos de gobernanza portuaria

El papel del sector privado se ha ampliado considerablemente en muchos sectores económicos importantes en los últimos decenios. Los puertos no han sido inmunes a este avance y muchos puertos de todo el mundo se han beneficiado de la intervención del sector privado. En el documento presentado por Baird (2000) se examinan los objetivos comúnmente asociados a la privatización de las funciones portuarias. Se presenta un marco (Matriz de Privatización Portuaria) que puede utilizarse para ayudar a establecer el alcance de la intervención del sector privado en un puerto determinado. Donde se examinan los principales métodos utilizados para lograr la intervención del sector privado en los puertos, con los ejemplos que procedan. Y, por último, se examina la forma bastante singular de privatización de los puertos (es decir, la transferencia de derechos de propiedad, etc.) adoptada en el Reino Unido. Las pruebas sugieren que el Estado no necesita transferir los derechos de propiedad de los puertos marítimos para beneficiarse de la experiencia del sector privado. De hecho, debido a la naturaleza específica de la inversión portuaria, y teniendo en cuenta el objetivo clave de los puertos de facilitar el comercio, esto puede ser contraproducente.

Cabe destacar que la mayoría de las tendencias a futuro sobre la gobernanza portuaria, enmarcadas en el contexto del libre mercado y la actual teoría económica, pasan por la desaparición de la propiedad pública en favor de la privada. Este hecho vendría reforzado por la idea de que la privatización del sector portuario se daría debido a la incapacidad del sector público de asumir los fuertes requerimientos de capital necesarios en el sistema, de continuar la evolución de volumen de tráfico como hasta ahora, para reforzar la infraestructura, la atracción de embarcaciones y el aumento de superficies destinadas al almacenamiento de mercancías. Por tanto, en la medida que las autoridades e instituciones públicas no sean capaces de afrontar las inversiones serían los agentes privados quienes (a través de adjudicaciones y/o concesiones) llevarían a cabo dichas inversiones en el futuro.

Ante este hecho, aparecen teorías como la de Lavaud-Letilleul (2007) que también afirman que las dinámicas portuarias estarán cada vez más ligadas a las empresas operadoras o propietarias de espacios portuarios y terminales, aunque, añaden que esta trayectoria puede implicar efectos sobre la relación entre los puertos y el territorio.

2.3 Antecedentes del Análisis Envolvente de Datos (DEA)

Farrell (1957) determinó empíricamente un estándar de referencia, la frontera, con el que comparar las empresas para determinar si son eficientes o no. Las medidas de eficiencia calculadas de esa manera definen lo que se conoce como eficiencia relativa, es decir, miden la eficiencia de una empresa comparando su actuación con la de las "mejores" empresas observadas, que son las que definen la frontera eficiente. Este trabajo puede considerarse como el origen de todos los estudios en este campo, si bien, el trabajo de Farrell tiene como antecedentes los de Debreu (1951) y Koopmans (1951).

El Análisis Envolvente de Datos (DEA) usa algoritmos de programación lineal para calcular la frontera. Esta idea fue originalmente propuesta por Hausman (1978) en su discusión del artículo de Farrell. La primera aplicación de la programación lineal al cálculo de la eficiencia se debe a Boles (1966). Posteriormente, Charnes, Cooper y Rhodes (1978) dieron a esta técnica el nombre de Data Envelopment Analysis, cuyo uso se ha popularizado y hoy en día sobrepasa a las aplicaciones basadas en fronteras estocásticas (Førsund y Sarafoglou, 1999).

Es interesante destacar aquí la diferencia fundamental entre el método del Análisis Envolvente de Datos (DEA) y el de Farrell (1957) para el cálculo de la frontera. Farrell no usa programación matemática, sino que calcula la frontera algebraicamente. Sin embargo, los resultados de ambas aproximaciones son equivalentes.

Entre las ventajas de la aproximación no paramétrica hay que mencionar que no hay que suponer una forma funcional concreta para la frontera. Algunos estudios han encontrado que los índices de eficiencia son sensibles a la especificación de la forma funcional. Por otra parte, la aproximación no paramétrica permite el tratamiento sencillo de tecnologías multioutput.

Entre los inconvenientes de esta aproximación cabe citar que es más sensible a los errores de medida que la aproximación econométrica, puesto que no existe un término de error que permita controlar el efecto que tienen los factores no controlables o no observados. Un segundo inconveniente es que no permite realizar inferencia estadística sobre los índices calculados. Este problema se corrige con los métodos Bootstrap, cuyo objetivo es dotar al análisis DEA de una naturaleza estocástica similar a la de los modelos econométricos.

2.4 Antecedentes de la competencia y la competitividad

Es importante realizar una distinción entre los conceptos de competencia y competitividad. La competencia es la concurrencia de una multitud de vendedores en el mercado libre, de forma que, para conseguir la venta de los bienes y servicios que producen, pugnan entre sí fijando los precios que les permitan sus costes y que estén alineados con los del mercado (Tamames y Gallego, 1996). En cambio, la competitividad se puede entender como la capacidad de competir de la empresa, que no va a depender sólo de sus propias fortalezas, sino también de la capacidad que tenga de hacer frente a sus debilidades y transformar sus amenazas en oportunidades (Winkelmans, 2003).

En definitiva, la competitividad depende de una multitud de factores, y para que una empresa pueda competir en el mercado debe explotar sus ventajas competitivas, principalmente a través de la diferenciación y del liderazgo en costes de los bienes y servicios que produce. En la actualidad, las empresas no sólo compiten con bienes o factores productivos tangibles, sino que, cada vez en mayor medida, la competencia se realiza mediante la provisión de servicios determinados por parte de ella y el desarrollo y aprendizaje de su núcleo específico de competencias específico para la consecución de sus ventajas competitivas (Winkelmans, 2003).

El núcleo de competencias de una empresa puede ser más o menos imitable por el resto; as., si un núcleo de competencias está basado en el desarrollo de complejas tecnolog.as y habilidades, ser. más difícil de imitar por otras empresas y tendrá una mayor probabilidad de desarrollar ventajas competitivas durante un periodo de tiempo más extenso, siendo el mejor núcleo de competencias el que posee un alto grado de durabilidad.

La competencia portuaria se refiere al desarrollo y aplicación de estrategias alternativas para atraer a más clientes o a clientes con un mayor potencial de negocio hacia el puerto (Cerbán Jiménez, 2009). Los puertos analizan continuamente estrategias con el objeto de alejarse de sus competidores. Como consecuencia, los puertos compiten localmente, pero también lo hacen a nivel global, incluso a grandes distancias, sirviendo a las mismas zonas comerciales.

Según Van der Voorde y Winkelmans (2002), la competencia portuaria se extiende a cuatro niveles:

- Competencia entre empresas de un puerto.
- Competencia entre puertos.
- Competencia entre grupos de puertos (por ejemplo, un grupo de puertos con características geográficas comunes compiten entre ellos).
- Competencia entre rangos portuarios (por ejemplo, puertos localizados a lo largo de la misma costa o con un hinterland prácticamente idéntico compiten con los de otro rango por unos tráficos determinados).

Los autores Fleming y Baird (1999) identifican que los principales factores que explican la competitividad portuaria, para todo tipo de tráficos, son:

- La tradición portuaria.
- El rango portuario (puertos que comparten misma costa y mismo transpaís).
- La accesibilidad portuaria.
- La productividad portuaria.
- El apoyo público.
- Las preferencias de los agentes implicados hacia los puertos.
- La localización geográfica.

3. METODOLOGÍA

3.1 Eficiencia

La técnica del Análisis Envolvente de Datos (Data Envelopment Analysis - DEA) es una técnica de programación lineal que facilita la construcción de una superficie envolvente, frontera eficiente o función de producción empírica, a partir de los datos disponibles del conjunto de entidades objeto de estudio, de forma que aquellas que determinan la envolvente son las denominadas entidades eficientes, y permiten la evaluación de la eficiencia relativa de cada una de las entidades.

El análisis basado en DEA, desarrollado por Charnes, Cooper y Rhodes en 1978, es un método extremal y no parámetrico para la estimación de fronteras de producción y evaluación de la eficiencia de una muestra de unidades de producción Decision Making Units (DMU´s), en la terminología científica. La metodología DEA, dado que es una técnica no paramétrica, no supone ninguna forma funcional de la relación entre los inputs y los outputs, ni una distribución de la ineficiencia. Además, es capaz de manejar situaciones de múltiples inputs y outputs, expresados en distintas unidades. Son precisamente estas ventajas de DEA las que han favorecido su eso extensivo.

Dentro de la metodología DEA, se pueden diferenciar varios tipos de eficiencias en función de la unidad de referencia que utilice:

a. Eficiencia Técnica Global (TE): Cuando se escoge como unidad de referencia la de mayor productividad de entre todas las unidades posibles. Se denomina eficiencia CCR, ya que fue desarrollada por Charnes, Cooper y Rhodes en 1978. También es denominada eficiencia CRS, acrónimo de “Constant Returns to Scale”.
b. Eficiencia Técnica Pura (PTE): Cuando se escoge como unidad de referencia la de mayor productividad de entre todas las unidades posibles de su tamaño. Se denomina BCC, por ser desarrollada por Banker, Charnes y Cooper en 1984. También es denominada eficiencia VRS, qye significa “Variable Returns to Sacale”.
c. Eficiencia de Escala (SE): Es el cociente entre la Eficiencia Global (TE) y la Eficiencia Técnica Pura (TE). Para caracterizar el rendimiento productivo de una DMU, no basta con el conocimiento de su eficiencia técnica. Es necesario, además, obtener su Eficiencia de Escala, es decir, conocer si está trabajando en el correspondiente tamaño de escala más productivo (Most Productive Scale Size – MPSS). Cuando una DMU es eficiente tanto en la aplicación del modelo CCR como en el modelo BCC, el valor de su Eficiencia de Escala (SE) es igual a la unidad, y podemos afirmar en ese caso que está trabajando en su tamaño de escala más productivo (MPSS). (Charnes y Cooper, 1989).

Por tanto, de esta expresión se deduce que la Eficiencia Técnica Global (TE), se descompone en Eficiencia Técnica Pura (PTE) y Eficiencia de Escala (SE). TE=PTE x SE.

Modelo	Orientación Input	Orientación Output
CRS	min $\theta = \varphi - \varepsilon\,(\sum_{i=1}^{m} S_i^- + \sum_{r=1}^{s} S_r^+)$ Sujeto a : $$\sum_{j=1}^{n}(\lambda_j x_{ij}) + S_i^- = \theta x_{io}$$ $i = 1,2,\dots,m;$ $$\sum_{j=1}^{n}(\lambda_j y_{rj}) - S_r^+ = y_{ro}$$ $r = 1,2,\dots,s;$ $\lambda_j \geq 0$ j = 1, 2, …, n. $\sum_{j=1}^{n}\lambda_i = 1$	max $\theta = \varphi + \varepsilon\,(\sum_{i=1}^{m} S_i^- + \sum_{r=1}^{s} S_r^+)$ Sujeto a : $$\sum_{j=1}^{n}(\lambda_j x_{ij}) + S_i^- = x_{io}$$ $i = 1,2,\dots,m;$ $$\sum_{j=1}^{n}(\lambda_j y_{rj}) - S_r^+ = \theta y_{ro}$$ $r = 1,2,\dots,s;$ $\lambda_j \geq 0$ j = 1, 2, …, n. $\sum_{j=1}^{n}\lambda_i = 1$
VRS	Añadir: $\sum_{j=1}^{n}\lambda_j = 1$	

Tabla 2-Formulación de modelos DEA. Fuente: Gil Ropero (2015).

Donde:

y_{r0} y x_{i0}: los rth outputs y ith inputs para cada DMU_0 evaluada.
λ_j: las variables de decisión que representan los pesos DMU_j que colocaría sobre cada DMU_0 en la construcción de su conjunto de referencia eficiente.
θ: la distancia proporcional en las entradas a la frontera y por tanto, la medición de la eficiencia técnica.
ε: el número real positivo más pequeño.
S_i y S_r: las holguras potenciales o factores de exceso para cada input.

En la siguiente figura (Figura 2) se ha representado ambos modelos.

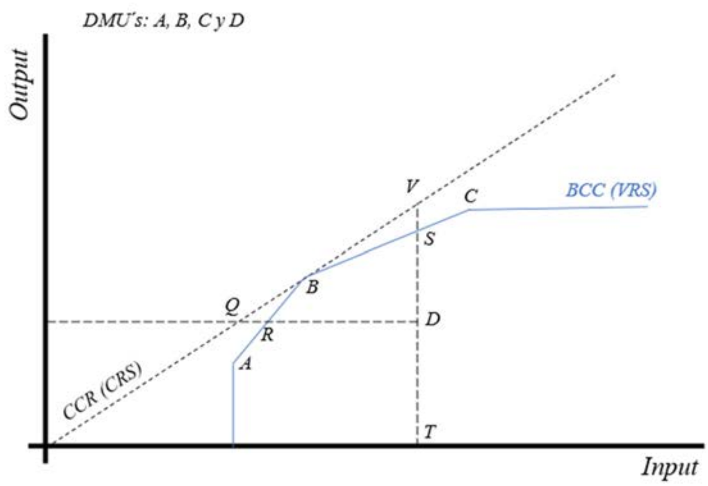

Figura 2-Representaión gráfica de las eficiencias CCR y BCC. Fuente: Elaboración propia, tomado de Gil Ropero (2015).

La técnica *Bootstrap* proporciona estimaciones del error estadístico imponiendo escasas restricciones sobre las variables aleatorias analizadas y estableciéndose como un procedimiento de carácter general, independientemente del estadístico considerado.

El *Boostrap* (Efron, 1979 y 1982) ofrece una aproximación alternativa para la inferencia y el contraste de hipótesis en los modelos DEA. De hecho, en el caso de los modelos DEA con múltiples inputs y outputs, el Bootstrap es la única aproximación existente.

a) Bootstrap orientación input (BCC): $\frac{AD-AC}{AX_0} = \frac{AC-AB}{AX_0}$

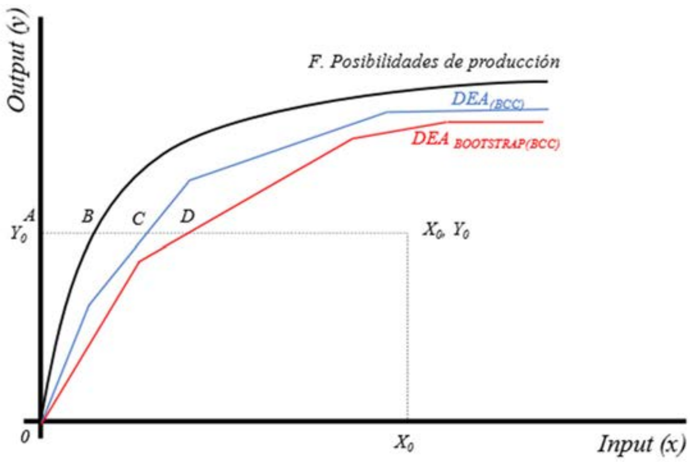

Figura 3-Representación gráfica del Bootstrap consistente Orientación input. Fuente: Elaboración propia, basado en Gil Ropero (2015).

b) Bootstrap orientación output (BCC): $\frac{AD-AC}{AY_0} = \frac{AC-AB}{AY_0}$

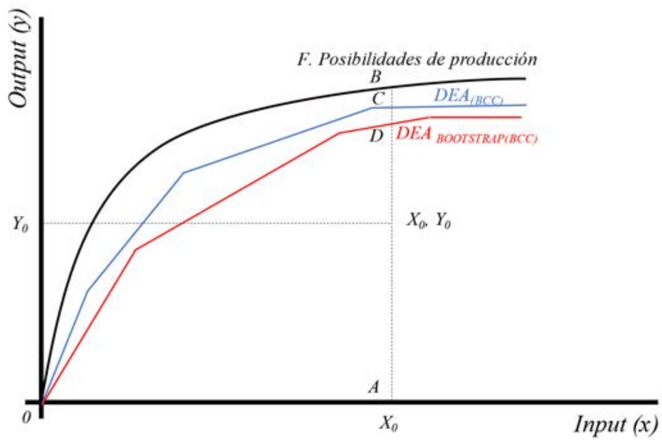

Figura 4-Representación gráfica del Bootstrap consistente Orientación output. Fuente: Elaboración propia, basado en Gil Ropero (2015).

3.2 Análisis de competitividad

La metodología propuesta se caracteriza por la observación de datos anuales y su transformación en forma de indicadores ponderados. La fuente de datos principal ha sido el Anuario Estadístico de Puertos del Estado para el ejercicio del año 2018.

Se observan indicadores pertenecientes a lo que se ha catalogado como tres tipos de "entorno portuario" dependiendo del nivel de escala sobre el que incide el indicador, lo que nos permitirá observar la competitividad de los puertos a distintos niveles, ya que en principio, no resultaría proporcional basar el análisis de competitividad en variables de producción o económicas que aportaría datos sesgados hacia los puertos más importantes, en términos de volumen de tráfico y recaudación, del sistema.

Así, los tres entornos observados y los indicadores que componen cada uno son:

a) El microentorno: se consideran indicadores propios del puerto en sí mismo, es decir, aquellos equipamientos y servicio básicos que proporciona el puerto e inciden en su productividad. Los indicadores estudiados para este entorno, y sus unidades de medida.
b) El mesoentorno: se consideran indicadores relativos al grado de calidad de interacción con otros entornos que presenta el puerto. Así, se consideran las aportaciones científicas y el desarrollo tecnológico o la existencia de sistemas de gestión de residuos y la calidad del agua. Es una forma de valorar la capacidad de los puertos más pequeños de incorporar nuevas funciones al sector portuario, que aportan un valor agrado al mismo más allá de la mera productividad.
c) El macroentorno: mediante este entorno se pretende definir la capacidad del puerto para competir a nivel internacional. Es indicativo del perfil económico del puerto.

4. RESULTADOS Y ANÁLISIS DE RESULTADOS

4.1 Escenario 0 o Situación Actual

Escenario base o de punto de partida, la cual se analiza la situación del actual sistema portuario español, comprendido por 28 Autoridades Portuarias que gobiernan 46 puertos de interés general.

Tabla 3-Resultados del escenario 0 con Índice de Competitividad. Fuente: Elaboración propia.

El mayor valor de Bootstrap operativo lo alcanza la Autoridad Portuaria de Castellón (0,90255), no alcanzando la eficiencia pura en el análisis DEA. Además, para el mayor valor de Bootstrap financiero, la Autoridad Portuaria de Marín y Ría de Pontevedra (0,98084), que además alcanza la eficiencia pura en el análisis DEA.

El menor valor de Bootstrap operativo se atribuye a la Autoridad Portuaria de Vigo, que alcanza los valores más bajos en los dos análisis (0,14159 y 0,12724, respectivamente).

Esto puede deberse a la gran variabilidad de sus ingresos por tasas en función del bajo crecimiento del número de buques. Además, el valor más bajo financieramente hablando se obtiene en Ceuta, tanto en el análisis DEA (0,28426) como en el Bootstrap (0,27573).

Añadir un input más, y además siendo un factor tan determinante como un indicador de competitividad ha resultado salir eficaz, ya que la mayoría de los datos de eficiencia mejoran y se obtienen mayores resultados.

La media del escenario 0 (Sistema Portuario actual), en la aritmética como en la geométrica de la eficiencia operativa es inferior a 0,75 o al 75%, lo que significa que es ineficaz. Sin embargo, en la eficiencia financiera, supera el 0,75 o 75%, lo que puede asimilarse o aceptarse como eficiente, que no es puramente eficiente sino en una escala de eficiente o ineficaz.

4.2 Escenario 1 o Fachadas Marítimas

Escenario en el cual, se agrupan puertos o Autoridades Portuarias de toda una fachada marítima, es decir, todos aquellos puertos o Autoridades Portuarias bañados por el mismo mar u océano, pertenecientes a una misma orientación cardinal, es decir, localizados al este, sur, oeste o norte de la costa española.

Tabla 4-Resultados del escenario 3 con Índice de Competitividad. Fuente: Elaboración propia.

En los resultados obtenidos, en el escenario 1, destacamos que de las 8 autoridades portuarias que se proponen, 4 alcanzan el valor de la frontera DEA igual a 1,0000 en el análisis operacional y otras 4 en el análisis financiero, es decir, el 50% de las autoridades son puramente eficientes operativa y financieramente. En el análisis Bootstrap, los valores mejoran con respecto al escenario 0, ya que 4 de 8 (50%) superan el umbral de 0,75 o 75% de eficiencia operativa, y, en la eficiencia financiera, algo más de la mitad superan el valor de 0,75 o 75%.

El mayor valor de Bootstrap operativo lo alcanza la autoridad portuaria formada por Alicante - Cartagena - Valencia - Castellón - Tarragona - Barcelona en su conjunto (0,88337), alcanzando la eficiencia pura en el análisis DEA. Además, para el mayor valor de Bootstrap financiero, la autoridad portuaria formada por el conjunto de Santa Cruz de Tenerife-Las Palmas (0,91672) alcanza la eficiencia pura en el análisis DEA.

El menor valor de Bootstrap operativo se atribuye a la agrupación de Autoridades Portuarias formada por Bilbao - Pasajes- Santander - Gijón - Avilés en su conjunto (0,48415), coincidiendo con el menor valor en el análisis DEA (0,52321). En el análisis financiero, corresponde al grupo formado por Bilbao - Pasajes- Santander - Gijón - Avilés obtener el valor más bajo en ambos análisis. En el análisis DEA, obtuvieron una eficiencia financiera de 0,74383 y el Bootstrap de 0,71417.

En este escenario, se da el caso de que una misma agrupación obtiene los valores más bajos en las cuatro eficiencias (dos para el operacional y otras dos para el aspecto financiero).

En la media del escenario 1, tanto la aritmética como la geométrica de la eficiencia operativa superan el valor de 0,5 o el 50%, lo que significa que están cerca de ser eficientes. Sin embargo, en la eficiencia financiera, supera el 0,9 o el 90%, lo que se puede asimilar o aceptar como eficiencia pura. En el caso operativo, habría que hacer un análisis más exhaustivo, pero por los resultados obtenidos, se podría decir que no se considera eficiente. Este escenario es el que mejores datos estadísticos alcanza, siendo el escenario con los valores medios más elevados.

5. CONCLUSIONES

Con el análisis del modelo DEA- Bootstrapping se han extraído los resultados a estudiar y se ha llegado a conclusiones satisfactorias. Esta metodología ha permitido analizar el Sistema Portuario español desde ambos puntos de vista: operativo y financiero. Partiendo de una serie de indicadores o KPI´s medibles y valorables, que son analizados por la metodología DEA extrayendo los valores de eficiencia y eficiencia corregida sobre la cual se ha desarrollado esta investigación de una manera muy satisfactoria.

La revisión bibliográfica que se ha realizado en esta investigación ha ayudado a portar gran valor científico a esta tesis doctoral, ya que se han extraído los principales hallazgos relacionados con la gestión portuaria, el Análisis Envolvente de Datos (en materia portuaria) y de la competitividad, y su análisis. Esto ha permitido que la aportación científica que se genera sea de alto valor, aportando conocimiento al ámbito portuario, más concretamente en la medida de la eficiencia del sistema portuario español.

La metodología aportada en esta investigación ha resultado ser novedosa en el ámbito, ya que cruzar el índice de competitividad con el Análisis Envolvente de Datos no lo había realizado ningún otro investigador. Por ello, esta tesis aporta valor en el desarrollo de nuevas metodologías que ayuden a poder medir índices de competitividad y trasladarlos a poder medir eficiencias mediante la metodología DEA.

Centrándose en los resultados obtenidos, la media global de la eficiencia operativa del sistema portuario español es baja, en torno al 0,5, debido en gran medida a la duplicidad en muchos casos de las infraestructuras que componen el sistema. Es cierto que, en muchos casos, los diferentes puertos cuentan con un amplio abanico de las mismas instalaciones a lo largo de nuestro litoral. Por tanto, esta duplicidad de infraestructuras, a veces en distancias cortas, provoca una duplicidad de activos que no se traduce en un aumento del tráfico de mercancías y, más aún, en un mayor atractivo para recibir un mayor número de buques, lo que, a su vez, se traduce en menores ingresos por las diferentes tasas portuarias.

Es decir, los escenarios muestran que una agrupación portuaria, o una reforma del sistema portuario español, favorece la eficiencia financiera y, más aún, la eficiencia operativa de nuestro sistema portuario porque pasan de valores de 0,4 en el análisis BOOT y de 0,5 en el análisis DEA de la eficiencia operativa, a valores superiores a 0,8.

Seguidamente, los puertos con mayor eficiencia financiera son los puertos consolidados del sistema portuario español, con un gran tráfico y con unos activos diseñados para favorecer la captación de nuevos buques y nuevas mercancías, y/o para realizar un gran trabajo operativo en la manipulación de estos casos. Algunos puertos pueden estar desaprovechados, pero esto se debe a los grandes activos que poseen y que no están expresamente dedicados al uso portuario, es decir, su explotación no influye en el rendimiento del trabajo portuario atrayendo más tráfico o influyendo positivamente en la manipulación de las mercancías que entran en el puerto.

Los puertos del norte, en los escenarios mediante agrupaciones, son los que menos eficiencia alcanzan, dado que existe una consecución de una serie de puertos en muy pocos kilómetros, limitando la competitividad intraportuaria. Esto además de sumarle la duplicidad de infraestructuras derivadas de intentar conseguir tráficos de puertos cercanos, no llegando a consolidar el grado de ocupación en el que se tenía esperado en los estudios previos de demanda.

Por último, se observa que la eficiencia mejora al considerar un menor número de DMUs, es decir, la eficiencia global mejora cuanto más se reduce el número de autoridades portuarias.

ABSTRACT

Nowadays, a major safety challenge in rail transport is to manage the incidents and emergencies in the most efficient possible way. The current contingency plans tend to be based on static procedures not taking into account how real-time conditions affect them.

Consequently, the decision-making process may well suffer delays and the possibility of occurrence for human mistakes could raise since the required measures are expected to be carried out under important pressure. In this study, focused on commuter trains, railway safety is enhanced by a new intelligent emergency management system which aims to support the operator tasks in a real-time incident or emergency situation. This cyber-physical system is composed by two main modules: one on board the train, including sensors and GPS, and other integrated in the control centre addressing four computational models. Those models cover (1) the detection of different types of incidents/emergencies using the information received from on board sensors, (2) the calculation of the evacuation process (if necessary), (3) the selection, estimation of routes and communication with emergency services required for each event, and finally (4) a provision of actions to support the operator decisions. Communication between modules is provided by GPRS due to actual technology available in the pilot trains. This system has been implemented in an actual railway line in Cantabria (Santander-Cabezón de la Sal) and three practical demonstrations were defined based on several use cases, which were tested using a pilot facility incorporating all sensors and devices installed in those trains. Results demonstrated the benefits of the new system.

1. INTRODUCTION

According to the last report of 2019 of the National Commission for Railway Accidents only in Spain during 2018 one serious accident (an impact against a landslide), nine events at railroad crossing, two fires and other thirty-one different types of serious incidents took place. This demonstrates the importance of managing such undesirable events in the fastest and safest manner via transportation policies.

Over the last decade, Intelligent Transportation Systems (ITS) have implemented new features, addressing safety and security issues. The importance of enhancing the protection of critical transportation infrastructures, due to the wide range of risks which impact their proper functioning, is shown in studies as Janusova and Ciemancova (2016) through different examples of goals and roles of using ITS in railway transport and its potential benefits for decision-making process of transport operators or emergency responders.

Regarding intelligent systems developments, there is a wide variety of areas and applications. As shown by Qureshi and Abdullah (2013), ITS technology operates in diverse fields of transportation through management systems of freight (e.g. Commercial Vehicle Operations (CVO) or Advanced Fleet Management System (AFMS)), transit (e.g. Automatic Vehicle Location (AVL) or Travel Assistance Device(TAD)), incident (e.g. Critical Incident Management System (CIMS) or Cyber Physical System (CPS)) or emergency (e.g. Emergency Management Information System (EMIS) or Multi-Commodity Stochastic Humanitarian Inventory Management Model (MC-SHIC)), all with the aim of improving safety. Other example of ITS applications is shown in (Shi and Ni, 2015) with the analysis, model and framework of Railway Intelligent Transportation Systems (RTIS) and its applications as the Transportation Management Information Systems (TMIS) or the Automatic Train Identification Systems (ATIS), among others. The application of this technology in urban transport is shown in (Qin, Yuan and Pi, 2016) introducing Urban Rail Intelligent Transportation Systems (URITS) divided into five layers (perception, communication, integration, operation and service) providing communication signals, integrated supervision and operations management.

Moreover, some research works have been done to improve individual components of the system. Developing an online real-time model which represent the normal behaviour of train trajectory, anomalies in train speed during the whole route from the departure location can be detected (Kang, Sristi, Karachiwala and Hu, 2018). Results from the validation of the system through simulations shown a sensitive improvement detection up to 22%. Another example proposes a security incident detection technique based on rough sets theory using a Multilevel Intelligent Control System (MICS) within ITS (Chernov, Butakova, Karpenko and Kartashov, 2016). Network security incidents were defined as a cause-effect chain of events for their classification (e.g. system malfunction incidents, incidents caused by user errors, intentional cyber-attacks). The proposed technique gives rise to a simple and fast calculation. Another important component of transportation is the travel time information, stressing the fact that the longer delay of train arrival means longer waiting time for passengers. To provide better service, researchers from India presented in (Krishna and Yugandhar, 2013) one of the first attempts at real-time short-term prediction of arrival time for ITS applications through the development of three modules (vehicle section module, base station section module and user mobile section module) integrated in a comprehensive system. The arrival time calculation uses the train location and the station location through Global Positioning System (GPS) modules placed on board the train and at each station.

One of the most recently published studies deals the implementation of satellite navigation elements for rail transport (Nedeliakova, Hranicky and Cechovic, 2019). An advantage of the functions is that it can be integrated in current technology systems and with new digital devices.

ITS have been also integrated with other intelligent systems from other type of transport. In (Osipitan, 2016) combining intelligent transportation system for roadways and an intelligent rail system technology developing an Intelligent Grade Crossing System (IGCS) which improves the security of highway-rail intersections.

Based on the importance of ITS, several countries have carried out their own studies to measure the benefits of implementing these technologies to their railway service. In 2012, China analysed the situation of their railway infrastructure, taking into consideration that it is its cheapest means of mass transportation, and how this infrastructure could be affected by the implementation of Rail Intelligent Transportation Systems (RITS) (Jiang, Yang, Yuan and Xu, 2012). This analysis established five sustainable development strategies which offer a transportation solution minimizing environmental impact and contributing to social and economic prosperity. Similarly, Tokody, Schuster and Papp (2015) developed an ITS ensuring the highest reliability implementation, taking into account technical and technological characteristics, probability of system failures and theories of normal accidents, reliability organizations and flexible engineering planning. Also, they paid special attention to safety risks of software and hardware products. Efficiency, safe operation and convenience, as well as the increment of the adaptability of the system were the key aspects considered by the authors for ITS development. In Poland, new concepts and innovative technologies were also implemented as the European Train Control System (ETCS), a subsystem of the ERTMS (Kornaszewski, Chrzan and Olczykowski, 2017). The idea of the ETCS is based on the digital track-vehicle transmission, supplying the engine driver of information concerning locations of trains, allowed speed or the closure of a level crossing. The GSM-R radio communication complete the system.

In essence, the stress produced by emergency events to control centre operators increase the likelihood of making mistakes. Emphasising that responsibility to manage emergency events through a decision-making process it is crucial to minimize risks and emergency consequences. Hence, the application of ITS is certain to provide elements to the operator for decision-making process. In this sense, the purpose of this study is to support the operator during the decision-making process slightly improving its activities.

This paper provides the explanation and characteristics of the four models integrated in SIGNAL system elaborating the corresponding communications protocols and the validation experiments conducted.

2. METHODOLOGY

SIGNAL is a cyber-physical holistic intelligent management system including both on board and control centre modules, see Figure 1. While the former, managed by the train driver, receives information from train devices as smoke and fire sensors, speedometer, accelerometer and GPS, the latter integrated in the control centre hardware aims to support the operator tasks during an incident. The control centre is composed by four independent models.

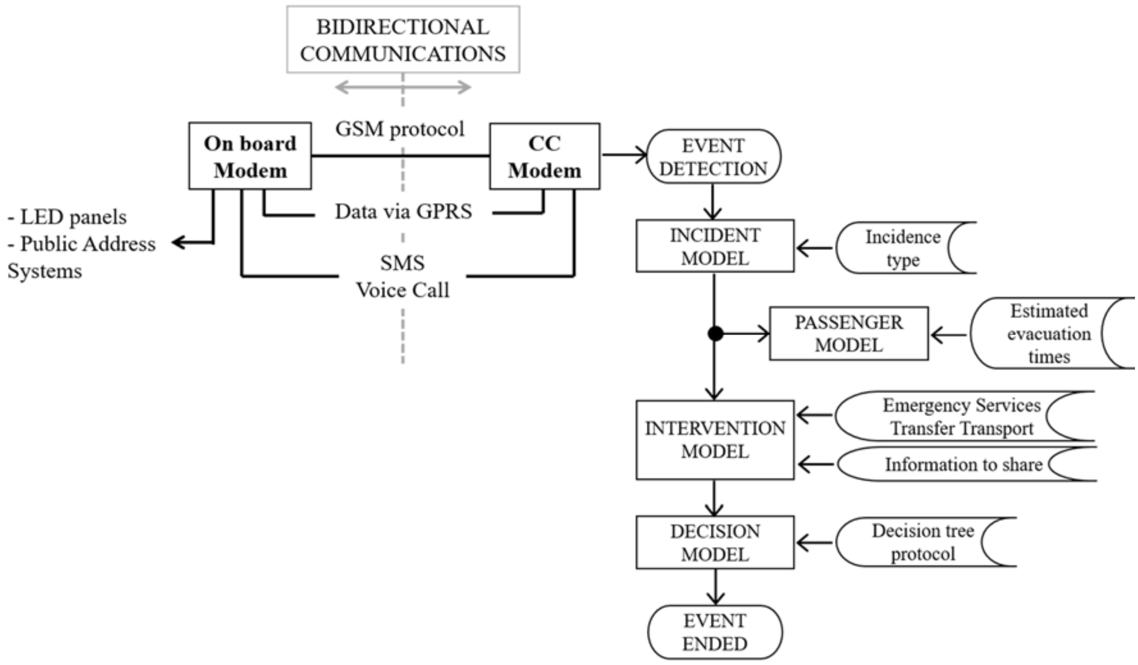

Fig. 1 – Intelligent Emergency Management global scheme

Based on the available technologies installed in the railway vehicles selected for the practical demonstrations, the communication between both modules is provided via General Packet Radio Service (GPRS) using User Datagram Protocol over Internet Protocol (UDP/IP). Likewise, in order to provide Voice Call and messaging services Short Message Service (SMS) and Global System for Mobile (GSM) communication are used. In case of a “dead man” warning from the train driver cabin, the communication between control centre operator and passengers through LED panels and audio system installed in the train is also feasible. The location of the train in both modules is shown through a Global Information System (GIS).

The characteristics of the four models developed are defined as follows:

1) Incident model. Through constant reception of train location via GPS and current status of sensors installed on board, it is able to detect different types of incidents in real-time clustered as can be seen in Table 1. To elaborate this classification an extensive review was conducted founded on previous railway emergency events.

Id.	Incident Code	Incident Designation	Sensors/Devices
1	NOGPS	GPS signal lost	GPS
2	FTEC	Stop due to a breakdown of rolling stock	Speedometer
3	DESC	Derailment	
4	FEVIAJE	Emergency break by passenger	
5	FECOND	Emergency break by engine driver	
6	FEHM	Emergency break for “dead man”	
7	IMPC1	Minor running-over due to the impact against a small object	Accelerometer
8	IMPC2	Major running-over due to the impact against a large object	
9	INCN	Fire in rolling stock	Fire detector

Table 1 – Incidents and its relation with sensors.

Once a sensor achieves threshold values capturing an abnormal behaviour, the model alerts both the driver and control centre. Communication is implemented using the following frame structure to receive and report the current status of the sensors:

UUUU; YYYYMMDDHHMMSSCC;EVENT;LON;LAT,SPD,SPDU

Where UUUU is the train unit identification, YYYYMMDDHHMMSSCC indicates time (Year, Month, Day, Hour, Minute, Second and Second hundredth) noted as DT for simplification, EVENT is the incident code from Table 1, LON is the GPS longitude, LAT is the GPS latitude, SPD is the instant speed (m/s) and finally SPDU is the instant speed-up (m/s^2).

Once an anomalous frame has been detected, the system initiates a voice call between the control centre operator and the engine driver to verify the incident. In case of reception of “dead man” incident code or similar code preventing the establishment of voice call, the operator immediately initiates the protocols for direct communication with the passengers using LED panels through the following frame:

UUUU;DT;MSGD;FMT;’MESSAGE’

Following the above notation, MSGD contains the message to be displayed and FMT controls the display mode being B-normal, R-blink and S-rotary.

Similarly, a Public Address system (PA) could be employed by control centre operator to remotely configure the audio devices installed on board allowing direct voice communication with passengers to provide instructions.

UUUU;DT;AUDIOV;ON/OFF

Where AUDIOV is the corresponding tag of the system and ON/OFF indicates the current status of the devices.

2) Passenger model. In case of remaining inside the train was not a safety alternative for passengers, this model runs stochastic simulations to calculate the total evacuation time under different conditions. The total time (T_{total}) is calculated by two terms: the egress time from the train (T_{egress}) and the movement time of passengers (T_{mov}) towards the access point for the alternative transfer transport (see Equation (1)).

$$T_{total} = T_{egress} + T_{mov} \quad (1)$$

Focus on the first term, trains are characterized as narrow spaces that limits the people movement inside, prevailing the queues discipline. According to (British Standards Institute, 2004; ISO, 2015) the required evacuation time for rail cars comprises two main variables: 1) the time of the first few occupants to reach the exit (movement time) and 2) the flow time of the rest of passengers through the available exits. The chance for passengers to leave the train is determined by the opening of exits, prior notice from the crew. The random flow rate of passengers through exits is expected to be the most decisive variable to calculate egress time. Also, flow rates depend on the operative conditions: the urgency (i.e. evacuation or normal alighting) and the evacuation destination (i.e. high platform, rail tracks). Hence, four egression classes were implemented: evacuation to platform, evacuation to tracks, alighting to platform and alighting to tracks. Data used for flow rates f are based on empirical data provided in (Cuesta, Abreu, Balboa and Alvear, 2017; Capote, Alvear, Abreu, Lázaro and Cuesta, 2008; Nelson, 2002; Norén and Winér, 2003) and its minimum and maximum values are shown in Table 2. The number of passengers (n_{occup}), the number of available exits (n_{doors}) and their width (w_{doors}) are also components of Equation (2). Train occupation is calculated using Equation (3) where n_{max} is the maximum occupation and P_{occup} is the occupation density assumed as 20, 40 and 80 %.

$$T_{egress} = \frac{n_{occup}}{n_{doors} * w_{doors} * f} \quad (2)$$

$$n_{occup} = n_{max} * \frac{P_{occup}}{100} \tag{3}$$

The second term is the movement time of passengers from the train to the transfer transport, which may have two situations, egress to platform or egress to rail level. Both distances are namely d_t. Equation (4) shows the corresponding formula to calculate the movement time.

Finally, walking speeds (v_i) are taken from empirical data (Chandra and Bharti, 2013; Henderson, 1971) (see Table 2). The movement time for each passenger is t_{mov_i}, the number of passengers is denoted as i and the total number of walking speed values is n_p (depending on train occupation load).

	Flow rate (per/s)		Walking speed (m/s)	
	Min.	Max.	Min.	Max.
Evacuation to platform	1.23	3.84	0.5	3
Evacuation to tracks	0.85	1.45	0.3	2.1
Alighting to platform	0.93	0.96	0.4	2.2
Alighting to tracks	0.56	0.69	0.2	1.4

Table 2 – Flow rate through exits and walking speed values.

$$T_{mov} = \max_i \left(t_{mov_i}\right) \qquad 0 < i < n_p \tag{3}$$

$$t_{mov_i} = \frac{d_t}{v_i} \tag{4}$$

Note that flow rates and walking speeds are random variables used to determine the evacuation times through Monte Carlo stochastic simulations, as it is described in (Alvear, Abreu, Cuesta and Alonso, 2014). Moreover, the time calculated from the Passenger model is the 95th percentile of the total evacuation time, resulting of sum up the 95th percentiles of each term (egress time + movement time).

3) <u>Intervention model</u>: this model supports operator and improve time required. The model works under real-time conditions using the information provided by previous models. The conceptual approach is based on defining the emergency services to report the situation and which data should be shared with them (the existence of injuries, access points to the railroad, etc.). To determine that, the model has a decision tree logic which guarantees the optimal information flows to external services. The intervention model also determines the nearest emergency services from the incident location, being essentially the advanced implementation of the geographical coordinates of each service. Finally, the model calculates the estimated arriving times of the corresponding emergency services and transit transport using OpenStreetMaps service (https://www.openstreetmap.org).

Mapping of railroad access points through video recording or GIS must be defined in advance to implement the corresponding information in the system, establishing three levels of access: free (without obstacles), medium (separation systems easy to take off) and no access (impassable areas).

4) Decision model: this model shows a summary of the actions taken during the incident/emergency and helps the operator to verify all those decisions and actions. It is based on a sequence of statements/decisions and is represented as a decision tree.

After each model and the communications between modules were developed, they were integrated in a main software called SIGNAL. The interface of the module on board emulator is shown in Figure 3 and the control centre interface is shown in Figure 4.

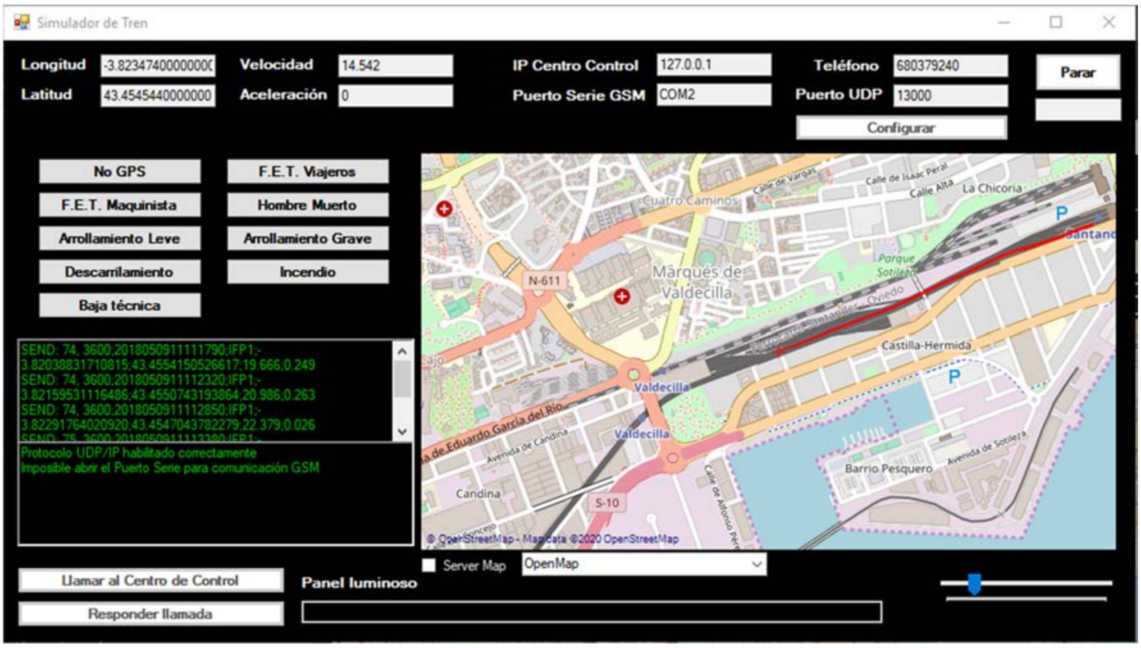

Fig. 3 – On board module interface.

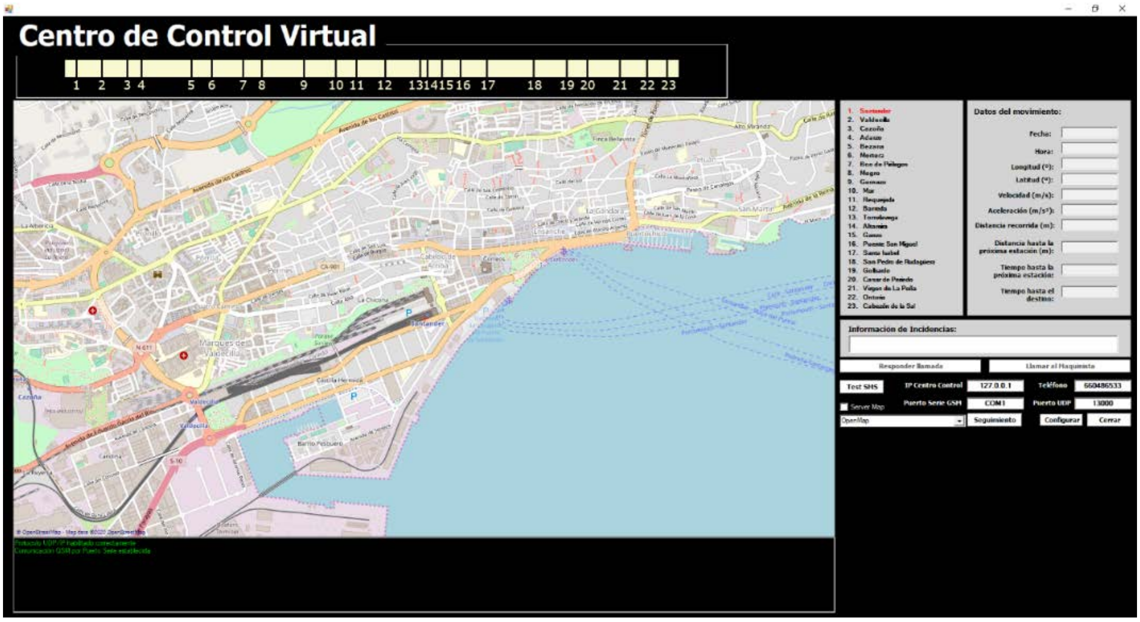

Fig. 4 – Control Centre module interface.

3. SOFTWARE VALIDATION

The evaluation of the proper functioning of SIGNAL was realized through the validation of a set of technical requirements in three use cases. The selected line was Santander-Cabezón de la Sal located in Cantabria (Spain) and operated by Renfe-Feve Railway Company. This line is approximately 48.6 km long and has 23 stations or halts. This line is operated by commuter trains with three coaches of 15.24 m long, 2.35 m width and 4 exits per coach (1.2 m in width each). The maximum speed is 80 km/h due to some operation constraints of the track.

The use cases selected were derailment, emergency brake by engine driver and fire in rolling stock as they cover the validation of all elements of the system. Firstly, a possible scenario was described and executed for each incident with their following descriptions:

Derailment. Partial derailment because of a landslide. Only derails the final coach and it is not overturning any coach. Due to the severity of the situation the presence of injuries is possible. The train occupation is between 20-60%. Passengers can wait for the transfer transport inside the train because the situation is assumed to be safe enough.

Emergency brake by engine driver. The engine driver pushes the emergency brake bottom due to the presence of a car on a railroad crossing. The train can stop before impacting because the engine driver starts the braked-on time. The incident is solved as a false alarm.

Fire in rolling stock. A problem in rolling stock produces a fire that affects the third coach. The train continues operating to reach the next station. They are no injured passengers. The train occupation load is between 20-60%. Evacuation to a platform becomes necessary when the train arrives at the station.

A methodology was defined to conduct the use cases. Each test should start with the constant exchange of frames showing normal operation conditions of the train. At a given time, the on board simulator activates the corresponding incident. The alarm appears at the control centre and the operator calls to the engine driver using a voice communication protocol GSM. For derailment and fire, the driver confirms the incident, but in the emergency break it established a false alarm because the train can continue the route. Then, for the use cases with a verified incident, the Intervention model runs and it allows the operator to implement the corresponding information from the engine driver. The Intervention model provides the course of actions to carry out (i.e. notification to the emergency services and mobilizing transfer transport), if it is necessary.

The operator notifies to the emergency medical services, firefighters and police services for the derailment case and it notifies to firefighters and police services in the fire case.

Also gives the location of the incident, the nearest access points and other relevant information (injuries, overturns,…). Then, the operator calls the engine driver to give him the estimated arriving times of the emergency services. The Passengers model works when it is necessary. Here, it calculates the times for a normal alighting in the derailment case and for an evacuation to platform in the fire case. The operator notifies to the transfer transport of the nearest access point to the railroad and the engine driver of the arrival times. The operator should be alert for possible changes until the incident is over. Its last responsibility is to check the decisions and actions carried out based on the Decision model.

4. RESULTS

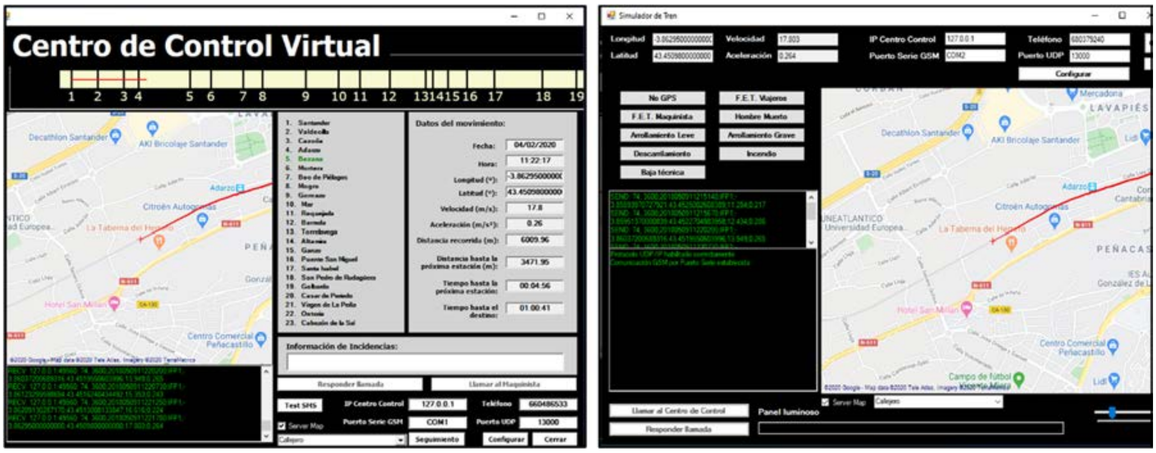
This section includes the validation of each model developed, the verification of operation and autonomy of both interfaces and the entire communications among modules. To limit the number of figures shown in the paper, we decided to include only those corresponding to the complete derailment use case development, since this use case deals all features of SIGNAL.

Table 3 shows a timeline with the corresponding interfaces and description of each moment during the development of the derailment use case. The first element of the temporal sequence X corresponds to the aspect of both interfaces in a normal situation during the train trajectory. When an incident occurs, the software detects it and an alarm is shown on the control centre interface as in the second element of the temporal sequence

X+1. In that moment, the Incident Model interface is activated as an emerging panel (third image of timeline). This panel enables the communication between the operator and the engine driver to confirm the incident and implement the corresponding information. Then, the interface of the Intervention, Passengers and Decision Models appeared (this moment corresponds with the X+3 element of the sequence). Through this screen, the models provide the corresponding results to the operator who can supply them to the engine driver and also notice to the services and transport.

Progress, description and interfaces

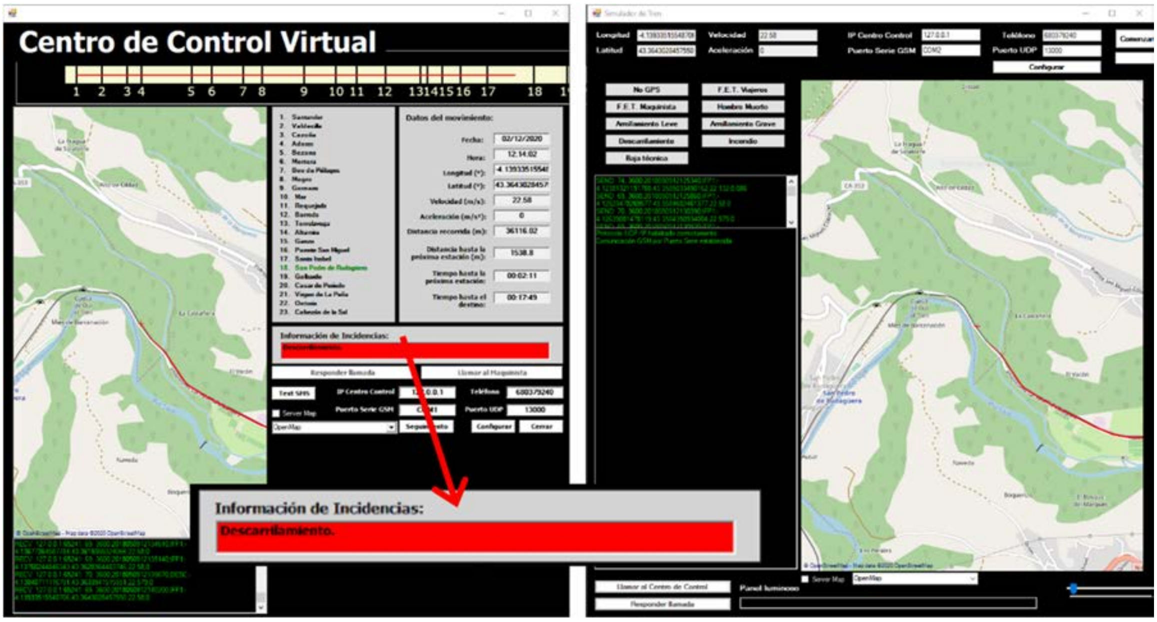
Time: X
Description: Control centre and train software working in a normal situation.
Interfaces:



Time: X+1

Description: Control centre and train software when an incident detection is produced.

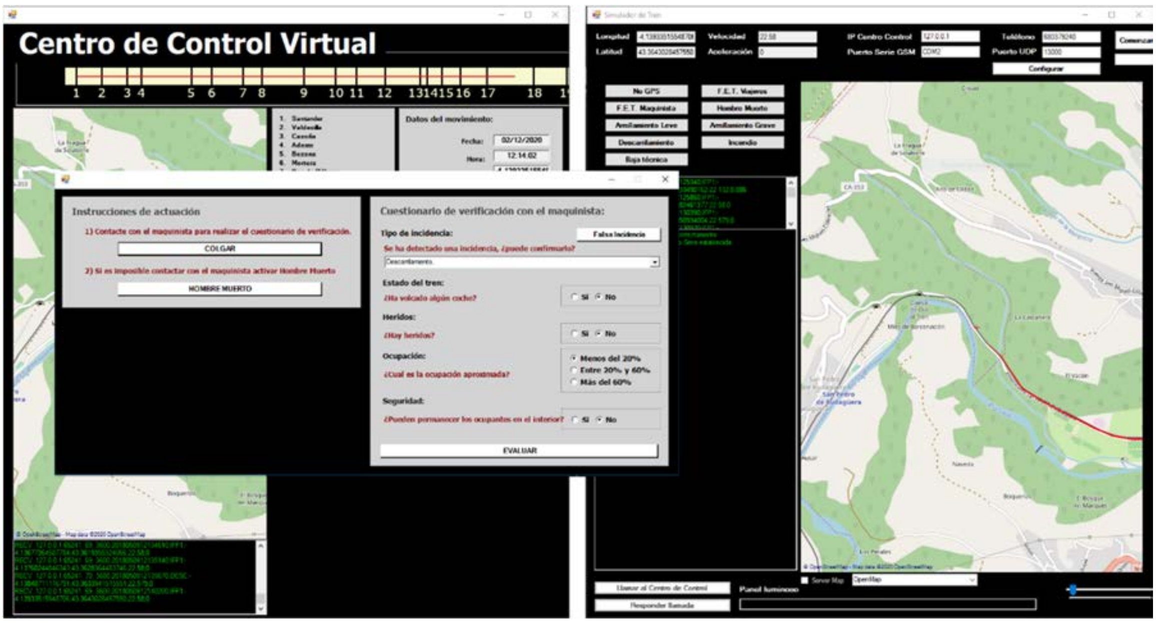
Interfaces:



Time: X+2

Description: Control centre and train software when the Incident Model works. Through a voice call (operator-engine driver) the incidence is confirmed. The first parameters about the event are implemented in an emergent window.

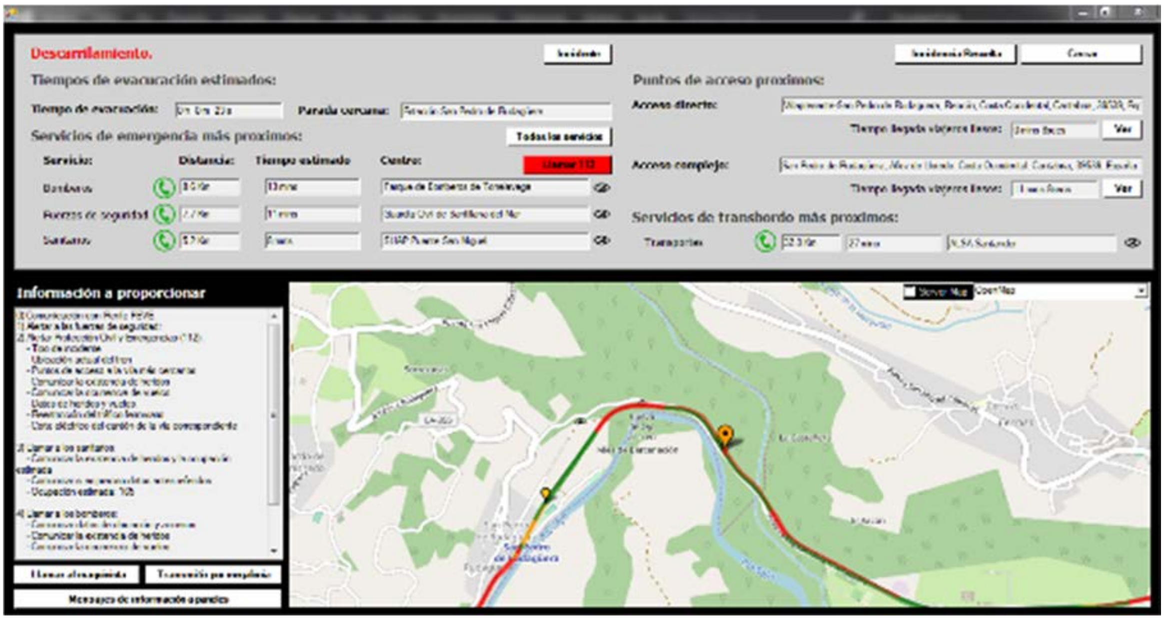
Interfaces:



Time: X+3

Description: Control centre interface meanwhile the Intervention, Passengers and Decision Models are working. Through this interface it is possible notice the emergency services and transit transport and inform the engine driver about the times.

Interfaces:



Time: X+4

Description: Incidence ended.

Table 3 – Development of the derailment use case through a timeline illustrated with images of the process.

5. DISCUSSION AND CONCLUSIONS

Safety and security for passengers of mass rail transportation systems is a major challenge. An incident or an emergency management with people involved is a serious and complicated process. To contribute to the improvement of railway transportation, we developed a prototype of an intelligent emergency management system. The aim is to support the operator tasks of a control centre in the decision-making actions in real-time and reduce the possibility of making mistakes at the minimum. To achieve the objective, we developed a module on board a train that can communicates and shares information from train sensors to the module integrated in the control centre hardware. This module is composed by four models that detect incidents automatically, that calculate evacuation times in a few seconds and that provide emergency management support in real-time.

The case studies have shown that the proposed system does its job opening the field to new application opportunities to emergency management response in rail transport.

First, it is possible to determine the nearest access point to the location of the emergency in a few steps. This is very useful for the emergency services that waste a lot of time defining the best entrance point. Furthermore, the system can be able to provide the type of services (emergencies or transfer transport) to demand their help. This is essential for a better work conditions of the services that are really necessaries. Second, the bidirectional communication among engine driver and control centre operator (or among operator and passengers in case of a dead man of the engine driver), reduces the global anxiety due to the exchange of information in real-time. Finally, the supporting given to the operator is crucial to decrease their responsibility, to reduce its stress and, consequently, to improve the incident management and also passengers safety.

The presented system provides consistent and reasonable results while providing demonstrated benefits. The system would drastically reduce evacuation, intervention and decision times. This paper goes beyond other contributions since it proposes the development and use of a real-time intelligent management system for incidents in rail transport. The next step is to achieve the completely installation and integration of the prototype in a real environment.

ACKNOWLEDGEMENTS

The authors would like to thank the Ministry of Economy, Industry and Competitiveness (MINECO) for funding the SIGNAL project on the frame of the Subprogram RETOS-COLABORACIÓN 2016 call (Ref-RTC-2016-5474-4), as well as the European Union through ERDF funding under the objective of Strengthening Research, Technological Development and Innovation and also to SETELSA company for their partnership, dedication and support for the developing of the project.

SAFETY AND ROAD INFRASTRUCTURE: A SPATIAL ANALYSIS IN SUBURBS OF BOGOTÁ

Julio Forigua
PhD Candidate, Universidad Nacional de Colombia, Colombia
Liliana Lyons
Associate Professor, Universidad Nacional de Colombia, Colombia

ABSTRACT

The research was focused in a multiple correspondence analysis. We analyzed the relationships between accident rates and road infrastructure variables in a municipality of Soacha (with more than five hundred thousand inhabitants in the suburbs of Bogota-Colombia). In Colombia, the fatality rate is 13 deaths per 100.000 inhabitants. In Soacha municipality the fatality rate is 10 deaths per 100.000 inhabitants. Soacha reports the highest number of deaths in the region (ANSV, 2020). In this research we performed a spatial analysis using a Kernel density graph to identify the areas with the highest concentration of fatal crashes.

We found that five dimensions explain 70% of the variability of data. We made a cross-dimension analysis by pairs, to obtain information on all possible combinations between that dimensions and used them as an input of a spatial distribution analysis of crashes in the municipality. We also calculated the contour curves for density modeling. We found that higher concentration of fatal crashes is around the highway "Autopista Sur". These crashes were associated whit crash hypothesis variables, immediate cause of the crash, crash class, crash severity and type of vehicle.

1. INTRODUCTION

The Global Report on Road Safety 2018 (World Health Organization – WHO, 2018), highlights that the number of annual deaths from crashes has reached 1.35 million. More than a half of the fatalities and serious injuries in crashes occurs on 10% of the road infrastructure and the most affected actors are pedestrians, cyclists, and motorcyclists. In addition, according to this report, 13% of fatalities occurs in low-income countries.

In order to reduce the rate of accidents, the WHO adopted the road safety factors based on the Haddon Matrix (1968) and proposed to the countries the implementation of programs and the introduction of the main pillars of road safety in their safety plans: safe infrastructure, human behavior, safe vehicles, institutional, environment and victim care. WHO emphasizes in the systematic analysis of accident data and the use of maps to locate accident hotspots in order to focus resources more effectively and efficiently in at-risk road infrastructure (WHO, 2019).

In Colombia (2020) there were 5,458 deaths in crashes, 82% of these fatalities correspond to vulnerable road actors: pedestrians, cyclists and motorcyclists. In the state of Cundinamarca occurred 6% of the total fatalities in the country (327 deaths in crashes), and the municipality of Soacha, located in this department, presented 53 fatalities and 189 injured. This municipality had the highest number of deaths in crashes in this department.

According to information from the *Agencia Nacional de Seguridad Vial* - ANSV, 84% of the fatalities in this municipality occurs on the national road that crosses the urban area of the municipality of Soacha (ANSV, 2020).

Moreover, the annual report of the Transport Ministry (2019) , define that primary roads correspond to 9.3% of the national network, 44% are concessioned roads. The “Via 40 Express”, a road under private concession cross the municipality and it has 144, 8 kilometers long and eight Functional Units – UF, and in the municipality of Soacha is located in UF-8 (Ministerio de Transporte, 2019).

The literature review presents models and techniques for the identification, analysis and assessment of crashes, involved with analysis in Geographic Information Systems (GIS) and spatial statistical methods. In our research, a descriptive statistics process was carried out to define accident patterns, in a second step a multiple correspondence analysis and a GIS analysis were performed. We found that the categories pedestrian, rollover, road, infrastructure, hit-and-run, according with original names of variables in database related to the hypothesis, immediate cause and accident class, that variables have the major contribution in the road accident rate. The multiple correspondence analysis together with the spatial analysis support the evaluation of the variables involved in the accident to generate prevention measures. These results contribute to improve current and future public policies in municipalities, departments and road safety agencies (Forigua, et al., 2020).

The purpose of this paper is to present the methodology based on spatial analysis to identify the areas with the highest concentration of crashes in Soacha and the main variables involved. The databases of crashes in the municipality and secondary information provided by the ANSV and other government organizations for the period 2014-2018 were used. The methodology proposes a multiple correspondence analysis in order to identify the relations between variables, and the variability in the information. We also applied an analysis of the spatial distribution of accident points using a Kernel density graph focused on localization of areas with the highest concentration of fatal crashes for spatial modeling.

2. LITERATURE REVIEW

In general, the models identified in the literature review for the analysis of road infrastructure and its impact on accident rates are from the temporal point of view, such the Accident Prediction Models (APM) that allow to consider road safety problems, identifying safety improvements and estimating the potential effect in terms of reduction of crashes (Kustra 2019, Raheel 2019, Wang 2017, Yannis 2016). Other researches include variables to define geometric and traffic characteristics with statistical analysis such as Loglogistic and Gamma distribution (Negative binominal), the variables of these models are related to traffic volume, distance, type of road, number of crashes, crash costs, crash density and the probability of occurrence according to the severity of the crash (Kustra, Żukowska, Budzyński, & Jamroz, 2019).

Velloso and Prudéncio (2012) in their study on pedestrian fatalities on rural roads passing through urban areas, perform a basic statistical analysis of the risk of crashes, since they have a mixture of the characteristics of a rural road with those of an urban road, where high speeds, wide roadways, high vehicle capacity can be observed and with heavy vehicle traffic, lack of facilities for vulnerable road users, high number of accesses on both sides of the road, cyclists and motorcyclists riding on the road, pedestrians crossing at any point of the road, among others, which is a very common feature in middle and low income countries where the suburbs of the cities are located.

Some authors (Galgamuwa 2019, Liu 2018, Erdogan 2015, Zhou 2015) propose spatial models, these analysis are performed by integrating quantitative methods with a Geographic Information System (GIS), identifying crash hotspots (crash frequency, crash rate and crash severity) with spatial statistical methods such as Moran's I Estimation, GetisOrd G and Kernel Density Estimation to apply actions to reduce the probability of road crash. Spatial road safety models consider crash data, traffic data and road infrastructure design variables. These models are generally developed as a simple regression equation (Safety Performance Function - SPF) where the spatial correlation considers multiple variables at the same location (Yannis, et al., 2016).

Based on this literature review and considering the scope of this research, a multiple correspondence analysis and a spatial analysis using a Kernel density plot are applied to identify the areas with the highest concentration of fatal crashes in the study area.

3. METHOD

According to the official data provided by the ANSV, the information was validated and processed. The road accident rate of the department of Cundinamarca and specifically for the municipality of Soacha for the period 2014-2018 was analyzed. A descriptive statistics analysis was performed with the statistical software RStudio® and we define the variables that have an impact on crashes, making groups to standardize the information. Subsequently, an extensive process of organization and georeferencing of the data was carried out to guarantee the accuracy of the information used for the study, from which the preliminary description of the road accident rate in the municipality was obtained (Forigua, et al., 2020).

The next step continues with the analysis of the points and periods with the highest concentration of crashes in the road network of the municipality, and we apply the multiple correspondence analysis of the variables that affect the response of crashes. After this analysis a Geographic Information System (GIS) was implemented to represent the spatial behavior of road accident rates by creating and designing base maps that illustrate the accident hotspots in different scenarios.

Based on these results, we propose a field inspection in the points with the highest concentration of crashes, followed by a new spatial analysis including variables on traffic, geometric design, signaling and other road infrastructure in order to suggest preventive and corrective recommendations to reduce the number of crashes in these areas and, consequently, contribute to the reduction of accident rates in the municipality.

4. RESULTS

For the development of this research, data from the Police Crash Report - IPAT collected by the National Crash Registry – RNAT, providing 100 attributes associated with each of the crashes presented in the country for 12 years. The distribution of the databases is shown in Table 1.

RNAT	Observations	Variables
RNAT_A	2,451,804	24
RNAT_H	2,692,050	2
RNAT_ML	4,331,376	8
RNAT_S	2,569,877	35
RNAT_V	7,858,013	31
TOTAL	**19,903,120**	**100**

Table 1. Observations and variables of road accident databases.

All the information was rigorously treated and a database was consolidated with the information of 4598 crashes between the years 2015 and 2018 for the municipality of Soacha. The distribution of these crashes according to the year of occurrence and the composition comparisons for 2015 to 2018 is shown in Table 2.

Year	Crashes	Passenger Car Occupants	Small-Truck Occupants	Heavy-Truck, Buses	Motorcyclists
2015	1,427	38%	34%	15%	12%
2016	1,141	39%	34%	11%	16%
2017	1,105	41%	33%	11%	14%
2018	925	41%	30%	14%	15%
TOTAL	4,598	40%	33%	13%	14%

Table 2. Crashes composition per year

According to the analysis of these information the following relevant aspects are identified:

- Regarding the severity of the accident, 65% present only economic damages, 32% injured, and 3% are with fatality.
- According to the type of accident, 81% correspond to collisions between vehicles, 18% to pedestrian collisions and 1% to vehicle rollovers.
- In terms of the type of vehicle responsible for the accident, 40% are trucks, 24% are buses, 13% are motorcycles, 13% are passenger cars, 6% are bicycles and 4% are taxi.
- In terms of the type of road infrastructure where the accidents occurred, 85% occurred on a stretch of road and the remaining 15% at intersections.
- In the area where road accidents occurred, 61% occurred on the "Autopista Sur" corridor and 39% in the urban area.
- In terms of the weather conditions when the accidents occurred, 97% occurred in normal weather and 3% in rainy weather.
- In the time of the week when the crashes occurred, 55% were on weekdays and 45% on weekends.
- In terms of the time of day when the crashes occurred, 32% occurred in the afternoon, 28% at night, 27% in the morning and 13% in the early morning.
- In the age ranges of people involved in road crashes, 36% were young people under 29 years of age, 28% were people between 30 and 39 years of age, 24% were people between 40 and 59 years of age, and 11% were people over 60 years of age.
- In terms of the gender of the people involved in the crashes, 92% were men and 8% were women.
- In terms of the agent that caused the crashes, 89% were caused by drivers, 9% by pedestrians and 2% by road infrastructure.
- In terms of the causes of road crashes, 92% were related to the behavior of people, 4% are related to the consumption of substances, 2% to the infrastructure, and 2% with excessive speed.

With the georeferencing of the crashes, it was possible to establish spatially the points where road accidents are occurring in Soacha, taking into account the severity of the accident. The spatial density of the crashes is shown in Figure 1.

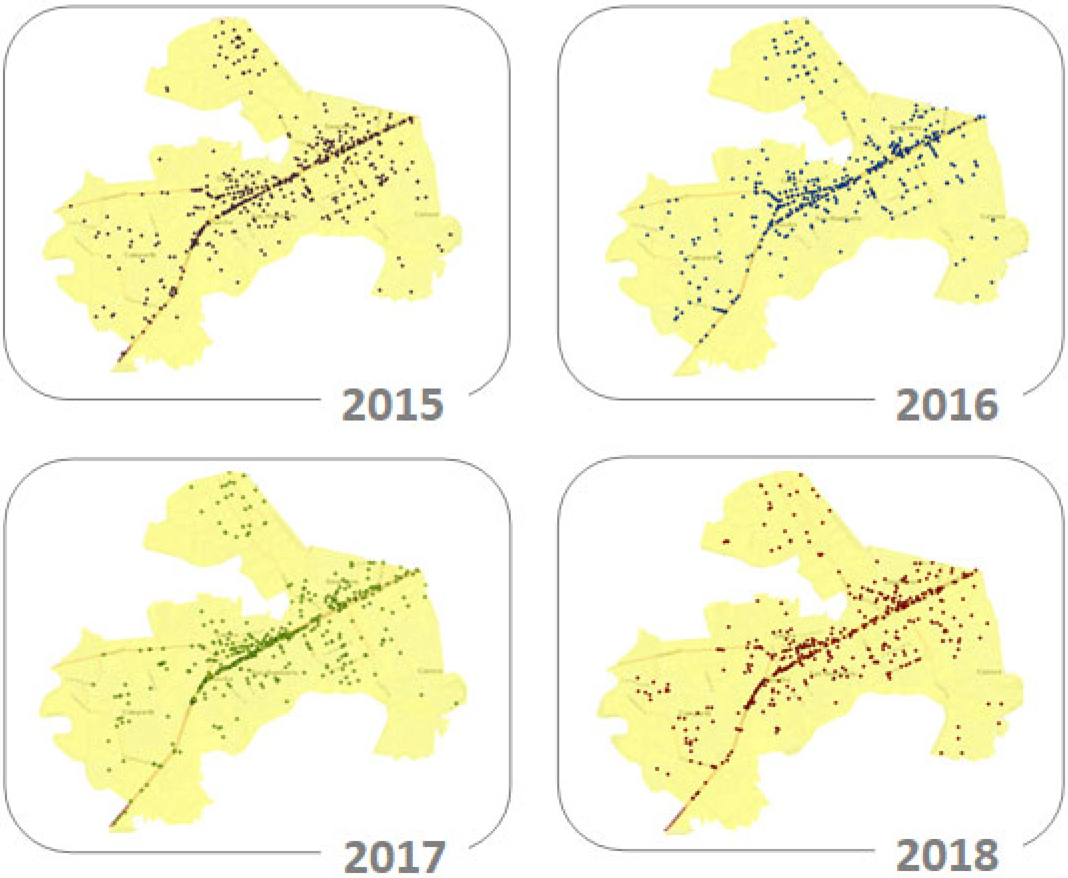

Figure 1. GIS crash localization per year. (Bermudez, Sanchez, Forigua, & Lyons, 2021)

5. ANALYSIS AND DISCUSSION

According with the statistical results, we observed that there are severity features in 35% of the crashes, 40% involves trucks and 61% occurs on the highway, these results confirm that the greatest risk is on the rural roads crossing the urban area particularly for freight vehicles.

We identified in the municipality of Soacha that main crashes do not occur at intersections, 85% of the infrastructure risk is found in continuous segments of roads, which is different from study cases in literature review.

Analyzing the immediate causes defined by the traffic police who report the crash, 98% of the responsibility for the accident corresponds to human factor and 2% to the infrastructure, however, the report does not identify the root cause of the crash.

According to the multiple correspondence analysis, the normal weather variables, throughout the day, during all days of the week do not contribute to the behavior of the accident rate in the municipality of Soacha.

In the spatial analysis of crashes with a GIS, it was possible to identify that the severity of road accidents occurs on the national road that crosses the urban area, confirming the argument of the authors Valenzuela and Burke (2020), where they state that the greatest risk of accidents occurs on this type of roads, because they have characteristics of national roads, but integrating characteristics of urban roads. Figure 2 shows the concentration of fatal crashes on the highway in the municipality of Soacha, while crashes with injuries occur in general throughout the urban area, but with a higher concentration on the national road.

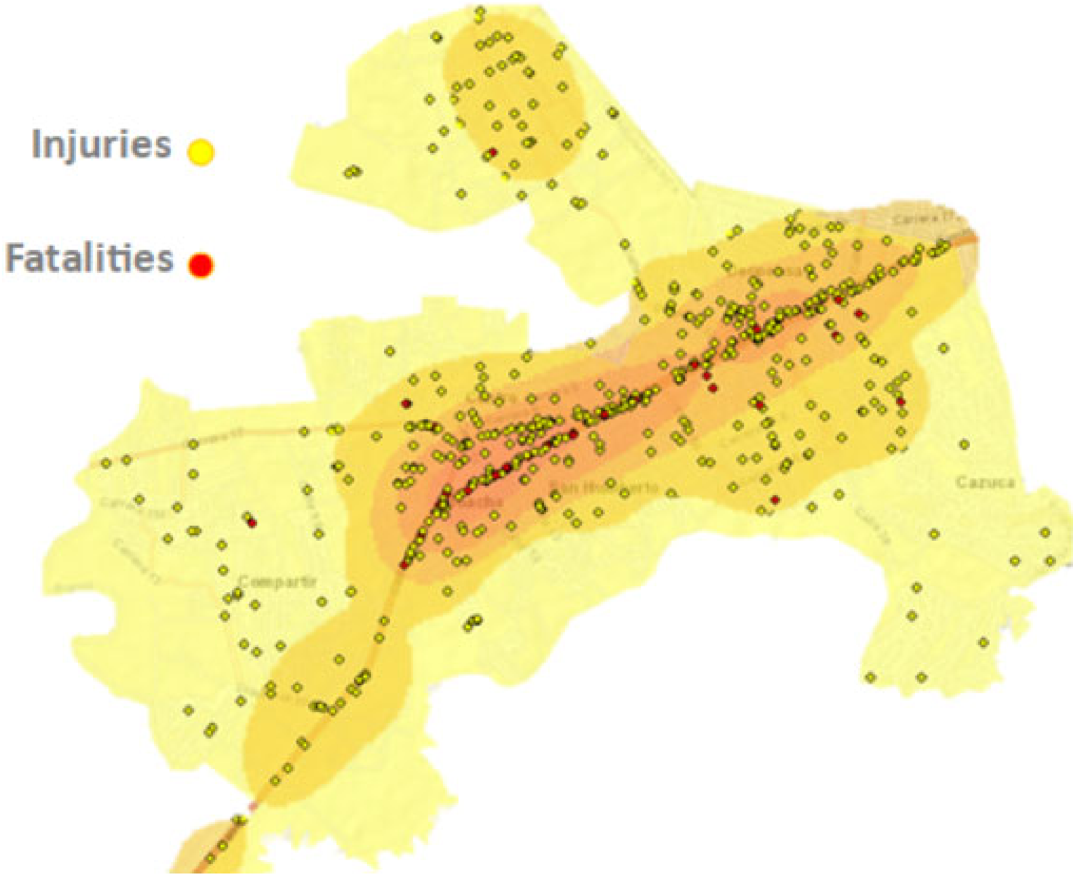

Figure 2. Severity GIS crash localization. (Bermudez, Sanchez, Forigua, & Lyons, 2021)

In the multiple correspondence analysis between the different variables mentioned in the descriptive statistics, it was possible to estimate the behavior of the variables due to the contribution of each one in the road accident problem. The crash hypothesis variables (HIP), immediate cause of the crash (CAU), crash class (CLA), crash severity (GRV) and type of vehicle (VEH), mainly denote a greater contribution to the behavior of the crash rate in the municipality of Soacha, Cundinamarca. The contribution of the variables is shown in Figure 3.

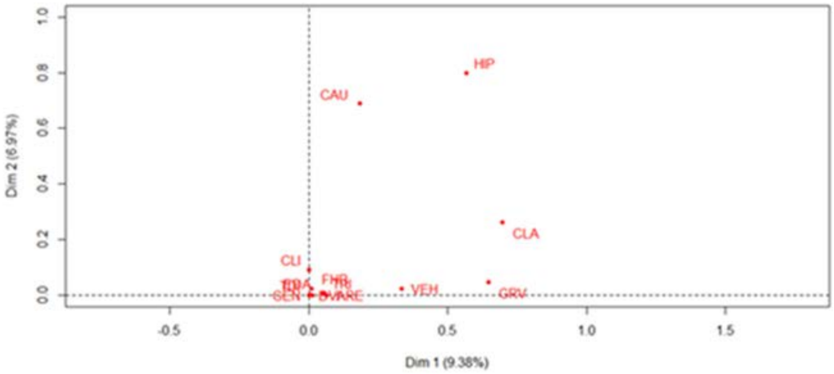

Figure 3. Contribution of variables in the multiple correspondence analysis. (Forigua, et al., 2020)

Variables related to the seasonality of accidents, weather conditions, age and gender characteristics do not contribute to the explanation of road accidents in the municipality of Soacha. Five dimensions explain 70% of the variability of data.

6. CONCLUSIONS

The traffic in rural roads that cross urban areas of conurbation municipalities represent a higher risk of crash severity.

The literature identifies studies that have shown that the use of different hot spot detection models leads to different results. In this research, multiple correspondence analysis together with spatial analysis supports the evaluation of variables involved in crashes.

These research continue with spatial analysis including variables on traffic, geometric design, signaling and other road infrastructure in order to propose preventive and corrective recommendations to reduce the number of crashes in these areas and, consequently, contribute to the reduction of accident rates in the municipality.

ACKNOWLEDGEMENTS

The authors express their acknowledgements to the Agencia Nacional de Seguridad Vial - ANSV for providing the road accident information base (RNAT) and to the Vicedecanatura de Investigación and the Research Seed of the Universidad Nacional de Colombia SIMUN for their contribution during the research process.

ABSTRACT

The time required for the evacuation of the occupants of buses and coaches, that is, Large-Dimension Passenger Transport Vehicles (V.G.D.T.P.) is a fundamental safety parameter for these vehicles. Starting from the fact that they are a mode of transport with very high levels of security, when events with collision and subsequent fire occur, or in cases of fire exclusively, it is when these events generate injuries or even deaths. Additionally, part of the UN CEPE regulations that affect these vehicles (e.g. R107) are defined in such a way as to reduce this evacuation time. Others, R118, are aimed at reducing the severity of the fire and, therefore, increasing the time available before suffering serious consequences.

Therefore, the need to know which are the fundamental aspects that can improve these two time intervals, evacuation and available, is concluded.

In the present work, a coach is modelled, and simulated by means of an agent-based model, both the boarding process, and the disembarkation or evacuation process. Some relevant characteristics of the model are that it allows to analyse the influence of the mobility of each agent (occupant) as well as that of the vehicle's configuration. Among others, some of the characteristics of the occupants are their average speed of movement and associated with a probability function, their size, the probability of using emergency exits (e.g. jumping through an emergency window), etc. Regarding the vehicle, the fundamental aspects contemplated in the model are those relating to accessibility to the interior of the vehicle and, once inside it in the corridors, access to the seats. Among other parameters, the width of the gangway, the distances between seats, the characteristics of the entrances, stairs, etc.

The model is used to analyse the influence of the variability of each of the occupant and vehicle parameters described, and the probabilities of complete and partial evacuation times are deduced. Based on these results, it is concluded that the exits locations, and the age (mobility) of the passengers are the main parameters influencing the probability of a high evacuation time,

The work has been performed thanks to the support of the Comunidad Autónoma de Madrid funding the program SEGVAUTO 4.0-CM. Ref: S2018/EMT-4362.

1. INTRODUCTION

Transportation by bus or coach is a means that has proven to be very safe for its occupants. However, given that they are a means of collective transport, and on many occasions public, the agents involved in the design, approval and use of these vehicles continue to seek to reduce the consequences of their accidents.

One type of accident that occurs with some frequency is fire. These accidents, in which the total or partial fire of the vehicle takes place, normally only have material consequences.

Fundamentally, the vehicle is damaged or partially destroyed. The absence of injuries to the occupants is mainly due to the design of the vehicles that is defined for a fast enough evacuation. The characteristics that buses and coaches must meet to ensure that they are safe in the event of an incident are defined in United Nations Regulation R107. UNECE. WP29. (2018). This regulation defines the maximum and minimum dimensions of each of the parameters that affect safety, including those related to evacuation, dimensions of service doors, emergency exits, etc.

However, and despite the measures ensured in the vehicle type-approval process, from time to time, an incident with fire in a bus, or coach, has as a consequence a significant number of victims. Often these incidents, with fire and serious consequences for the occupants, are the consequence of a collision prior to the fire and a, for different reasons, defective faulty evacuation. This was the case of the accidents that occurred in Bailen Spain (1996) and in Puisseguin, France (2015) with 28 and 43 deaths respectively.

The importance of evacuation, or more specifically of the speed of evacuation of the vehicle, lies in the need to minimize the risk of loss of consciousness due to the inhalation of gases from combustion. There are many studies that analyse the evacuation times of infrastructures, and also some of means of transport including coaches. Some of these studies are carried out by means of evacuation tests, one of the most relevant is the one carried out by JK Poland and SH Markos (2009) where they measure times of passage through different types of emergency exits, service doors, windows, hatches, and used different lighting conditions.

However, all these studies cannot be exhaustive in terms of the profile of the passengers involved in the drill, or the variety of vehicle models based on their interior configuration, entrances and exits. That is why it was decided to approach the study by simulation with a stochastic model that allows to obtain with fidelity an interval of evacuation times associated with a probability of occurrence.

2. OBJECTIVE

Through this WORK, it is intended to carry out an evacuation model for vehicles of class M2 and M3, commonly known as buses or coaches, using the service doors and, also, analysing the probability of using the windows as an emergency exit. This objective has been raised by observing that in certain accidents, in which the vehicle

For this, some partial objectives have been met, which are:

1.- The characterization of the mobility of people, so that the analytical model allows determining the interval of evacuation times of the vehicles, based on the characteristics of the travellers, and the probability associated with each value of evacuation time of the vehicle. model.
2.- The characterization of the vehicle, so that by introducing the plan of the vehicle and the characteristics of the accesses, the evacuation time can be determined.
3.- By using the vehicle model, and the mobility of the agents (passengers), obtain valid results and conclusions on the following factors:

- Evacuation times and uncertainty in their determination.
- Influence of the characteristics of the passengers on the evacuation time.
- Influence of the plant and the distribution of the vehicle.

Finally, the model can be used to obtain an optimal configuration and determine possible improvements to reduce evacuation times, referring to both passenger education and vehicle layout.

3. METHODOLOGY

The model has been developed using the AnyLogic software. This code uses agent-based simulation algorithms and is supported by the Java language. An advantage of this software is that it allows to perform dynamic simulations, discrete events simulations and combined models applying a stateflow to a continuous dynamic model. This type of models allows assigning individual characteristics to each passenger (and vehicle), modify these characteristics during the simulation process, as well as defining the interactions passenger-passenger and passenger vehicle. It is taken the advantage of the fact that AnyLogic already has implemented the internal algorithms for the movement of individuals and the interactions between them.

To analyse the evacuation, the coach layout is modelled based on the requirements reflected in Regulation R107 of the UNECE. In this model, three dimensions are chosen as critical: distance between seats, aisle width and door width. In the standard coach used to determine passenger influence, the aisle is 530 mm wide, the seats are 720 mm apart, and the front and rear doors are 800 and 700 mm wide, respectively. The rear door is located in front of the rear axle, as is common in many M3 Class III vehicle configurations. Stairs are defined as an area in which passengers see their speed reduced to 50%.

The movement of passengers has only been defined by the maximum speed they can reach and by their size. For this, and because the achievable speed is not determined by the size of the vehicle aisle, for values from 40 cm as demonstrated by Huang, S. et al. (2018), various studies on achievable speed according to age are analyzed (Bohnannon 1996 and 1997; Capote 2011; Chiu, 2007; hoogendoom, 2005 and Spearpoint, 2012) and it is decided to use normal speed distributions for each group decreasing with the age, and increasing fixed sizes. This variation is very marked when reaching the third age.

The movement of passengers has been defined considering the maximum speed that they can reach in a corridor (Huang, 2018), and by their size, which determines their mobility. The maximum velocity has been characterized by an approximation to a normal probability distribution assigning the value of the mean and the standard deviation.

To analyse the influence of passengers, simulations are carried out by varying the age distribution within the vehicle. Evacuation is designed as a process in which passengers initially go to the nearest door, since they do not know if it is possible to open that door. Subsequently, and after checking whether it is possible to open the doors, the passengers head towards the available doors following the same principle of proximity. During the entire evacuation time, passengers periodically check if the condition of the doors has changed and after 60 seconds, they begin to consider using the windows as exits (Aparicio, et al 1996).

3.1 Vehicle plant model

This plant of the vehicle is defined by several wall-type elements (Wall). The strange shape of both doors is due to the fact that the entire simulation must take place within a closed wall and because we want to consider that the passenger has left the vehicle once they have managed to cross the line that runs along the side of the coach. Striped areas are areas where passengers cannot enter.

Next, the lines (Target Line) that act as doors are drawn and also another, continuous, on the entire left side that simulates the emergency window. It is decided to simplify the window in this way since it is not used as the main exit in a real evacuation. The hatches are not included and are not used in the case of no overturning.

Lastly, the seats are modelled. The seats are represented by their positions. These positions are fixed by Attractor elements. As the Attractor elements are linked to an area, the area areaAreasSeats is defined and the points are marked on it. The Final model of the vehicle is shown at Fig. 1.

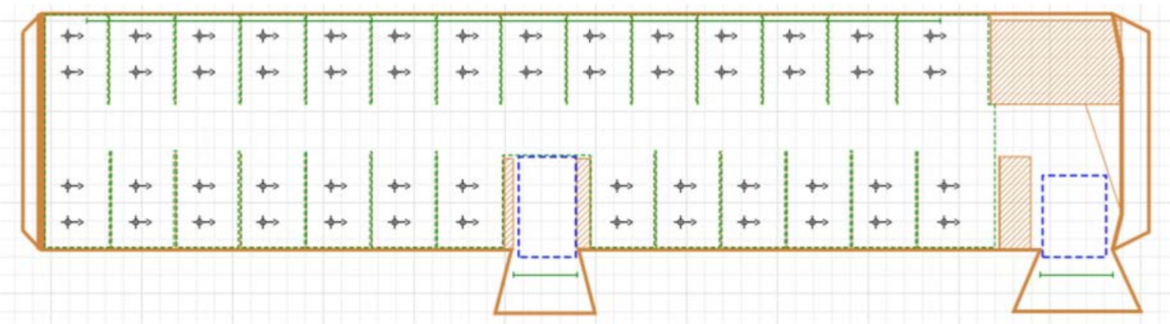

Fig. 1. Complete model of the vehicle plant.

3.2 Passenger model

Before modelling the passengers, it is useful to know the limitations that AnyLogic has when it comes to simulating a Pedestrian-type agent. Passengers are created in a block Ped Source has three mandatory parameters: size, initial speed and maximum speed. The latter, called Comfortable Speed, is the maximum speed at which it travels if there are no obstacles on the road.

Other internal variables of the passengers are also created, which are explained after the three that are indispensable.

3.2.1 Passenger Size

The main limitation in the size of the agents is the size of the coach aisle itself, which is the smallest dimension of the vehicle. Because the agents are represented as circles, it is necessary to check the appropriate size not to create agents that cannot access into the vehicle.

Through test simulations, it has been found that passenger diameters greater than 0.30 meters pose serious problems during evacuation and, therefore, prevent passengers from approaching this size in any evacuation. The lower diameter limit is less critical, but is set at 0.15 meters for very agile passengers or children. This size allows one passenger to outrun another down the aisle.

Therefore, a standard population distribution will contain passengers between 0.15 and 0.25 meters, indicating greater and less mobility and agility, respectively. Each population group will have a fixed size.

3.2.2 Confortable Speed

AnyLogic defines this speed as the speed at which the agent moves in the absence of external factors. In the simulation it will be the maximum speed at which the passengers can move inside the bus. In the simulation, it cannot be considered that there is an absence of external factors.

The backs of the seats act as walls that make the officers stop and they can never move at the speed that is chosen as comfortable. For this reason, the speed values that are finally applied are slightly lower than the movement of a person in an aisle.

The speed of the passengers depends mainly on the age since the gender barely has an influence of between 10 and 15%, which is considered negligible in order to simplify the model. The dependence of speed with respect to age is decreasing, with a more pronounced influence after 60 years of age, and as age increases, the uncertainty in determining said speed also increases.

Group	Reference	Avg speed (m/s)	Standar dev. (m/s)	Size Φ (m)
< 30 yo	G1	2	0,1	0,17
[30 yo: 50 yo]	G2	1,8	0,1	0,2
[50 yo: 65 yo]	G3	1,7	0,2	0,2
[65 yo: 80 yo]	G4	1,3	0,15	0,23
> 80 yo	G5	0,8	0,1	0,25

Table 1 – Passengers study groups

In this way, only the percentage of passengers belonging to each group will have to be established to run the model.

3.2.3 Initial velocity

The initial speed of an agent is the speed with which it is generated in the Ped Source block. It is verified that changes in this value have no influence on the results obtained, since, in the evacuation, the agents start at zero speed from their seats. Therefore, it is set at 0.5 meters per second, the value that AnyLogic assigns by default.

3.4 Validation

Once the construction of the model is finished, four experiments of a thousand test simulations are carried out to analyze if values similar to those found in the literature in simulations and in models are achieved based on the following factors: times used, standard deviations of the times, trends with the variation of passengers and trends when locking the doors.

When carrying out the four experiments and checking the influence of the erroneous simulations, between 1 and 2%, it is decided that the evacuation time taken as a reference will be the time95, since on certain occasions the last two passengers take illogically high times in get out of the vehicle.

When the time95 is excessively high and goes outside the range of times determined by the other simulations, this data is eliminated from the analysis. The loss of 1% of the data is considered acceptable for the statistical analysis.

This is verified by ordering the results from highest to lowest and eliminating those that are 2 seconds or more apart from the next.

The four experiments carried out for the validation, with their results, are shown at table 2:

Run	**Available exits**	**Age**	**AVG (s)**	**Standard Deviation (s)**
1	Front + Rear	100% Young	*53,5*	*5,9*
2	Front + Rear	100% Above 65	*74,4*	*7,5*
3	Front	100% Young	*68,7*	*12,6*
4	Rear	100% Young	*101,0*	*7,1*

Table 2 – Validation Runs

The values obtained, although they differ slightly from other models, are close and follow the same trends as them. So, the model is considered correct as an explanatory method and as a correct estimate of evacuation times for the following reasons:

- Times when evacuating in similar conditions are similar, although slightly higher than in drills. This increase in time is followed by all the models studied and is considered to correct the preparation and learning of the participants in a drill.
- The standard deviation is in the existing values in other models and correctly corresponds to what is expected and found in other stochastic models.
- Locking a door produces time increases of the same order as in drills and models. In this case, the blockage may involve increases between 30 and 90%.

3.5 Evacuation study

Once considered that the model represents the best state of art of evacuation simulations it was used to perform three independent analysis: Analysis of the standard evacuation, Analysis of the influence of the passengers' characteristics and Analysis of the influence of the vehicle configuration

3.5.1 Standard evacuation analysis

The standard evacuation process study employs a population distribution similar to that of aerial evacuation. For the standard evacuation, passengers are chosen from the first four groups, in such a way that it is considered a worse situation than that assumed by the air regulations. G5 passengers, who are very elderly, are not included, because the usual drills do not use people with reduced mobility or who could be injured.

POPULATION GROUP	PERCENTAJE
Jóvenes – G1	30%
Media edad – G2	40%
Mayores de 50 – G3	20%
Mayores de 65 – G4	10%

Table 3 – Vehicle passengers distribution configuration

Regarding standard evacuation, the following parameters are studied:

- Normal development of the evacuation and shape of the time-passengers graph
- Development of evacuation with only one available door
- Door Blocked during the evacuation.

3.5.2 Passengers characteristics influence analysis

To study the influence of passengers, the distribution of speeds and sizes will be varied, separating them from the previously defined as standard distribution. The following experiments are performed with the following distributions:

NÚMERO EXPERIMENTO	JÓVENES	MEDIA EDAD	MAYORE S DE 50	MAYORES DE 65	MUY ANCIANOS
1	100%	-	-	-	-
2	80%	20%	-	-	-
3	-	100%	-	-	-
4	20%	40%	20%	20%	-
5	-	-	100%	-	-
6	-	20%	40%	40%	-
7	-	-	-	100%	-
8	-	-	10%	70%	20%
9	-	-	-	50%	50%

Table 4. – Experiments to study the influence of passengers

The evacuation times and the standard deviations in each case will be analysed, checking how they vary when the distribution of passengers in the coach changes and trying to obtain an estimate of the evacuation time through linear regression.

3.5.3 Vehicle characteristics influence analysis

Considering the standard passenger distribution – defined at para 2.5.1. –, relevant parameters of the coach seat layout are modified to see how they influence the evacuation.

The 54 seats of the coach are maintained at all times. There are three parameters that are analysed to evaluate the coach:

- Width of the doors
- Aisle width
- Rear door position

In this base approach, the two doors are the same width as opposed to the standard evacuation and the corridor is reduced up to 500 mm in its narrowest configuration. The experiments to be performed are shown below.

The increase of the aisle to 600mm is unrealistic and exceeds the legal limit, even taking into account the adaptations of the model, but it is included when considered interesting.

Experiment number	Door width	Aisle Width	Door location
1	700 mm	500 mm	Middle
2	700 mm	500 mm	Rear
3	700 mm	550 mm	Middle
4	700 mm	550 mm	Rear
5	800 mm	500 mm	Middle
6	800 mm	500 mm	Rear
7	800 mm	550 mm	Middle
8	800 mm	550 mm	Rear
9	700 mm	600 mm	Middle
10	700 mm	600 mm	Rear
11	800 mm	600 mm	Middle
12	800 mm	600 mm	Rear

Table 5– Experiments to study the influence of the vehicle

4 EXPERIMENT RESULTS AND DISCUSSION

4.1 Standard evacuation analysis

As it was presented in the paragraph dedicated to the methodology the objective was to characterise de variability of the evacuation process. To perform this characterisation, it the corridor average $\pm\ 2\cdot\sigma$ was represented considering each percentage of the passengers evacuated.

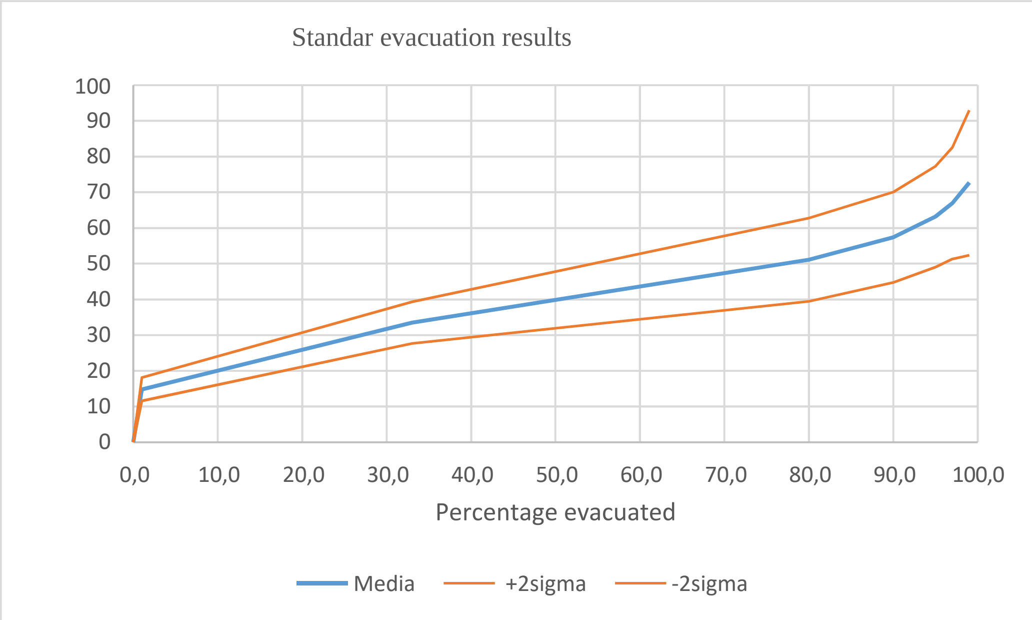

Fig. 2 Standard evacuation Charaterisation

From this standard evacuation and the filtered graphs, the histogram of the value time95 is obtained, the one chosen as the representative time of the evacuation, which is used as a reference to compare other experiments.

The distribution followed by the results of each time has also been studied using the SPC extension for Microsoft Excel. Despite the fact that sometimes follow the Beta4 distribution, it is chosen to define them by means of a log-normal distribution, since this is better adapted to all cases on average.

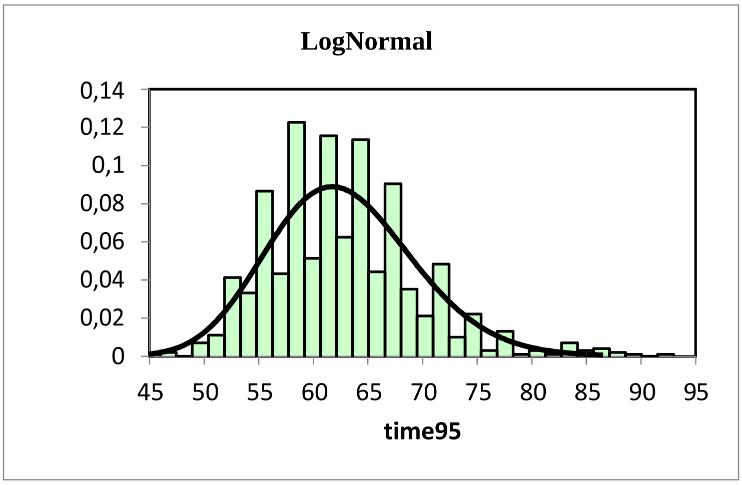

Fig. 3. Time 95 evacuation distribution

4.1.1 Standard evacuation with on door Blocked before the evacuation start

Studies with only one available door are carried out with the standard passenger distribution, obtaining the results shown in the table. During the obtaining of results, it is observed that when evacuating through the rear door there are an average of 12.2

passengers who use the emergency window. For this reason, another experiment is carried out in which the emergency windows are not used. The standard evacuation process through the two doors is included for comparison.

Experiment	Averrage Evacuation Time (s)	Standard deviation (s)
Standard, two exit doors	*62,7*	*6,8*
Front door	*78,4*	*13,6*
Rear door	*109,5*	*10,5*
Rear door and windows	*104,8*	*6,9*

Table 6. – Experiments with only one door available

A clear increase in evacuation times is observed when evacuating with a single door compared to when evacuating through both. This increase is 25% when the door is locked at the back and 75% when the front door is locked. This second case is more common when it comes to frontal crashes or when the fire starts in the front, for example, in the tank or in the front brakes.

The use of the emergency windows in the case of evacuating only from the rear does not significantly affect the times.

The standard deviation also increases with increasing evacuation time: it doubles with the rear locked and 55% more when the front is locked. The fourth experiment shows atypical results, since the standard deviation does not increase with respect to the standard evacuation, something that can only be explained assuming that the people that abandon the vehicle through the windows have less variability and the number of the passengers that exit through the doors is reduced by the same amount.

4.1.2 Standard evacuation with on door Blocked during the evacuation

This experiment considers the situation where some passengers start the evacuation through both available doors, and at some point – e.g. Bailén accident – one of the doors is blocked.

It is decided that the door block occurs when 40% of the passengers have evacuated, in order to observe its influence from time to time50.

Two experiments are performed, the first blocking the front door and the second blocking the back door. In this case, the use of emergency windows is allowed, which are used by a variable number of passengers between 0 and 8, considered reasonable in the face of the panic situation that would be generated.

Below are the evacuation times when the front door is blocked and when the rear door is locked:

% Evacuated	T1 (s)	T25 (s)	T50 (s)	T80 (s)	T95 (s)
Media	*14,3*	*23,6*	*38,0*	*63,9*	*81,5*
Desviación típica	*1,7*	*1,9*	*3,6*	*4,1*	*13,8*

Tabla 7. - Results with blocking the front door during evacuation

% Evacuated	T1 (s)	T25 (s)	T50 (s)	T80 (s)	T95 (s)
Media	*14,3*	*23,6*	*35,3*	*54,7*	*65,7*
Desviación típica	*1,7*	*2,0*	*3,7*	*4,6*	*7,4*

Table 8. - Results with blocking the rear door during evacuation

The development of both evacuations is identical until any of the doors is blocked. From that moment on, all passengers head towards the only one available, or towards the emergency windows if the conditions are met. This difference is observed from time50.

From then on you can consider a situation such as where only one door is available. The same trends are observed as in the previous case: a substantial increase in time when the available door is the rear and this is in an intermediate position of the vehicle.

Rear lockout assumes an average of 16 more seconds of evacuation for the last 30 occupants, or 50% more time since lockout occurs.

The drift of the data also increases with the elapsed time due to the same reasons as in the previous cases: an increase in time implies a greater probability of a blockage in the continuous flow of passengers. This blocking is favoured if two flows mix, as happens when evacuation is through the back door.

4.2 Passengers characteristics influence analysis

As has been performed in the previous analyses, the reference value considered as the evacuation time is the value time95. The results of erroneous simulations are eliminated and the means and standard deviations of the experiments carried out are found.

Finally, a linear regression is carried out in order to estimate the evacuation time of the vehicle as a function of the distribution of passengers. To carry out the study, the results of means and standard deviations of the standard evacuation and the other nine experiments carried out were used.

Young	Mid age	Above 50	Above 65	Above85	avg (s)	SD (s)
1	0	0	0	0	*55,8*	*5,5*
0,8	0,2	0	0	0	*57,3*	*5,6*
0	1	0	0	0	*62,9*	*6,6*
0,2	0,4	0,2	0,2	0	*66,1*	*7,7*
0	0	1	0	0	*65,2*	*7,1*
0	0,2	0,4	0,4	0	*72,4*	*8,8*
0	0	0	1	0	*82,9*	*9,4*
0	0	0,1	0,7	0,2	*101,2*	*16*
0	0	0	0,5	0,5	*128,2*	*18,2*
0,3	0,4	0,2	0,1	0	*62,7*	*6,8*

Table 9 - Percentage of passengers and evacuation results obtained

If a qualitative analysis of the results is carried out, it is observed that, indeed and as expected, the evacuation time grows with the presence of older passengers and therefore slower and less agile.

The big differences in evacuation times occur when dealing with very elderly passengers and with reduced mobility due to age. The presence of these passengers significantly increases the time required to evacuate the vehicle. While the presence of passengers over 65 in good physical condition increases the time by 49% compared to young people, the fact that half of these passengers have mobility problems increases the time by 150% compared to the initial proposals.

In turn, it is observed that the standard deviation increases when the mean evacuation time increases. This indicates that the results of each simulation are more different from each other the slower the entire evacuation process is carried out.

4.3 Vehicle characteristics influence analysis

The results of the experiments defined at paragraph 2.5.3 are collected in the table below:

Experiment number	Door width (mm)	Aisle width (mm)	Door location	Average (s)	SD (s)
1	700	500	Middle	*66,5*	*15,0*
2	700	500	Rear	*53,3*	*6,0*
3	700	550	Middle	*69,3*	*15,0*
4	700	550	Rear	*53,6*	*5,9*
5	800	500	Middle	*66,0*	*12,9*
6	800	500	Rear	*49,9*	*5,0*
7	800	550	Middle	*67,4*	*11,6*
8	800	550	Rear	*51,1*	*5,6*
9	700	600	Middle	*74,6*	*16,5*
10	700	600	Rear	*54,2*	*6,2*
11	800	600	Middle	*71,5*	*12,5*
12	800	600	Rear	*51,0*	*5,0*

Table 10 - Results of the experiments on the influence of the vehicle

In the results it is observed at a glance that the constructive parameter that has the most influence is the position of the rear door. An increase in standard deviations is also observed, linked to the increase in evacuation time. The slower the output, the more difficult it is to predict.

Focusing first the analysis on the average evacuation time a 100 mm increase in the width of the doors causes a minor decrease of 2.4 seconds in the evacuation time. This is due to a greater ease of leaving the vehicle for passengers.

The increase in the width of the corridor causes an increase of 3.9 seconds in said time.

This result is inexplicable and needs further experimentation. If correct, it could be because, with a wider corridor, several people could try to move through it simultaneously, impairing the normal flow of people towards the door.

Placing the rear door at the end of the seats is the factor that most influences the evacuation time. When the door is located in the back of the bus, the passengers are distributed more or less evenly between the two doors and, in addition, the flows towards both doors are unidirectional so that traffic jams are not created either. Placing the door at the back of the coach reduces the estimated evacuation times by 17 seconds and the standard deviation of the simulations by 8.3 seconds.

Broadly speaking, the position of the door has seven times more influence than its width and four times more than the width of the corridor.

5 CONCLUSIONS

It has been developed a bus and coach evacuation model that allows a stochastical analysis of the influence of vehicle and passengers variables.

The model has a good behaviour compared with evacuation drills performed by relevant transport safety institutions as INSIA in SPAIN and RISE in Sweden. The S shape behaviour of the evacuation percentage vs time curve is also coherent with the drill results.

The passengers profile may lead to double the time needed for a full evacuation of the vehicle in case of emergency, this value, even being significantly high is a result that can been used to define the burning behaviour of the materials used for vehicle interiors.

Considering the vehicle design a door blocked can slow down the process by 25-65%. The consequences are much more severe if the blocked door is the front one, which is usually the most common due to a frontal collision. These trends are also observed when the blockage occurs with the evacuation in progress.

ABSTRACT

The SESAR programme aims at developing the future European air traffic management system. It focuses on four keys areas: capacity, safety, efficiency and environment. In view of the expected growth in air traffic demand in the coming years, the current goal is to increase the airspace capacity, which is already close to saturation in many cases.

Currently, the separation standards applied in a given volume of airspace are fixed, both horizontally and vertically, which means that in many cases this is one of the determining factors of capacity. Separation management is an area where improvement is sought, in particular through the application of new operational concepts (separation modes) which include the redefinition of aircraft separation minima. One of the solutions to be investigated is the variable (Ad Hoc) separation proposal put forward by SESAR.

This future concept implies a change in the application of separation minima from the current fixed standards to a new variable approach. With this new concept, ATCo (Air Traffic Controller) would separate aircraft by applying different separation minima in the same volume of airspace. These separation values are tactically determined for each particular aircraft pair (Ad Hoc) depending on a number of factors: aircraft categories, encounter geometry, atmospheric conditions, etc.

Applying different separation minima in the same volume of airspace implies a substantial change in some of the ATC activities. Also, new functionalities in ATC support tools are needed. This study presents the Ad Hoc separation operational concept and provides the basis for the development of the algorithm for calculating variable separation minima.

1. INTRODUCTION

The SESAR (EUROCONTROL, 2020a) and NextGen (FAA, 2019) programmes in Europe and the United States are aimed at developing the future air traffic management (ATM) system. They are geared towards achieving benefits in four areas: capacity, safety, efficiency, and environment. Both programmes envisage a transition from the current system to the implementation of new operational concepts over the coming decades (BROOKER, 2011).

Since 2014 in Europe there has been a steady growth in air traffic. The year 2018 saw an all-time record of 11 million flights in European Civil Aviation Conference (ECAC) airspace, an increase of 4% over 2017 (EUROCONTROL, 2020a). Last year 2020, as a consequence of the global pandemic resulting from COVID-19, traffic levels dropped drastically (by more than 50% compared to 2019 levels (EUROCONTROL, 2021)). However, a recovery of the sector is expected in the coming years and a return to air traffic growth levels is foreseen. The most reliable traffic forecast scenarios anticipate, by 2040 in ECAC, more than 15 million flights per year (EUROCONTROL, 2020b) . In order to meet this expected growth in demand in the coming years, solutions must be found to increase current airspace capacity in some scenarios already close to saturation.

The separation standards applied in a specific volume of airspace are fixed, both in their horizontal and vertical dimensions (PÉREZ-CASTÁN et al., 2020), which means that in many cases this is one of the determining factors of its capacity. Additionally, the separation minima that are currently applied in a specific volume of en-route airspace were determined decades ago (REYNOLDS & HANSMAN, 2000) when the existing navigation, communication and surveillance systems did not provide the performance of today's systems and when the air traffic controller did not have the advanced support tools available today.

Separation management is therefore an area where improvement is sought, namely through the implementation of new operational concepts (ConOps) which include both the redefinition of the separation minima and the way they are applied. It is therefore necessary to implement a new separation mode, which consists of an approved set of rules, procedures and conditions of application associated with separation minima (ICAO, 2008).

Separation minima studies started with Reich (P.G. REICH, 1964) who developed the first collision risk model (CRM) in order to assess whether a reduction of lateral separation between tracks from 120 NM to 90 NM in the North Atlantic Region (NAT) was safe. Since then several authors have developed this initial CRM in order to extend its application to other scenarios and to overcome certain limitations of the model (MACHOL, 1975), (HSU, 1981), (ANDERSON & LIN, 1996), (BLOM et al., 2003). ICAO adopted the Reich and Hsu models and presented a unified derivation of these (the

Rice formula) based on a general framework (ICAO, 2009). In (BARNETT, 2000) it is proposed a CRM for safety assessment in a free flight scenario while the CRM developed in (SÁEZ NIETO et al., 2010) assesses risk in all three dimensions in an en-route scenario with radar surveillance.

This work develops the operational concept for the application of a minimum variable separation (Ad Hoc) between aircraft, already proposed in a preliminary way as a solution to be studied and developed in some ATM programmes such as SESAR (SESAR EUROCONTROL/EUROPEAN UNION, 2019). This study is organised as follows. Section 2 describes the variable separation operational concept and proposes the basis of the algorithm for the real-time implementation of the concept. Section 3 presents the approach for the reduction of separation minima, the development of which will be presented in future work. This study is concluded in Section 4.

2. VARIABLE SEPARATION (AD HOC) CONOPS

An operational concept (ConOps) is a statement of "what" is envisaged. It asks and answers what results are expected from the future ATM system. It is a vision statement (ICAO, 2005).

2.1 Operational scenario description and CNS requirements

The Ad Hoc separation concept refers to the application of a variable separation value for each aircraft pair within the same volume of airspace, depending on a set of factors (aircraft categories, encounter geometry, atmospheric conditions, etc.). This is therefore a change in the application of separation minima, migrating from the current fixed standards to a new variable approach. Thus, ATCo will separate aircraft, applying different separation minima in the volume of airspace in which the concept is implemented. Implicit in the development of this concept is the research into the reduction of separation minima in order to be able to apply new standards.

The development of this new operating mode will follow a two-step approach, similar to the RECAT project (EUROCONTROL, 2015), where initially static aircraft characteristics are considered, and at future levels a dynamic approach is adopted, considering non-stationary factors such as aircraft weight.

In the initial stage of the concept development, variable separation will be applied in a specific scenario: continental en-route airspace between the upper flight levels (FL 245 - FL 660) where control service is provided. Control sectors of low - medium complexity and traffic density are considered.

In upper airspace the aircraft mix consists mainly of medium, heavy and super heavy aircraft category according to wake turbulence.

In a first step, the airspace structure is assumed to have prefixed routes in which aircraft fly at constant altitudes. Future work will study the implementation of this concept in a free route scenario.

The fundamental factor in the Ad Hoc separation concept is the minimum separation. In this context, this term refers to surveillance minimum radar separation (MRS). However, it is relevant to consider the effects of wake vortex and thus the derived minimum separation (MWS). The variable separation minimum (DS) should always be greater than or equal to the minimum wake separation (MWS).

The main feature of this new operating mode is that there is no single fixed minimum separation value. Instead, there is a set of possible values within a range (3 NM - 5 NM, NM: nautical mile), which extreme values are:

- Upper limit value (5 NM): currently in en-route scenarios with surveillance the defined minimum separation is 5 NM.
- Lower limit value (3 NM): in en-route phase the longitudinal MWS value is considered to be 5 NM for cases where the preceding aircraft belongs to a higher category than the succeeding one. However, when the situation is the opposite, the MWS separation may be smaller (i.e., preceding aircraft of equal or lower category than the succeeding one). There are currently several projects studying the reduction of minimum wake separations and proposing new en-route MWS values: 3 NM, 5 NM (SESAR, 2018). Therefore, it has been decided to take the value of 3 NM as the lower limit of the range of variable separations. Moreover, the reduction of the ATC minimum separation is based, in first instance, on the improvement of the technical systems currently available.

In the initial stage of the development of this concept, the possible Ad Hoc separation values within the defined range will be specific (i.e., 3 NM - 3.5 NM - 4 NM - 4.5 NM - 5 NM). In future work the separation could be specified with a resolution of one tenth (0.1) in NM. These minima will be determined automatically, with a given time horizon, by the Separation Minima Tool. Ad Hoc separation values shall be determined based on a set of conditions:

- Aircraft Category (Super Heavy, Heavy, Medium or Light)
- Navigation Capability
- Surveillance Capability
- Communications Capability
- Encounter geometry
- Aircraft speed
- Wind conditions and ATC procedures.

The implementation of this concept and the consequent reduction of MRS requires aircraft to be capable of ensuring minimum performances from the improved technical systems available. Failure to comply with any of the CNS requirements would reinstate a reference separation value of 5 NM which corresponds to the current applicable standard and the maximum value of the Ad Hoc minima range.

Aircraft operating in these scenarios are required to have PBN (Performance Based Navigation) capability, in particular RNP (Required Navigation Performance). Performance-based navigation requires that for 95% of the flight time, performance related to lateral and longitudinal accuracy, continuity, availability and integrity are guaranteed. Aircraft approved to RNP navigation specifications have an on-board monitoring and alerting system capable of predicting whether the required performance (navigation accuracy) can be met with a probability greater than 10^{-5}. Communications service is available throughout the volume of airspace. Non-urgent communications would be via data link (CPDLC) while urgent communications would be oral in the VHF band.

In scenarios where this concept is implemented the ATC surveillance service shall be based on ADS technology (upgraded with GNSS). The on-board global navigation satellite system (GNSS) receiver provides the ADS-B transmitter with a position accuracy indicator (figure of merit, FOM) and a position integrity indicator (horizontal protection level, HPL) together with other data (ALI et al., 2016). It is a prerequisite that the figure of merit corresponds to the satellite navigation system (FOM 6) and not to other systems (FOM 5 - DME/DME, FOM 3 - Inertial, etc.), otherwise the default separation value (5 NM) would be applied among those aircraft not complying with this requirement. In the event of a regional loss of GNSS positioning capability, radar surveillance would be used as a contingency system and separation management would be provided under current conditions (5 NM fixed separation value).

2.2 Separation Minima Tool

The determination of variable separation minima shall be performed by the Separation Minimum Tool (SMT) integrated in the ground segment. It shall display to ATCo the applicable minimum separation value between two aircraft. While the controller remains the separation agent, the notion in the control exercise will have to change somewhat. Applying different separation minima in the same volume of airspace means that the ATCo is unable to mentally calculate the variable separation value, as opposed to the current fixed value (5 NM). Therefore, controllers need a new tool which presents this separation value for each aircraft pair in the airspace under their responsibility. In this separation mode the supervisory/monitoring role of the controllers become more important and even more complex, so that the operational concept must be defined in order to ensure that the new situation is safe.

In the initial stage, the SMT ground system consists of a single module called 'Separation Proof (SP)'. The function of this tool will be to determine the minimum lateral or longitudinal separation value between two aircraft that meets the required safety threshold (TLS). In order to do so, it requires other systems to provide it with the necessary information.

The trajectory prediction information shall be provided by a predictor tool which will use ADS B data transmitted by the aircraft and the flight plan information (FPL) to perform the 4D prediction. The prediction shall comply with a minimum quality factor in order to achieve a required level of accuracy. The 4D trajectory prediction shall be received by the SMT 20 minutes in advance of the aircraft's planned sector entry time. Information regarding wind conditions and aircraft performance shall be provided to the SMT tool by the aircraft. The FPL information shall be received from the flight data processing system (FDP) (Figure 1).

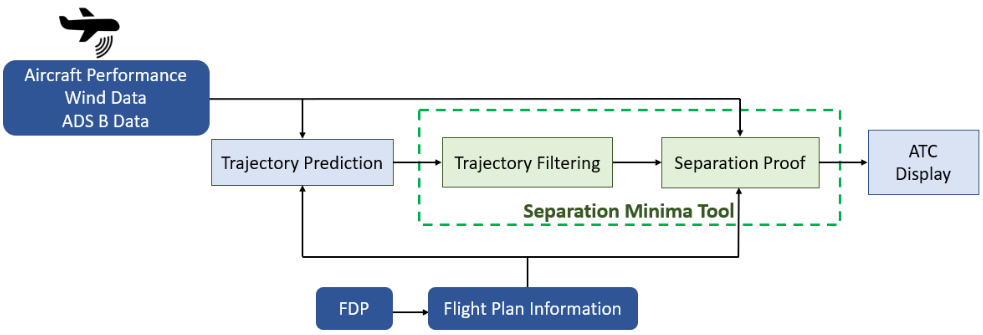

Figure 1. Information flow for Ad Hoc separation determination

Initially the SMT shall filter trajectories by discarding those situations that are not of interest, i.e. aircraft whose trajectories do not intersect, aircraft whose trajectories intersect at a crossing point but with a time difference between them of more than 2 minutes (and therefore separated by a distance of more than 15 NM), aircraft not flying on the same airway and aircraft flying on the same airway but whose time difference at the sector entry time is greater than 6 minutes (and therefore separated by a distance greater than 45 - 50 NM which assumes that differences in aircraft speeds would not give rise to overlap conflicts). After this first filtering, the SP module shall initiate the separation determination between the interest aircraft pairs. This variable separation minimum shall be determined and displayed to the controller 2 minutes in advance of the expected sector entry time of the first aircraft. This time horizon has been selected in order to allow ATCo to have some advance knowledge of the applicable minimum separation value between two aircraft. These initially proposed time values are subject to modification depending on the results obtained in the validation level.

It should be noted that some systems will need to be upgraded in order to be compatible with the proposed concept. In particular, the ATC tool "Conflict Detection" will adopt a more dynamic behaviour by monitoring that there will be no loss of separation between aircraft with the conflict limit distance being the minimum Ad Hoc distance determined.

The same applies to the ACAS system, which operates on time scales that should be analysed to avoid excessive generation of Traffic Advisory (TA) and Resolution (RA) alerts. Also, one of the future challenges to be dealt with in the development of this Ad Hoc separation project is the compatibility with the Trajectory Based Operations (TBO) concept strongly promoted by SESAR. While the former is eminently tactical, the TBO concept has a greater focus on strategic planning. The idea behind this concept is that trajectories are negotiated between all the actors involved before the flight and that the ATM system is aware of them and modifies them, if appropriate, in order to be free of conflicts. The possible discrepancy lies in what minimum separation would be used to make the trajectories strategically conflict-free, as the Ad Hoc separation would be tactically determined. The harmonisation between these two concepts will be explored in future work.

2.3 Separation Proof module

The algorithm for the Ad Hoc separation minima determination implemented in the Separation Proof module aims to determine the smallest safe separation value between two aircraft. Figure 2 shows the flowchart representing the sequence of activities carried out by the algorithm. Four activities are distinguished:

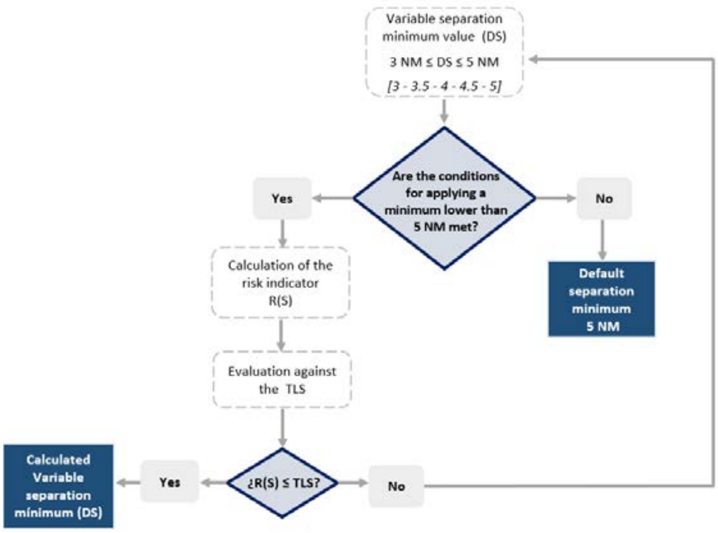

Figure 2. Ad Hoc Separation Determination Algorithm Flowchart

<u>1.- Variable Separation Minimum (DS).</u>

The algorithm has information on the aircraft pairs labelled as "pair of interest" and their specific characteristics (performances, trajectories, etc.). The en-route turbulent wake separation minima between aircraft, depending on the possible sequences (i.e., heavy-medium, medium-super heavy, etc.), are given to the algorithm.

In the initial step of the development of this concept the minimum variable separation (DS) will be determined and not calculated from this information. That is, in the first activity the algorithm will specify in real time for the "pair of interest" the lowest applicable separation value within the range of Ad Hoc separations (3 NM - 3.5 NM - 4 NM - 4.5 NM - 5 NM).

The Ad Hoc value shall always be higher than the corresponding MWS for that situation. If the Ad Hoc value does not meet the requirements of the following activities in the flowchart (target level of safety) the algorithm, following the feedback, would return to the initial step, would take the variable separation (DS') value immediately above the previous one and would repeat the sequence until an Ad Hoc separation value judged as safe is obtained. It is a prerequisite that the required conditions are met in order to be able to apply variable separation. Among those aircraft that do not meet these conditions, the default value of 5 NM shall always be applied.

2.- Calculation of the aircraft pair risk indicator R(S).

After determining the minimum variable separation (DS) the algorithm estimates the risk of collision R(S) of the aircraft pair for which the minimum variable separation (DS) has been calculated. The input variables for the calculation of the risk indicator are:

- Characteristics of the encounter geometry (angle of intersection between trajectories, aircraft speeds, altitudes, etc.).
- Minimum variable separation value determined (DS).
- Aircraft horizontal overlap probability (as a function of DS separation)
- Errors (aircraft position uncertainties, human factor, time windows, etc.)
- Meteorological conditions (wind) affecting aircraft ground speed (GS).
- ATC Intervention Capability

3.- Safety assessment.

After estimating the risk of collision R(S), it is compared with the Target Level of Safety (TLS) whose value is fixed. In making this comparison, the possibilities are:

- If the risk indicator R(S) ≤ TLS, then the minimum variable (DS) is applied.
- If the risk indicator R(S) > TLS, then:

    1. A new variable separation minimum (DS') value is determined that is higher than the previous DS value which did not comply with the TLS threshold.
    2. It is checked whether the new DS' value satisfies with the TLS fixed safety target level. If yes, the applicable separation value is DS'.
    3. If not, the process is iteratively repeated until the value of the minimum variable separation is 5 NM. This value corresponds to the current en-route (with surveillance) separation standard and therefore satisfies with the defined TLS.

4.- Display of the applicable minimum variable separation value to ATCo.
Finally, the minimum variable separation value applicable between the aircraft pair is displayed to the controller with a reasonable amount of time in advance.

3. APPROACH FOR THE ATC SEPARATION MINIMA REDUCTION STUDY.

Separation minima can be described as a function of three factors: navigation performance, risk exposure and intervention capability (Communications, Surveillance and ATC procedures and tools) (ICAO, 2020).

ICAO adopted collision risk models for the purpose of determining minimum separation in airspace with procedural control. However, in scenarios with ATS surveillance services (ATS surveillance systems: radar, ADS-B, etc.), the determination of separation minima appears to lack rigorous formal development. To determine the appropriate radar separation minima the analysis is related to the effect of inaccuracies, in the displayed radar data, so as to estimate the risk of collision and to decide whether the risk, for the implementation of a separation minimum, is acceptably safe (EUROCONTROL, 1998). Some authors have followed this approach and address the determination of the separation in scenarios with surveillance from the uncertainties of the different elements that make it up (REYNOLDS & HANSMAN, 2000). These uncertainties associated with the errors can be approximated by probability density functions (generally Gaussian and Double Exponential distributions).

The separation between aircraft displayed on screen to ATCo (apparent separation) does not correspond to the actual separation between aircraft, due to the associated errors. The actual separation value will depend on the probability density functions of the errors (Figure 3). The limiting case occurs when the apparent separation between aircraft is 5 NM (current separation standard), a value for which the collision risk meets the absolute target level of safety (TLS), but the actual value is less than the standard.

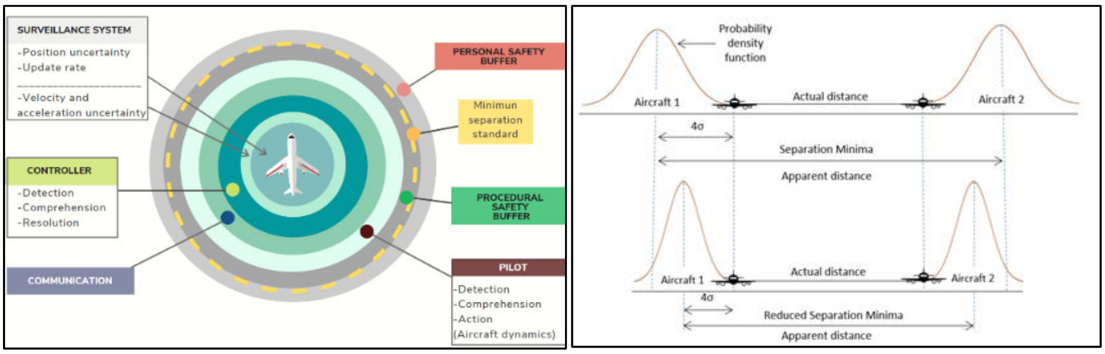

Figure 3. Representation of: left) Separation assurance budget components (REYNOLDS & HANSMAN, 2000) and right) errors probability density functions

The reduction of the ATC separation minimum is based on improvements in the technical systems currently used, in particular in the field of surveillance and navigation. These, not only offer better performance, but also predict whether this performance will be maintained during the flight, as is the case with RNP navigation. In addition, ATC is now equipped with more advanced support tools. The aim is to reduce the uncertainty associated with the various factors influencing separation (modification of the density function). Thus, the actual separation between aircraft would be maintained and, consequently, so would the risk of collision. However, the minimum separation (apparent separation) could be smaller.

In the framework of the minimum separation definition, the navigation and surveillance domains are the ones where most progress has been made. The progress achieved with Performance Based Navigation has been discussed in Section 2. In the surveillance domain, ADS overcomes some of the limitations of radar (positioning accuracy and system update time). In radar, accuracy is dependent, among other factors, on the distance to the target. Furthermore, different separation values are applied depending on the surveillance signal processing mode (5 NM multi-radar, 10 NM mono-radar, etc.). The information captured by the radars is not displayed directly to ATCo but is processed beforehand. This entails a processing time, especially in multi-radar processing, which means that the information displayed on the screen to ATCo corresponds to positions from previous time instants. Likewise, it should be considered that the mode S radar update frequency or information refresh time (speed at which the position of the aircraft is updated to users) is 4 - 15 seconds. In ADS the positioning accuracy is dependent on the aircraft avionics and therefore independent of the sensor range. With the GNSS navigation system (FOM 6) the position accuracy values achieved are less than 0.25 NM. In addition, since the information is received directly from the aircraft, the processing time is shorter than with multi-radar processing, with the update rate in the ADS typically being 1 second.

Research on the reduction of ATC separation minima will be developed in future studies and will be mainly based on the improvements referred above.

4. CONCLUSIONS AND FUTURE WORK

The SESAR and Next Gen macro programmes propose new projects in order to drive the future development of air traffic management (ATM) and ensure benefits in the capacity, safety, efficiency and environment areas. This study has laid the foundations for the development of the concept of variable separation in continental en-route airspace. In particular, the Ad Hoc separation framework or operational concept is defined. Variable separation involves applying different separation minima between aircraft in a specific volume of airspace according to a specific set of characteristics (aircraft category, navigation performance, surveillance, etc.) and external characteristics (conflict geometry, ATC procedures, wind conditions, etc.).

There is no fixed separation value, but a range of possible values that define new standards. For this reason, implicit in the development of this concept, research will be carried out on the reduction of the current separation minima. The approach to be followed to study this reduction lies in maintaining a fixed safety threshold (risk of collision) by reducing the uncertainties associated with the different factors that determine the minimum separation (surveillance, navigation, ATC procedures, etc.) thanks to improvements in the technical equipment currently available. This study also describes the operation of the Separation Minima Tool and the steps carried out by the algorithm in charge of determining the variable separations. Different operational issues are identified that need to be developed in future work to make new concepts proposed by SESAR (Trajectory Based Operations, TBO) compatible with the one proposed in this study. Finally, the implementation of variable separation has the final goal of increasing capacity. This study will be carried out in parallel.

Laura Lorenzo Carrascosa
Jefa de Sociología del Transporte; Fundación de los Ferrocarriles Españoles, España

RESUMEN

Los accidentes en pasos a nivel constituyen un significativo problema de intersección ferrocarril –carretera, pero también conlleva unas consecuencias relevantes sociales a nivel personal, social, de salud pública y de impacto social. Adicionalmente, estos sucesos tienen importantes repercusiones para la operación ferroviaria y por carretera debido a los elevados costes económicos, de tiempo y sanitarios.

Entre 2010 y 2019 fallecieron 2.736 personas en los pasos a nivel localizados en la UE-27. En España, en este período se registraron 74 decesos en los pasos a nivel, a lo que se suman 32 personas que sufrieron heridas graves y 125 con heridas leves.

Los pasos a nivel representan, por tanto, un punto de seguridad crítico en el transporte ferroviario y por carretera que requiere un continuo análisis. Teniendo en cuenta que, el factor humano es la causa del 90% de los accidentes de tráfico, resulta fundamental identificar los errores humanos y los requisitos de los usuarios, para mejorar la seguridad en las infraestructuras de los pasos a nivel.

El artículo aborda el tema del Factor Humano en los Pasos a Nivel con el objetivo de contribuir a la reducción de la siniestralidad. Este estudio se basa en la experiencia adquirida en el proyecto europeo SAFER-LC: Pasos a nivel más seguros mediante la integración y optimización de la gestión y el diseño de infraestructura vial y ferroviaria, (2017-2020), y que se enmarca en la línea de investigación sobre seguridad ferroviaria desarrollada por los grupos de investigación de la FFE.

Los resultados de este análisis permitirán incorporar elementos del comportamiento humano en las soluciones tecnológicas y no tecnológicas de los diseños de pasos a nivel. También tienen como objetivo impulsar la cooperación entre las diferentes partes interesadas de los diferentes modos de transporte implicados en los pasos a nivel.

1. INTRODUCCIÓN

En el año 2014 había 114.580 pasos a nivel en la Unión Europea (UE-28). Sin embargo, se pueden encontrar muchas diferencias entre países en cuanto al número de pasos a nivel. Por ejemplo, Francia, Alemania y Polonia tenían el mayor número de pasos a nivel de Europa (más de 9.000) e Irlanda, Portugal, Eslovenia, Bulgaria, Letonia, Estonia y Luxemburgo el menor número (menos de 1.000) (ERA, 2016) (Figura 1).

En promedio, había 5 pasos a nivel por cada 10 kilómetros de línea en la UE, pero esta proporción variaba considerablemente entre países. Por ejemplo, Suecia, Austria, la República Checa y Hungría tenían la mayor densidad de pasos a nivel en términos de pasos a nivel por línea-kilómetro (más de 75 por cada 100 kilómetros) y, Bulgaria y España la densidad más baja (menos de 25 por cada 100 kilómetros de línea) (ERA, 2016).

Hay que tener en cuenta que, los pasos a nivel son una parte fundamental de la infraestructura ferroviaria. Por ello, a nivel general, las estrategias se han centrado en introducir mejoras técnicas en las infraestructuras y eliminar los pasos a nivel, pero también se han combinado estas medidas con otras que reducen los riesgos para los usuarios (por ejemplo, medidas educativas y de sensibilización).

En Europa, el número de víctimas mortales en accidentes ferroviarios ha disminuido, salvo las relacionados con los accidentes en pasos a nivel. En los últimos años, de media, en Europa todos los días ha muerto una persona y casi una ha resultado gravemente herida (ERA, 2016). En 2014, Alemania y Polonia eran los países de la EU-28 con más muertes de usuarios en los pasos a nivel (41 y 38, respectivamente). Del total de países estudiados, España ocupaba el décimo puesto en mortalidad en pasos a nivel (8 fallecidos).

El objetivo del proyecto europeo SAFER-LC (SAFER Level Crossing by integrating and optimizing road-rail infrastructure management and design; Proyecto de investigación de la Comisión Europea, Programa Horizonte2020 (2017-2020) coordinado por la UIC y en el que participa la FFE en el Consorcio del proyecto.) era mejorar la seguridad y minimizar el riesgo mediante el desarrollo de un conjunto de soluciones innovadoras, y herramientas para la gestión proactiva y el diseño de la infraestructura de los pasos a nivel.

Las herramientas desarrolladas permiten a los agentes encargados de la toma de decisiones de las infraestructuras de carretera y ferrocarril encontrar formas más eficaces de detectar situaciones potencialmente peligrosas, evitando incidentes en el cruce de nivel mediante un diseño innovador y métodos de mantenimiento predictivo.

El proyecto se centró en las soluciones técnicas (como los servicios de detección inteligente y sistemas de comunicación avanzada infraestructura-vehículos), los procesos humanos para adaptar el diseño de la infraestructura a los usuarios finales, y la cooperación entre las diferentes partes interesadas de los distintos modos de transporte implicados en los pasos a nivel.

Con el objetivo de demostrar cómo estos avances tecnológicos y no tecnológicos se podían integrar en soluciones, así como validar su viabilidad y evaluar su desempeño se llevaron a cabo una serie de pruebas piloto en diferentes ciudades europeas.

A partir de los resultados obtenidos en SAFER-LC, en esta comunicación se presenta una propuesta de marco descriptivo útil para el diseño de los pasos a nivel y los sistemas de seguridad teniendo en cuenta la perspectiva de los usuarios de carreteras y ferrocarriles, especialmente de los usuarios vulnerables (El informe completo de esta tarea (Tarea 2.1.) se puede encontrar en la extranet del proyecto: https://safer-lc.eu/)

La comunicación se estructura en tres partes. Con el objetivo de mejorar la comprensión de los indicadores clave de seguridad relacionados con errores humanos e infracciones en los pasos a nivel, en el primer apartado se presentan un marco teórico relacionado con el análisis de los factores humanos en los sistemas de seguridad de los pasos a nivel. A continuación, se describen las fuentes de datos y metodología usada en el desarrollo de los principales indicadores relativos a los requerimientos de los usuarios, errores humanos e infracciones en pasos a nivel. El tercer apartado presenta los resultados del análisis de las variables identificadas en la literatura y los principales indicadores propuestos. Por último, se incluye un apartado que incluye las principales conclusiones extraídas del análisis realizado.

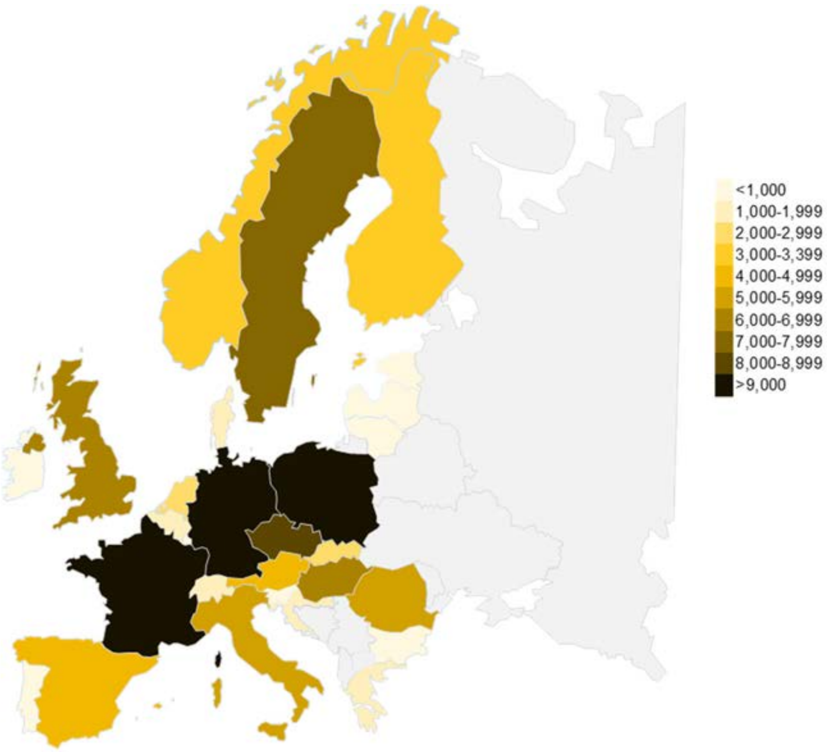

Figura 1. Número total de pasos a nivel en la Unión Europea-28, 2004

2. MARCO TEÓRICO. ANÁLISIS DE LA SEGURIDAD EN LOS PASOS A NIVEL DESDE EL FACTOR HUMANO

Según la Asociación Internacional de Ergonomía, el factor humano es un enfoque teórico relacionado con la comprensión de las interacciones entre personas y otros elementos de un sistema. Este enfoque aplica teoría, principios, datos y métodos al diseño, con el fin de optimizar la seguridad de las personas y el rendimiento general del sistema. De esta manera, el error humano ya no se considera la causa principal de los accidentes, sino una consecuencia de los fallos lógicos del sistema.

De acuerdo con el enfoque de los “sistemas seguros”, los accidentes en los pasos a nivel son el resultado de la interacción compleja entre los usuarios (por ejemplo, peatones, conductores, etc.), vehículos (por ejemplo, vehículos pesados, trenes de alta velocidad, etc.), la infraestructura en el cruce (por ejemplo, distancias de visibilidad, señalización, etc.) y otras condiciones del entorno (por ejemplo, condiciones meteorológicas). De esta manera, la clave para unos pasos a nivel más seguros surge de la responsabilidad compartida entre los peatones, los usuarios de carretera, las operadoras y los administradores de la infraestructura ferroviaria, y los órganos de gobierno. Las contramedidas adoptadas de acuerdo a este enfoque buscan hacer que las características de los pasos a nivel tengan en cuenta la existencia de errores humanos y minimicen su impacto, y reduzcan los comportamientos inseguros de los usuarios (Searle et al., 2012).

El concepto de infraestructura resiliente y autoexplicativa se ha aplicado con mayor frecuencia al contexto de la seguridad vial en carretera. Desde esta perspectiva, una carretera resiliente sería aquella que está diseñada y construida de tal manera que interfiere o bloquea el desarrollo de errores de conducción y, evita o mitiga las consecuencias negativas de los errores de conducción, permitiendo así que el conductor recupere el control, regrese al carril de circulación o pueda detenerse sin lesiones ni daños. Por otro lado, una carretera que se explica por sí misma estaría diseñada y construida para inducir a una conducción adecuada (ya sea por el diseño de su trazado o mediante la señalización existente), reduciendo así la probabilidad de errores del conductor y mejorando la comodidad de conducción (Bekiaris et al., 2011).

Un número creciente de investigaciones abordan el análisis del factor humano en los pasos a nivel, aunque la mayoría de estos estudios se han centrado más en las colisiones de trenes y vehículos que en los arrollamientos de peatones. A continuación, se presentan algunos temas comunes que aparecen en la literatura en relación con la perspectiva del usuario en los pasos a nivel. Debido al enfoque de este estudio, es importante distinguir primero entre dos categorías amplias de incumplimiento en los pasos a nivel: el error humano y la infracción deliberada de las normas.

La mayoría de los usuarios de pasos a nivel tienen comportamientos de riesgo no intencionados (Searle et al. 2012), siendo estos denominados en la literatura como errores humanos. Ejemplos de estos podrían ser, no percibir el acercamiento del tren, o la mala valoración del riesgo ante la proximidad del tren. Factores cognitivos como la falta de atención, distracción, poco conocimiento, mal juicio, distancia de visión limitada, etc. (Freeman et al., 2013) pueden ser los que llevaran a la aparición de este tipo de errores.

Por otro lado, hay usuarios que incumplen voluntariamente las reglas de cruce de los pasos a nivel. Estos hechos se conocen como infracciones deliberadas. En la literatura se citan varios factores que influyen en la tendencia de los usuarios a incumplir las reglas, entre ellos: factores individuales como la edad, el género, la personalidad y las actitudes; factores sociales como normas, cumplimiento y comportamiento de otras personas cercanas; y factores puntuales como el tiempo de espera, el clima, la distracción y el estado de ánimo (Edquist, 2011). Algunas razones más específicas para infringir deliberadamente las reglas de tránsito o de los pasos a nivel incluyen: tener prisa, la conveniencia, la familiaridad, la fatiga o el consumo de alcohol y drogas, entre otros (Freeman et al., 2013).

Según la literatura estudiada, hay menos ejemplos de infracciones deliberadas de pasos a nivel que de errores humanos.

Al analizar los factores humanos en los sistemas de seguridad de pasos a nivel habría que tener en cuenta la tipología (pasivo, activo y peatonal) y el usuario del paso a nivel (usuarios motorizados, no motorizados y vulnerables), ya que estas variables pueden influir en la naturaleza del riesgo y los factores humanos en juego. Por ejemplo, los arrollamientos en pasos a nivel controlados pasivamente que involucran el incumplimiento involuntario del conductor, tienen más probabilidades de estar relacionados con factores humanos que por factores relacionados únicamente con fallos técnicos de los sistemas (Rudin-Brown et al., 2014). Además, ciertos factores humanos pueden ser más prevalentes en un grupo de usuarios de la carretera que en otro (Searle et al., 2012).

Searle et al. (2012) establecieron un conjunto definido de categorías de factores humanos aplicadas a la seguridad de los pasos a nivel (Figura 2):

2.1 Factores humanos relacionados con errores humanos

- Visibilidad de cruces y trenes.

Para cruzar de forma segura un paso a nivel, el usuario debe de tener una visibilidad tal que sea capaz de detectar y percibir con éxito la presencia o proximidad de un tren.

Algunos factores que pueden afectar a la visibilidad de los usuarios/conductores son:

- el contraste visual de los objetos con su entorno más amplio;
- las condiciones climáticas;
- las condiciones de luminosidad: la oscuridad en la noche o el resplandor del sol que pueden cegar temporalmente a los usuarios de la vía (Searle et al., 2012);
- el tamaño percibido;
- el color oscuro de los objetos que se acercan desde la distancia pueden también contribuir a una peor detección y reconocimiento por parte de los conductores (Rudin-Brown et al., 2014).

Las líneas de visión limitadas a lo largo de la vía son otro factor de percepción importante que puede afectar la capacidad del usuario de la vía para detectar un tren que se aproxima en un cruce pasivo. La distancia visual debe permitir a los usuarios de la carretera no sólo darse cuenta de la presencia de un tren, sino también aportar la información suficiente para que se detenga de manera segura antes del cruce. Otros estudios destacan factores como la existencia de vegetación o edificios ubicados a lo largo de la vía, la curvatura en la carretera o vía, o el cruce en ángulo agudo de las vías del camino y del ferrocarril, como elementos que pueden afectar la línea de visión y, por tanto, conducir a una mala visibilidad (Searle et al., 2012).

- Distracción y falta de atención.

La atención de un usuario de la vía puede desviarse de un paso a nivel debido a distracciones externas (por ejemplo, semáforos, señales de ceda el paso, tráfico de peatones, tiendas, etc.). Este problema se experimenta con mayor frecuencia en los cruces activos, dado que se encuentran en entornos urbanos en los que existen muchas distracciones visuales y mentalmente complejas (Searle et al., 2012). Cuando se sobrecarga con otros estímulos, la conciencia de la situación del usuario de la vía puede verse comprometida perdiéndose la atención en el paso a nivel. En esta situación, los estímulos como los propios trenes o luces intermitentes pueden ser completamente visibles pero inadvertidos, un fenómeno conocido como "ceguera atencional", o un "miraron, pero no pudieron ver" (Searle et al., 2012).

Los usuarios también pueden presentar distracciones internas como resultado de realizar tareas secundarias a la conducción o la acción de caminar, como el uso de dispositivos multimedia, conversaciones con pasajeros o con otros peatones, atender a los niños o procesos mentales que distraen, como soñar despierto o abstraerse en pensamientos. Rudin-Brown et al. (2014) argumentan que las distracciones no visuales del conductor que surgen como resultado de estímulos cognitivos (pensamientos) pueden tener un impacto negativo en el comportamiento de exploración visual del conductor o usuario. Este factor podría estar presente entre los usuarios de cruces activos y pasivos, y podría aplicarse tanto a usuarios motorizados como no motorizados.

Otro problema potencial de falta de atención que experimentan los conductores en los cruces pasivos está relacionado con la relajación provocada por la falta de atención al entorno más amplio, debido al aislamiento rural de los cruces pasivos y su bajo tráfico de trenes y carreteras, lo que conlleva que el usuario puede equivocarse en la percepción de la distancia de un paso a nivel o del acercamiento del tren (Searle et al., 2012).

El tema de la presencia (y la conciencia) de un segundo tren que aparece poco después de que el primero ha pasado, está recibiendo cada vez más atención dentro de la literatura (Freeman et al., 2013). Los trenes que se aproximan pueden actuar como una distracción que afecta tanto a los peatones como a los usuarios motorizados. Primero, los peatones pueden concentrarse en intentar coger un tren que llega a una estación de ferrocarril y, al hacerlo, no percibir la llegada de un segundo tren que se aproxima. En segundo lugar, los automovilistas pueden centrar su atención de manera similar en un tren que se acerca, y se detiene en una estación adyacente o que acaba de pasar, y suponer que ya es seguro cruzar, cuando en realidad se acerca un segundo tren que no verán.

- Falta de conocimiento.

Otro factor humano que conduce al uso indebido involuntario de los pasos a nivel es la falta de conocimiento sobre las reglas y normas existentes en los pasos pasivos. Esto suele ir acompañado de una falta general de conciencia sobre los riesgos asociados en los entornos ferroviarios, como las largas distancias de parada de los trenes y la incapacidad para detenerse o reducir la velocidad para evitar una colisión o arrollamiento. Este desconocimiento puede extenderse a que los usuarios desconozcan la ilegalidad de sus comportamientos y la existencia de sanciones.

Existe un problema particular con la comprensión de la forma correcta de actuar en los pasos a nivel pasivos. Varios estudios señalan el hecho de que muchos conductores no esperan el paso de trenes en los cruces pasivos. Se sugiere que esto puede deberse al hecho de que los conductores no distinguen entre cruces activos y pasivos y, por lo tanto, esperan ser informados si se acerca un tren.

En este sentido, varios expertos coinciden en la necesidad de abordar la educación dentro de un programa más amplio de gestión de riesgos para aumentar la seguridad en los entornos ferroviarios y, más concretamente, en los pasos a nivel de peatones y vehículos. Esto implica aumentar la conciencia pública sobre los peligros de los cruces y educar a los peatones, conductores de vehículos de carretera y otros usuarios sobre cómo usarlos correctamente (Metaxatos et al., 2015).

- Percepción de riesgo inexacta.

Algunos usuarios desconocen los riesgos reales que implica el uso indebido de un paso a nivel. Según Searle et al. (2012) hay dos factores clave relacionados con la percepción inexacta del riesgo:

- Familiaridad y expectativa. La familiaridad con los pasos a nivel conduce una baja expectativa de encontrar trenes en los cruces. Los conductores que utilizan los pasos a nivel con regularidad, llegan a desarrollar expectativas sobre la frecuencia de los trenes y la probabilidad de encontrar un tren en ellos. Basándose en su experiencia en esos cruces realizan esquemas o modelos mentales para esos pasos. La familiaridad con un paso a nivel o tipo de paso a nivel en particular, junto con una expectativa reforzada de que no haya trenes, lleva a que se active un esquema de "no trenes" en los enfoques de pasos a nivel futuros (Rudin-Brown et al., 2014). El relacionar la familiaridad y la expectativa de que un tren no esté presente hace que los conductores se sientan satisfechos con los malos hábitos a la hora de usar los pasos a nivel (Caird et al., 2002). La percepción de riesgo inexacta por familiaridad y expectativa se daría en los usuarios frecuentes de cruces pasivos debido a los bajos volúmenes diarios de trenes de este tipo de cruces.

- Juicio erróneo de la velocidad y la distancia del tren. Para los usuarios de la carretera es difícil juzgar la velocidad y la distancia de los trenes que se aproximan y, por lo tanto, el tiempo que tardan los trenes en llegar al cruce. Searle et al. (2012) señalan dos problemas de percepción principales que pueden afectar la capacidad para juzgar con precisión la velocidad del tren, lo que los lleva a subestimar la velocidad del tren y a tener demasiada confianza en su capacidad para "ganarle al tren" y poder cruzar el paso a nivel antes de que este llegue: el efecto Leibowitz que describe el fenómeno en el que los objetos más grandes parecen moverse más lento que los objetos más pequeños, viajando ambos a la misma velocidad; y el efecto amenazante, por el que no se percibe el tamaño real del tren hasta que está a una distancia muy próxima. Esta situación puede agudizarse en los cruces rurales y de noche.

2.2. Factores humanos relacionados con las infracciones en los pasos a nivel

- Comportamiento deliberado en la toma de riesgos.

El comportamiento deliberado que conlleva una asunción de los riesgos puede ser debido o bien a la frustración e impaciencia del usuario que tiene que esperar en el paso a nivel el paso de un tren o trenes que se acercan; o bien también por que el usuario tiene una personalidad que busca riesgos. En el primer caso, el usuario puede decidir infringir las reglas de cruce porque considera que los beneficios de reducir el tiempo de espera superan los riesgos percibidos de infringirlas. Las infracciones tienden a aumentar significativamente cuando el tiempo entre la activación de la alerta y la llegada del tren excede los 20-30 segundos. La impaciencia con los retrasos en los pasos a nivel puede surgir cuando los usuarios de la carretera tienen prisa por llegar a su destino, lo que puede acentuarse en momentos específicos del día, como la hora punta de la mañana. Los usuarios de la carretera también pueden infringir deliberadamente los controles de los cruces si los consideran poco fiables, o si perciben que las consecuencias de sus acciones, en términos de ser sancionados o de que llegue un tren, son poco probables.

Por otro lado, se ha identificado que determinadas personalidades pueden infringir deliberadamente las reglas. En este caso, el desafío del usuario a las reglas de cruce y los controles de seguridad de los pasos a nivel activados puede ser solo un ejemplo de distintos comportamientos de riesgo.

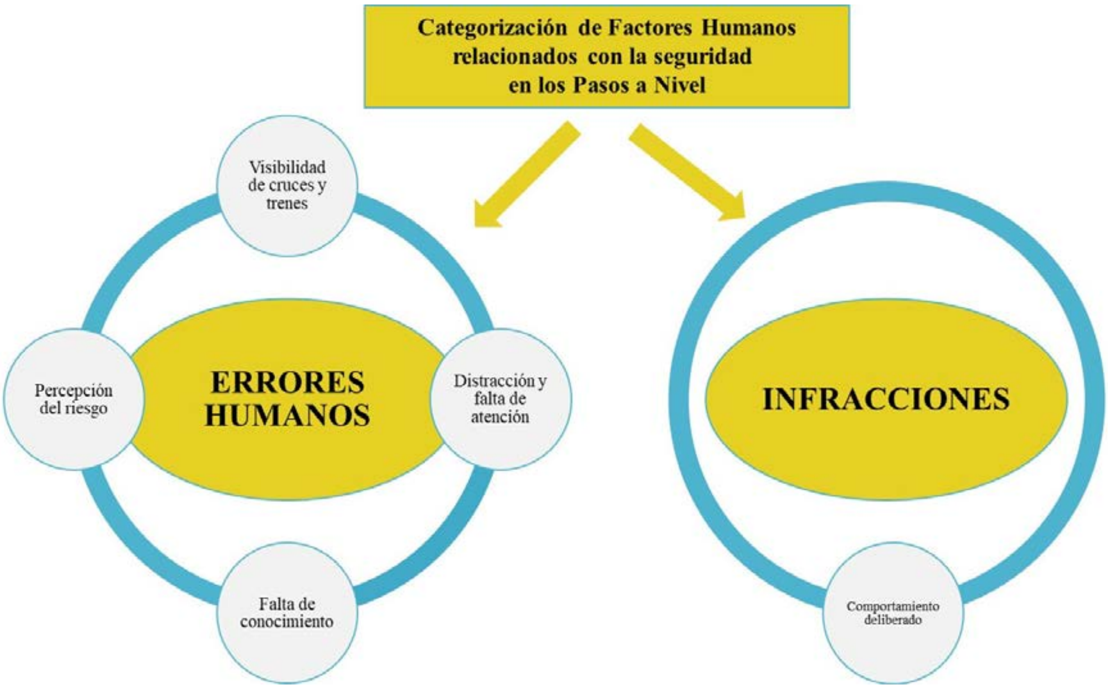

Figura 2. Categorización de Factores Humanos relacionados con la seguridad en los pasos a nivel

3. FUENTES DE DATOS Y METODOLOGÍA

A continuación, se presenta un resumen de la metodología que se utilizó en la Tarea 2.1. (“Estado del arte de la seguridad en los pasos a nivel: identificación de indicadores clave de seguridad relacionados con los errores humanos y las infracciones”) del proyecto SAFER-LC (Figura 3).

Utilizando una metodología que combinaba la revisión de la literatura y la opinión de expertos, se creó una base de datos que identificaba unos indicadores clave de seguridad relacionados con los requisitos de los usuarios y, los errores humanos e infracciones. La creación de la base de datos se realizó en 5 fases:

1. Construcción de una base de datos bibliográfica sobre factores humanos en pasos a nivel y sistemas de seguridad. Los socios de la tarea participaron en la construcción de una base de datos bibliográfica sobre factores humanos en pasos a nivel y sistemas de seguridad. Después de la depuración de la información, la base de datos quedó integrada por 125 documentos: artículos científicos (n = 72); trabajos de investigación (n = 29); otros resultados/informes (n = 22); y otra información (n = 2) (Se puede acceder a la base de datos en la extranet del Proyecto)

2. Revisión de la literatura. Esta fase implicó un análisis de los documentos de la base de datos. Para ello, se desarrolló un formulario de revisión que facilitaba la identificación y el análisis de la información relevante mediante 6 campos de información clave. Con el fin de informar las categorías contenidas en este formulario de revisión, particularmente las relacionadas con el factor humano, se llevó a cabo una revisión preliminar de una muestra de documentos contenidos en la base de datos bibliográfica (Caird et al., 2002; Ngamdung y DaSilva, 2013; Read et al., 2013; Rudin-Brown et al., 2014; Searle et al., 2012). A partir de esta breve revisión, se compiló e incluyó en el formulario una síntesis de las variables relacionadas con el factor humano. El diseño de este formulario se basó en los principios metodológicos del análisis de contenido, una técnica de investigación para hacer inferencias replicables y válidas de los textos (u otra materia significativa) a los contextos de su uso (Bengtsson, 2016).

3. Definición de los indicadores relacionados con los requisitos del usuario. Con el objetivo de definir un conjunto de indicadores relativos a los requisitos del usuario, se diseñó un formulario en el que los socios identificaban las variables sobre factor humano de los documentos de la base de datos. Mediante el programa SPSS se realizó un análisis de frecuencia de las variables identificadas: tipo de paso a nivel, condiciones personales del usuario, tipo de distracción, visibilidad de cruces y trenes, variables relacionadas con el contexto, etc. Las variables más frecuentes (enumeradas en 3 o más documentos) se agruparon en 7 categorías amplias de indicadores de requisitos de los usuarios: condiciones personales; distracción y falta de atención; visibilidad de cruces y trenes; desconocimiento; percepción de riesgo no exacta; conductas de riesgo deliberadas; e información sobre el contexto. Finalmente, se obtuvieron 35 indicadores relacionados con los requisitos de los usuarios . Para explorar posibles asociaciones entre las variables de factor humano de la base de datos y el tipo de paso a nivel y tipo de usuario, se realizó un análisis bivariado de algunas de las variables (prueba de la Chi-cuadrado de Pearson (x2) de $p < 0.05$). (Un pequeño número de indicadores se basa en "nuevas" variables. Se refieren a variables que no se habían incluido en el Formulario de revisión, pero que se detectaron en la literatura revisada. Se consideró de interés incluir todas las variables adicionales con el fin de obtener un análisis más completo de los factores humanos)

4. Validación de los indicadores de requisitos del usuario e identificación de otros nuevos. Para validar los indicadores identificados en la fase anterior y capturar otros no referidos, se desarrolló un formulario de clasificación. Con este formulario cada socio clasificaba la relevancia de medir cada uno de los indicadores en términos de seguridad en los pasos a nivel desde una perspectiva del factor humano. A cada indicador se le asignó una clasificación en una escala Likert de 5 puntos (de "extremadamente importante" a "nada importante").

5. Identificación de indicadores clave de seguridad relacionados con errores humanos e infracciones. Los indicadores de requisitos del usuario creados a partir de las variables identificadas en la revisión de la literatura, se clasificaron como errores humanos e infracciones en los sistemas de seguridad de pasos a nivel utilizando el marco de clasificación de errores humanos del German in Depth Accident Study (GIDAS) (Grippenkoven et al., 2012). GIDAS clasifica los errores humanos y las infracciones en categorías de acuerdo con las diferentes etapas del procesamiento de la información humana: acceso a la información; admisión de información; evaluación de información; planificación y operación. GIDAS fue diseñado originalmente para usuarios de automóviles, aunque también se ha aplicado al estudio de accidentes de pasos a nivel.

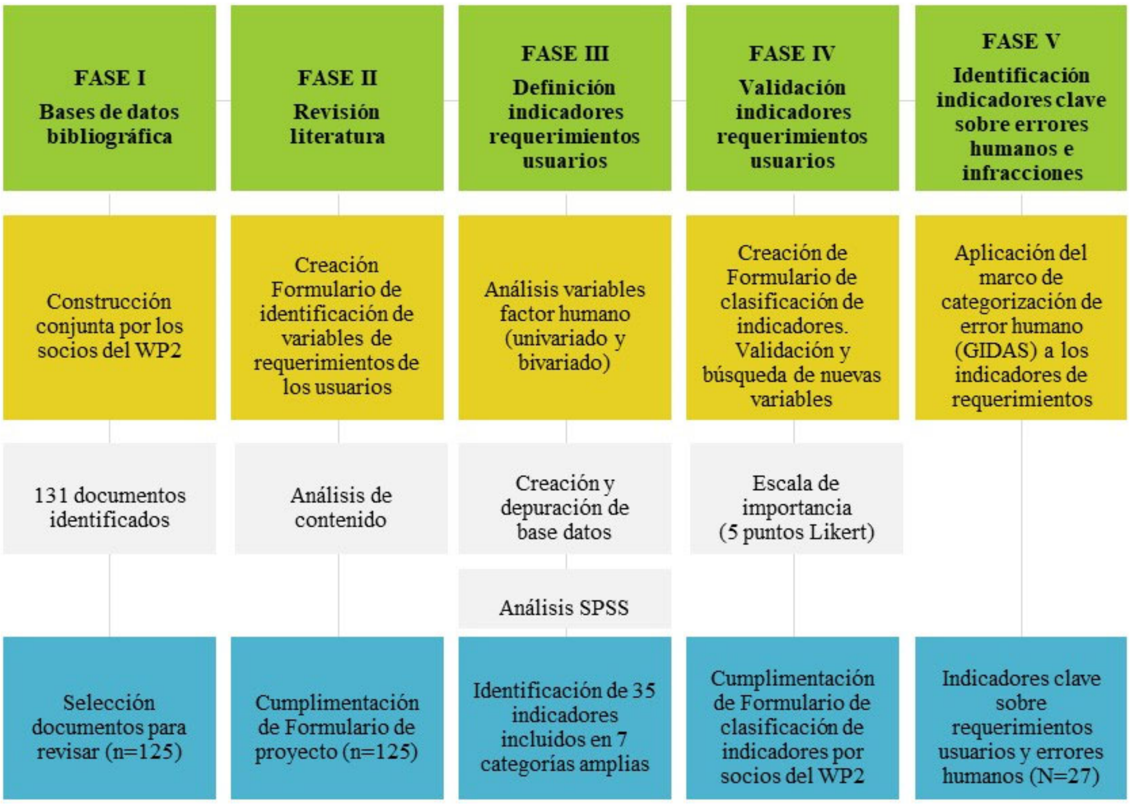

Figura 3 – Resumen del marco metodológico

4. RESULTADOS

La revisión de la literatura reveló que la mayoría de los estudios y proyectos relacionados con los requisitos de los usuarios y, los errores humanos y las infracciones en los pasos a nivel se centran, por un lado, en los pasos a nivel pasivos y los pasos a nivel activos controlados automáticamente y, por otro lado, en usuarios de automóviles y peatones. Casi todos estos estudios, aunque no estuvieran directamente relacionados con los factores humanos, subrayan la relevancia de estas variables y la necesidad de tenerlas en cuenta para comprender mejor la seguridad en los pasos a nivel.

De acuerdo con los documentos revisados, las variables relacionadas con los factores humanos que aparecían con mayor frecuencia eran:

- La distancia visual y las señales.
- Localización de los pasos a nivel.
- Distracciones externas.
- Percepción de la velocidad y distancia del tren.
- Ángulo de cruce.
- Falta de comprensión de la acción correcta que se requiere.
- Personalidades que buscan riesgos.
- Desconocimiento de la señalización en los pasos a nivel.
- Frustración e impaciencia ante la demora en los pasos a nivel.

También se analizaron las variables vinculadas a las condiciones personales de los usuarios para identificar los grupos de riesgo, según la literatura revisada, en los últimos años las investigaciones se han centrado en el análisis de los comportamientos según género y edad.

Como se explicaba en el apartado de Fuentes de datos y Metodología, las variables más frecuentes se agruparon en 7 categorías amplias de indicadores de requisitos de los usuarios

A continuación, se presenta un breve resumen de los principales hallazgos sobre los indicadores relacionados con los errores humanos y las infracciones de acuerdo a las valoraciones realizadas por los socios de la tarea:

- Indicadores relacionados con las condiciones personales. En términos generales, la edad y la discapacidad se consideraron más relevantes que el género en el estudio de las necesidades de los usuarios en los pasos a nivel. El uso de sustancias adictivas también se consideró relevante.

- Indicadores relacionados con las distracciones y la falta de atención. En general, se consideró que todo el conjunto de indicadores relacionados con la distracción y la falta de atención eran relevantes.
- Indicadores relacionados con la visibilidad de los cruces y los trenes. Estos indicadores se consideraron fundamentales, sobre todo, la distancia y el ángulo de las señales visuales.
- Indicadores relacionados con la falta de conocimiento. En términos generales, el conjunto de indicadores relacionados con la falta de conocimiento se valoró como relevantes para el análisis de factores humanos en los pasos a nivel.
- Indicadores relacionados con la percepción inexacta del riesgo. Los resultados apuntaron a que era de particular interés tener en cuenta para el estudio del factor humano la familiaridad del usuario con el paso a nivel.
- Indicadores de comportamiento de riesgos deliberados. Los más relevantes se dividían en 2 categorías principales: los ocasionados por la frustración y la impaciencia del usuario que tiene que esperar en el paso a nivel, y los relacionados con usuarios que tienen una personalidad propensa a la búsqueda de riesgos.
- Indicadores relacionados con la información sobre el contexto. Del conjunto de estos indicadores, el destacado como más importante fue el del entorno del paso a nivel (por ejemplo, si es rural o urbano).

Con el objetivo de examinar los factores humanos que pueden contribuir a los accidentes en los pasos a nivel, estos indicadores se analizaron frente a las categorías de error del marco de clasificación de errores humanos de GIDAS. Teniendo en cuenta el procedimiento secuencial del procesamiento de la información humana, las categorías GIDAS son: acceso a la información, procesamiento de la información, evaluación de la información, planificación y acción (Grippenkoven, Giesemann & Dietsch, 2012).

La Figura 4 incluye una descripción de la influencia y los indicadores identificados y clasificados según las categorías de error del marco de categorización de errores humanos de GIDAS. La Figura 2 se enfoca en las etapas del procesamiento de la información que están más afectadas por cada uno de los factores. Sin embargo, esto no excluye la influencia en otras etapas por los ciclos de retroalimentación de las etapas.

Los indicadores relacionados con las condiciones personales están vinculados a errores de acceso a la información, errores de procesamiento de la información, errores de evaluación y errores de operación. En este caso, pueden producirse errores por no percibir información relevante, experimentar interferencias dentro y fuera del vehículo, realizar una interpretación incorrecta de la información por experiencia previa y conocimiento del lugar, y/o realizar acciones incorrectas.

La visibilidad en los pasos a nivel puede verse reducida debido a condiciones climáticas que reducen la visibilidad, condiciones nocturnas, deslumbramientos del sol, crecimiento excesivo de vegetación, distancia de visión, etc. Estos indicadores están vinculados a errores de información de acceso y de procesamiento de la información.

Los indicadores relativos a la información sobre el contexto están vinculados a errores de acceso a la información, errores de procesamiento de la información, errores de evaluación y errores de operación. En este caso, pueden producirse errores por no percibir información relevante, experimentar interferencias dentro y fuera del vehículo, realizar una interpretación incorrecta de la información recibida por familiaridad con el lugar, y/o realizar acciones incorrectas.

La atención de un usuario de un paso a nivel puede desviarse debido a distracciones externas (por ejemplo, semáforos, señales de ceda el paso, tráfico de peatones, etc.). Los usuarios de la carretera también pueden presentar distracciones internas como resultado de realizar tareas secundarias a la conducción, como el uso de dispositivos multimedia, conversar con pasajeros o con otros peatones, atender a los niños o por distracciones. Estos indicadores están vinculados a errores de procesamiento de la información.

Los indicadores relacionados con la toma de riesgos deliberados están vinculados con situaciones de frustración e impaciencia debido a tiempos de espera en el paso a nivel y con personalidades con inclinación a la búsqueda de riesgos. Estos indicadores están vinculados a conductas voluntarias inseguras o violaciones.

Un factor humano involuntario que conduce al uso indebido de los pasos a nivel es la falta de conocimiento sobre las normas y la falta de conciencia de los riesgos asociados con el entorno ferroviario. Estos indicadores están vinculados a errores de evaluación de la información porque la información se puede interpretar incorrectamente.

En general, la percepción inexacta del riesgo está relacionada con la familiaridad con los pasos a nivel, lo que conduce a una baja expectativa de encontrar trenes en los cruces y a un error de cálculo de la velocidad y la distancia del tren.

Estos indicadores están vinculados a errores de evaluación de la información. La información puede malinterpretarse debido a la experiencia previa y el conocimiento del lugar, y a la falta de conciencia y conocimiento de los ferrocarriles y los riesgos relacionados con las infraestructuras de los pasos a nivel.

Hay que tener en cuenta en el análisis de las medidas de seguridad de acuerdo a los requerimientos del usuario y el factor humano, que existen comportamientos inseguros involuntarios (errores y fallos) y comportamientos inseguros voluntarios (infracciones).

Los indicadores identificados en la literatura revisada relacionados con las conductas de riesgo deliberada y el suicidio, se consideran conductas peligrosas voluntarias o infracciones.

CATEGORÍA DE INDICADORES DE SAFER-LC	DESCRIPCIÓN DE LA INFLUENCIA	CATEGORÍA DE ERROR
INDICADORES RELACIONADOS CON LAS CONDICIONES PERSONALES	La información relevante no se puede percibir. La información de dentro y fuera del automóvil puede interferir e influir. Información interpretada de forma incorrecta Toma voluntaria de decisiones erróneas.	Acceso a la información. Procesamiento de la información. Evaluación de la información. Acción.
INDICADORES RELACIONADOS CON LA VISIBILIDAD DE LOS CRUCES Y LOS TRENES	La información relevante no puede ser percibida. La información de dentro y fuera del automóvil puede interferir e influir.	Acceso a la información. Procesamiento de la información.
INDICADORES RELACIONADOS CON LA INFORMACIÓN SOBRE EL CONTEXTO	La información relevante no se puede percibir. La información de dentro y fuera del automóvil puede interferir e influir. Información interpretada de forma incorrecta. Toma voluntaria de decisiones erróneas.	Acceso a la información. Procesamiento de la información. Evaluación de la información. Acción.
INDICADORES RELACIONADOS CON LA DISTRACCIÓN Y FALTA DE ATENCIÓN	La información de dentro y fuera del automóvil puede interferir e influir.	Procesamiento de la información.
INDICADORES RELACIONADOS CON LA TOMA DE DECISIONES DE RIESGO	La información de dentro y fuera del automóvil puede interferir e influir. Información interpretada de forma incorrecta. Infracción de las reglas debido a la creencia de que no va a suceder nada. Toma voluntaria de decisiones erróneas.	Acceso a la información. Evaluación de la información. Planificación. Acción.
INDICADORES RELACIONADOS CON LA FALTA DE CONOCIMIENTO	Información interpretada de forma incorrecta	Evaluación de la información.
INDICADORES RELACIONADOS CON UNA PERCEPCIÓN DE RIESGO NO EXACTA	Información interpretada de forma incorrecta	Evaluación de la información.

Figura 4 – Categorización de errores GIDAS e indicadores identificados en la literatura revisada

5. CONCLUSIONES

El objetivo de esta comunicación, y de la Tarea 2.1. del proyecto SAFER-LC, es contribuir a la mejora de la seguridad en las infraestructuras de los pasos a nivel desde la perspectiva del factor humano. Mediante una metodología que combinaba la revisión de la literatura y la opinión de expertos, se identificaron indicadores clave de seguridad relacionados con los requisitos del usuario y, los errores humanos y las infracciones.

La introducción de estos indicadores tiene como finalidad apoyar la planificación y evaluación de acciones de seguridad en los pasos a nivel desde la perspectiva del usuario, de modo que las medidas tecnológicas y no tecnológicas puedan adaptarse mejor desde el enfoque del factor humano, haciendo que los pasos a nivel sean más autoexplicativos y resilientes.

Específicamente, la identificación de estos indicadores clave de seguridad favorecerá el desarrollo de un marco del factor humano que, a su vez, permitirá valorar hasta qué punto se tienen en cuenta las variables del factor humano en el diseño y la evaluación de las medidas de seguridad en los pasos a nivel.

Para la construcción de estos indicadores clave de seguridad se utilizaron numerosas fuentes de información cuantitativas y cualitativas (tanto primarias como secundarias), que tenían en cuenta la perspectiva y experiencia del usuario en los pasos a nivel tanto en situaciones de la vida real como en condiciones experimentales.

La literatura revisada constituye, por ende, una rica fuente de información para el desarrollo de los indicadores clave de seguridad relacionados con los errores humanos y las infracciones. No obstante, aunque se incluyó en el análisis una gran variedad de literatura especializada y actual, no representa una revisión exhaustiva de la literatura disponible sobre el tema. Además, la mayoría de los estudios se han realizado en países del ámbito anglosajón, factor a tener en cuenta a la hora de considerar la representatividad de la información recopilada y proponer la extensión de medidas de manera internacional.

Con el objetivo de que los requisitos del usuario sean considerados en el diseño de las infraestructuras ferroviarias, los expertos en factor humano y transporte ferroviario que participaron en la tarea recomiendan realizar definiciones más exhaustivas de los distintos indicadores.

Esto ayudaría a enfocar la discusión sobre qué indicadores clave adoptar en el futuro. Además, estos expertos realizaron algunas propuestas útiles para el diseño de las medidas de seguridad en los pasos a nivel de acuerdo con la perspectiva del usuario:

- En el estudio se destacó la importancia de considerar a todos los usuarios de la vía al diseñar una contramedida (independientemente de su sexo, edad o condición de discapacidad), aunque estimaban fundamental contemplar las necesidades de grupos particulares y realizar las correspondientes modificaciones, por ejemplo, en el caso de los usuarios con problemas de movilidad. Por ejemplo, y dado que los datos evidencian que los hombres son responsables de más accidentes en tránsito que las mujeres, algunos expertos señalaron la importancia de desarrollar medidas específicas (por ejemplo, campañas) que se dirijan a los hombres.
- Dada la importancia de la falta de atención y las distracciones para cometer errores e infracciones, se propuso diseñar medidas de seguridad centradas en evitar distracciones externas y sobrecargas de estímulos en la zona de aproximación al paso a nivel, minimizando la variedad de señales que los usuarios de la carretera deben ver, leer, interpretar y responder antes de llegar al paso a nivel.
- En general, la distancia visual de las señales y el ángulo de cruce se destacan como factores importantes que pueden conducir al incumplimiento en los pasos a nivel. Pero también se propusieron otros elementos que pueden implicar riesgos en la seguridad en los pasos a nivel, como la iluminación del tren, de las calles (por la noche), la orientación de la calle, la dirección de conducción con referencia al sol o el color del material rodante.

- En lo que respecta a la relación entre las infracciones y la personalidad, los expertos señalaron como recomendación para las soluciones tecnológicas y no tecnológicas reflexionar sobre cómo incorporar elementos que eviten las situaciones de riesgo por la frustración o la impaciencia de los usuarios de los pasos a nivel.
- Las multas se consideraron útiles como estrategia disuasoria que reduce los comportamientos de riesgo a corto plazo, pero a medio y largo plazo la conducta persiste, por lo que las recomendaciones deberían centrarse en diseñar programas educativos y de sensibilización para la seguridad en los pasos a nivel.
